Notice
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

PREFACE

While no single text can encompass the wealth of knowledge that underpins the practice of nursing, we believe that this significantly updated third edition will continue to be an invaluable resource, not only for student nurses, but also for qualified nurses, including those returning to practice and those coming to nurse in the UK from other parts of the world, and for nurse educators. All face the challenge of new knowledge.

The structure of the book

As in the first two editions, the book is divided into three sections which are progressive in nature, encouraging the reader to move from the broad approach of Section 1 to a more in-depth appreciation of specific patient concerns and nursing issues in Sections 2 and 3. There is sufficient cross-referencing to encourage readers to make links and pursue lines of enquiry.

Section 1 — Care of patients with common disorders

Our existing confidence in the decision to adopt the systems approach for this section has been strengthened in light of the new developments in the skills and expertise that nurses may attain. They must have a thorough grounding in anatomy, physiology and disease pathology, therefore the structure of this chapter remains that of:

- anatomy and physiology
- pathophysiology
- medical management
- nursing priorities and management.

Essential anatomy and physiology have been presented. Recommendations for further reading and web addresses are given where more detail can be gained. We have been selective about the disorders chosen, concentrating on those commonly encountered by nurses in hospital and the community. Clearly, the nursing priorities and management content is the most important part of each chapter of Section 1; the wording of the heading reminds the student of the need to make appropriate clinical judgments and decisions, according to the individual's unique needs and circumstances.

Section 2 — Common patient problems and related nursing care

This section presents another way of examining nursing and builds on the foundations laid in Section 1. The focus is on common patient problems, which are not merely physiological in origin, but also arise from the subtle, complex interplay of social, psychological and economic factors. Some of these problems have a high profile, such as stress and pain. Others, such as nutrition and sleep, are often relatively neglected, but are very much the concern of nurses. These problems are not confined to, or only evident in, hospital care. They are part of life and may be experienced in many settings and at any time. Throughout the section, both the nurse's and the patient's perspectives have been considered and the basis for all interventions is that of best available evidence.

Section 3 — Nursing patients with special challenges

Some of the most challenging areas of nursing are explored in this section. By addressing these, the broad spectrum and contrasts of adult nursing are revealed. Such challenges, some long-term in nature, often make the greatest demands on the nurse's clinical and interpersonal skills. Section 3 addresses stereotypes and examines values and beliefs, raising awareness of the moral decision-making that underlies so much of day-to-day nursing practice.

Key features

In harmony with our commitment to exploring the different ways of knowing about nursing, a variety of features have been used throughout the book. These include:

- self-assessment questions 

- further reading suggestions 
- illustrations
- care plans and pathways, which are both educational and useful practice tools
- case histories, including accounts of personal 'lived experience'
- boxes highlighting key information
- research abstracts
- references
- useful addresses and websites.

The contributors and advisors

We owe a sincere debt of gratitude to the many authors and advisors who have contributed to the significant updating of this text. The authors represent many areas of adult nursing, and advisors include nursing and medical colleagues and members of the allied health professions. We pay sincere tribute here to their knowledge, experience and skills and thank them all for their key contributions to this text. We also greatly appreciated the informal advice received from academic and clinical colleagues.

As editors we have been delighted by the value placed on this book by readers, particularly the students, who are our future.

Whether you read this book, therefore, as a student nurse, a novice nurse, an expert practitioner, a preceptor/mentor or as an educator, it will provide a wealth of knowledge, derived from many sources: from professional nursing practice, from research and from the experiences of countless patients, clients and carers.

Edinburgh, 2006

Margaret F. Alexander
Josephine (Tonks) N. Fawcett
Phyllis J. Runciman

ACKNOWLEDGEMENTS

The editors would like to thank all who kindly granted permission to borrow material such as illustrations and tables from existing publications.

The editors would like to thank Roseanne Cetnarskyj for acting as coordinator for chapter 6. The editors also wish to record their thanks to those authors who contributed to the previous edition and whose work has provided the foundation for the current volume. These are:

Joyce M. Brown
S. Jose Closs
David B. Cooper
Aileen E. Crosbie
Claire Dibbs
Frances M. Davidson
Christine Docherty
Elizabeth S. Farmer
Ruth F. M. Gardner
Margaret Harris
Rhoda Hodgson
Evelyn Howie
Liz Jamieson
Vivian Leefarr
Cath M. McFarlane
Rosemary McIntyre
Mary B. Murchie
Marie-Noelle Orzel
Muriel E. Reffin
Billie Reynolds
Sheila E. Rodgers
Marion C. Stewart
Kathy Strachan
Margaret A. Studley
Jean Swaffield
Colin Torrance

Specific thanks are also expressed to the following:

For Chapter 5 Part 2, the authors wish to thank Gillian Aitken (Project Manager, Queen Margaret University College, Edinburgh) and Florence Brown (Diabetes Specialist Nurse, Gartnavel General Hospital, Glasgow).

For Chapter 9, the author wishes to thank Sarah Canning, Student Nurse, University of Edinburgh, for her contribution of Case History 9.2.

For Chapter 16, the authors wish to thank Marion Bennie, J. Claire Cameron, Beth Cullen, Simon Fallows, Jim McMenamin, Clare Mitchell, Jacqui Reilly and Vivienne Simpson for assistance with the chapter, and Hannah O'Regan, Student Nurse, University of Edinburgh, for her contribution to Figure 16.5.

For Chapter 21, the authors wish to thank Zillah Leach (Nutrition Support Nurse, Southampton University Hospitals Trust) and Peter Austin (Senior Pharmacist, Nutrition Support Team, Southampton University Hospitals Trust) for their advice and assistance on the sections on enteral and parenteral nutrition and the role of the Nutrition Support Team and the Clinical Nurse Specialist in nutrition.

For Chapter 33, the authors wish to thank Dr T. F. Benton (Medical Director) and Dorothy McArthur (Clinical Pharmacist), as well as many other members of staff at St Columba's Hospice, Edinburgh.

For chapter 37, the author wishes to thank Laura Mathers, Blood Borne Viruses Specialist Nurse, North Glasgow University Hospitals Division, for reviewing the chapter.

Unless we are making progress in our nursing every year, every month, every week, take my word for it we are going back.
Florence Nightingale, cited in Skeet (1980, p. 100).

Introduction

Welcome to the third edition of *Nursing Practice*. The main purpose of this book is, and has been since its inception, to present knowledge about nursing, knowledge which comes to life when applied in the actual practice of nursing care. The education and practice of nursing inform each other and this book makes its contribution to both of these integral elements. Nursing is continually and rightly informed by new knowledge, new technologies and new research, much of which is incorporated in this new edition, an edition which comes at a time when nursing, its relationship with other professionals and with patients and carers, and its approaches to education and learning are undergoing significant transformation. Within a changing health care system, it is a time of rapid growth in the range and type of nursing roles and skills and nurse-led initiatives. For example, there is an increase in the number of nurse consultants and nurse endoscopists, and the prospect of nurses carrying out procedures such as angioplasty and minor surgery. A wide range of nurse-led clinics exist for prevention, treatment and rehabilitation in conditions such as heart attack, diabetes mellitus, chronic obstructive airways disease and asthma. This book reflects these changes. However, it particularly seeks to demonstrate the enduring essence of nursing care in helping individuals to maintain good health, recover from episodes of ill-health, cope day by day with chronic illness and experience dignity and comfort at life's end. So, in response to Florence Nightingale's exhortation, we are indeed making progress in our nursing; however, while welcoming the new, we are also acutely aware that the 'heart' of nursing beats on, in timeless rhythm. The nurse's sensitive communication skills, the eye contact, the listening ear, the informed and gentle hands-on care are the essential foundation for all of the complex nursing procedures and highly technical skills which nurses today are competent to carry out. Countless patients will testify to that.

Therefore, as editors, we have certain goals for this text:

- to present the knowledge and skills required for competent, evidence-based practice in the variety of settings in which nurses work, e.g. in hospitals, the community and in patients' own homes
- to value the individual 'lived experience' of health and illness, and the importance of listening carefully to the voices of patient and carers
- to illustrate the changing context and dynamic nature of health care
- to develop ways of thinking, learning and exploring critically the nature of nursing
- to encourage constructive reflection and analysis of care, the bases of sound clinical judgement
- to demonstrate the essential contribution of research in practice.

The current challenges for health care

Although the focus of this book is on health care in the United Kingdom (UK) and the context in which nursing takes place, its content has much wider relevance. As the World Health Organization points out (WHO 1996, 2003), 'health care does not take place in isolation from political, economic and cultural realities' within a country. Nurses, who constitute a major proportion of the health care workforce in many countries, and certainly in the countries of the WHO European Region, of which the UK is a part, do provide nursing care in environments which are touched by these realities. Many of the challenges which face nurses

here in UK are not dissimilar to those facing nurses in other countries (WHO 2000, 2003).

Changing demography

Populations are ageing. Within the next 25 years or so, there will be a marked increase in the proportion of the population who are over 65 years of age, i.e. 1 in 4, with 1 in 12 over 80 (Scottish Executive 2005). Nurses will therefore contribute increasingly to health care for the older sector of the population and will need to acquire sound understanding of older people's perspectives and of their experiences of illness and disability. Also significant will be nursing's contribution to active ageing and to maintaining health in old age, both for older people who remain fit, and for those who must cope with health-related problems (Audit Commission 2004, WHO 2005).

Changing patterns of disease

Older people are more likely to have long-term illness, more likely to have a combination of such illnesses, e.g. cancer and cardiovascular disease, more likely to be admitted to hospital or require long-term care within the community, i.e. in care homes and at home (Scottish Executive 2005). Affecting the wider age range, there is a resurgence of diseases thought to have been eradicated, such as tuberculosis, the challenge of hospital acquired infection (HAI) and the enduring concern posed by HIV.

Changing care provision

There are tensions in current approaches to health care delivery, all of which affect nursing practice. For example, there is a mismatch between the need for proactive, integrated and preventive care for people with chronic conditions and a health care system which is perceived as prioritising specialised, episodic care for acute conditions. There are major technological and medical advances, from which arise both ethical concerns and issues of cost containment.

There are challenges associated with the integration of health and social care and with the provision of increasingly complex technical care to support patients who experience early supported discharge schemes and outreach care initiatives.

Changing expectations

Within this climate of change, there are also greater expectations from patients and carers for clear information and understanding of their health, illness and health care experience, and an increasing expectation of participation in decision making about their care (DH 2001). Effective communication underpins good care.

These challenges suggest a future in which the role of the nurse may be less hospital and medically dominated. They also may presage new opportunities for nurses to extend their knowledge and skills in many settings.

Partnerships

Partnership is a key issue in both policy and practice, here in the UK and further afield. In 1998, the World Health Organization stressed the need for partnerships and the importance of the contribution of nurses at the forefront of change in health care (WHO 1998). Partnership is essential, not only with other health and social care professionals, but also with patients and carers. In the coming decades, the consumer's voice will increasingly be sought and heard in the development and evaluation of health and social care. The emphasis on partnership means that nurses in hospital and in the community must find new ways of working with colleagues in the NHS and in a wider range of service sectors and agencies. Partnership also implies a need for strong clinical leadership. Effective partnerships are fundamental to the aims of clinical governance, with its emphasis on creating an environment in which clinical excellence will flourish. There are references throughout the text which reflect the importance of clinical judgement, decision making and risk management, all of which require clinical leadership.

Health, illness and disease

As our understanding of health grows, questions emerge:

- Why does disease develop in some healthy individuals and not in others?
- How is it possible that people manage to feel healthy in the face of coexisting disease?
- Why do such stark inequalities of health status persist between people and within communities?

Health and ill-health are now known to be influenced by a wide range of factors in people's life circumstances — economic, social, cultural, educational, psychological and genetic. Promoting health is a complex process. Nurses should be aware of the broader concepts of health currently being debated and at the same time be ready to respond in practical ways to patients' growing desire for more health-related information.

A useful distinction can be drawn between 'illness' and 'disease'. An 'illness' is what the patient experiences; a 'disease' is a description of pathological abnormality, made from the clinician's point of view. As long ago as 1977, Eisenberg drew this distinction between the personal and professional views, stating, 'Illnesses are experiences of changes in one's state of being and social function; diseases are abnormalities in the structure and function of the body organs and systems' (Eisenberg 1977). The concept of 'illness' therefore embraces all the experiential aspects of a disorder: what that patient *lives through*. The text reflects the emphasis on all three concepts — health, illness and disease — and the 'lived experience' of illness is clearly illustrated by the voices of a number of patients, 'heard' in many of the chapters of the text.

Hospital and home

The shift towards community care has had far-reaching implications for the traditional views of health, illness and disease, and for the way in which the patient's role is conceptualised. The image of the helpless person in a hospital bed — a passive recipient of paternalistic beneficence from the medical and nursing professions — has, wherever feasible, been replaced with the concept, referred to above but as yet not fully realised, of patients as partners.

The blurring of boundaries between hospital and home has made it essential for nurses to gain and interpret their knowledge and skills in a range of settings. For many people, a hospital stay may be a very brief life episode; for others, periodic visits to hospital or to/from the primary care team will become a regular, routine part of life. For some, a care home or hospital may replace their own home.

Reflection and the patient's experience

Some of the most sensitive insights of experienced nurses come from their careful, thoughtful analysis of daily work. Much can be learned from patient narratives and the telling of nursing stories, for example 'critical incidents'. Throughout this text, as noted above, we have incorporated narratives and stories which illustrate richly, in people's own words, the lived experience of health and illness at home and in hospital. Working closely with people in health and illness can be immensely satisfying, but also profoundly distressing; telling the stories of the day to those who have had similar work experiences and who share the same code of patient confidentiality can be immensely therapeutic and provide a meaningful learning experience.

In conclusion ...

The poet William Blake (1757–1827) wrote that 'art and science cannot exist but in minutely organised particulars'. This book strives to illuminate many of the particulars of nursing, but in the context of the whole. It responds to the current challenges within health care, and the need to find a meeting point between professional knowledge and expertise and the patient's lived experience.

Nursing must never be seen as 'a given', but as always developing. Practice must never be viewed complacently; its rationale must always be sought. The ways of thinking and learning, implicit in the whole approach of this book, are ways intended to encourage in the reader a love of learning, of questioning, of searching for 'the best available knowledge' which will inform nursing practice.

The knowledge needed for nursing can never be static and those who, as professional nurses, pursue such knowledge will undertake a journey of life-long learning, a journey of discovery and challenge.

To all our readers, enjoy your journey as a nurse, never lose the urge to explore, to discover or to face a challenge and, above all, never lose the gift of curiosity!

INTRODUCTION

The cardiovascular system consists of the heart and blood vessels. It is a closed circuit and is responsible for ensuring that blood flows throughout the body.

Heart and circulatory disease, cardiovascular disease (CVD), includes all the diseases of the heart and blood vessels. The two main diseases in this category are coronary heart disease (CHD) and stroke, but CVD also includes congenital heart disease and a range of other diseases of the heart and blood vessels.

CVD is the greatest cause of death in the United Kingdom (UK), accounting for 39% of the deaths in 2002, a total of just under 238 000 people. Coronary heart disease is the most common cause of death in the UK, accounting for 1 in 5 deaths in men and 1 in 6 deaths in women (British Heart Foundation 2004).

Because CVD is so prevalent in Western industrial societies, it is likely to be encountered by all nurses, whether hospital- or community-based. This is particularly true now that an increasing percentage of the population is over 60 years old, an age group in which CVD is very common. However, CVD also affects the younger population, being the main cause of premature death and disability in the UK. There are marked regional variations in death rates. East Anglia, the south-east and the south-west of England have the fewest deaths from heart disease; Northern Ireland, the north of England and Scotland have the most (British Heart Foundation 2004). There is also a clear difference between socioeconomic groups in the prevalence of CVD, with the lowest incidence among the professional groups and the highest among the unskilled manual group. Ethnic background is also a significant factor. For example, a high mortality from CHD has been found in immigrants from the Indian subcontinent (Khunti & Samani 2004) and a high mortality from hypertension and stroke in immigrants from the Caribbean and Africa (Townsend et al 1992).

The burden imposed by CVD on the National Health Service (NHS) is substantial. The annual cost of health service resources for treating CHD is at least £1700 million (Liu et al 2002). In 1999, production losses and informal care associated with CHD cost the UK economy approximately £5300 million. Of the total cost of CHD to the UK, 25% was due to direct health care costs, 41% to productivity losses, and 34% to the informal care of people with CHD (British Heart Foundation 2004). CVD also has an immense impact on society in human terms. Bereavement, disability, changing roles within the family and society, and fear are some examples of its consequences.

Many cardiovascular diseases take the form of progressive debilitating illness, often becoming chronic with intermittent acute episodes. Individuals are faced with the prospect of a lifelong problem. In contrast, a heart attack (myocardial infarction, MI) is often sudden and unexpected, arousing acute distress in the individual and family as they

confront a life-threatening crisis. Nurses, as one of the largest groups of health professionals, must inevitably bear some responsibility for helping to reduce the mortality, morbidity and personal suffering caused by CVD. Over a decade ago, Ashworth (1992) identified ways in which nurses can intervene to contribute to such a reduction:

- facilitating lifestyle adjustment to enable people to attain and maintain a level of health compatible with their personal goals
- assisting people to modify the demands of their activities of living, to balance with their capacity to meet them
- modifying the environment to achieve for each person the optimum possible environment within available resources
- providing physical treatment and monitoring for pathophysiological conditions
- reassuring, supporting and comforting patients and their families.

In addition, nurses are also increasingly in roles where they are able to assess and monitor the individual and make appropriate decisions about management priorities and treatment programmes. This should afford optimal care for each individual, thereby limiting symptoms, reducing the impact of the disease process and reducing the risk of adverse events and side-effects of treatment.

This chapter is based upon a nursing framework of activities of living. This framework reflects Roper et al's (2000) activities of daily living model of nursing, which has traditionally been used by many UK nurses caring for people with cardiovascular disorders. Whilst such models have been criticised for being too simplistic and not placing enough emphasis on psychosocial aspects of care, they continue to be a helpful basis for nursing assessment and care planning, even in environments where there is increased emphasis on nursing documentation as part of a critical care pathway, multidisciplinary care plan, clinical algorithms or guidelines.

Cardiovascular nursing is evolving as nurses move on from practising the skills of advanced life support, cannulation and phlebotomy, to taking greater responsibility for decisions which influence patient care management. Government frameworks and standards of care, such as the *National Service Framework for Coronary Heart Disease* (DH 2000) have resulted in opportunities for nurses to lead and develop services in and between primary, secondary and tertiary care environments. Increasingly, experienced nurses are part of the multidisciplinary team, admitting and discharging patients from specialist units via triage and fast-tracking; others are now prescribing thrombolytic therapy for patients with acute myocardial infarction (Caunt 1996), coordinating specialised clinics and leading rehabilitation and health promotion programmes (Quinn & Morse 2003).

The specialised nature of much cardiovascular nursing with established continuing educational opportunities, coupled with lower nurse–patient ratios, are other factors in the ongoing development of nursing roles in these areas. There is often the potential for therapeutic nurse–patient relationships to develop which can be used effectively in health promotion and psychological support (Broomfield 1996a). There is an increased focus on examining, from a multiprofessional perspective, the patient's experience, from onset of symptoms at home to discharge and follow-up, in an attempt to provide seamless, high-quality, evidence-based care. 'Process management', 'case management' and 'managed care' are terms which refer to this method of coordinating care. The pivotal tool for these approaches is the 'critical pathway' or 'integrated care pathway', used by medical, nursing and other professionals to provide standards for treatment plans, record progress against and monitor deviations from these standards, and document care (Kegel 1996). Despite concerns that this might limit individualised care, reduce nursing to a series of tick boxes and limit effective communication, care pathways have been developed for several cardiovascular diseases and procedures and have been shown to help in treatment decisions (Scott 2002, Kamineni & Alpert 2004). For an example of a critical pathway, see Figure 2.11 (p. 29).

The chronic nature of a large proportion of cardiovascular disease means that health professionals within the hospital see only certain episodes within the total spectrum of care. Much care is carried out in the community by the primary care team, with a focus on health education, promoting lifestyle adaptation and coping, and monitoring responses to treatment and disease progression. It is important that when people with cardiovascular problems are admitted to hospital, an emphasis is placed on a holistic multidisciplinary assessment so that staff have an understanding of the individual's home, family and work circumstances. Preparing a patient for return to their own environment with an optimum level of independence, together with any necessary support, requires good liaison between the hospital and community health care teams.

ANATOMY AND PHYSIOLOGY OF THE HEART

The heart is a muscular pump that generates pressure changes resulting in the propulsion of blood around the vascular system. The right side of the heart pumps blood around the pulmonary system where gaseous exchange takes place and then on to the left side of the heart. The left side of the heart operates under much greater pressure to enable it to pump blood around the systemic circulation. The various chambers of the heart are illustrated in Figure 2.1.

The heart is composed of three layers:

- *Pericardium* — a thick fibrous outer layer that protects the heart from injury and infection.
- *Myocardium* — a muscular layer that varies in thickness throughout the heart. The atria, which act as filling chambers, have a thin layer of myocardium as they do not, in the fit individual, have to generate high pressures. In the ventricles, the muscular layer is better developed, particularly on the left side, which is larger and thicker than in the right side, as a more forceful contraction is required to pump blood through the systemic circulation.
- *Endocardium* — a thin layer of endothelium and connective tissue that lines the inner chambers of the heart and coats the valves, which open and close to ensure a forward flow of blood at all times.

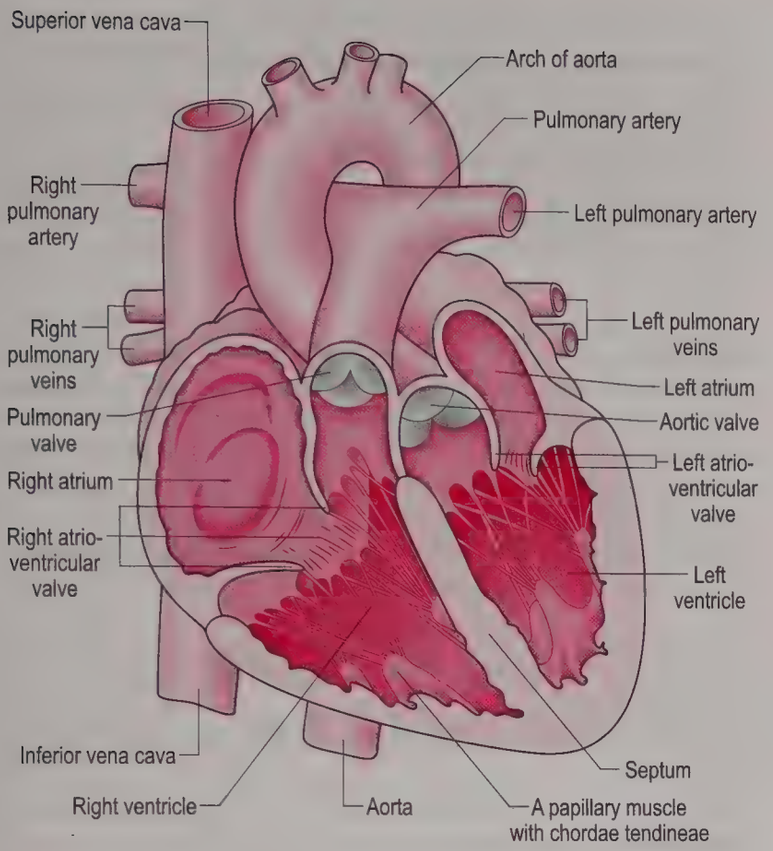

Fig. 2.1 The internal anatomy of the heart.

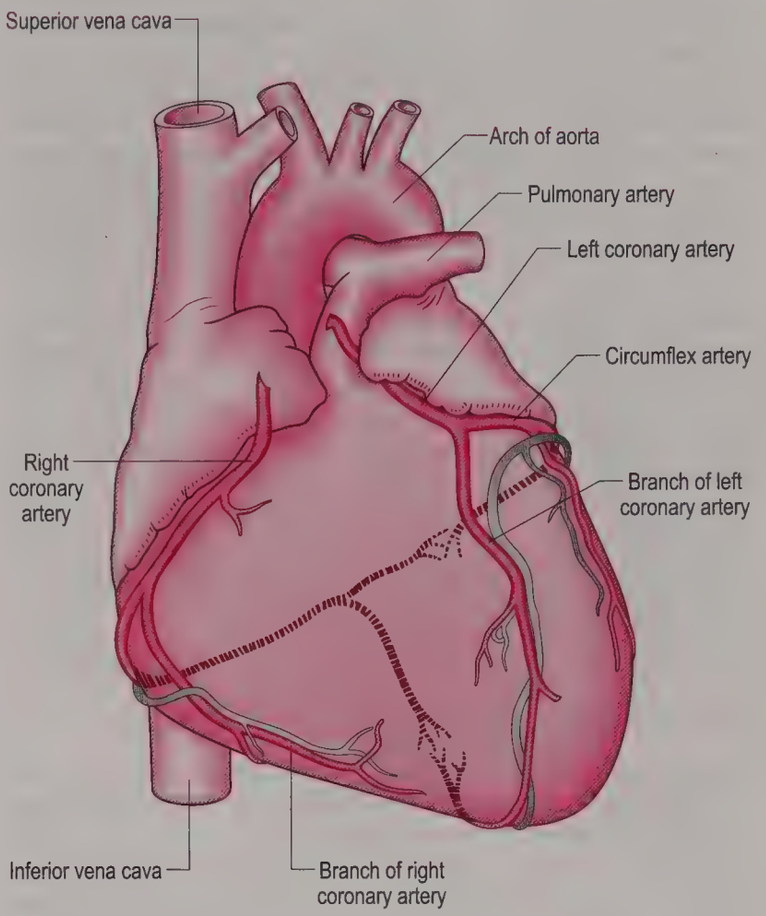

Fig. 2.2 The coronary circulation.

Coronary blood supply

Like all major organs, the heart requires blood flow to maintain cellular activity. The myocardium cannot derive oxygen and nutrients from the blood within the chambers. It receives its blood supply from the right and left coronary arteries which arise from the aorta just beyond the aortic valve (see Fig. 2.2).

The left coronary artery runs towards the left side of the heart and divides into two major branches: the left anterior interventricular branch or left anterior descending artery (LAD) and the circumflex artery (CX). The LAD follows the anterior ventricular sulcus and supplies blood to the interventricular septum and the anterior walls of both ventricles. The CX follows the coronary sulcus and supplies blood to the lateral and posterior regions of the left atrium and left ventricle. The right coronary artery (RCA) runs to the right side of the heart and divides into two branches: the posterior interventricular artery and the marginal artery. The more important posterior interventricular artery follows the posterior interventricular sulcus to the apex of the heart and supplies blood to the posterior ventricular walls. It is near the apex of the heart that the posterior and anterior interventricular arteries merge. The marginal artery follows the coronary sulcus and supplies the right ventricle. It is the RCA that normally supplies the sinoatrial (SA) and atrioventricular (AV) nodes (see Fig. 2.3).

After passing through the cardiac capillary bed, the blood drains into the cardiac veins. These join to form the coronary sinus on the posterior surface of the heart from where venous blood drains into the right atrium.

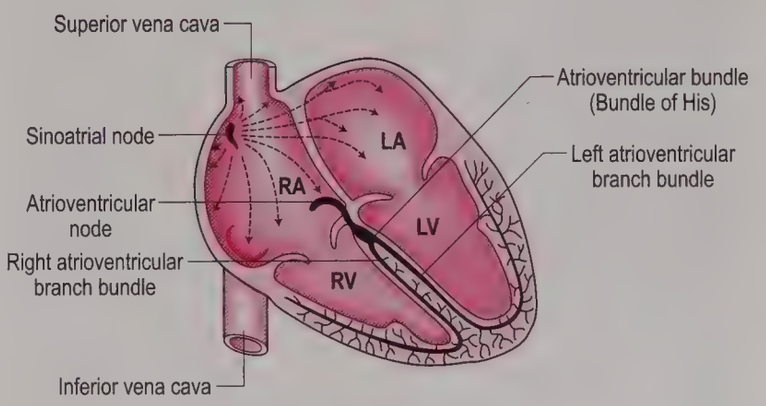

Fig. 2.3 The conducting tissues of the heart.

Structure and function of cardiac valves

The atrioventricular valves, i.e. the tricuspid and the mitral, function in a similar manner. During ventricular diastole (relaxation), they act as a funnel to promote rapid filling of the ventricles. Most of ventricular filling is passive. During ventricular systole (contraction), intraventricular pressure rises, pushing the cusps, which are restrained by the chordae tendineae, back and up towards the atria, thus preventing back-flow of blood during systole. These valves

can withstand high pressure, since their surface area is much greater than the orifice itself.

The semilunar valves, i.e. the pulmonary and the aortic, have three cusps each. They are closed during ventricular diastole. Once ventricular contraction begins, the intraventricular pressure rises, and when it exceeds that in the aorta and the pulmonary artery, the semilunar valves are forced open and blood is ejected. After ventricular systole, the pressures in the aorta and pulmonary artery exceed those in the left and right ventricles, respectively. Retrograde blood flow therefore occurs due to the difference in pressure, which fills the valve cusps and snaps them home. The closure of the valves produces the sounds referred to as heart sounds. Mitral and aortic valve closure produces the first heart sound (S1) which precedes that of the tricuspid and pulmonary valves known as the second heart sound (S2). The second heart sound is normally split because the aortic valve closes before the pulmonary valve, on inspiration, when the right ventricle takes longer to expel the increased venous return.

The conducting system of the heart

It is important that the contraction of the atria and ventricles is organised to ensure that filling and emptying of the chambers is coordinated and controlled.

Cardiac cells contract and relax as a result of a stimulus response system. The heart consists of two major types of cardiac cells: unspecialised myocardial cells, which are designed for contraction, and automatic cells, which specialise in impulse formation.

The main bulk of the atria and ventricles consists of unspecialised myocardial cells. Adjacent myocardial cells are held together by a complex system of projections known as intercalated discs with relatively low electrical resistance. These permit the movement of ions (electrically charged particles) which facilitates the propagation of action potentials from one myocardial cell to another. The main ions involved in the generation of a cardiac action potential are sodium (Na^+), potassium (K^+) and calcium (Ca^{2+}). In the normal resting state, the myocardial cell is said to be polarised and, due to the distribution of ions across its cell membrane, it is negatively charged on the inside (intracellular) and positively charged on the outside (extracellular). When electrical activation of the cell occurs, changes in the cell membrane permeability result in the movement of ions, with a resulting change in electrical polarity. The membrane is now said to be depolarised and has an intracellular positive charge and an extracellular negative charge. Return to the resting state for each cell is called repolarisation and involves active pumping of ions against concentration gradients.

For further details, consult Jowett & Thompson (2003).

As the myocardial cells are 'knitted' closely together, the electrical stimulation of any one single cell causes the action potential to be propagated through all adjacent cells, eventually reaching the entire lattice work of the myocardium.

The automatic cells regulate the contraction of the myocardial cells by providing the initial electrical stimulation. They do not contribute significantly to the cardiac contraction itself. These cells possess three specific properties:

- automaticity — the ability to generate action potentials, spontaneously and regularly
- excitability — the ability to respond to electrical stimulation by generating an action potential
- conductivity — the ability to propagate action potentials.

The electrical charge on the surface of an automatic cell leaks away until a certain threshold is reached, when spontaneous complete depolarisation occurs over the whole cell surface and spreads to adjacent cells, both automatic and unspecialised. The automatic cell with the most rapid leak of charge becomes the principal pacemaking cell. Normally this is located within the SA node.

The automatic cells are found in the cardiac conducting system (see Fig. 2.3), which consists of:

- the sinoatrial (SA) or sinus node
- the atrioventricular (AV) junction (the AV node and bundle)
- ventricular conducting tissue (the right and left bundle branches).

Sequence of excitation

Depolarisation begins at the SA node and spreads through both atria. The activating impulse travels at a rate of about 1 m/s and reaches the most distant portion of the atria in about 0.08 s. The atria and ventricles remain electrically separate except via the AV junction, which allows the action potential to be conducted from the atrial to the ventricular conducting system. When the impulse reaches the AV node, there is a delay of about 0.04 s to allow blood flow from the atria to the ventricles. After emerging from the AV node, the impulse enters the rapidly conducting tissue of the bundle of His and the right and left bundle branches. The rapid spread of the impulse throughout the ventricles means that the entire ventricular mass is depolarised almost simultaneously, which is necessary for efficient contraction and pumping.

Electrocardiography

Electrocardiography is the graphic recording from the body surface of potential differences resulting from electrical currents generated in the heart. This recording may be displayed on special graph paper or on an oscilloscope (monitor) and is known as an electrocardiogram (ECG). An ECG is a graphic record of electrical changes at the skin surface plotted against time. The main value of the ECG is in the detection and interpretation of cardiac arrhythmias, diagnosis of CHD and assessment of ventricular enlargement (hypertrophy).

The sequence of electrical events produced at each heartbeat has arbitrarily been labelled P, Q, R, S and T (see Fig. 2.4).

The P wave

is associated with atrial activation. The width of the P wave represents the time necessary for the atrial activation process. Following atrial depolarisation, an absence of

Fig. 2.4 ECG of one cardiac cycle.

electrical activity is noted on the ECG for a brief period, representing the passage of the impulse through the AV node. The PR interval, measured from the beginning of the P wave to the beginning of the QRS complex, is the time taken for the action potential to spread from the SA node, through the atrial muscle and the AV node, down the bundle of His and into the ventricular muscle mass.

The Q, R and S waves
are associated with ventricular activation. The first downward deflection after the P wave is always labelled the Q wave and the R wave is the first upward deflection. If a negative deflection follows an R wave, it is labelled an S wave. The width of the QRS complex shows how long the action potential takes to spread through the ventricles.

The ST segment,
a flat line between the S wave and the T wave, represents the early phase of ventricular muscle repolarisation, or recovery.

The T wave
represents the actual recovery of the ventricular muscle. Occasionally, a U wave can be observed following the T wave. The origin of this wave is not well understood, but it is considered significant in a state of hypokalaemia.

For more details on the ECG, see Houghton & Gray (2003).

Excitation–contraction coupling

Excitation–contraction coupling is the term used to describe the link between the electrical events and the contraction of the myocardial muscle. When an action potential passes over the cardiac muscle cell membrane, it is able to pass into the interior of each muscle cell down a series of fine branching tubules until it reaches the cell's contractile elements and stimulates the release of calcium ions. Calcium ions act as a catalyst for the chemical reaction that activates the sliding of thin muscle filaments (myofilaments) over each other to produce contraction. The strength of myocardial contraction is thus partly dependent on the intracellular concentration of free calcium ions.

Cardiac cycle

The cardiac cycle is the cyclical contraction (systole) and relaxation (diastole) of the two atria and the two ventricles. Each cycle is initiated by the spontaneous generation of an action potential in the SA node.

During diastole, each chamber fills with blood. Diastole usually lasts about 0.4 s, and during this time blood enters

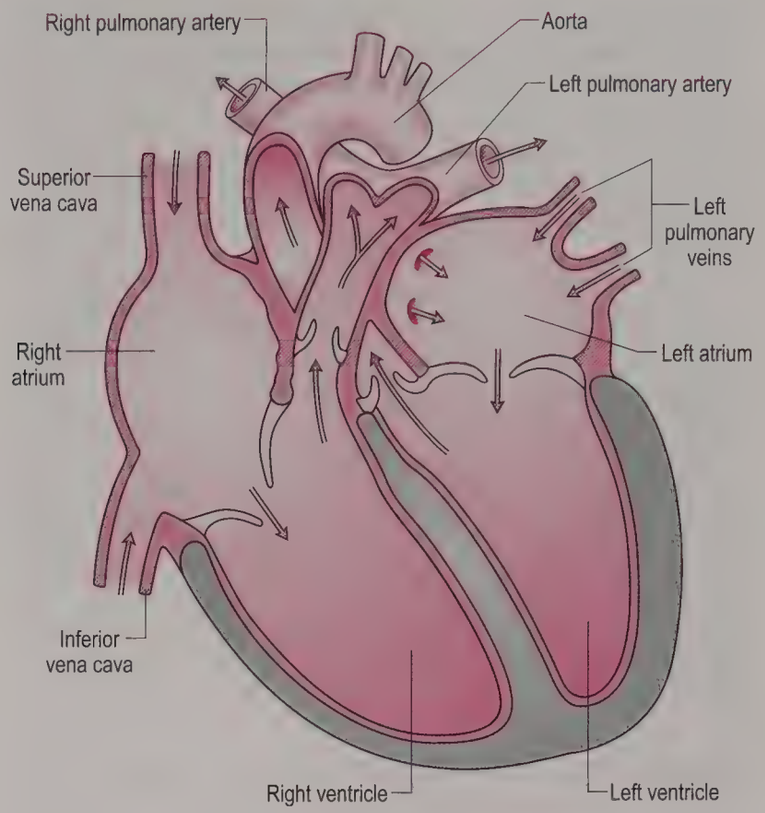

Fig. 2.5 Blood flow through the heart.

the relaxed atria and flows passively into the ventricles. During ventricular diastole, the mitral and tricuspid valves are open and the aortic and pulmonary valves are closed.

Blood is expelled from the chambers during systole. The atria contract fractionally before the ventricles and complete ventricular filling. The ventricles then begin to contract. Increasing pressure in the ventricles closes the mitral and tricuspid valves so that all four valves are closed. This is known as the isometric phase of ventricular contraction because the volume of blood in the ventricles remains constant. Ventricular pressure continues to rise until eventually the pulmonary and aortic valves are forced open and blood is ejected into the pulmonary artery and aorta. When the ventricles stop contracting, the pressure within them falls below that in the major blood vessels, the aortic and pulmonary valves close and the cycle begins again with diastole (see Fig. 2.5).

The normal heart rate is approximately 70 beats/min in the resting adult, with each cardiac cycle lasting approximately 0.8 s. With each ventricular contraction, 65–75% of the blood in the ventricle at the end of diastole is ejected. This is usually a volume of 70–80 mL of blood and is known as the stroke volume.

Cardiac output is the volume of blood ejected from one ventricle in 1 min. Although cardiac output is a traditional measure of cardiac function, it differs markedly with body size. Thus, a more informative measure is the cardiac index, which is the cardiac output per minute per metre squared of body surface area. Usually it is about 3.2 L/m^2.

The primary factors which determine cardiac output are:

- preload — the amount of tension on the ventricular muscle fibres before they contract, determined primarily by the end-diastolic volume (EDV)

- afterload — the resistance against which the heart must pump. Major components of afterload are:
  — blood pressure in the aorta
  — resistance in the peripheral vessels
  — the size of the aortic valve opening
  — left ventricular size
- contractility of the heart
- heart rate.

Within physiological limits, the volume of blood pumped out by a ventricle is the same as that entering the atrium on the same side of the heart, i.e. cardiac output matches venous return. This principle is often referred to as the Frank–Starling law of the heart. This means that the heart is able to adapt to changing loads of inflowing blood from the systemic and pulmonary circulations. Within certain limits, cardiac muscle fibres contract more forcibly the more they are stretched at the start of contraction. Once the venous return increases beyond a certain limit, the myocardium begins to fail. This regulation of the heart in response to the amount of blood to be pumped is known as intrinsic regulation.

Regulation of cardiac function by the autonomic nervous system

The autonomic nervous system alters the rate of impulse generation by the SA node, the speed of impulse conduction and the strength of cardiac contraction. It regulates the heart through both sympathetic and parasympathetic nerve fibres. The sympathetic fibres supply all areas of the atria and ventricles, and the effects on the heart include increased heart rate, increased conduction speed through the AV node and increased force of contraction. Parasympathetic impulses are conducted to the heart via the vagus nerve and affect primarily the SA node, the AV node and the atrial muscle mass. Parasympathetic stimulation produces decreased heart rate, decreased conduction rate through the AV node and decreased force of atrial contraction.

Sympathetic and parasympathetic control of the heart occurs by reflexes coordinated in the medulla oblongata of the brain. The group of neurones in the brain that affects heart activity and the blood vessels is known as the cardiovascular centre. This centre receives information from various sensory receptors. Baroreceptors, located in the atria, the aortic arch and carotid sinuses, alter their rate of impulse generation in response to changes in blood pressure; chemoreceptors, located for example in the carotid artery, respond to changes in the chemical composition of the blood.

ANATOMY AND PHYSIOLOGY OF THE BLOOD VESSELS

Systemic circulation

The systemic circulation is a high-pressure system that supplies all the tissues of the body with blood. It consists of the arteries, arterioles, capillaries, venules and veins. Blood flows through the system because of a downward pressure gradient from the aorta to the superior and inferior venae cavae. Arteries distribute oxygenated blood from the left side of the heart to the tissues, and veins convey deoxygenated blood from the tissues to the right side of the heart. Adequate perfusion resulting in oxygenation and nutrition of body tissues is dependent in part upon patent and responsive blood vessels and adequate blood flow.

Arteries and arterioles

Arteries are thick-walled structures that carry blood from the heart to the tissues. The major arteries leading from the heart branch to form smaller ones, which eventually give rise to arterioles. The walls of the arteries and arterioles are divided into three layers:

- the inner layer provides a smooth surface in contact with the flowing blood
- the middle layer, the thickest, consists of elastic fibres and muscle fibres; the elasticity of the arterial wall enables it to recoil during ventricular relaxation and maintain blood flow
- the outer layer of connective tissue anchors the vessel to its surrounding structures.

There is much less elastic tissue in the arterioles than in the arteries. The middle layer of the arteriole wall consists primarily of smooth muscle which, by contraction and relaxation, controls the vessel's diameter. Arterioles regulate the pressure in the arterial system and the blood flow to the capillaries. The arterioles respond to local conditions such as a decrease in oxygen concentration or an increase in the concentration of carbon dioxide or other waste products. This ensures that tissue that needs extra oxygen receives extra blood flow.

Arterioles will sometimes respond to changes in blood pressure. A local increase in blood pressure will cause the arterioles to constrict, in order to protect the smaller vessels in the tissue from increased pressure. If pressure in the arterioles suddenly decreases, the arterioles will dilate to ensure that the tissue receives sufficient blood flow for nutrition. This local regulatory mechanism is sometimes referred to as autoregulation and is an important factor in determining relatively constant blood flow despite alterations in arterial pressure, for example, the autoregulation ensuring glomerular filtration (see p. 358). The sympathetic nervous system will also influence the diameter of the arterioles. Increased sympathetic stimulation to blood vessels usually produces constriction, whereas decreased sympathetic stimulation results in vasodilatation.

Capillaries

The velocity of the blood is at its slowest in the capillaries, thus allowing sufficient time for exchange of materials between the blood and the interstitial space. Capillary walls lack muscle. They consist of a single layer of cells and have a large total surface area. Their thin walls allow efficient transport of nutrients to the cells and the removal of metabolic wastes. The density of capillary networks varies in different tissues.

Veins and venules

Capillaries join together to form larger vessels called venules, which in turn join to form veins. The walls of the veins are thinner and much less muscular than the arteries. This allows the veins to distend more, which permits storage

of large volumes of blood in the veins under low pressure. Approximately 75% of total blood volume is contained in the veins. Some veins are equipped with valves to prevent the reflux of blood as it is propelled towards the heart. The sympathetic nervous system can stimulate venoconstriction, thereby reducing venous volume and increasing the general circulating blood volume. This adjustment of the total volume of the circulatory system to the amount of blood available to fill it contributes to the regulation of blood pressure.

Blood pressure

Blood pressure refers to the hydrostatic pressure exerted by the blood on the blood vessel walls and is a consequence of blood flow and vascular resistance. As most of the resistance to blood flow is due to the peripheral vessels, especially the arterioles, it is often described as the total peripheral resistance, as in the equation:

$$\text{mean arterial pressure} = \text{cardiac output} \times \text{total peripheral resistance}$$

Blood pressure varies in different blood vessels. However, clinically the term 'blood pressure' refers to systemic *arterial* blood pressure.

Arterial blood pressure

Arterial blood pressure fluctuates throughout the cardiac cycle. The maximum pressure occurs after ventricular systole and is known as the *systolic* pressure. Systolic pressure is dependent on the stroke volume, the force of contraction and the stiffness of the arterial walls. Systolic blood pressure normally falls a little on standing and this fall may be particularly marked in those with autonomic failure, taking vasodilator medication or in shock. The level to which arterial pressure falls before the next ventricular contraction is the minimum pressure, known as the *diastolic* pressure. Diastolic pressure varies according to the degree of vasoconstriction and is dependent on the level of the systolic pressure, the elasticity of the arteries and the viscosity of the blood. Normally the diastolic blood pressure rises a little on standing. Alterations in heart rate will also affect diastolic pressure. A slower heart rate produces a lower diastolic pressure as there is more time for the blood to flow out of the arteries. The difference between the systolic and diastolic blood pressures is known as the 'pulse pressure'. The average pressure attempting to push the blood through the circulatory system is known as the 'mean arterial pressure'.

Blood pressure values

There is no such thing as a 'normal' blood pressure, as it varies both from person to person and in individuals from moment to moment, under different circumstances. The optimal blood pressure targets are a systolic blood pressure of less than 120 mmHg and a diastolic blood pressure of less than 80 mmHg (Williams et al 2004). Factors such as age, gender and race influence blood pressure values. Pressure also varies with exercise, emotional reactions, sleep, digestion and time of day.

The predominant mechanisms that control arterial pressure within the 'normal' range are the autonomic nervous system and the renin–angiotensin–aldosterone system.

Baroreceptors respond to changes in arterial pressure and relay impulses to the cardiovascular centre in the medulla oblongata. When the arterial pressure is increased, baroreceptor endings are stretched and relay impulses that inhibit the sympathetic outflow. This results in a decreased heart rate and arteriolar dilatation and the arterial pressure returning to its former level. If the blood pressure remains chronically high, the baroreceptors are reset at a higher level and respond as though the new level were normal.

When blood flow to the kidneys decreases, with a fall in blood pressure, renin is released. Renin is an enzyme which acts on the blood protein angiotensinogen, which is converted to angiotensin I in the liver and then, by another enzyme in the kidney, to angiotensin II. Angiotensin II produces an elevation in blood pressure by direct constriction of arterioles. Angiotensin II also directly stimulates the release of the hormone aldosterone from the adrenal cortex which leads to renal retention of sodium and water in the distal convoluted tubules. This increases extracellular volume, which in turn increases the venous return to the heart, thereby raising stroke volume, cardiac output and arterial blood pressure. The kidneys respond to an increase in arterial pressure by excreting a greater volume of fluid. This decreases the extracellular fluid, resulting in a lower venous return and reduced cardiac output until arterial pressure is returned towards normal.

DISORDERS OF THE CARDIOVASCULAR SYSTEM

Atherosclerosis

Atherosclerosis is a complex disorder of the arteries characterised by the progressive accumulation of cholesterol within the intima of large and medium arteries. It is a disease with phases of stability and instability. Although the pathogenesis of atherosclerosis is still not fully understood, it is thought to involve endothelial injury, inflammatory processes and the focal distribution of lipids and fibrous tissue in the form of atheromatous plaques, particularly around branching vessels and arterial curvature. These plaques evolve over decades, a mature plaque having a soft, lipid-rich core surrounded by a hard fibrous capsule. There is thickening and hardening of the vessel walls with resultant loss of elasticity (see Figs 2.6 and 2.7).

For further details of the pathogenesis of atherosclerosis, see Jowett & Thompson (2003).

Atherosclerosis is responsible for most CHD and much peripheral and cerebrovascular disease. Emboli may arise as a result of pieces of dead tissue from the damaged arterial wall breaking off. With progression of the process, the lining of the vessel wall may become eroded and, especially if the blood pressure is elevated, the vessel may become permanently dilated and weakened, forming an aneurysm. Vessels may become blocked or stenosed or, as a result of endothelial damage and platelet adhesion, an ulcer-like site can develop, leading to thrombus formation. This thrombus may cause complete obstruction of the artery or may break down spontaneously. This dynamic process occurs over a period of hours to days, preceding an acute coronary event or spontaneous resolution.

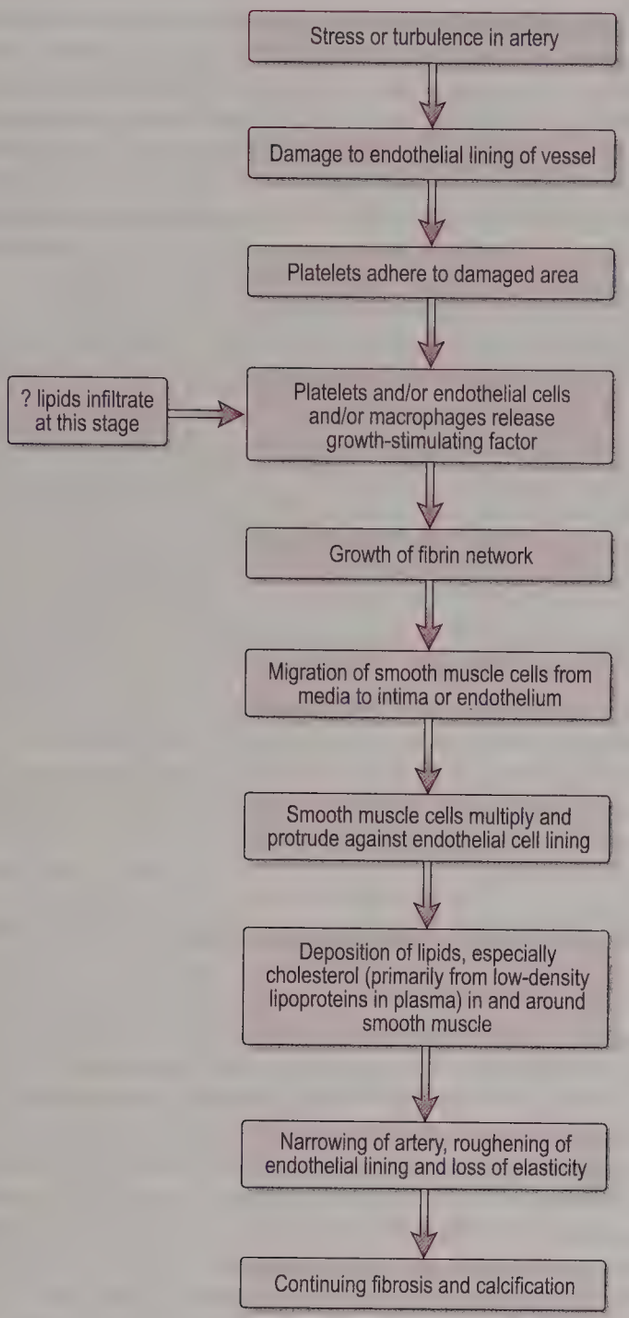

Fig. 2.6 Probable course of events in the development of atheroma.

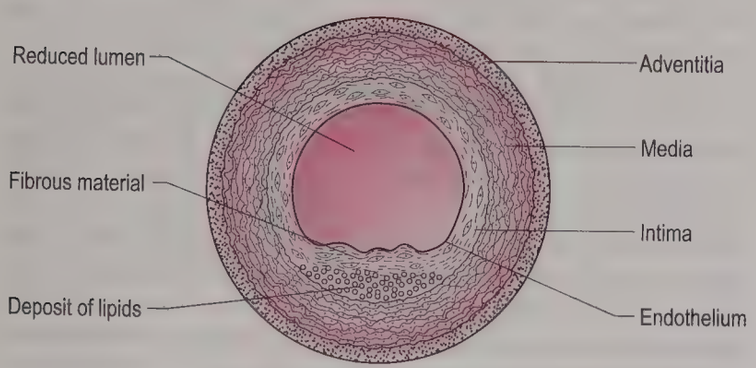

Fig. 2.7 Cross-section of an artery.

Myocardial ischaemia

Traditionally, myocardial ischaemia is defined as a condition of the heart in which there is an imbalance between oxygen supply and demand. Oxygen demand depends mainly upon heart rate, myocardial contractility and tension in the myocardial wall. Oxygen supply to the myocardium varies with coronary blood flow. The heart extracts the maximum amount of oxygen from its blood supply and is dependent upon an increased volume of blood in times of increased demand. Myocardial blood supply may be compromised by abnormalities of the vessel wall, the blood flow or in the blood itself.

Localised myocardial ischaemia may be intermittent and have reversible effects, but it inevitably causes decreased myocardial function. Ischaemia results in acidosis and the rapid accumulation of potassium in the extracellular space. Pain is usually experienced after about a minute of myocardial ischaemia.

Coronary heart disease manifests itself as:

- stable angina
- acute coronary syndrome, including unstable angina and myocardial infarction
- sudden death.

Risk factors

Epidemiological studies have sought to find associations between CHD and physical, biochemical and environmental characteristics of a population or individuals. As a result, predictive variables, termed risk factors, have been defined, which have been shown to be associated with the development of disease. These include male gender, increasing age, ethnic origin, low birth weight and a history of premature CHD. These are unavoidable risk factors; however, modifiable risk factors include:

- raised serum cholesterol levels
- cigarette smoking
- hypertension.

The known risk factors are extremely common in the UK and they tend to 'cluster' in individuals with one factor adding to the risk of another. The average level of serum cholesterol in different populations roughly predicts the risk of CHD. A raised serum blood cholesterol has been defined as being above 5.2 mmol/L, with the mean cholesterol level for men in England being 5.5 mmol/L and for women 5.6 mmol/L (British Heart Foundation 2004). The average diet in the UK is unhealthy. In particular, fat intake, especially of saturated fat, is too high and fruit and vegetable consumption is too low. More than a quarter of the population smoke cigarettes (Joint Health Surveys Unit 2001). Almost a quarter of the deaths from CHD in men are attributable to smoking (British Heart Foundation 2004) and there is a marked social class difference in smoking habits. Less than half the population take no moderate intensity physical activity in a typical week (British Heart Foundation 2004).

Individuals with blood pressure at the upper limits of the population distribution have an increased incidence of atherosclerotic, thrombotic and haemorrhagic vascular disease and an increased morbidity and mortality due to stroke, myocardial infarction and peripheral vascular

disease. The systolic blood pressure is the better predictor of subsequent cardiovascular risk. The World Health Organization (WHO) has estimated that over 50% of CHD in developed countries is due to a systolic blood pressure in excess of the theoretical minimum of 115 mmHg (WHO 2002). In England, 37% of men and 34% of women have hypertension, defined as a systolic blood pressure over 140 mmHg and a diastolic blood pressure over 90 mmHg (British Heart Foundation 2004). Hypertension Society guidelines support initiation of intervention on the level of overall cardiovascular risk rather than absolute blood pressure values (Williams et al 2004).

Other risk factors are:

- obesity
- lack of physical exercise
- stress (see Ch. 17)
- diabetes mellitus and glucose intolerance.

Major geographical variations in the incidence of CHD are apparent. Mortality rates from CHD have been falling in the UK since the late 1970s; however, the rates in the UK are very close to the top of the international league table. Scotland, Northern Ireland and the north of England have the highest mortality rates; the south-east of England has the lowest. Mortality from CHD differs significantly between ethnic groups. It is highest in those born in the Indian subcontinent and is also raised in Irish- and Polish-born immigrants. Risk factors need to be viewed in conjunction with each other, as their effect is cumulative. Although, by definition, each risk factor associates positively with increased risk of CHD, it does not follow that risk factors are causal. It is also important to remember that a significant number of patients presenting with CHD do not have identifiable risk factors and that standard risk factors explain less than half the disease (see Table 2.1).

2.1 Empowering people is neither simple nor easy. What might hinder people from taking greater control over their health and what might encourage them to do so?

For more information on coronary heart disease prevention, see Lindsay & Gaw (2003).

Stable angina

Angina is a symptom, rather than a disease, describing discomfort or pain resulting from a transient, reversible episode of inadequate coronary circulation occurring as a result of an imbalance between oxygen supply and demand. Similar symptoms may be caused by disorders of the oesophagus, lungs or chest wall. It is estimated that over 1.2 million people in the UK suffer from angina (British Heart Foundation 2004). Angina is regarded as stable if it has been recurring over several weeks without major deterioration, although symptoms may be variable depending on environmental temperature and emotion.

Table 2.1 Modifiable and non-modifiable risk factors for coronary heart disease

Non-modifiable risk factors	Modifiable risk factors
Age	Blood cholesterol
Gender	Tobacco smoking
Ethnicity	High blood pressure
Genetic predisposition	Overweight and obesity
Low birth weight	Diet
Diabetes mellitus	Alcohol consumption
Hormonal and biochemical factors	Social class Geographical distribution

PATHOPHYSIOLOGY

Ischaemia usually occurs as the result of reduced coronary artery blood flow following coronary artery obstruction caused by fixed atheromatous deposits in the major epicardial arteries. Spasm or thrombus may also contribute to the obstruction. There is insufficient oxygen delivery for local metabolic demand and this releases lactic acid as cells switch to anaerobic metabolism. Pain is experienced, as sensory neurones innervating the heart are richly endowed with an ion channel that is opened by the increase in lactic acid concentration. It is usually felt that a coronary artery must be narrowed by at least 50% before coronary blood fails to meet the demands of the heart during exertion. Severe anaemia and hypoxia can also produce a decreased myocardial oxygen supply. Increased demand for myocardial oxygen can occur in a variety of clinical conditions, including tachycardia, hypertension, valvular stenosis, left ventricular hypertrophy and hyperthyroidism.

Common presenting symptoms

The presentation and history may vary and initially mislead the practitioner if a thorough examination is not undertaken. The history is usually of discomfort, often related to specific events. The presenting features indicate a deficiency in the oxygen supply, such as:

- episodic pain or discomfort occurring centrally in the chest, often described as 'dull', 'aching' or a 'tight band'. This may radiate to the arms, particularly the left arm, jaw or neck. It is often induced by exercise or emotion and relieved by rest. Angina takes many forms. Typically, the duration of an attack of angina is 2–5 min
- breathlessness on exertion, e.g. walking uphill, or in cold weather
- discomfort in the epigastric region after a heavy meal.

Diagnosis

Angina is diagnosed by the nature of the symptoms, the perceived likelihood of coronary artery disease in that individual and the results of various diagnostic tests. It is recommended that all newly diagnosed cases of angina be referred to a physician with a specialist interest and training in cardiology (De Bono 1999). Where the diagnosis is in doubt, or where a positive diagnosis of angina would have significant implications, patients should have rapid access to, and be assessed by, a cardiologist within 2 weeks of referral via a rapid access chest pain clinic (DH 2000).

A good history is the most important part of the assessment as the pain of angina may be confused with the pain of oesophagitis or the pain of peptic ulceration. Patients, fearing a 'heart attack', may choose to interpret the pain as 'a little indigestion'.

MEDICAL MANAGEMENT

Investigations

are as follows:

Electrocardiogram (ECG) An abnormal ECG both supports the diagnosis and identifies those with a poor prognosis. The recording is invariably normal between attacks of angina; however, during an episode of pain, the segment between the end of the QRS complex and the beginning of the T wave may be depressed (ST depression), indicating ischaemia. The T wave may also be flattened or inverted.

Exercise tolerance test This is a means of assessing the heart's response to increased demand. It is useful for both diagnosis and assessing prognosis. The test is based on the theory that patients with ischaemic heart disease will produce marked ST segment depression on the ECG when exercising. The test is considered negative if there are no significant ECG abnormalities and the patient experiences no significant symptoms. Three common methods of exercise testing include:

- climbing stairs
- pedalling a stationary bicycle
- walking on a treadmill.

In the exercise tolerance test, the ECG, heart rate and blood pressure are recorded while the patient engages in some form of physiological stress. The principle is that coronary arteries that may be occluded will be unable to meet the heart's increased oxygen demand, resulting in chest pain, fatigue, dyspnoea, excessive heart rate (tachycardia), a fall in blood pressure or the development of arrhythmias. The test is stopped if any of these occur, or before, at the patient's request. The patient needs to have the procedure explained in detail before the test, should be advised to avoid a heavy meal prior to the test and to wear loose-fitting clothes. The term 'stress' test is best avoided as it may sound ominous and increase patient anxiety. The procedure takes about 30 min.

Holter monitoring Continuous monitoring of the ST segments of the ECG can be used to detect transient changes compatible with ischaemia.

Myocardial perfusion imaging is a non-invasive method of assessing myocardial perfusion by intravenous injection of a radioisotope, usually thallium or technetium, which is taken up by the heart and distributed throughout the myocardium in proportion to regional blood flow.

Radionuclide ventriculography is used to identify patients with poor left ventricular function.

Stress echocardiography involves the imaging of altered myocardial contractility during exercise or pharmacological stress. Using medication rather than exercise to induce stress is particularly useful if the patient is unable to exercise.

Coronary angiography involves the injection of contrast medium into the heart during cardiac catheterisation. The procedure shows the shape and size of the heart chambers and will pinpoint any stenosis or occlusion in the coronary arteries. This test is described in Box 2.1. Angiography is justifiable in all cases where the results would alter patient management. It carries a mortality of 0.1%. Elective referral for angiography is warranted for

Box 2.1

Cardiac catheterisation

Purpose

Cardiac catheterisation involves the insertion, usually under screening, of a fine, flexible, radio-opaque catheter into one or more of the heart chambers. It is increasingly being performed as a day-case procedure. The catheter is inserted via a peripheral vein or artery under sterile conditions in a cardiac catheterisation laboratory. The femoral artery/vein are the most common entry sites although the radial and brachial are also used. The right and left side of the heart may be investigated separately or together. The procedure is performed to:

- visualise the heart chambers and vessels by means of a radio-opaque substance under X-ray control (angiography), e.g. used in the diagnosis of angina
- measure pressure and record waveforms from the cavity of the heart
- obtain blood samples from the heart
- measure left ventricular function (ejection fraction).

Cardiac catheterisation will always be performed on a prospective candidate for coronary artery bypass graft surgery, valve surgery and heart transplantation. It is also used to evaluate the effect of thrombolytic agents and the patency of coronary bypass grafts.

Procedure

The patient must give written informed consent for the procedure. Cardiac catheterisation is usually carried out under local anaesthesia and the patient may be given diazepam as premedication. The patient is usually asked to fast for 4 h to prevent aspiration, should cardiac arrest occur. The groin area will be shaved. The procedure is performed by a cardiologist and takes approximately 90 min. The patient will be asked to wear a gown and should be prepared to lie flat on their back on a hard table during the procedure. A needle with a guide wire attached is inserted into the vessel and the needle then removed. A sheath is then threaded over the guide wire, the guide wire removed and the catheter inserted through the sheath. The patient is warned to expect a sudden burning sensation as the dye is injected into the heart. Angina may occur as a result of the catheter blocking the artery and may be treated with sublingual glyceryl trinitrate (GTN) spray, oxygen therapy and intracoronary isosorbide dinitrate.

Following the procedure the patient may require analgesics and should be allowed to rest. Observations are taken and the sheath removed. A pressure dressing will be applied to the wound site, which must be observed for excessive bleeding. The limb should be kept straight for 1–2 h to prevent turbulence of blood flow at the incision site. Patients usually stay in bed for 2 h and most are ready for discharge 2 h later.

Possible complications

Patients may experience transient cardiac arrhythmias and syncope. A reaction to the dye may produce symptoms ranging from a rash to anaphylaxis. There is a 0.5% risk of thrombus formation, leading to a cerebrovascular accident or myocardial infarction, and a 0.1% risk of dying from such a complication. Coronary artery dissection is a rare complication. The patient may experience pulmonary oedema whilst lying flat and this is treated with oxygen, nebuliser therapy and diuretics.

those with a positive exercise test and on maximsum medication therapy.

Treatment

The aim of treatment for angina is to:

- restore and maintain cardiac output necessary for normal living activities
- reduce the workload of the heart
- bring back into balance oxygen supply and demand
- reduce the risk of progression to acute coronary syndrome.

Treatment is achieved by:

- medication to optimise cardiac function by relieving the pain of angina and improving myocardial perfusion (see Table 2.2)
- reduction in myocardial workload
- reducing risk factors
- percutaneous coronary interventions (PCI). This describes a group of techniques that include percutaneous transluminal coronary angioplasty (PTCA), stenting, coronary artery bypass graft (CABG), athero-ablation and, more recently, transmyocardial laser revascularisation and angiogenesis. These interventions would be considered if conventional medical therapy failed to control symptoms.

(a) What is the significance of this test result?
(b) What other tests might be requested?

NURSING PRIORITIES AND MANAGEMENT: Angina

The major goals for the patient are to:

- prevent or minimise chest pain
- cope with the anginal pain and any other symptoms
- reduce anxiety
- be aware of the underlying nature of the disorder
- understand the prescribed care and be able to make informed decisions about future lifestyle in order to reduce the risk of disease progression.

Nursing input will vary according to the type of contact a person has with health care services. Practice nurses and occupational health staff may be the main source of professional information and support for those in the community. Admission to hospital is likely to occur only if the angina becomes unstable or further investigation is warranted.

Nursing assessment should pay particular attention to those activities that have been found to precede and precipitate attacks of angina pain and associated symptoms, so that a logical programme of prevention can be worked out with the patient, who needs to feel in control of their condition and to regain a realistic outlook for the future. Nurses are in a prime position to contribute to risk factor management, particularly in terms of patient education (Scholte-op-Reimer et al 2002). They also have a significant role in the care of patients with chronic angina who get limited relief from conventional medical treatment (Stewart 2003).

Maintaining a safe environment

The effect of angina on the person and on those around them needs to be considered. The patient needs to know both how to prevent attacks and how to manage them when they occur. As the nurse will not witness many of the attacks, it should be impressed upon the patient that their management lies with them and their family. As much of the nursing management involves advice about potential adaptations in lifestyle, family members will require similar information and support.

The individual needs to be advised to plan their day-to-day life around adequate rest periods. If they cannot avoid activities liable to precipitate an attack, then they should rest before and after such activity. For example, a large family gathering such as a wedding can be very stressful, with socialising, a large meal to eat and considerable preparation. As much time as possible should be spent quietly, with rest periods after dressing and after the meal. Explaining to other members of the family the reason for this is better than suffering an attack during the proceedings.

Taking glyceryl trinitrate (GTN) prophylactically is often the best way of managing situations likely to induce angina.

A change of occupation is sometimes necessary following a diagnosis of angina; it could, for example, be unsafe to drive public transport vehicles. This double blow can be very difficult for the person to accept. The occupational health nurse can help, as they will be aware of other areas to which the individual can be relocated. If retraining is required, social worker and retraining counsellors may be involved from the outset.

Mobility

Exercise is the most common cause of an attack, and patients should understand that they must stop and rest and not attempt to work through the pain. The patient should know how to use GTN, both to prevent and to treat an attack. If the patient takes GTN prior to an activity likely to cause angina, they may prevent an attack and still complete the activity. However, the patient needs to appreciate that they should not use GTN in order to over-exercise, but to maintain a reasonable quality of life and to achieve some control over the condition. They should be encouraged to keep records of the activities that induce angina. These can be reviewed with their practitioner to provide a reliable

CASE HISTORY 2.1(A)

Mr B

Mr B is a 55-year-old factory foreman who regards himself as being fit and well for his age. He plays badminton at the local sports club two or three times a week and enjoys taking his dog on regular rambles. He does not smoke and, being aware of factors leading to heart disease, has tried to reduce the fat intake in his diet over the past few years. His father died of a heart attack at the age of 73. Mr B's company offer regular medical checks to screen for health problems and on his last visit he underwent an exercise test. After 5 min of the test he felt short of breath. He was noted to have ST-segment depression.

Table 2.2 Medications used in angina

Medication	Use	Physiological action	Comments
Nitrates			
Glyceryl trinitrate (GTN) spray or tablets	Used for relief of angina Administered as spray form or tablet under the tongue to ensure rapid release into the bloodstream Can be given i.v., maintenance dose 6–10 mg/h	Venodilatation with consequent reduction in preload Also causes systemic arteriolar vasodilatation with decrease in afterload	Tablets need to be stored correctly Tablets lose potency over time and if exposed to light Tablets should not be kept for more than 2 months, should be stored in an airtight container and not be exposed to light
Suscard buccal	Slow-release form of nitrate placed in the buccal cavity	As above Used for effect for 4–5 h	
Isosorbide mononitrate (oral or i.v.)	Used for prevention of angina	As above Used as longer-term control	Patient can develop tolerance
Beta-blockers e.g. atenolol	Used in preventing angina Given once or twice daily Dose lower than when prescribed for hypertensive patients	Block sympathetic stimulation, so slowing the heart rate and reducing oxygen demand	Used with caution in patients with chronic obstructive airways disease and asthma as it may cause bronchospasm
Calcium channel blockers e.g. nifedipine	Used in preventing angina	Interfere with calcium transfer across the cell membrane, causing relaxation of arteriolar smooth muscle, thus reducing afterload Affects rate of action potential and reduces oxygen demand	
Potassium channel activators e.g. nicorandil	Have a role in unstable angina	Similar to that of nitrates May reduce transient myocardial ischaemia	
Angiotensin-converting enzyme (ACE) inhibitors e.g. captopril, enalapril, ramipril	Of particular benefit for patients with clinical signs of heart failure	Prevents the production of angiotensin II, thereby limiting vasoconstriction and decreasing aldosterone-induced sodium reabsorption in the kidney Reduces fluid load within the patient and the work of the heart	
Angiotensin-II receptor antagonists e.g. losartan	Effective alternative for patients intolerant of ACE inhibitors	Prevents the action of angiotensin II	
Anticoagulants			
Unfractionated heparin	Full anticoagulation with heparin is recommended in patients with increased risk of thromboembolic complications	Prevents the initiation as well as the propagation of thrombi Has a less predictable anticoagulation effect than low molecular weight heparin	Used in patients with cardiac failure, anterior MI Requires anticoagulation monitoring using the activated partial thromboplastin time (APTT)
Low molecular weight heparin, e.g. enoxaparin	Started early in unstable angina to inhibit thrombus formation	As effective and as safe as unfractionated heparin of longer duration, given once daily	The standard regimen does not require monitoring as low molecular weight heparins have a more predictable effect
Warfarin	Used for patients with arrhythmias, e.g. atrial fibrillation May also be used for anticoagulation with certain high risk MI patients	Antagonises the effect of vitamin K, essential for the formation of prothrombin	Takes 36–48 h to become effective Oral anticoagulation is monitored by the prothrombin time estimation expressed in terms of the international normalised ratio (INR)

Table 2.2 Medications used in angina *(Continued)*

Medication	Use	Physiological action	Comments
Antiplatelets			
Aspirin	Small dose taken daily to protect against MI	Aspirin prolongs the prothrombin time as well as decreasing platelet viscosity	Small dose should not affect the stomach lining
Clopidogrel	Used as an alternative to aspirin, particularly for medium to high risk patients	Helps prevent platelet aggregation by inhibiting the expression of the glycoprotein IIb/IIIa inhibitor	There are proven benefits of reducing MI in unstable angina if clopidogrel is used in conjunction with aspirin
Glycoprotein IIb/IIIa inhibitors, e.g. abciximab, eptifibatide, tirofiban		Inactivating the glycoprotein IIb/IIIa inhibitor blocks the final common pathway in platelet aggregation and therefore prevents clot formation	
Fibrinolytic agents			
Streptokinase, reteplase, tissue plasminogen activator (tPA)	Used in patients with ST elevation myocardial infarction (STEMI)	Induce dissolution of the thrombus that is blocking the coronary artery but do not affect lumen narrowing caused by atherosclerosis	Needs to be given within 12 h and, ideally, within 1 h, after the onset of chest pain in appropriate patients Contraindications include CVA, recent trauma, surgery, bleeding
Lipid regulating therapy			
Statins: e.g. atorvastatin, simvastatin			It is reasonable to start all cardiac patients on a statin regardless of their cholesterol level
Fibrates: e.g. bezafibrate			Fibrates are particularly useful in patients with high triglyceride levels

CVA, cerebrovascular accident; MI, myocardial infarction.

assessment of angina and of the effectiveness of therapy. Knowledge of their limitations gives the patient some feeling of control over their own life and they can then attempt to address them.

Many of the heavier household tasks induce angina, e.g. shopping, ironing and vacuuming, and often make patients feel vulnerable. A basket with wheels can be used to transport shopping, and other such simple measures are easily adapted into people's lifestyles. Help from other family members or domestic help in the home may be another solution.

Breathing

In some individuals, angina presents as, or is accompanied by, difficulty in breathing. This is often worse in cold or windy weather. Such individuals need to be advised against walking great distances in these conditions. Smokers need to be clear about the association between CHD and cigarette smoking, so that they can make informed decisions about stopping.

Cigarette smokers have a two to three times greater risk of death from CHD than non-smokers. The risk is greater in young adults and in those who smoke more than 20 cigarettes a day. Nicotine stimulation results in increased catecholamine release with an increase in heart rate, cardiac output, blood pressure and coronary blood flow. Carbon monoxide attaches itself to the haemoglobin molecule and therefore reduces its ability to transport oxygen. Oxygenation is therefore reduced, despite increased myocardial requirements. Additionally, nicotine inhibits the breakdown of fibrin and increases platelet aggregation and stickiness, making clot formation more likely.

The nursing history should include information as to whether the patient has previously tried to give up smoking and, if so, how they planned to stop, how long they were able to stop, what support they received and why they started smoking again. Any perceived benefits of smoking, e.g. stress reduction, need to be discussed and plans for stopping based on experience gained in conjunction with new information and advice given (see Ch. 3).

2.3 Many strategies for giving up smoking exist and not all will suit everyone. What strategies can you identify?

Nutrition

Obese people develop CVD more frequently than others. Obesity also denotes an increased likelihood of hypertension, hyperlipidaemia and diabetes mellitus. Obese individuals also tend to take less exercise. Subjective assessments of obesity are often inaccurate and a more precise method of assessment is often made using the body mass index (BMI) that adjusts the weight for height (see Ch. 21).

However, the hip:waist ratio may be a better predictor of cardiovascular risk than the BMI as it identifies abdominal obesity which is frequently linked with impaired glucose intolerance, lipid abnormalities and hypertension.

Total serum blood cholesterol levels have been shown to be associated with CHD mortality and morbidity (see Box 2.2). However, there is a negative association between one category of lipoproteins, high-density lipoproteins (HDLs), and CHD: the risk of the disease is lower when the concentration of HDLs is raised. Dietary advice needs to take into account personal preferences and domestic, socio-economic and cultural factors. Alterations to general eating habits are preferable to restrictive diets. Sensible dietary advice includes:

- losing excess weight
- reducing fat, particularly saturated fat intake
- reducing salt intake
- increasing fibre intake
- eating five portions of fruit and vegetables a day.

Eating more fish, poultry, vegetables, grains, cereals and fruit should be encouraged. Keeping within an ideal body weight range and taking suitable physical exercise are logical recommendations (see Ch. 21).

Large meals may trigger an attack of angina, so small, frequent meals are preferable. It can be difficult to motivate people to change their diet. Involving the family is very important, particularly the person primarily responsible for buying food and preparing meals.

The patient who presents to the medical services with epigastric pain may not have a digestive problem, but have angina, particularly if the history is vague. Diagnosis requires history-taking skills and spending time with the patient.

Alcohol intake should be discussed with the individual. In small quantities, alcohol has a vasodilatory effect which is beneficial in CHD, so a small nightcap will help to relax the patient and aid sleep. However, heavy drinkers are at greater risk of cardiac events and of hepatic dysfunction.

The patient should know whether their medication should be taken before or after meals and its effect if taken alongside alcohol intake.

Work and recreation

The person with angina has to come to terms with the progressive nature of the disease. People with limited energy reserves may put all their effort into work and find they have little left for leisure pursuits. The nurse's role is to assist the individual to assess their lifestyle and make decisions about priorities and possible changes. Those with sedentary lifestyles should be advised to take regular exercise, such as walking to work, climbing the stairs, swimming and cycling. Some apparently sedentary jobs may be mentally exhausting, which can put severe strain on the compromised myocardium and lead to an anginal attack. Planning the day is important, to allow for quiet periods, particularly before and after long meetings or heavy business lunches. For certain individuals, therapy such as relaxation techniques or yoga may help. If a change of occupation, or early retirement, is proposed as the only solution, the person may resist, particularly if they are the family breadwinner.

Box 2.2

Understanding cholesterol

Definition: a steroid found in animal fats and most body tissues, especially nervous tissue.

Cholesterol has received rather bad publicity in recent years because of the role it has been found to play in the formation of atheromatous plaques, but it must be remembered that, although it is not used as an energy fuel, cholesterol is an important dietary lipid, essential in maintaining homeostatic mechanisms in the body. It is a vital constituent of cell membranes and forms the structural basis of many steroid hormones and bile salts.

The recommended daily intake of cholesterol for adults is approximately 250 mg or less. However, cholesterol is not only obtained from the diet but is synthesised in the liver, the intestinal mucosa and, to a lesser degree, other body cells. It is excreted from the body in bile salts.

Cholesterol, like fatty acids and glycerol, is insoluble in water and therefore cannot circulate freely in the bloodstream. It is transported, bound to small lipid proteins (lipoproteins), which are essentially of high-density or low-density compositions. Low-density lipoproteins (LDLs) are responsible for transporting cholesterol to the peripheral tissue so that it is available for membrane synthesis, hormone synthesis and storage, for later use. Excessive cholesterol leads to 'dumping' of the excess in the lining of the blood vessels, e.g. the coronary arteries. High-density lipoproteins (HDLs) have a different function in that they transport cholesterol from the peripheral tissue to the liver to be broken down. HDLs have been described as scavenging excess cholesterol for disposal.

High levels of total serum cholesterol have been repeatedly shown to be associated with the development of coronary artery disease and myocardial infarction. However, it is not enough merely to measure cholesterol, but rather the form in which it is being transported. HDLs can be thought of as beneficial because they promote the degradation and removal of cholesterol. On the other hand, LDLs, when excessive, can lead to a potentially serious deposition of cholesterol in the artery walls.

Although it is now regarded as important to limit our dietary cholesterol, severe restriction does not lead to a correspondingly dramatic drop in plasma cholesterol. This is because, although cholesterol production is to some extent adjusted by a feedback mechanism such that a high dietary intake will inhibit hepatic synthesis, the liver will always produce a certain amount irrespective of the diet.

It would seem that the factor that has the most significant effect on plasma cholesterol is the amount of saturated and unsaturated fat in the diet. Saturated fats, found essentially in animal produce, stimulate the hepatic synthesis of cholesterol whilst inhibiting its removal. In contrast, unsaturated fats, found in vegetable oils, enhance the excretion of cholesterol in the bile salts, thereby reducing cholesterol levels.

Other factors also appear to affect plasma cholesterol levels. Stress, coffee and smoking are thought to be implicated in increased levels of LDLs. Regular aerobic exercise has been associated with the lowering of LDLs and raising of HDLs.

If research continues to support the above findings, there are clear implications for the role of the nurse in promoting nutritional health and well-being.

Rest and sleep
Taking frequent naps throughout the day is often better than a longer sleep at night. The bedroom should be well ventilated but not cold or draughty (see Ch. 25). Certain medication, for example beta-blockers, and/or a reduction in cardiac output may make the patient feel tired and lethargic.

Sexuality
In some people with angina, sexual intercourse can trigger an anginal attack. This can be stressful for both the sufferer and their partner. Prophylactic use of GTN and some planning may help. The couple may have to adapt their usual position or the partner may have to take on a more dominant role. Touching and caressing may replace full intercourse and satisfy both. This subject needs to be approached sensitively but must be addressed, as the individual's perceived view on this aspect of daily living can affect all other aspects. A man receiving beta-blocker therapy may suffer from both weariness and impotence and the reason for this should be explained.

An important related aspect of sexuality is role reversal, e.g. if a housewife has to hand over some of her role and feels a loss of self-worth, or where the family breadwinner is forced to give up work. This may greatly affect self-esteem.

Fear of dying
People who have angina may have difficulty coming to terms with the fact that they have a progressive disease affecting their heart and probably other parts of their body. Angina can progress to myocardial infarction, which can cause death and this has to be discussed with the person to keep the situation in perspective. If they feel in control over some aspects of their condition, e.g. stopping smoking or altering their diet, they will possibly cope better than the person with a strong family history over which they have no control. Encouraging the patient to discuss their fears may help them to cope with them or alert the nurse to the fact that expert counselling is required.

Communication
Getting to know the person as an individual is important if appropriate support is to be given. The patient needs to be guided towards pinpointing aspects of lifestyle that will be affected by angina and then learning through discussion and counselling how to minimise their effect. If the person can communicate what causes pain and what relieves it, management is often simplified. Anxiety will reduce the ability to communicate, particularly when in an unfamiliar environment, such as the occupational health department or hospital. The use of a scoring table or a continuum for assessing and comparing attacks of angina may prove beneficial for monitoring the effect of therapy.

Personal hygiene and dressing
Here again, the key is living within the constraints of the condition. The person should be advised against locking the bathroom door whilst in the bath so that help can reach them if necessary. Other family members must remember this and respect privacy. Spacing activities throughout the day rather than rushing to do everything first thing in the morning may minimise the occurrence of symptoms.

CASE HISTORY 2.1(B)

Mr B — invasive treatment for angina

Mr B has now had the following investigations, all of which are normal: chest X-ray, ECG, cardiac enzymes and weight. His serum lipids are high, so, having had dietary advice, he has begun medication therapy to reduce these levels.

Cardiac catheterisation revealed that he had an 85% reduction of the lumen of the left coronary artery main stem. Mr B is advised that he should undergo percutaneous transluminal coronary angioplasty (PTCA). This is planned for the next day.

Constrictive clothing may induce breathlessness and chest tightness, and so should be avoided; however, the person should be advised to wrap up warmly in cold weather to limit increased workload on the heart for thermoregulation.

Elimination
Diuretic therapy may be indicated if a degree of cardiac failure is present (p. 45). The timing of ingestion of these medications can be controlled by the angina sufferer so that the ensuing diuresis does not disrupt daily routine.

Straining at stool should be avoided. A healthy diet will help, but the judicious use of a mild aperient may be indicated.

Cardiac catheterisation
The patient should be fully informed about the procedure (see Box 2.1, p. 16), its findings and their implications. Nurses need to be aware of the possible complications and place particular importance on pain relief.

Percutaneous transluminal coronary angioplasty (PTCA) (Box 2.3)
The patient will need to be fully aware of both the benefits and drawbacks. The importance of reporting any pain or discomfort during or following PTCA should be stressed. Pain is most likely to be experienced when the balloon is inflated over the narrowed area and the patient should be warned of this. Nitrate therapy is used for pain relief. Weight-adjusted heparin and an antiplatelet medication are also given. Increasingly, the procedure is performed in the morning and stable patients are discharged home in the evening or the next day. The patient may require assistance with various activities of living whilst mobility is temporarily limited. Discharge planning should include explaining the medication, risk factor modification and follow-up assessment. An exercise test may be performed prior to discharge, and a thallium scan, which detects myocardial perfusion, can give further information as to the achieved patency of the vessel.

If re-stenosis does occur, the procedure can be repeated.

Coronary artery stents
Coronary artery stents, a means whereby arteries can be held open, are used increasingly as an alternative to conventional angioplasty as they limit the long-term risk of

Box 2.3

Percutaneous transluminal coronary angioplasty (PTCA)

Purpose

PTCA is a technique involving the introduction of a balloon catheter into the coronary artery up to the site of a coronary stenosis, where it is inflated. This process produces compression and redistribution of the lesion and a substantial increase in the size of the lumen. PTCA may be performed to relieve the symptoms of angina if medication is ineffective, or it may be performed soon after successful thrombolysis (see p. 27) to restore perfusion to the ischaemic zone.

Procedure

PTCA is carried out under local anaesthetic in a cardiac catheterisation laboratory. If the procedure is planned, the patient will be admitted to hospital the day before and asked to fast for 4 h prior to the procedure. This is to prevent the risk of complications if bypass surgery is required. The patient will be given 300 mg aspirin prior to the procedure and the preparation is as for cardiac catheterisation.

Usually, two arterial catheters are used: a guiding catheter and a dilating catheter. The guiding catheter is inserted, usually in the leg, and advanced to the coronary artery to be dilated. The dilating catheter is then inserted and manipulated into the stenotic area of the artery. Angiography is performed and heparin administered to avoid clot formation at the catheter site. When the dilatation catheter is placed over the stenosis, it is inflated for 5–6 s and then deflated. Blood flow around the balloon is assessed by angiography. Once it has been decided that maximum dilatation has been obtained, the catheters are removed.

Following this procedure, the patient's cardiac status is usually monitored for 24 h. Peripheral pulses are checked frequently for occlusive thrombus at the insertion site. The patient is advised to rest for 4–6 h, lying as flat as is comfortably possible, to keep the leg used for catheter insertion straight in order to minimise the risk of thrombus formation at the insertion site. The introducer sheath is often left in situ for 2–3 h, until the effects of heparin have been reduced.

The patient should be encouraged to drink extra fluid to help eliminate contrast medium.

Re-stenosis occurs in 15–30% of patients, more frequently within the first few months. Repeat angioplasty may be appropriate for some patients. In an increasing number of patients, a stent is inserted at the time of angioplasty. Drug eluting stents inhibit smooth muscle migration around the stent and have a low (2–3%) re-stenosis rate. All patients will be commenced on clopidogrel and high risk patients on glycoprotein IIb/IIIa inhibitors.

Possible complications

Complications tend to be sudden and include:

- myocardial infarction
- chest pain
- vagal reaction
- intimal injury
- bleeding at the puncture site
- occlusive thrombus at the puncture site
- coronary artery spasm
- coronary artery dissection.

re-stenosis of the vessel wall. There are two main types of stent — coil and mesh — which are inserted into the widened coronary artery during cardiac catheterisation. Intravascular ultrasound is useful for accurate placement of the stent. The National Institute for Clinical Excellence (NICE) guidelines (1999) advised routine stenting during PTCA for coronary arteries between 2.5 and 3.5 mm, which should make their use appropriate for about 80–90% of procedures.

Patient management is similar to angioplasty, although more time may have to be spent in hospital in order for the patient to be stabilised on the anticoagulant warfarin. Stenosis within the stent itself can be a problem and the use of specialised stents which contain and release drugs to limit this is increasing (Gershlick 2002). Radiation emitters have also been used to reduce in-stent stenosis, a procedure known as vascular brachytherapy. Repeat PTCA is the most useful way of clearing in-stent stenosis, but laser angioplasty, which uses pulsed ultraviolet light to ablate the plaque, and atherectomy, which involves drilling into the plaque, may also be used. Levine et al (2003) provide an overview of the management of patients undergoing percutaneous coronary revascularisation.

Coronary artery bypass grafting (CABG)

This is now a routine operation performed on patients whose angina is severely limiting their lives but whose left ventricle is functioning reasonably. It is particularly appropriate for patients with triple vessel disease. It may also be carried out in the phase of myocardial infarction and for those who have experienced complications after angioplasty. The procedure is described in Box 2.4.

Bypass surgery is a potentially traumatic event, and apprehension about the procedure is common (Lyons et al 2002). Patients awaiting surgery have been found to experience a sense of dependency and impending doom (Lindsey et al 2000). Pre-admission education programmes are now offered at many centres and a visit to the operating theatre and ITU may also help. Male patients need to know that their chest will be shaved prior to the operation and all patients need to know that they may be asked to take a bath using antibacterial soap. An aperient may be required to reduce the likelihood of postoperative abdominal discomfort. Patients will be asked to fast prior to surgery and may benefit from a sedative to help them relax the night before.

The nurse should prepare the patient for what to expect on regaining consciousness, i.e. an endotracheal tube, chest drains, intravenous infusions, arterial lines, urinary catheter, cardiac monitoring and possibly a nasogastric tube. The patient should be taught breathing, coughing and leg exercises by the specialist physiotherapist.

After the operation, nursing objectives include:

- pain relief (see Chs 19 and 26)
- fluid management — patients can quickly become dehydrated
- assistance with activities of living
- psychological support — patients may become disorientated and confused and need help coming to terms with the effect of the operation (Laitinen 1996)
- preparation for discharge home.

Box 2.4

Coronary artery bypass graft surgery (CABG)

Purpose

Coronary artery bypass graft surgery is a technique in which an occluded or stenosed section of a coronary artery is bypassed using part of a vein or artery from elsewhere in the body. Most commonly, the long saphenous vein is used, although increasingly the internal mammary artery is being considered. The objectives of CABG are:

- restoration of perfusion and increased oxygenation to the ischaemic myocardium in the peri-infarction patient
- relief of angina pectoris
- improvement of functional status and quality of life
- prolongation of life.

Surgery is only feasible if the risk of the operation is less than continuing with medical therapy. The procedure tends to be offered to those who have:

- symptoms despite maximum therapy
- triple vessel disease or left main stem coronary artery stenosis
- unstable angina.

Procedure

During surgery, the heart is exposed by median sternotomy, the aorta clamped off and cardiopulmonary bypass maintained via cannulae in the descending aorta. The body temperature may be reduced to 32°C and cardiac arrest induced with a cardioplegic solution.

Revascularisation with arterial grafts is becoming more common, as they last longer (10–15 vs. 5–10 years for veins). The internal mammary artery is biologically superior for grafting compared with the saphenous vein.

The artery or vein being used is harvested whilst the chest is being opened. The distal end of the bypass graft is sutured to the required vessels. The aorta is then unclamped, the patient rewarmed if cooling has been used and normal cardiac rhythm re-established by internal defibrillation. The proximal ends of the grafts are sutured to the ascending aorta and cardiopulmonary bypass is then stopped, the cannulae removed and the chest closed. The whole operation takes up to 4 h.

The patient is normally cared for in an intensive care unit after the procedure and will be ventilated until they are haemodynamically stable. An arterial line and pulmonary artery flotation catheter will be used to monitor cardiac pressures for 24 h.

The patient will usually be able to eat a normal diet on the first or second day. Activity is increased as tolerated over the first 2 days and early mobilisation is encouraged. Patients are often fit for discharge home after about a week.

Possible complications

Complications include:

- leakage at the incision site, producing discomfort and shock
- hypertension as a result of increased sympathetic activity
- hypotension as a result of reduced cardiac output following hypothermia
- pain at both the graft and incision sites
- post-pump cardiotomy syndrome (up to 3 months)
  - — problems with coordination
  - — loss of memory
  - — loss of sense of taste
  - — disturbance of vision
- shortness of breath due to heart failure or chest infection.

Patients will be told to expect some degree of pain from the sternotomy for several weeks, discomfort on coughing or lifting the hands above the head and leg swelling (Levine et al 2003). Short-term anxiety and depression may occur if patients feel that recovery is slower than anticipated. Partners and other family members will also need ongoing information and support.

Minimally invasive cardiac surgery

This is an option for some patients with CHD. Access to the heart is made through a small thoracotomy. This procedure has the advantage of reducing patient problems associated with sternotomy, including less pain, increased mobility and a reduced hospital stay. The left internal mammary artery is grafted through an incision between the fourth and fifth intercostal spaces. Pre- and postoperative care is similar to that in conventional cardiac surgery.

Minimally invasive direct coronary artery bypass surgery (MIDCAP)

is an alternative procedure that does not require cardiopulmonary bypass. It is also termed off-pump or beating heart surgery. For selected patients, this procedure offers a less invasive approach with a faster recovery and an improved cosmetic appearance of the wound.

Fast-tracking

Patients are increasingly being 'fast-tracked' after cardiac surgery (Howard 1996). This focuses on early extubation and a move away from elective overnight ventilation following surgery. The recovery of low-risk patients can therefore be managed without overnight admission to the ITU.

The procedures outlined above unfortunately do not stop the process of atherosclerosis; they only delay it and aim to provide the sufferer with a good quality of life for a limited time. All procedures can be repeated, but ultimately the blood supply may become insufficient to sustain the ventricle so that cardiac failure ensues.

ACUTE CORONARY SYNDROME

The term acute coronary syndrome defines a continuum of manifestations of CHD. It includes all cases of unstable angina and acute myocardial infarction which have as common underlying pathology the abrupt, total or subtotal obstruction (occlusion) of a coronary artery, most often triggered following the rupture or erosion of an atheromatous plaque. This occlusion may be temporary, and often recurrent, as in unstable angina, or it may be permanent as in an acute transmural myocardial infarction. Clinical presentation of acute coronary syndrome depends predominantly

CASE HISTORY 2.1(C)

Mr B

Mr B's angioplasty has proved to be unsuccessful, as it has not been possible to enter the left coronary artery (LCA) and pass the balloon over the occlusion. Mr B is returned to the ward after 2 h in the cardiac catheterisation room. He is told that he can go home that evening but is asked to return in 2 weeks for cardiac surgery.

on whether the obstruction is abrupt or staggered in onset, the site of the occlusion, the resulting loss of blood flow to the myocardium and whether there is an alternative blood supply to the area in the form of a collateral circulation.

Unstable angina

In unstable angina, the coronary artery occlusion tends to be episodic and transient. There is often a fissuring of a plaque with the development of a thrombus, but the thrombus does not completely block the artery and subsequently breaks down with no detectable damage to the myocardium. Patients complain about angina symptoms that become progressively more frequent, more severe, triggered by less physical and/or emotional effort and unrelieved by GTN. Initial diagnosis is based on the clinical history and the standard resting ECG which may show ischaemic changes but no ST segment elevation. The lack of myocardial damage is confirmed by measurement of the highly sensitive marker troponin or other cardiac marker concentrations which will give negative results. Management for patients with unstable angina needs to be based on the risk of progressing to a totally occluded coronary artery (British Cardiac Society 2001). Low-risk patients, with a non-diagnostic ECG, negative exercise test and normal troponin marker levels, can be managed in the community with secondary prevention measures including aspirin, beta-blockers, angiotensin-converting enzyme (ACE) inhibitors and statins, plus lifestyle advice and support as discussed in the earlier section on stable angina. High-risk patients identified by history and exercise testing, who remain unstable, warrant immediate coronary angiography and revascularisation.

Myocardial infarction

Myocardial infarction, also known as a 'heart attack' or a 'coronary', refers to the death or necrosis of a portion of myocardium as a result of interruption or cessation in blood flow. Myocardial infarction is part of the spectrum of acute coronary syndromes and as a diagnosis is now divided into two categories based on ECG findings.

1. Those cases where there is some detectable myocardial injury, i.e. troponin testing will be positive, but where this damage has not affected the full thickness of the myocardium and hence there is no ST elevation on the ECG, are known as non-ST elevation myocardial infarction (NSTEMI). This condition is potentially unstable and it may be more appropriate to describe both high-risk unstable angina and NSTEMI as 'unstable coronary syndromes'. Both are high-risk conditions requiring admission to coronary care for urgent intervention to prevent progression to transmural, full thickness, myocardial infarction. Without early treatment, around 5–10% of patients will progress to more extensive myocardial damage or death within 30 days (Collinson et al 2000).
2. Those cases where there is total occlusion of a coronary artery and transmural muscle damage, i.e. troponin testing will be positive, and there is ST segment elevation on the ECG, are known as ST segment elevation myocardial infarction (STEMI). It is this group of patients who benefit from prompt reperfusion.

Nearly all the deaths from CHD are the result of myocardial infarction. In the UK, some 300 000 people suffer myocardial infarction each year, of which about 50% are fatal. In 25–30% of cases, the patient with myocardial infarction dies before reaching hospital (British Heart Foundation 2004).

PATHOPHYSIOLOGY

Myocardial cells require a constant supply of oxygen and nutrients in order to generate the high-energy phosphate compounds required for contraction. Generally, myocardial cells are irreversibly injured by 30–40 min of total ischaemia. It is now clear that the muscle damage associated with myocardial infarction almost always results from total occlusion of a coronary artery by a thrombus, usually at the site of a recently cracked or fissured atheromatous plaque. If the lumen of an artery is blocked for about 20 min, and blood supply by the small vessels of the surrounding collateral circulation is inadequate, infarction may develop. Surrounding the area of necrotic tissue there is usually a zone of injury. This tissue cannot contract but may be salvaged if an adequate blood supply can be quickly established; this is sometimes known as 'hibernating' myocardium. The ischaemic zone separates the zone of injury from undamaged tissue (see Fig. 2.8).

During the first 6 h after the onset of symptoms, the affected myocardium becomes oedematous. There is a shift in the distribution of sodium and potassium ions and an increased risk of arrhythmias. A summary of events following a myocardial infarction is given in Table 2.3. The infarcted area is replaced by fibrous scar tissue over the course of 3–6 weeks.

The site of infarction depends on which coronary artery has become occluded. The extent of infarction, and therefore the amount of muscle involved, depends on the artery involved, the previous rate of progression of the disease and

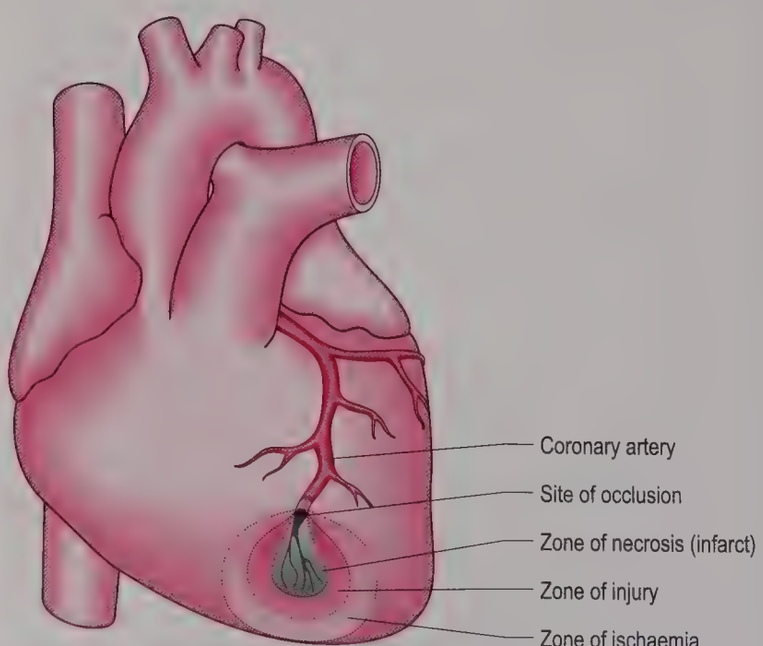

Fig. 2.8 Zones of necrosis, injury and ischaemia.

Table 2.3 Events following anterior myocardial infarction (AMI)

Length of time following AMI	Event
0–6 h	Cellular breakdown No electrical impulses conducted Necrosis occurs
24 h	Phagocytosis occurs in the infarcted area
5 days	Area infiltrated by fibroblasts, capillaries and collagen tissue Reperfusion of capillaries
2–3 weeks	Fibrosis occurs
2–3 months	Ventricular scarring

the effectiveness of the surrounding collateral circulation. In a majority of fatal myocardial infarctions, death occurs in the first hour after the attack, usually as a result of a cardiac arrhythmia.

Common presenting symptoms

Myocardial infarction can occur both in people who are known to have angina and in those who are not. Pain is usually experienced about 60 s after the onset of ischaemia and occurs in the majority of people, but is less likely to be experienced in older people or in those with diabetes mellitus. Pain typical of myocardial infarction often:

- occurs at rest
- awakens the individual from sleep
- is unrelieved by rest or nitrates
- lasts longer than 20 min
- is described as crushing, vice-like, tight or constricting in nature
- may radiate to the arms and neck.

Other signs and symptoms may include:

- shortness of breath at rest, on exertion or when lying flat
- hyperventilation as a result of anxiety
- change in cardiac rhythm or rate
- change in blood pressure
- change in level of consciousness
- increased anxiety or restlessness
- pallor
- sweaty or clammy skin
- nausea and vomiting
- cyanosis.

MEDICAL MANAGEMENT

Diagnosis may be difficult in the early stages. The ECG may be non-diagnostic and the pain difficult to quantify. Biochemical markers may also be non-specific. Therefore, high-risk patients with atypical presentations need to be observed closely.

The modern management priorities depend on whether the symptoms are thought to be the result of a thrombus occluding the coronary artery (STEMI) or an unstable coronary syndrome (NSTEMI). Management has historically been divided into three overlapping stages:

- treatment of the acute attack through:
  - — relief of symptoms by analgesics (opiates) plus antiemetic, oxygen and nitrates
  - — monitoring for and treating life-threatening complications
  - — improving blood flow to the myocardium and modification of the infarct process in STEMI
  - — thrombolysis or percutaneous coronary intervention
  - — reduction of oxygen demand by rest and beta-blockade and alteration of early physiological changes by ACE inhibition
- risk stratification (1–6 weeks)
- secondary prevention, including aspirin, or clopidogrel, beta-blocker, ACE inhibitor and a statin.

Patients should ideally be managed in a coronary care unit (CCU) and preferably be admitted there directly. In hospitals where suspected myocardial infarction patients are admitted to Emergency Departments, nurses have a role in identifying patients experiencing an acute cardiac event so that appropriate treatment can be initiated promptly and safely (Kucia et al 2001).

History and examination

The history provides subjective information about the presenting symptoms, previous patterns of health and illness, and the activities of living. A family history of ischaemic heart disease together with risk factor identification and social and psychological background adds to the picture.

It may be inappropriate to obtain a full history if the patient is in pain, acutely ill, or would benefit from prompt reperfusion therapy. An initial assessment can be enough to set early priorities, without a full physical examination or diagnostic tests.

Clinical examination includes:

- observation of general appearance, build, body posture and facial expression
- assessment of the location, nature and severity of the pain, any relieving or aggravating factors, and attempted methods of pain relief
- observation of other signs of reduced cardiac output
- observation of vital signs — arrhythmias are common; blood pressure may be low with reduced cardiac output or high due to pain and anxiety; slight pyrexia is a common response to muscle damage
- auscultation — a third heart sound is an important indicator of left ventricular dysfunction and poor outcome; it is found in 5–10% of patients with myocardial infarction
- palpation — involving a systematic examination of the chest to feel for abnormal vibrations or pulsations.

Investigations

Electrocardiogram may show characteristic changes, pinpointing the area of ventricle affected. The ECG is an imperfect diagnostic tool and, as early ECGs may appear normal, a series is necessary. The classic change is ST elevation (see Fig. 2.9).

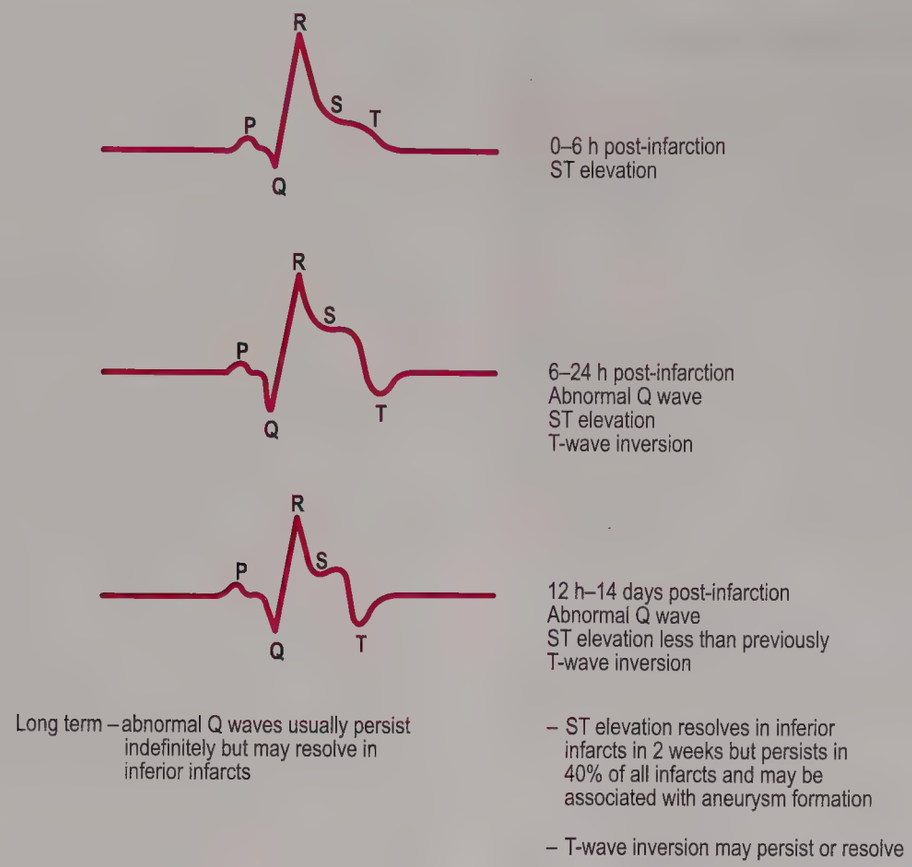

Fig. 2.9 ECG changes in myocardial infarction.

Blood tests

- *Serum cardiac markers*. Myocardial necrosis results in the release of certain molecules into the circulating blood. The rate and pattern of release are important (see Fig. 2.10). The traditional role of biochemical testing has been to provide retrospective confirmation of the presence or absence of myocardial damage through sequential measurement of serum cardiac markers on consecutive days. Modern analytical equipment now allows for certain markers, in particular the troponins, to be measured in minutes. Bedside analysis is possible, with rapid diagnosis having implications for patient triage and shortening length of hospital stay. Increasingly, measurement of cardiac troponins is allowing cardiac damage to be diagnosed with high sensitivity and specificity. Measurement of cardiac troponin T and cardiac troponin I also allows prognostic risk stratification of patients.
- *White cell count*. This is usually elevated for the first few days following acute myocardial infarction.
- *Erythrocyte sedimentation rate (ESR)*. This usually rises after the first few days and may remain elevated for several weeks.
- *Glucose*. Stress-related hyperglycaemia is common in the acute phase following infarction. Previously undetected diabetes is found in approximately 5% of coronary patients admitted to hospital.
- *Electrolytes*. It is important to know the serum sodium and potassium levels, as these electrolytes can have a major effect on cell excitability.
- *Lipids*. The important lipids in ischaemic heart disease are plasma cholesterol and triglycerides. Total cholesterol should be measured within the first 24 h and a full lipid profile done at 6–8 weeks.

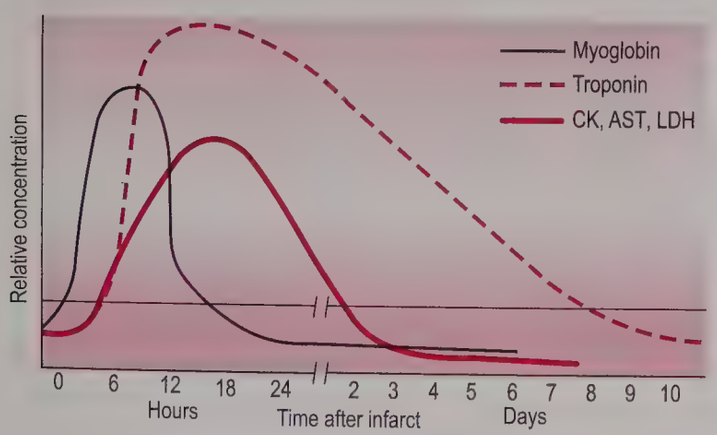

Fig. 2.10 Time–activity curves for diagnostic biochemical markers following acute myocardial infarction.

Chest X-ray may show evidence of pulmonary oedema or hypertrophy.

Prevention of complications

Acute myocardial infarction is a very serious condition in the early stages, although the risks diminish rapidly after the first 48 h. Muscle damage will affect different areas of the heart and therefore put the patient at risk of various complications. Careful observation of the patient will help in the prevention, or at least early treatment, of these complications to prevent them becoming life threatening.

NURSING PRIORITIES AND MANAGEMENT: Thrombolytic therapy

Patients with ST elevation myocardial infarction (STEMI) will be potential candidates for thrombolytic therapy. The nurse needs to be aware of patient selection criteria and be able to assist in identifying patients who are candidates for therapy (see Box 2.5). Awareness of contraindications to therapy and of the importance of initiating therapy as soon as possible after the onset of chest pain are also necessary. Mortality in patients given thrombolytic drugs sufficiently early is one-third less than in those left untreated and the *National Service Framework for Coronary Heart Disease* (DH 2000) set specific targets for thrombolysis times. The targets are that thrombolysis should be given within 60 min from the call for help and within 20 min of the patient's arrival at hospital. Nurses in some CCUs are taking on the responsibility of initiating and/or prescribing thrombolytic therapy in accordance with agreed protocols (Rhodes 1998, Holland & Foxcroft 2000). The nurse should explain to the patient the benefits and potential problems of this therapy. It is important that the nurse is aware of possible complications so that they can monitor and observe appropriately.

On discharge, people who have been thrombolysed receive a card, indicating what medication they received and when. It may be inappropriate for them to have a second treatment with certain thrombolytics. Thrombolysis does not have any effect on the underlying cause of thrombus formation and reocclusion remains a problem. Heparin, warfarin and aspirin have been used to reduce re-thrombosis. Patients may require subsequent mechanical recanalisation with either PTCA, rescue angioplasty or surgery. Glycoprotein IIb/IIIa inhibitors which prevent platelet aggregation are recommended for use in unstable angina or NSTEMI (NICE 2002).

Primary angioplasty

Angioplasty, with or without stenting, used instead of thrombolytic therapy in acute infarction, results in better patency and causes fewer strokes. Patients most likely to gain from this procedure are those with cardiogenic shock, anterior infarcts and older people. It is also an option for patients not eligible for thrombolysis (Kastrati et al 2004). However, primary angioplasty is unlikely to become widely available because most patients with myocardial infarction are admitted directly to hospitals without intervention facilities (De Belder & Thomas 1997).

NURSING PRIORITIES AND MANAGEMENT: Acute coronary syndrome

Most unstable patients admitted to hospital are likely to benefit from admission to a CCU for monitoring and assessment for reperfusion therapy. These units were first

Box 2.5

Thrombolytic therapy

Purpose
The primary aim in limiting infarct size is the rapid recanalisation of the occluded coronary artery. Occlusion is most often caused by a thrombus at the site of a ruptured atheromatous plaque. The aim of thrombolysis is to induce dissolution of the thrombus through the administration of an intravenous drug in order to establish recanalisation and provide subsequent reperfusion to the ischaemic zone. Thrombolysis is the single most important advance in coronary care since defibrillation, resulting in increased survival and quality of life.

Action
Optimal benefit results when the thrombolytic drug is given promptly after the onset of chest pain, although it is considered worthwhile administering the treatment up to 12 h later. The main thrombolytic drugs currently available are:

- *Streptokinase* — to date, the most widely tested and used, and also the cheapest. It is a bacterial protein whose administration results in a systemic lytic state, with reduced levels of circulating fibrinogen and clotting factors V and VIII. Once given, the patient will produce antibodies to streptokinase and so the medication would be ineffective if given a second time.
- *Recombinant tissue-type plasminogen activator (tPA)* — a naturally occurring human protease that is fibrin-specific and thus works predominantly on the clot, with less risk of systemic bleeding.
- *Reteplase* — a new generation thrombolytic which appears to be as effective as streptokinase. It has the advantage that it can be given as a bolus and is non-antigenic.

Patient selection
Patients considered to be having an acute myocardial infarction, with the onset of symptoms within the previous 12 h. Contraindications include:

- active or recent bleed
- major surgery or trauma within the previous month
- cerebrovascular accident within the previous 3 months
- severe systemic hypertension.

Reperfusion
Signs and symptoms of reperfusion may include:

- abrupt cessation of chest pain
- reperfusion arrhythmias or conduction disturbances
- rapid return of the ST segment to normal
- improved left ventricular function
- an early peak in cardiac enzymes as a result of enzymes being washed out of the infarct area by the reperfused artery.

Complications
These include:

- bleeding episodes (including rarely cerebral bleeds)
- reperfusion arrhythmias
- allergic reactions
- hypotension.

established in the 1960s in order to provide surveillance from skilled personnel with electrocardiographic and resuscitation facilities in a specialised setting.

Possible patient problems include:

- pain and discomfort
- fear and anxiety
- decreased activity levels
- lack of knowledge and understanding
- misconceptions
- altered activities of living
- loss of control
- ineffective or inappropriate coping responses.

Immediate priorities

The priorities on admission to hospital include:

- cardiac monitoring (see Table 2.4); ECG
- establishment of intravenous access

Table 2.4 Observing the cardiac monitor*

Parameter	Aspect to note
Rate	Is it fast/slow/normal?
Rhythm	Is it irregular/regular?
P waves	Are they present/absent?
QRST complex	Is each complex preceded by a P wave? Is each complex the same?
PR interval	Is it normal/prolonged?
Ectopics (extras)	Are there any extra P waves or extra QRST complexes?

* While observing, note whether the patient is experiencing any symptoms, such as pain, shortness of breath or light-headedness.

- relief of pain and anxiety
- reperfusion therapy where appropriate
- decrease in the workload of the heart.

Nursing management reflects the above and is also aimed at:

- observation for signs of complications
- rehabilitation and recovery.

For a critical care pathway illustrating the management of a patient with a myocardial infarction, see Figure 2.11.

Maintaining a safe environment

The nurse is responsible for the patient's safety. This involves being aware of possible complications and how they are likely to present. The temptation to respond to monitor tracings without concurrently assessing the patient should be avoided.

Pain control

The patient must be kept free from pain. It is a sign of ongoing myocardial ischaemia and should be controlled. Patients should be told of the importance of reporting pain.

Accurate pain assessment is essential to ensure that appropriate analgesics are given. Assessment scales, where patients rate their pain numerically, can be useful (see Ch. 19). Pain can be difficult to assess and nurses have been shown to be unreliable in assessing cardiac pain (O'Connor 1995), although this can be improved with appropriate education (Thompson et al 1994). Ischaemic pain can easily be confused with pain from other sources, particularly pericarditic or pleuritic pain (see Table 2.5). Opiates are the first-line analgesics for ischaemic pain and diamorphine i.v. is the medication of choice. It is likely to produce beneficial effects through:

- decreasing anxiety through action on the central nervous system
- vasodilatation of the peripheral circulation

Table 2.5 Characteristics of chest pain*

Description	Location	Medical diagnosis
Tight, like a band around the central chest	Central chest Radiating to jaw, shoulders and arms usually on left side	Angina pectoris
Precipitated by cold, exercise, large meals, emotion Usually relieved by rest and glyceryl trinitrate (GTN)	May be associated with shortness of breath	
As above, but not relieved by GTN or other measures. Lasts longer and is more severe	As above	Myocardial infarction
Stabbing or burning pain Worse on deep inspiration, often relieved by bending forwards	Substernal and often affecting the trapezius muscle and upper abdominal area	Pericarditis
Sudden sharp pain, worsened by inspiration Dyspnoea, cough, cyanosis and possible haemoptysis	Very often lateral	Pulmonary embolus
Excruciating pain 'burning' towards the spine	Intrascapular region	Dissecting aneurysm

* Not all patients present in the manner described above. The description of chest pain to aid diagnosis should be used in conjunction with an assessment of the patient's risk of coronary heart disease and a history, physical examination and diagnostic tests.

Care categories	Admission Day 1	Day 2	Day 3	Day 4/5	Day 5/6
Hospital location	CCU	Ward	→	→	Home
Personnel	Appropriate specialists	Cardiac rehabilitation Dietician Social services if necessary Physiotherapy/OT	→	→	→
Tests	12-lead ECG - every 20–30 mins on admission - if pain reoccurs - 90 mins post thrombolysis Chest X-ray, 0_2 sat Cardiac enzymes x 2 FBC, U&Es, glucose on admission Cholesterol	12-lead ECG Cardiac enzymes x 1 U&Es Echocardiogram	12-lead ECG	12-lead ECG	Risk stratification via exercise, stress testing and thallium imaging Cardiac catheterisation if necessary
Activities	Bed rest and commode privileges	Sit in chair Self-care in bed/chair	Sit in chair ad lib Walk in bed area	Self-care as tolerated Walk to bathroom then walk in ward Supervised activity	Shower with supervision Walk in ward Climb stairs with supervision

Fig. 2.11 Critical care pathway for myocardial infarction.

- central nervous system sedation and primary analgesia through stimulation of opiate receptors.

Intravenous diamorphine has immediate effect, reaches its peak effect within 20 min of administration and lasts 3–4 h. Undesirable effects include:

- nausea and vomiting, due to reduced gut motility, so it should be given with an antiemetic
- depressant effects on the central nervous system, so the antidote naloxone should be available
- hypotension, if vasodilatation occurs alongside hypovolaemia
- dry mouth and slow heart rate as a result of decreased sympathetic activity.

Patients need to know that they may experience episodes of angina after discharge. They should be aware of the importance of reducing activity if such pain occurs and feel confident to use GTN. They should also be aware of the importance of dialling 999 and summoning an ambulance if the pain has not responded to rest and GTN after 15–20 min. GTN is available in tablet or spray form, and patients need to appreciate that it is not addictive and will not mask the symptoms of a heart attack. GTN can also be taken before doing something known to produce pain. It should be taken sublingually and the person should sit down before taking it, to minimise the risk of fainting. Any pain should be resolved 5–10 min after taking the drug; if not, a further dose should be taken. Once the pain has gone, any remaining tablet should be spat out or swallowed.

GTN, particularly on initial use, can produce unpleasant side-effects such as flushing and headache due to generalised vasodilatation. Paracetamol can be taken to ease a headache.

Observation of vital signs

This is aimed at early detection of complications.

Pulse The ECG will be continuously monitored on a screen. Knowledge of the normal rhythm is vital and diagnosis of arrhythmias is part of the CCU nurse's role.

Deviations from the normal must be noted and the patient's concurrent condition assessed. Someone who is in pain or who is anxious may be tachycardic (heart rate >100 beats/min); however, the heart rate is likely to fall once analgesics have been given.

Blood pressure Recording the patient's blood pressure is a means of assessing how effectively blood is being pumped from the left ventricle. Frequency of recordings needs to be balanced against the patient's need for undisturbed rest. A fall in blood pressure may indicate that further damage or complications are occurring and that there is a reduced supply to the vital organs. Cardiac output can also be assessed by examining perfusion in the peripheries.

Temperature Pyrexia as a response to muscle damage is normal in the first 48 h, following which it should settle. Continued pyrexia may indicate pericarditis.

Respiration Changes in respiratory rate can be the first sign of patient deterioration. The patient with an acute coronary syndrome is frequently given oxygen therapy in conjunction with analgesics on admission. However, there is little evidence to support this practice in terms of evidence that oxygen reduces acute myocardial ischaemia (Nicholson 2004). Dyspnoea may indicate hypoxia or the onset of pulmonary oedema, which is a serious complication. It can also be induced by anxiety. Raised anxiety levels in coronary patients admitted to hospital have been well documented, with serial measurements generally showing that anxiety is highest on admission to the CCU (Mayou et al 2000). To exclude anxiety from masking more serious complications, the patient may benefit from the use of anxiolytics for a short period, particularly at night.

Ongoing care

The majority of life-threatening problems develop within the first 36 h, and once the patient is stable they will be transferred to the ward. The move is likely to induce anxiety and the patient will be aware that the nurse:patient ratio has been reduced. Explaining that the immediate danger period is over and that they are now beginning to recover will help to convey optimism to the patient and family. Ideally, the transfer can be planned well in advance and the nursing staff on the ward should take time to discuss natural fears and vulnerability.

These same feelings are likely to resurface as the time of discharge from hospital approaches and again nursing staff must prepare both the patient and the family to resume their life as an integral unit.

Any restrictions, such as not smoking and limiting activity, should be fully explained. Although certain activities should ideally be avoided, the patient may feel less stress if permitted a low level of involvement; for example, the business person who requires to continue working may rest more easily if they have some contact with their staff.

Communicating

Someone who has suffered an acute cardiac event is likely to be worried about the eventual outcome. Some people are able to express their feelings openly, but others find this difficult. The nurse should try to probe beneath outward signs such as hostility, withdrawal and denial to ensure the patient is not masking fear. The nurse should keep the patient informed of their progress and how it will affect their stay in hospital. Communication skills are important and answers to questions should be honest and supportive. The hospital chaplain or the patient's own spiritual advisor may be of help in this area.

Communication must also extend to the family members. They experience shock and anxiety on seeing their loved one in such an environment. Involving family members, particularly the partner, in information-giving and support can significantly reduce distress at this time (Moser & Dracup 2004). Spending time with the relatives, both when they are visiting and when they are alone, may allow fears and worries to be expressed. Frequent and adequate information about the equipment and the patient's progress is vital. The family member whose trust is gained can be a source of information to the nurse and an ally in helping to reduce anxiety in the patient. Unrestricted visiting for designated close family members is also useful in reducing anxiety.

Appropriate advice for the patient and family in hospital may include:

- explaining the structure and function of the heart as a pump, where it lies in the body and how it works

- explaining narrowing of the coronary arteries, obstruction and heart muscle damage
- describing symptoms and explaining terminology
- outlining the reasons for admission and treatment
- explaining possible angina and shortness of breath that may be experienced after discharge
- explaining the recovery process, e.g. muscle damage, swelling, scar formation and the healing period for those with myocardial infarction
- discussing the outlook for the future and the need to accept the illness
- describing the likely activity level
- explaining the reasons for stopping smoking
- explaining how to recognise possible limiting factors in physical activity
- giving advice on diet, social activities and sexual life
- giving advice on resuming work
- being prepared for changes in mood, e.g. anxiety and depression, as these can be predictors of outcome after myocardial infarction (Mayou et al 2000)
- preparation of the partner and family.

Preparation for discharge

Patients and their families need to be prepared for rehabilitation and recovery. Patients' needs for information and support should be assessed individually as people cope differently. For example, women have been found to have different concerns from men after a heart attack (Radley et al 1998).

Issues to be addressed may include:

- concerns about resumption of activities, including return to work and sexual activity
- overprotectiveness by the family
- use of medication, including GTN
- lifestyle changes
- uncertainty about informing the insurance company and Department of Social Security
- the need for definite guidelines about the amount of weight to lose and how to stop smoking.

Both community and hospital nurses have a role in tackling many of the above issues, so that the sufferer and family are equipped to cope with recovery and future lifestyle (Murchie et al 2003). Conflicting information needs to be avoided. Advice needs to be realistic, practical and accurate (Thompson & Lewin 2000). There is an increasing number of coronary rehabilitation nurses who visit both in hospital and at home. The first 2 or 3 weeks at home can be the most stressful for the person and the family, particularly the partner, as they attempt to come to terms with a frightening and often unexpected event (Thompson et al 1995). Coronary rehabilitation programmes that offer individualised packages of information, support and secondary prevention strategies on both a one-to-one and group-session basis, in addition to a graduated programme of exercises, have the potential to restore the individual to an optimum level of recovery (physical, emotional, economic and vocational) and to minimise the risk of the underlying disease progressing (NHS Centre for Reviews and Dissemination 1998). It is now recommended that every major district hospital treating people with heart disease should provide such a cardiac rehabilitation service (Thompson et al 1996, DH 2000). This programme should ideally begin from the time of admission and diagnosis and encourage long-term adherence to therapy, regular exercise and a healthy lifestyle. Home-based programmes involving cassette tapes and a manual have been shown to be effective for myocardial infarction patients not able to access a group programme (Linden 1995). The patient is likely to leave hospital having been prescribed medication they need to take long term, including aspirin, beta-blockers, a statin and an ACE inhibitor and they may need support in order to continue with this regimen. Nurses working in primary care are potential sources of support, particularly in the area of secondary prevention (Fullard 1998, Scholte-op-Reimer et al 2002; see also Research Abstract 2.1).

2.4 Find out about cardiac rehabilitation services offered locally. Is there any selection process or are there exclusion criteria? Are there any outcome measures in place to measure the effectiveness of taking part in the programme?

For further information on the effectiveness of cardiac rehabilitation, see Dinnes et al (1999) and Jolliffe et al (2005).

Mobility

In hospital

While experiencing symptoms such as pain and dyspnoea, the patient should remain in bed and receive analgesics and oxygen therapy. The reasons for limiting activity should be explained. As symptoms resolve, activity levels can increase.

In recent years, the trend has been towards early resumption of activity. This allows the patient to carry out activities such as washing and going to the toilet and to progress from passive to active limb exercises when they are symptom free. Periods of gentle activity should be followed by rest periods and all activity should be stopped if the patient experiences pain, dyspnoea or palpitations. The ability to increase activity gradually is a positive reinforcement for recovery and the patient's family will also experience relief at seeing the patient regain independence. By the time of discharge, usually after 5 or 6 days, the person should be fully independent in the activities of living.

Some centres have programmes in which the patient can chart their progress towards specific goals (see Box 2.6). In other centres, activity is increased on a much less formal basis and the nurse can point out to the patient that they are making progress. Realistic aims, both pre- and post-discharge, are important.

The patient should be prepared to have good and bad days and be aware of symptoms that suggest they are doing too much, such as pain, palpitations, dyspnoea, fatigue and dizziness.

At home

Graduated physical activity should permit a return to previous daily activities over a 2–12 week period after myocardial infarction and, if applicable, return to work after 6–8 weeks. The ultimate aim should be to take some exercise at least three times a week. Recommended exercise, after 6–8 weeks, includes walking, swimming and cycling, for 15–20 min at a time.

RESEARCH ABSTRACT 2.1

Secondary prevention for coronary heart disease: How can the service be improved? Do nurses have a significant role?

People with pre-existing coronary heart disease are at particularly high risk of coronary events and death, but effective secondary prevention strategies can reduce admissions to hospital and improve quality of life and the processes of care delivery in the short term. Effective secondary prevention comprises several elements, including pharmaceutical interventions, using antiplatelet agents, statins and beta-blockers, and interventions to change behaviour and modify lifestyle, relating to smoking cessation, regular exercise and healthy eating. Most people with coronary heart disease are cared for in the primary care setting and general practitioners have been encouraged to target them for secondary prevention. This has proved difficult and surveys of baseline provision consistently show that secondary prevention is suboptimal.

This research project aimed to evaluate the effects of nurse-led clinics in primary care on secondary prevention, total mortality and coronary event rates after 4 years. It involved 1343 randomly selected patients with a diagnosis of coronary heart disease from 19 general practices in north-east Scotland. Patients in the intervention group were invited to attend nurse-led secondary prevention clinics at their general practice during which their symptoms and treatment were reviewed. The use of aspirin was promoted, lipid management reviewed, lifestyle factors such as exercise assessed and, if appropriate, behavioural changes negotiated. Patients were followed up every 2–6 months. Patients in the control group received the usual care.

Subjects were followed up over a 4-year period by postal questionnaires and review of their case notes. Significant improvements were shown at 1 year in key components of secondary prevention (aspirin, blood pressure management, lipid management, healthy diet), except smoking. These improvements were sustained at 4 years except for exercise. The authors of the report conclude that the improved medical and lifestyle components of secondary prevention produced by nurse-led clinics seem to lead to fewer total deaths and coronary events. They also conclude that nurse-led clinics should be started sooner rather than later.

Murchie P, Campbell N C, Ritchie L D et al 2003 Secondary prevention clinics for coronary heart disease: four year follow up of a randomized controlled trial in primary care. British Medical Journal 326: 84–87

Box 2.6

A typical activity programme for a patient following acute myocardial infarction

Phase 1 (in the coronary care unit)

Step 1
- Rest in bed. Out to chair for short periods
- 2-hourly passive range of motion exercises
- Twice-daily breathing exercises
- Independent with personal cleansing at bedside, i.e. wash hands and face
- Use bedside commode

Step 2
- Up to sit unlimited by bedside
- Walk around bed area

Phase 2 (in the ward area)

Step 3
- Walk to bathroom/toilet
- Personal cleansing in bathroom on chair

Step 4
- Unrestricted walking in ward area
- Sit in day room if desired
- Shower/bath unaided

Step 5
- Climb one flight of stairs
- Increase exercises, e.g. use of exercise bike

Phase 3 (early days at home)

Step 6 (first week at home)
- Stay within own home/garden
- Use the stairs two to three times daily
- Undertake any activity that involves standing for short periods, e.g. washing up, dusting, shaving
- Keep as active as possible and walk around little and often

Step 7 (second week)
- Walk approximately 100 yards on flat ground, increasing by approximately 10 yards daily, e.g. walk to the corner shop
- Use the stairs four to five times daily

Step 8 (third week)
- Walk 250–300 yards, two or three times a day
- Use stairs as normal
- Begin to do light shopping, gardening or housework
- Take a bus

Step 9 (fourth week onwards)
- Begin to resume a normal way of life; participate in most normal daily activities, avoiding heavy gardening, moving heavy furniture, etc.
- Begin to take regular exercise, e.g. swimming and walking, progressing gradually
- Start driving again

The activity plan for convalescence should be based on a knowledge of the person's functional capacity, interests, previous lifestyle, needs for the future and home environment. Any inhibiting factors such as arthritis also need to be acknowledged. Many hospitals now offer formal structured exercise programmes as part of a coronary rehabilitation programme and exercise-based cardiac rehabilitation has been shown to reduce both cardiac and total mortality (Taylor et al 2004). However, such programmes might not begin for 3–6 weeks after discharge and the patient needs specific advice to prepare for the first few weeks at home. For example, most patients would be able to walk 2 miles a day at the end of 4 weeks. Patients can resume driving 4 weeks after an uncomplicated myocardial infarction although HGV drivers have to show evidence of a negative exercise test. Return to work provides increased self-satisfaction, restored self-respect and relief from financial worries, although early retirement may be a more realistic

option for some. Occupational health and community nurses can support the patient and family throughout convalescence.

The aim for all patients is that they will be able to resume their daily lifestyle without physical symptoms, but this depends on their residual left ventricular function. An important part of the rehabilitation process is teaching the person and family how to live with these new limitations. If there is residual ischaemic tissue and angina, medication will help to control this (see p. 18).

Breathing

Oxygen therapy should be given alongside analgesics, to ensure maximal relief of pain. A semi-upright position also eases breathing. Anxious people often hyperventilate and deep breathing exercises may help.

Smoking is not permitted if oxygen therapy is being given and the patient should be encouraged to give up this habit. Stopping smoking is not easy and the best results come with encouragement and support (Van Berkel et al 1999).

Sleeping

The importance of punctuating exercise with rest periods is vital and people should be encouraged to have catnaps at home. In hospital, night sedation may help the patient to settle in a strange environment where noise levels are often high. Interventions need to be coordinated to allow the patient undisturbed periods of rest. A patient who is unable to sleep at night often becomes worried and anxious. An observant nurse can talk to the patient and help to put these fears into perspective.

Fear of dying

This is a very real fear for someone who has had a myocardial infarction (Thompson et al 1995). Once the initial fear has subsided, the patient has to come to terms with the cause of the cardiac event and the consequences of atherosclerosis. Complications with a high mortality rate occur at two stages after myocardial infarction:

- in the first 48 h, when cardiogenic shock and arrhythmias cause death
- 7–10 days later, due to myocardial rupture and ventricular septal defect.

Family fears of death must also be discussed. If not put into perspective, relatives can become overprotective once the person returns home.

Nutrition

In the early stages of myocardial infarction, the patient may have little appetite and opiates may induce nausea. Antiemetics should always be given in conjunction with opiates. Dietary advice should be tailored to the individual and will be similar for all patients with CHD.

Diabetic patients are likely to have raised blood glucose levels following a myocardial infarction. There is evidence that rigorous control of plasma glucose by insulin infusion, followed by subcutaneous insulin, can have a positive effect on long-term prognosis, and therefore patients' blood glucose levels need to be monitored closely and insulin therapy altered accordingly (Yudkin 1998).

Eliminating and fluid and electrolyte balance

Fluid balance is a vital means of assessing renal function, as 25% of cardiac output goes to the kidneys. If left ventricular function is compromised, fluid intake may be restricted to prevent the onset of cardiac failure and pulmonary oedema (p. 43). Electrolyte balance must also be maintained within normal limits and any deviations from normal acted upon.

Potassium regulation is important in the cardiac patient, as both low and high levels of serum potassium lead to life-threatening arrhythmias. Hypokalaemia causes ECG changes and increases the susceptibility to digoxin therapy and therefore toxicity. It can result from acidosis and diuretic therapy with insufficient potassium replacement. Hyperkalaemia in the cardiac patient also results in bradycardia and heart block, and leads to other ventricular arrhythmias. Causes include renal failure and tissue breakdown, which leads to large amounts of intracellular potassium being released into the circulation.

Sodium levels also require to be kept within normal limits. Assessment for obvious signs of fluid overload, such as oedema in the ankles and other dependent parts, and a daily weight check are also part of fluid-balance monitoring.

An increased workload is placed on the heart if there is straining at stool to aid defaecation. Aperients may be used to soften stools and there should be sufficient fibre in the diet. A commode is usually easier to use than a bedpan and even someone confined to bed is likely to expend less energy using a commode than balancing on a bedpan.

Personal hygiene

Initially the patient will be dependent on nursing staff, but this is one of the first areas where independence can quickly be regained. It is possible even in bed to wash the face and upper body and by discharge to be fully independent. It is safer not to lock the bathroom door, in case of emergency, and the family should discuss how to maintain the person's privacy while using the bathroom.

Sexuality

Although discussion of this intimate aspect of life is often difficult, sexual counselling should be an integral part of cardiac rehabilitation. The severity of the infarction and resulting cardiac decompensation are much less important causes of sexual debility than the person's psychological state (Freidman 2000). Reasons for not resuming previous levels of activity include:

- fear of chest pain or another heart attack
- feelings of depression
- partner concern about symptoms
- lack of, or poor, sexual advice from health professionals.

The energy levels and demands placed on the heart during sexual intercourse are comparable to walking briskly or climbing two flights of stairs. It is very rare for sexual intercourse to trigger another heart attack and, as a general guide, intercourse can usually be resumed approximately 2 weeks after discharge, although touching and caressing may be comfortable for some earlier than this.

The subject of sexual activity is best approached as a routine part of the rehabilitation of all coronary patients. The patient needs to feel at ease and the nurse needs to be

well informed and prepared for questions. Written information may be useful as a starting point for discussion (Albarran & Bridger 1997). The aim of sexual advice is to restore, as nearly as possible, pre-infarction levels of sexual activity.

Complications of acute coronary syndromes

There are a considerable number of complications of acute coronary syndromes which tend to be related to the site and size of damaged myocardium. The most common are listed in Box 2.7. It is not possible to look at each one in detail, but the nurse should be able to recognise and report the following major problems and carry out the appropriate nursing intervention.

Cardiac arrest

Cardiac arrest may be defined as failure of the heart to pump sufficient blood to maintain cerebral function. It is a term often used synonymously with sudden death, although death is not always the outcome of a cardiac arrest. The three main mechanisms of cardiac arrest are:

- ventricular fibrillation (VF)
- ventricular asystole
- pulseless electrical activity (PEA).

Brain death usually occurs because of the failure of oxygenation of brain cells associated with either failure in ventilation or failure of the heart to pump oxygenated blood to the brain. The brain can tolerate only 4–6 min of anoxia. The signs of cardiac arrest are:

- abrupt loss of consciousness
- absent carotid and femoral pulses
- absent respirations.

A rapidly developing pallor often associated with cyanosis follows. Apnoea, gasping and gagging may occur.

The risk of sudden death in myocardial infarction patients is great. In 25% of cases, this occurs within minutes of the onset of pain, before the patient has reached hospital. The nurse must be familiar with resuscitation procedures within the hospital but should also know how to perform basic cardiopulmonary resuscitation (CPR) without hospital technology. Training programmes in basic CPR for lay people are aimed at reducing this very high early mortality rate, as are the development of trained paramedical staff in ambulances, mobile coronary care units and defibrillators in public places.

To be effective in resuscitation, regular education and training update is necessary, ideally 6-monthly, particularly for those who do not use these skills frequently (Broomfield 1996b, Wynne et al 1999).

The risk of sudden death remains high for the first 24 h after infarction, following which it rapidly diminishes. In the CCU, cardiac arrest may be anticipated; in the ward it is often diagnosed by the nurse, who finds the patient unconscious and pulseless. This is an emergency and every nurse is responsible for:

- recognising that cardiac arrest has occurred
- knowing the procedure for summoning help within the hospital
- commencing effective resuscitation.

The priorities of CPR are:

- airway
- breathing
- circulation.

The nurse is also responsible for maintaining the person's comfort and dignity, anticipating events and procedures, and giving care and support to the patient and relatives after the event.

Restoration of an oxygenated blood supply to the brain involves artificial ventilation and external cardiac massage.

Medical help should be summoned once it has been established that the patient is not breathing. Presence of breathing is assessed by looking for a rise and fall in the chest wall, listening for any breath sounds and feeling for any expelled air.

Artificial ventilation

involves:

- maintaining a clear airway through the removal of loose-fitting dentures, food, sputum, vomit or other obvious debris
- performing the head tilt/chin lift method, or the head tilt/jaw thrust if suspected spinal injury, to allow maximum air entry with the patient in a supine position
- inserting an oesophageal airway, laryngeal mask or endotracheal tube if available
- ventilating the patient mouth to mouth, mouth to mask or with a self-expanding bag and valve mask and pure oxygen if available
- observing for a rise and fall in the patient's chest wall.

The patient should be given two effective rescue breaths, determined by a rise and fall in the patient's chest wall, before assessing for signs of circulation. Each rescue breath should last about 2 s, with a pause of 2–4 s before the next breath.

Box 2.7

Complications of acute coronary syndromes

- Sudden death
- Arrhythmias
- Cardiac failure
- Hypoxia
- Hypotension
- Cardiogenic shock
- Papillary muscle insufficiency
- Ventricular septal defect
- Ventricular aneurysm
- Myocardial rupture
- Pulmonary embolus
- Pericarditis
- Deep vein thrombosis
- Post-MI syndrome
- Emotional difficulty

Circulation
is assessed by feeling for a carotid pulse for up to 10 s. If there is no pulse then external cardiac massage needs to be commenced.

External cardiac massage
can provide only limited cardiac output. If the arrest is witnessed, an initial blow to the chest, precordial thump, may be attempted by professional health care providers, as this may restore the heart rhythm and takes only seconds to perform. Blood flow during cardiac massage is thought to occur due to increased intrathoracic pressure rather than direct heart compression. External cardiac massage involves:

- placing the patient supine on a firm surface
- placing the heel of one hand on the lower half of the patient's sternum, and the other hand on top of the first
- keeping the rescuer's arms straight and elbows locked
- kneeling level with the patient and applying firm downward pressure, depressing the sternum approximately 4–5 cm
- compressing the sternum at a rate of about 100/min.

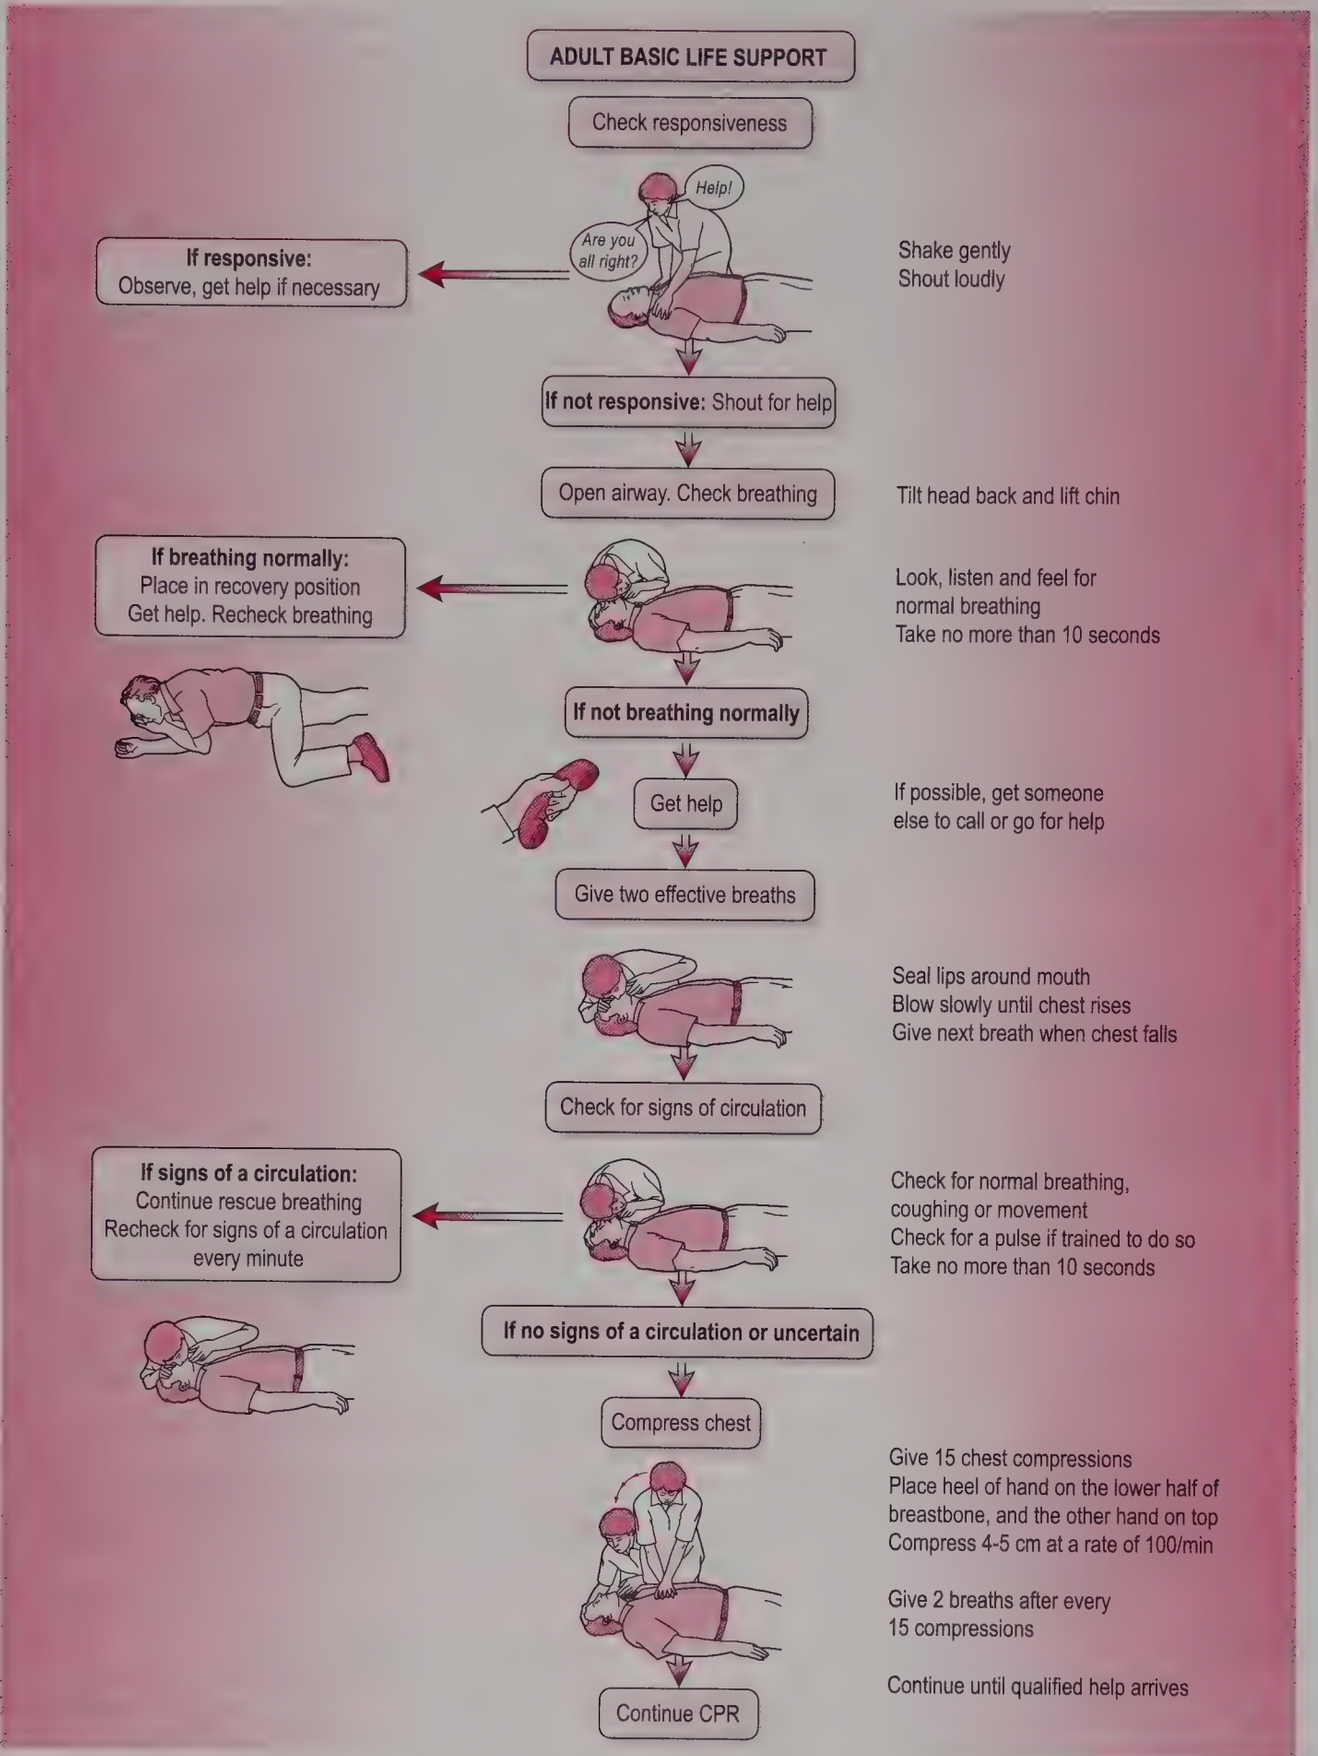
The internationally recognised guidelines developed by the American Heart Association (2000) and the European Resuscitation Council recommend a cycle of two inflations followed by 15 compressions for both one and two rescuers (see Fig. 2.12).

Medication
Ideally, all medications used during CPR are best administered through a central line to ensure swift distribution, as circulation time is greatly reduced. CPR should continue for 3 min to allow circulation of the drug. Adrenaline (1 mg i.v.) is given every 3 min during cardiac arrest.

Defibrillation
involves the delivery of a direct current (DC) shock to the heart through the chest wall. This causes depolarisation of all the myocardial cells that are able to respond to a stimulus, thereby terminating the fibrillation and allowing the normal conducting pathways to regain control of the heart. Monophasic defibrillation, with the current going one way through the heart muscle, is increasingly being replaced with equipment that delivers a shock in two directions, biphasic defibrillation. This means that lower energy levels are required and damage to myocardial muscle is reduced. The current can be delivered through hand-held paddles placed over gel pads or via pads stuck to the patient's chest. One pad should be placed below the right clavicle and the other over the apex of the heart in the fifth intercostal space. Ideally, the first shock should be administered within 90 s of the cardiac arrest. Precautions should be taken to ensure that floor surfaces are dry and all personnel warned that the shock is about to be delivered. Defibrillators that interpret the patient's heart rhythm and advise about defibrillation are increasingly available in areas where health professionals are less experienced in advanced life support and also in public places such as shopping centres and airports.

After-care
After successful resuscitation, the patient will require skilled nursing care. Full recovery can only be said to have occurred when the patient is fully conscious, with full cardiac, cerebral and renal function. The chances of achieving this are greatly enhanced if the patient is in a CCU where the arrest is witnessed and treatment initiated promptly. Success is less likely in the street where resources are limited.

Several body systems need assessment post-arrest, including the cardiovascular, renal, respiratory and central nervous systems. The patient may have been incontinent, have a sore chest and feel exhausted and somewhat embarrassed by their current state. An assessment of their level of orientation, recall, anxiety and general feelings should be made. The psychological support needed will vary. Relatives and witnesses to the arrest and the resuscitation attempt will also need support.



Ethical considerations
Unsuccessful resuscitation attempts do not enhance the dignity that is hoped for when we die. The appropriateness of merely prolonging the process of dying is often the subject of heated debate (Cotler 2000). The decision not to attempt resuscitation should involve the patient and the family and be documented to avoid confusion. The decision needs to be reviewed on at least a 24-h basis.

The Resuscitation Council (UK) (2000) points out that 'do not attempt resuscitation' (DNAR) orders may be a potent source of misunderstanding and dissent amongst doctors, nurses and others involved in the care of patients. Issues surrounding this dilemma include whether resuscitation is appropriate, involvement of the patient and family in the decision-making process and communication difficulties between doctors and nurses once the decision is made (Mason 1996). Increasingly, living wills are being made by patients, and nurses need to be aware of the significance of these when making decisions about resuscitation. It is important that it is understood by all that DNAR orders apply only to the decision whether or not to initiate resuscitation in the event of cardiac or respiratory arrest and should not in any way limit other medical or nursing care (Shepardson et al 1999, Jackson et al 2004).

2.5 Should relatives be permitted to witness resuscitation attempts? See Connors (1996).

Cardiogenic shock
This is a serious degree of heart failure, precipitated by extensive (>40%) left ventricular damage in which the cardiac output is not sufficient to give an adequate blood pressure to maintain perfusion. The patient develops clinical shock with low urine output, cold clammy skin and hypoxia. Lactic acid is produced in the skeletal muscle beds as the metabolism changes, giving rise to a metabolic acidosis. This process is cyclical, with the heart continually trying to pump harder for an ever falling stroke volume (see Ch. 18).

ADULT BASIC LIFE SUPPORT
Check responsiveness
Help!
Are you all right?
If responsive:
Observe, get help if necessary
Shake gently
Shout loudly
If not responsive: Shout for help
Open airway. Check breathing
Tilt head back and lift chin
If breathing normally:
Place in recovery position
Get help. Recheck breathing
Look, listen and feel for normal breathing
Take no more than 10 seconds
If not breathing normally
Get help
If possible, get someone else to call or go for help
Give two effective breaths
Seal lips around mouth
Blow slowly until chest rises
Give next breath when chest falls
Check for signs of circulation
If signs of a circulation:
Continue rescue breathing
Recheck for signs of a circulation every minute
Check for normal breathing, coughing or movement
Check for a pulse if trained to do so
Take no more than 10 seconds
If no signs of a circulation or uncertain
Compress chest
Give 15 chest compressions
Place heel of hand on the lower half of breastbone, and the other hand on top
Compress 4-5 cm at a rate of 100/min
Give 2 breaths after every 15 compressions
Continue until qualified help arrives
Continue CPR

A

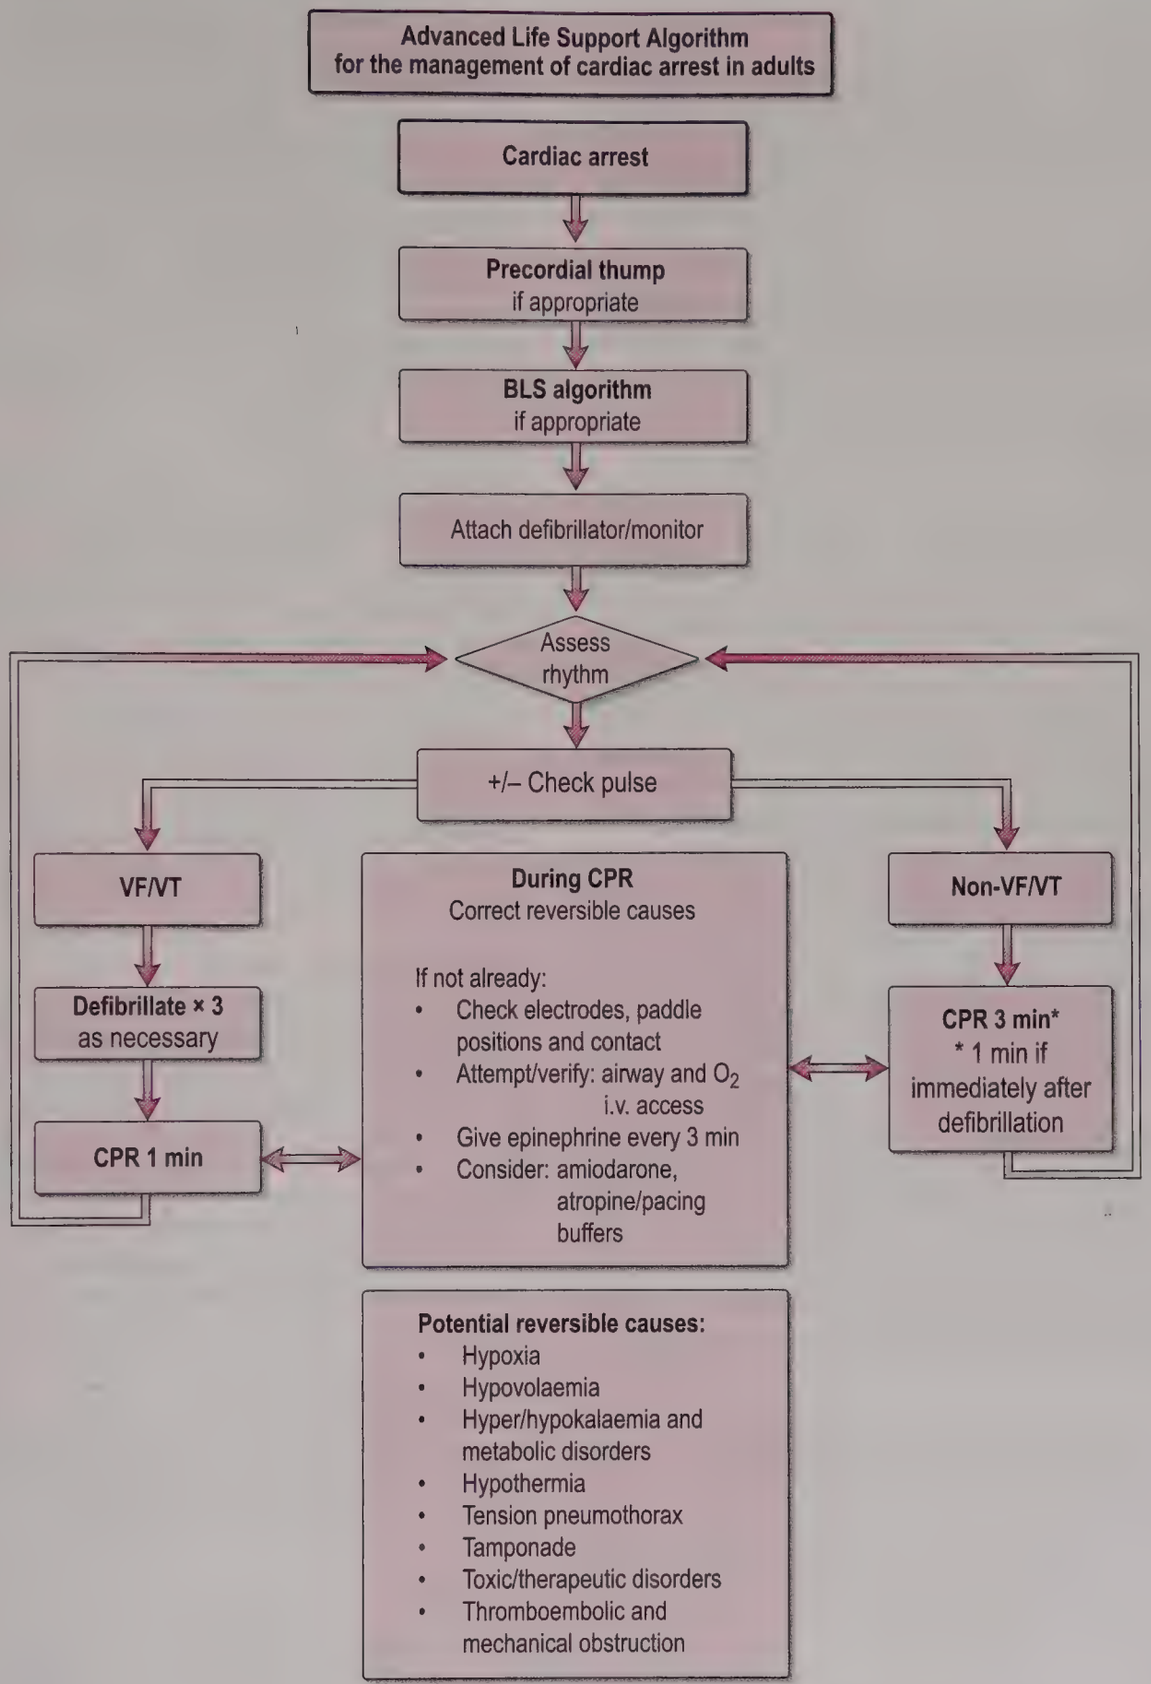


Fig. 2.12 A: An algorithm for basic life support. B: An algorithm for the management of cardiac arrest. (Reproduced with kind permission from the European Resuscitation Council.)

NB: Cardiopulmonary resuscitation – 2005 revised guidelines www.resus.org.uk

The Resuscitation Council (UK) recommends for adults:

- CPR with a chest compression to ventilation ratio of 30:2
- No initial ventilations before starting compressions
- When professional help is delayed for more than 4-5 minutes, one option is to give compressions for up to three minutes before attempting defibrillation
- Compressions for two minutes after defibrillation

If coordinated rhythm is not restored by defibrillation, second and further shocks should be given only after additional cycles of chest compressions.

PATHOPHYSIOLOGY

Clinical features

In the early stages, the patient may be restless and agitated, followed by mental confusion and lethargy as cerebral hypoxia increases. The skin becomes cold and clammy to touch.

Examination

There will be signs of central cyanosis. Vital recordings will reveal a rapid, thready pulse, hypotension, tachypnoea and hypothermia. Urinary output will be reduced.

MEDICAL MANAGEMENT

The priorities are to:

- enhance cardiac output
- restore tissue perfusion
- effect a diuresis through increased renal flow.

This often requires manipulation of several medications in order to obtain the best effect for the patient. Medications commonly used in myocardial infarction such as nitrates, beta-blockers, calcium antagonists and opiates may produce hypotension and worsen cardiogenic shock and therefore should be used with caution (Williams et al 2000). The aim is to improve cardiac output using inotropic drugs such as adrenaline, dopamine and dobutamine. These medications, often given via a central line, improve cardiac output by increasing contractility and often heart rate, which increase the demand on the myocardium for oxygen. Cardiac output can also be improved by using vasodilators to reduce afterload. Diuretics are widely used in cardiogenic shock to induce a diuresis. The patient will require urinary catheterisation to assess hourly urine output and may be haemodynamically monitored using a pulmonary artery flotation (Swan–Ganz) catheter (see Ch. 18). If pharmacological intervention is ineffective in treating cardiogenic shock, then more invasive therapy such as the intra-aortic balloon pump (IABP) (see p. 727) or left ventricular assist device may be required. Some patients may be appropriate for PTCA.

The outlook for patients developing cardiogenic shock is poor and mortality is high (45–80%), as the process is very difficult to reverse (Goldberg et al 1999).

NURSING PRIORITIES AND MANAGEMENT: Cardiogenic shock

The priority in caring for these patients is prevention or early recognition of the signs that shock is developing (O'Neal 1994, De Jong 1999).

Observation

Recording and assessment of all vital signs are important. The pulse will initially be rapid and thready as a compensatory response to the falling cardiac output; in the late stages, bradycardia develops.

Initially, systolic and later, diastolic pressure will fall. A fall in pulse pressure of more than 30 mmHg may be an indication that shock is developing in the hypertensive patient. The initial response to hypoxia is tachypnoea, which later becomes shallow and irregular. Most patients benefit from oxygen therapy. Urine output falls as a result of the falling cardiac output, leading to inadequate perfusion of the kidneys.

Nursing management of these patients requires careful observation and recording of response to medication. Patients are likely to become increasingly drowsy, confused, immobile and dependent on nursing care. They may also be lethargic or semi-conscious. Anxiety and fear need to be recognised and addressed (Williams 1993). Small doses of opiates may promote comfort and rest. The relatives need time spent with them to explain the condition of their loved one and how they can best help. The hospital chaplain or other spiritual advisor may provide comfort for the patient and family at this time.

Medical complications of myocardial infarction

The risk of complications following acute myocardial infarction is mostly dependent on the size of the infarcted area, the total loss of functional myocardium following previous ischaemic damage and the extent and severity of coronary artery disease.

Myocardial rupture

This very rare complication results in instantaneous death. It usually occurs 3–5 days after an extensive infarction in a heart with poor collateral blood flow. Necrosis occurs before fibrosis of the myocardium is complete, causing muscle rupture and the pumping of blood into the pericardium.

Ventricular septal defect

This occurs more frequently than rupture but in some cases is amenable to treatment. The pathophysiology is the same as that for myocardial rupture, with a hole developing in the septum separating the right and left ventricles. The right ventricle has to cope with increased pressures and blood volumes while the left ventricle suffers a fall in cardiac output. Rapid onset of cardiogenic shock may be the result. Operative repair can be undertaken but the mortality rate is high. If the patient can be supported for 2–4 weeks by aggressive medical management until the septum has become fibrosed, then the surgical results are slightly better.

Papillary muscle rupture

Loss of blood supply to the muscle supporting the mitral valve leads to prolapse and malfunctioning of the valve. If acute rupture occurs, then sudden death may result. Surgical repair can be attempted, but again survival rates are low.

Ventricular aneurysm

This occurs when the infarction involves the full thickness of the myocardium. As the necrotic tissue is replaced by fibrous tissue, it is subject to the high pressures in the left ventricle. This fibrous tissue balloons out to form a blood pouch, which does not contract. Blood stagnation in this pouch leads to the development of thrombi and systemic emboli complicate approximately half of cases of left ventricular embolism. If a large area of myocardium is affected then it can lead to cardiac failure; if the aneurysm is near the papillary muscle or mitral valve then incompetence will result. Surgical resection can be undertaken successfully with some of the smaller aneurysms.

Pericarditis

This is thought to be due to an autoimmune reaction in which antigens from the damaged myocardium cause inflammation of the pericardium. The patient presents with pain at any time from 24 h to 1 week after the myocardial infarction. On examination, a 'friction rub' caused by friction between the pericardium and myocardium is often heard, accompanied by an unresolving post-infarction pyrexia. Medical treatment and nursing care involve treating the pain with analgesics and non-steroidal anti-inflammatory agents. Reassurance that the pain is not an extension of the infarction is important.

Emboli

Embolism of a pulmonary or systemic vessel can occur after myocardial infarction. Emboli arise from clots forming in the healing myocardium or from circulatory stasis causing clot formation in the lower limbs. Nursing care involves maintaining passive exercises for the patient, whose mobility is restricted. The use of anti-embolism stockings should be considered. All post-myocardial infarction patients and those with known CHD should be given aspirin, which, taken daily, has been shown to be effective in reducing clot formation. In most patients this may be sufficient, but in people with pulmonary emboli or who are known to have mural thrombi, a more aggressive approach to anticoagulation is required.

ARRHYTHMIAS

The term arrhythmia is used to imply an abnormality in either electrical impulse formation or electrical impulse conduction within the heart. An arrhythmia may cause an effect by any one of the following changes:

- change in heart rate
- increase in myocardial oxygen requirement
- decrease in myocardial blood flow
- loss of synchronicity of ventricular contraction.

PATHOPHYSIOLOGY

Clinical features

The clinical manifestation of an arrhythmia depends on the ventricular rate, the conduction of the myocardium and the psychological response of the patient. Patient problems include:

- palpitations
- dizziness
- faintness
- shortness of breath
- chest pain
- headache
- reduced activity tolerance
- anxiety.

Nursing assessment includes the apparent effect of the arrhythmia on the patient, a history of any past experiences of the problem, a knowledge of any relevant medications or other treatments and identification of any possible precipitating factors.

In cardiac disease, the normal sinus mechanism can be altered if the disease affects the heart's specialised conduction tissue. Various conditions result in specific conduction disturbances, and while this chapter cannot deal with them all, it will concentrate on a few of the more common conditions with which the nurse should be familiar. In interpreting heart rhythms, the method used must be systematic and consider all components of the ECG complex.

Normal sinus rhythm should be recognisable to all nurses, as patients attached to cardiac monitors are increasingly nursed on general wards. The nurse's priorities are to:

- recognise and immediately report anything abnormal
- assess quickly the effect of the abnormality on the patient and take the appropriate action.

The normal electrocardiogram and the basic rules for observing cardiac monitors discussed earlier in the chapter apply here.

Sinus arrhythmias

The SA node is under autonomic control, primarily vagal, but is influenced by sympathetic stimulation, temperature, oxygen saturation and other metabolic changes. Sinus arrhythmias are often secondary to these influences.

Sinus arrhythmias are characterised by a constant PR interval but progressive beat-to-beat change in R–R intervals. During expiration, the reflex discharge of the vagal nerve slows the sinus mechanism; during inspiration this influence is diminished, allowing a speeding up of the sinus rhythm. Sinus arrhythmias are not life threatening and resolution of the primary cause resolves the arrhythmia.

Sinus bradycardia

This meets the criteria for sinus rhythm but the rate is less than 60 beats/min. It may result from increased vagal tone but also results from hypothermia, certain medications, e.g. beta-blockers, raised intracranial pressure and inferior myocardial infarction. Some individuals may experience sinus bradycardia when sleeping. It may be the norm in athletes. Intravenous atropine is given for symptomatic sinus bradycardia.

Sinus tachycardia

This also fits the criteria for sinus rhythm, but the rate is greater than 100 beats/min. It is a direct result of decreased vagal tone and often a response to sympathetic stimulation.

Narrow complex tachycardias

Atrial flutter

This is characterised by rapid and regular atrial excitation at a level above 200 beats/min. The AV node is not capable of conducting atrial rates above this level. The atrial waves form a sawtooth pattern. Ventricular deflections usually occur regularly within the atrial pattern and the block is described as a ratio, e.g. 4:1, which means four P waves per QRS complex.

Atrial flutter is not a stable rhythm and often progresses to atrial fibrillation.

Atrial fibrillation

When individual muscle fibres of the atria or ventricles contract independently, they are said to be 'fibrillating'. There is rapid disorganised atrial depolarisation because the atrial tissues have lost synchrony with each other. The atrial waves can occur up to 600 times per minute. Ventricular depolarisation is also irregular as a result of the variable response at the AV node, but the QRS complex is normal. It occurs in congestive cardiac failure and mitral valve disease, and commonly presents with ischaemic changes in old age.

MEDICAL MANAGEMENT

Atrial fibrillation can severely compromise cardiac output, as the loss of the effect of atrial systole can reduce stroke volume by up to 25%. With chronic atrial fibrillation, the danger of thrombi forming in the atria and then embolising is high.

Treatment

is aimed at reducing the rapid ventricular rate through chemical or DC cardioversion (see Box 2.8) to revert to sinus rhythm. Cardioversion after digoxin therapy may precipitate ventricular fibrillation if large doses of digoxin have been used. Anticoagulation in the form of heparin or warfarin may be prescribed to reduce the risk of thrombi.

Box 2.8

Cardioversion

Purpose

The term 'cardioversion' is used to mean the delivery of a specific and predetermined amount of energy to the heart, timed (synchronised) in such a way that the shock is delivered well away from the vulnerable period of the T wave on the ECG. It is usually performed electively, with the patient lightly anaesthetised. This differs from defibrillation, which usually involves the delivery of a larger amount of electricity to a patient in ventricular fibrillation without anaesthetic, as the patient is usually unconscious. Elective cardioversion is used to treat supraventricular and ventricular arrhythmias.

Electrical treatment has the advantage that it is free from pharmacological side-effects.

Procedure

Monophasic or biphasic electrical wave forms are used for cardioversion, the latter requiring lower energy settings. Energy levels are titrated upwards if an initial shock is unsuccessful. The patient is asked to remove any dentures or restrictive clothing. An ECG will be performed before and after the procedure, and the patient attached to a cardiac monitor throughout. Oxygen is given both before and after the procedure. A light anaesthetic is usually given and the patient asked to fast for 4–6 h prior to the procedure. Resuscitation equipment needs to be on hand. The defibrillator is set to the required output and the paddles or pads are placed in position, usually with one below the right clavicle and the other over the apex of the heart in order to depolarise an optimum mass of myocardial cells. The patient is usually awake and talking 5–10 min after the procedure; nausea and vomiting are not uncommon, as are a sore throat from the endotracheal tube and chest wall soreness due to the cardioversion. Cardioversion is often performed on a day-case basis and is frequently coordinated and led by nurses (Quinn 1998).

NURSING PRIORITIES AND MANAGEMENT: DC cardioversion

The procedure should be fully explained to the patient so that they are aware of what to expect. They will be prepared as for all patients prior to a general anaesthetic. The thought of an anaesthetic and an electric current being put across the heart may be frightening. Care should be taken to ensure that the area is dry and that all personnel are warned that the shock is about to be delivered. The patient is likely to want to know the outcome of the procedure and this should be explained. Topical creams may help to ease any chest soreness caused by the electric shock.

2.6 Clarify the difference between emergency defibrillation and elective cardioversion.

Junctional tachycardias

The AV node, unlike the SA node, normally has no pace-making role. Impulses must travel in both directions to stimulate atrial and ventricular contractions, so the position of the P wave varies. The QRS complex is of normal configuration and duration since the normal conduction pathway is followed below the AV node. Junctional tachycardia is characterised by the sudden onset of tachycardia greater than 150 beats per minute. There are three forms of junctional tachycardia: AV nodal re-entry tachycardia, AV re-entry tachycardia and paroxysmal atrial tachycardia. These are discussed in more detail in Jowett and Thompson (2003). The urgency of treatment depends on symptoms, which tend to be related to the ventricular rate. Carotid sinus massage may terminate junctional re-entry tachycardias and allows differentiation from atrial flutter.

Supraventricular tachycardia

This term is still often used but is anatomically incorrect because most narrow complex tachycardias incorporate both ventricular and atrial myocardium within the conduction circuit. Medical management of narrow complex tachycardia aims to reduce the rapid ventricular rate using carotid sinus pressure or antiarrhythmic drugs, e.g. amiodarone, adenosine or digoxin.

If these measures are unsuccessful then cardioversion may be indicated.

Ventricular arrhythmias

In these rhythms the ectopic focus arises below the AV node.

Ventricular tachycardia

This is a broad complex tachycardia with a QRS complex that looks wide and bizarre. The rate is regular at around 140–200 beats/min. It is generally caused by an irritable or ischaemic myocardium. Treatment, if the patient is symptomatic, is with immediate synchronised cardioversion and/or intravenous lidocaine. Other medication includes amiodarone, flecainide and mexiletine. Persistent

episodes of ventricular tachycardia may be treated with override pacing or ablation therapy, where the ectopic focus or source of the arrhythmia is identified and removed.

Ventricular fibrillation

In this rhythm, there are no distinguishable complexes on the screen and only an erratic baseline trace is evident. Treatment is by immediate initiation of resuscitation procedures and defibrillation.

Cardiac electrophysiology studies and ablation processes

Electrophysiology studies involve the introduction of an intravenous or intra-arterial catheter with multiple electrodes positioned at various intracardiac sites for the purpose of recording or initiating electrical activity from specific areas of the atria or ventricles. These studies are performed on patients with arrhythmias which are resistant to medication, in order to identify the nature of the rhythm disturbance — also known as cardiac mapping.

Ablation therapy requires the delivery of a high-energy electric shock through a catheter in order to produce localised tissue damage in the unstable area identified as producing the arrhythmia, e.g. in Wolff–Parkinson–White syndrome.

Implantable cardioverter defibrillators

The implantable cardioverter defibrillator is an electronic device used to detect and terminate potentially lethal arrhythmias through the delivery of an electric shock. Current models weigh less than 200 g and are implanted without open chest procedures. They are particularly suitable for patients who have survived one episode of cardiac arrest not thought to be the result of myocardial infarction and for those with recurrent episodes of ventricular tachycardia unresponsive to optimal medication. Appropriate patients are likely to need individualised information and support to enable them to cope with the concept of being dependent on the device (James 2002).

Heart block

This arrhythmia results when there is a delay or interruption of impulse conduction from the atria to the ventricles at the AV node. It is described as:

- first-degree heart block
- second-degree heart block
- third-degree (complete) heart block.

Heart block is usually a complication of myocardial infarction.

First-degree block

appears as a prolonged PR interval with a mild bradycardia. It is asymptomatic and seldom requires treatment.

Second-degree block

appears as occasional blocking; for example, there may be alternate conducted and non-conducted atrial beats, giving twice as many P waves as QRS complexes. The patient may have no symptoms and require no treatment. If a fall in blood pressure or other signs of reduced cardiac output develop, the heart block is treated by the insertion of a pacemaker (see Box 2.9).

Complete heart block

exists when atrial and ventricular activity are uncoordinated. The atria and ventricles are electrically dissociated and desynchronised, with a subsidiary pacemaker developing in the ventricles. Cardiac output is reduced and the patient is haemodynamically compromised. The ventricles often contract at a rate of less than 40 beats/min and a pacemaker requires to be inserted immediately to restore cardiac output. The nurse's role is one of observation, reporting and patient support.

NURSING PRIORITIES AND MANAGEMENT: Arrhythmias

The clinical consequences of arrhythmias are extremely variable, but are likely to be more pronounced in those with chronic heart disease. Treatment usually aims to restore sinus rhythm and prevent recurrence of the arrhythmia. Nursing management involves anticipating and resolving patient problems, monitoring the patient, including their response to treatment, and providing information and support.

Pacemakers

Indications for pacing vary both nationally and internationally, although the American College of Cardiology, the American Heart Association and the North American Society for Pacing (ACC/AHA/NASPE 2002) have produced pacemaker guidelines. Nursing considerations include assessing pacemaker function, ensuring patient comfort and safety, preventing and dealing with complications, and teaching the patient about their condition and its management. The patient needs to be prepared for the procedure, even if it is done as an emergency (see Box 2.9).

Following pacemaker insertion, the patient should be attached to a cardiac monitor to assess whether the pacemaker is functioning properly. Cardiac output needs to be assessed frequently by recording the patient's blood pressure and asking them to report any symptoms of faintness, dizziness, chest pain or shortness of breath.

Limited mobility may make the patient more dependent on nursing care for a while. The patient with a temporary pacemaker should be aware of how long the temporary pacing is likely to continue and appreciate what is likely to happen next.

Removal of the temporary pacemaker is performed at the patient's bedside under aseptic conditions.

Permanent pacing

Initially, the nursing considerations are similar to those for temporary pacing. Some patients will be helped by a visit from a person who already has a permanent pacemaker, and also by being given an opportunity to handle a pacemaker. The patient needs to be reassured that the pacemaker will not be damaged by day-to-day activities. They should be taught to take their own pulse and be aware of the signs of

Box 2.9

Pacemaker insertion

Purpose
Pacemakers are used to gain control over the electrical activity of the heart. They have two basic components:

- a pulse generator containing a power source and electrical circuitry
- one or two pacing leads, each with an electrode on its tip.

Pacemakers may be either temporary or permanent, depending on whether the pulse generator is located externally or implanted. If pacing is planned for a short duration, an external source is used to deliver electricity to the heart via the skin. When long-term control of the heart is required, a permanent pacemaker is implanted. The two most common modes of pacing are:

- demand (ventricular inhibited) — senses intrinsic cardiac rhythm and stimulates myocardial depolarisation and contraction as necessary
- fixed rate — fires at a predetermined rate, irrespective of intrinsic cardiac activity.

Temporary pacing
This is used to maintain cardiac output during episodes of extreme bradycardia, heart block and asystole. It may also be used for the suppression of tachyarrhythmias, which are resistant to medication. It is usual for a special room to be set aside for temporary cardiac pacing, with ECG monitoring, fluoroscopy and resuscitation equipment being readily available.

Most commonly, a bipolar catheter is inserted into the subclavian vein, external jugular vein or antecubital fossa under local anaesthesia. The catheter is then passed into the right atrium and thence through the tricuspid valve and into the apex of the right ventricle, where the tip of the catheter is lodged against the ventricular wall. The external end of the catheter is stitched into place at the skin surface. The bipolar catheter is stimulated by the pacemaker's external pulse generator. Verification of pacing is judged from the appearance of a pacing spike preceding the QRS complex of the ECG. Pacing 'threshold' is obtained by determining the lowest voltage needed to elicit a paced beat, ideally less than 0.5 V. The threshold needs to be checked at least every 12 h, as it may increase over time.

Possible complications
These include arrhythmias, failure of the electrode to sense the heart's own electrical activity, failure of the electrode to generate a contraction, abdominal muscle twitching, pneumothorax and infection.

Permanent pacing
The decision to implant a permanent pacemaker is made after careful patient assessment. It is usually offered to patients with symptomatic bradycardias and heart block. The modern pacemaker is a small metal unit weighing between 25 and 30 g. It is powered by a lithium battery with a life of up to 15 years. Two types of pulse generator are currently available:

- single chamber with an electrode placed in either the atrium or the ventricle
- dual chamber with electrodes situated in both chambers.

The pacemaker is usually implanted under local anaesthesia in a cardiac catheterisation laboratory. The pulse generator is implanted in a subcutaneous pocket, usually under the clavicle, axilla or abdominal wall. The procedure is usually performed on a day-case basis.

reduced cardiac output. Signs of infection, such as redness or increased soreness at the implantation site, should also be reported. The importance of follow-up appointments should be explained. It is also useful to warn people that the pacemaker may trigger off alarms at airports. The patient should refrain from driving for 1 month (6 months for LGV and PCV, and re-licensing may be permitted thereafter providing there is no other disqualifying condition).

For further information see the Driver and Vehicle Licensing Agency (DVLA) website – www.dvla.gov.uk; for further information on the use of pacemakers and implantable internal defibrillators, see the ACC/AHA/NASPE (2002) guideline update for implantation of cardiac pacemakers and antiarrhythmia devices.

HEART FAILURE

The term 'heart failure' is used to describe a clinical syndrome that has a characteristic group of signs and symptoms. It results from an inability of the heart to provide an adequate cardiac output for the body's metabolic requirements. It is increasing in prevalence and the prevalence rises steeply with age. Statistical data suggest that after an initial diagnosis of heart failure, 16% of patients die within a year of diagnosis, 40% within the first 2 years and 61% within 5 years (British Heart Foundation 2004). Patients living with heart failure have been shown to visit their GP on average between 11 and 14 times per year (Gnani & Majeed 2001).

Heart failure is often referred to as either acute or chronic. Acute heart failure is a complex syndrome in which the patient's condition changes from moment to moment. It arises from the loss of functional myocardial tissue and the reduced contractility of the myocardium. It complicates between 25 and 50% of acute coronary syndrome patients. The clinical condition is often complicated by arrhythmias which reduce the cardiac output further. It may develop suddenly or during the first few hours or days after the infarction. Acute heart failure may resolve with medical therapy as the patient's condition stabilises. However, infarction may result in a long-term reduction of the functional capacity of the myocardium and chronic heart failure. Chronic heart failure can also occur as a result of hypertension, aneurysm, cardiomyopathy, arrhythmias and medication, such as beta-blockers and antiarrhythmics, often used in acute cardiac events.

The diagnosis of heart failure is not difficult to make, but identifying the underlying cause can be. Heart failure can result from primary heart disease or from non-cardiac causes (see Box 2.10). Many of these conditions are very

Box 2.10

Primary cardiac conditions causing heart failure

Right heart failure
- Pulmonary hypertension secondary to left heart failure
- Congenital heart defect
- Thromboembolism
- Cor pulmonale
- Atrial septal defect
- Pulmonary venous stenosis

Left heart failure

Ventricular origin
- Coronary artery disease
- Aortic or mitral valve disease
- Congenital heart defect
- Hypertension
- Ventricular septal defect

Atrial origin
- Atrial myxoma
- Mitral stenosis

common, particularly in older people. They are often found in combination, making their individual contribution to the heart failure difficult to assess. Non-cardiac causes include chronic obstructive airways disease (COAD), hyperthyroidism and chronic anaemia (see Chs 3, 5 and 11).

PATHOPHYSIOLOGY

Heart failure can involve either ventricle independently or both together. Pure left or right ventricular failure may not exist for long because of their dependence on each other to maintain adequate blood flow. However, it is useful to look at the heart as two pumps. The left ventricle can cope better with alterations in pressure and the right with alterations in volume. Failure of the left side of the heart causes accumulation of blood in the left ventricle and left atrium with subsequent congestion of the lungs. Right-sided failure, where the right ventricle cannot effectively transfer deoxygenated blood to the pulmonary circulation, subsequently causes congestion of the circulation in the rest of the body (systemic circulation).

Cardiac reserve

The function of the heart is to pump blood to the body at sufficient volume and pressure to perfuse the tissues with oxygen. The requirements of many tissues are fairly constant, but the needs of the skeletal musculature vary with the level of physical activity. An increase in activity leads to an increase in cardiac output, this capacity to increase being the 'cardiac reserve'. The increase results mainly from increased heart rate and contractile force as a direct result of sympathetic nervous system (SNS) stimulation. In the patient with heart failure, the cardiac reserve is used to maintain baseline cardiac function and so the ability to respond to increased activity is limited. When the baroreceptors at various points in the body sense a fall in pressure and therefore a fall in cardiac output, the principal response is to increase stimulation of the SNS, followed up by a longer-term response.

Myocardial dilatation

Increased stretching of the myocardial cells, which occurs immediately after a sudden reduction in the ability to expel the stroke volume, increases their force of contraction and increases the cardiac output correspondingly. This compensatory mechanism becomes limited as myocardial oxygen demand increases.

Renal response

Reduced cardiac output has a depressant effect on the kidneys, which will not improve until the cardiac output returns to normal. The fall in blood pressure and sympathetic constriction of renal arterioles reduce the glomerular filtration rate (GFR). Reduced blood flow through the kidneys results in instigation of the renin–angiotensin–aldosterone mechanism and leads to increased angiotensin production, increased secretion of aldosterone and therefore increased sodium and water reabsorption. The fluid retention in itself does not interfere with the pumping ability of the heart, but it does increase venous return. The rise in extracellular fluid and blood volume increases systemic filling pressures, so more of the cardiac reserve has to be used to maintain perfusion, further reducing the heart's ability to respond to increased physical activity.

Congestive cardiac failure (CCF)

This term describes a state in which there is both right and left ventricular failure with a corresponding combination of systemic and pulmonary symptoms.

Myocardial hypertrophy

In response to the increased workload, the individual myocardial cells enlarge, thus increasing the total amount of contractile tissue. This compensation is usually of a temporary nature, and at this stage the prognosis is poor.

Oedema

Oedema may result when anything increases the movement of fluid from the bloodstream and impairs its return. One of the commonest causes is CCF, where the failure of the pump to move the blood volume forward results in back pressure, which raises the hydrostatic pressure such that it exceeds the colloidal pressure created by plasma proteins. As a result, the excess tissue fluid formed accumulates, exceeding the ability of the lymphatic system to drain the excess away.

In the early stages of heart failure, patients may complain of 'puffy ankles', being unable to fit comfortably into their shoes. There will also be sacral oedema.

Pulmonary oedema As systemic arterial pressure, and therefore afterload, increases, so does pressure in the left heart. Increased left ventricular end-diastolic pressure (LVEDP) results in increased pulmonary pressure and an accumulation of blood in the lungs. If the pulmonary pressure rises above 28 mmHg, there is movement of fluid from the capillaries into the alveoli and interstitial spaces. This causes pulmonary oedema. If this occurs as an acute event, it can lead to death in 30 min. In the congestive failure situation, it is a chronic progressive state where the reduced lung compliance and high pulmonary pressure lead to increased right heart pressures and blood congestion on this side. This further raises pressure in the systemic circulation,

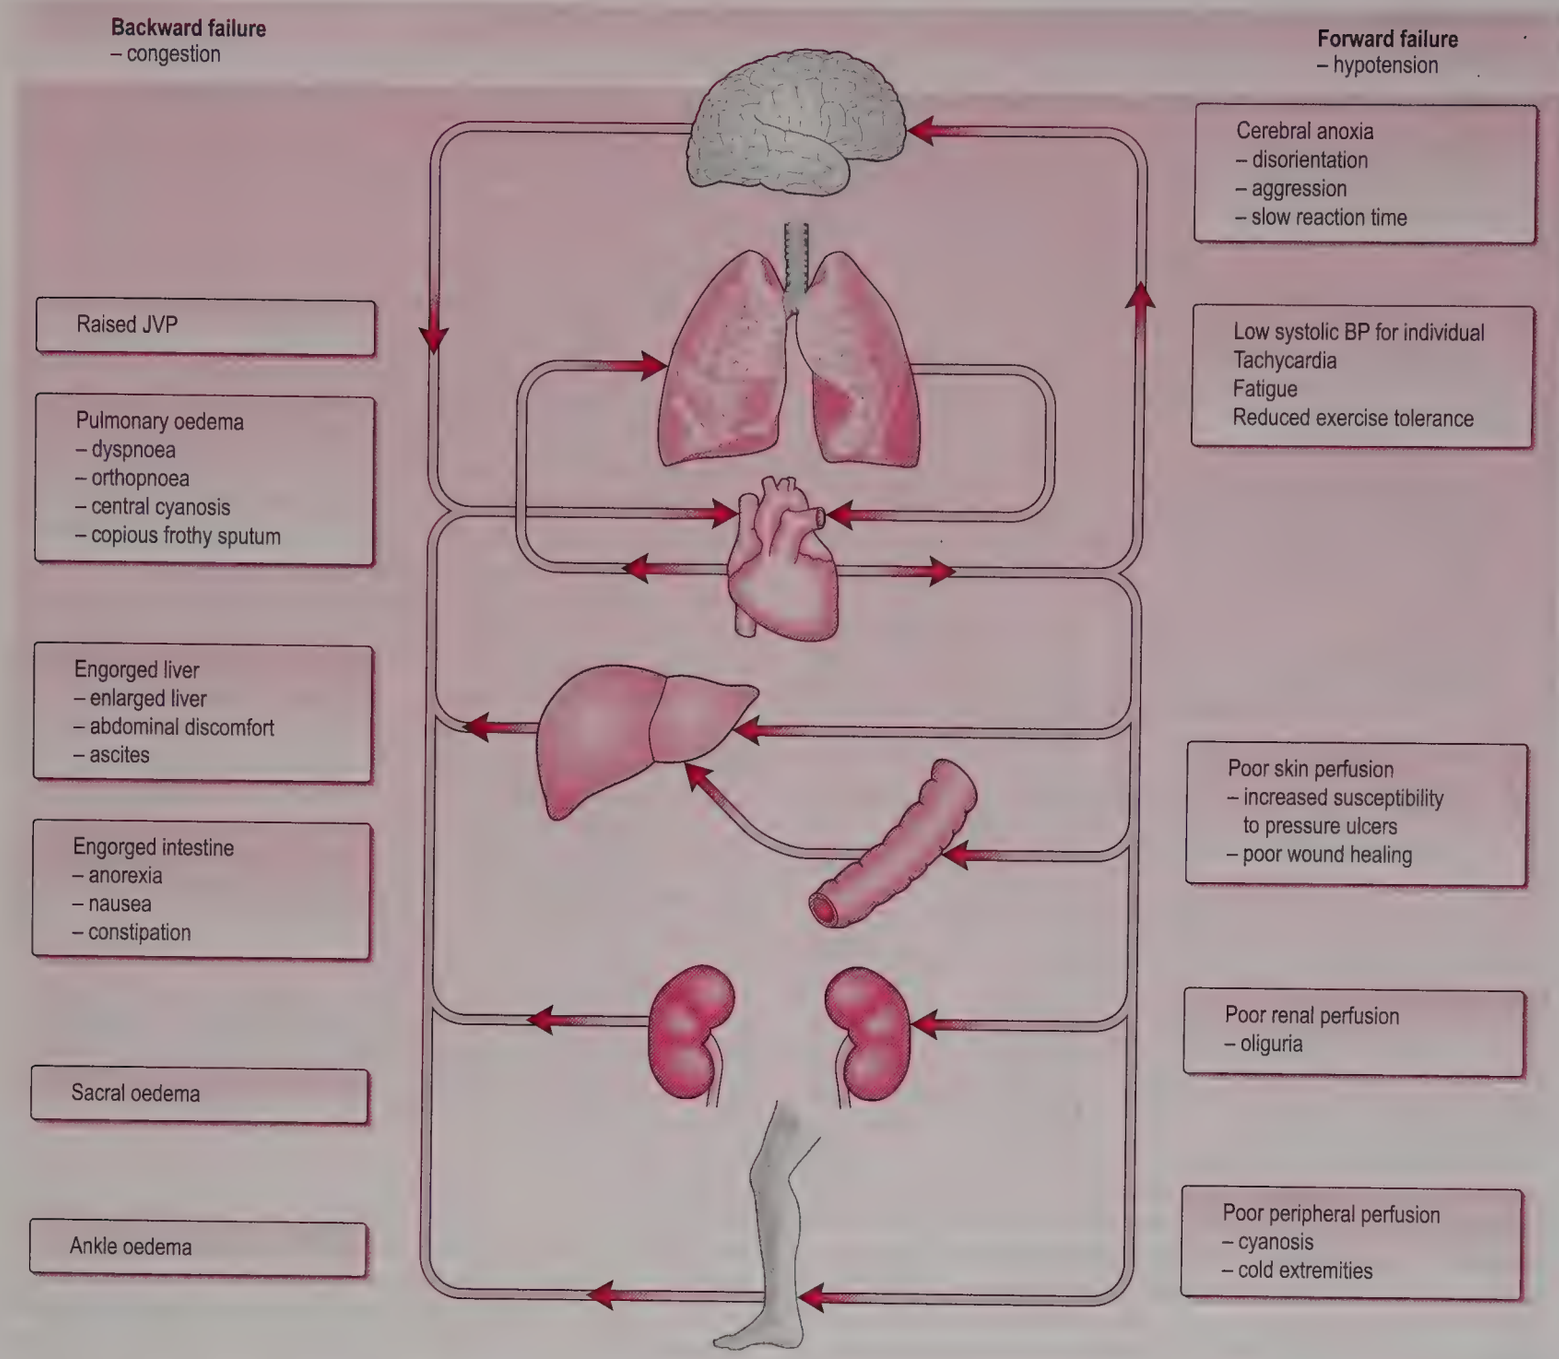

Fig. 2.13 Clinical effects of the decompensatory phase of ventricular failure.

making the whole process one of cyclical deterioration. As the systemic pressure rises, there is movement of fluid into the tissues giving rise to peripheral oedema. This is initially gravitational, but as the condition progresses the oedema becomes more widespread (see Fig. 2.13).

Common presenting symptoms

The presentation and history will depend on which side of the heart is failing. It may present gradually, as occurs in the ageing process, or suddenly, manifesting as acute pulmonary oedema with marked breathlessness, anxiety and tachycardia.

- Fatigue on exertion, dyspnoea with mild exercise and paroxysmal nocturnal dyspnoea are common early signs of failure of the left ventricle.
- Fatigue, awareness of fullness in the neck and abdomen, and ankle swelling are early signs of failure of the right ventricle.

Features appearing in systemic examination are listed in Table 2.6.

MEDICAL MANAGEMENT

Heart failure is suspected because of the patient's history, signs and symptoms. This diagnosis is then confirmed or excluded through a 12 lead ECG, which may show left ventricular hypertrophy, ischaemia or infarction; natriuretic peptides — B type natriuretic peptide (BNP) and its end terminal fragment N-BNP where available; a chest X-ray, blood tests, i.e. urea and electrolytes, creatinine, full blood count, thyroid function test, liver function test, glucose and lipids; echocardiography; urinalysis and peak flow.

Table 2.6 Systemic examination in heart failure

System	Points to note	Rationale
CVS	Chest X-ray	Evaluation of chamber enlargement Indication of primary cardiac abnormality
	Auscultation	Arrhythmia (especially AF) common A prominent third heart sound with a tachycardia (gallop rhythm)
	Vital signs	Venous hypertension common Observe jugular venous pressure
	Presence of oedema	Visible oedema in dependent parts, e.g. ankles, hands and sacrum, in bed-bound patients is a sign of inability to excrete sufficient water
Respiratory	Wheeze, bronchospasm	Possible increased pulmonary fluid
	Paroxysmal nocturnal dyspnoea	Evidence of poor left ventricle compensation
	Amount and consistency of sputum	Evidence of pulmonary oedema
	Pleural effusion on right side	Often found in patients with congestive cardiac failure
GIS	Chest X-ray	Recognition of oedema
	Diet	Sodium control is an important part of controlling fluid retention
	Palpation of abdomen	Signs of hepatic and splenic engorgement Presence of ascites
GUS	Micturition	Frequency and amount of urine passed; vital to assess effect of diuretic therapy
MS	Physical activity levels	Often severely limited by reduced cardiac reserve
CNS	Mental status	Signs of cerebral hypoxia
Skin	Skin integrity	Risk of pressure ulcers and delayed healing

Treatment

The main treatment approaches are:

1. oxygenation to improve myocardial contractility
2. rest to reduce cardiac workload
3. medication designed to improve cardiac function.

Diuretics, direct vasodilators and ACE inhibitors can be used to reduce symptoms, prolong life, or both, in heart failure patients.

- Diuretics, e.g. furosemide, induce sodium and water excretion, leading to decreased cardiac preload and wall tension, and an effective decrease of symptomatic pulmonary and systemic congestion. However, they have not yet been shown to prolong life in patients with congestive cardiac failure.
- Direct vasodilators, which induce venodilatation, arterial dilatation, or both, i.e. balanced vasodilators, may improve symptoms:
  - — venodilators, such as nitrates, exert a venous pooling effect, decreasing cardiac preload and symptoms of congestion
  - — arterial dilators, such as diltiazem hydrochloride and hydralazine, decrease afterload and improve cardiac output.
- The ACE inhibitors, e.g. enalapril and captopril, can cause haemodynamic and neurohormonal changes that lead to a reduction of preload and afterload, decreasing symptoms of heart failure. They might also deter the development of overt heart failure in some asymptomatic patients with left ventricular dysfunction.
- Beta-blockers are used to reduce the myocardial workload and myocardial contractility can be enhanced with, e.g. dopamine, but with caution, as inotropes increase myocardial oxygen demand and may produce arrhythmias. Arrhythmias associated with heart failure need to be treated to maximise cardiac output.

Patients with heart failure due to left ventricular dysfunction are usually prescribed a diuretic, an ACE inhibitor and a beta-blocker licensed for use in heart failure.

For further information on the pharmacological management of heart failure, see Gupta (2005).

Other treatment options for heart failure include intra-aortic balloon pump, revascularisation, biventricular pacing, valve replacement/repair, ventricular assist devices, cardiomyoplasty, ventricular volume reduction and heart transplant.

NURSING PRIORITIES AND MANAGEMENT: Heart failure

Patients with heart failure need a clinical assessment of cardiac output, cardiac rhythm, cognitive function, nutritional status and functional capacity. The patient's fluid balance status, blood urea, electrolytes and creatinine levels must be monitored to assess renal function and the effect of medication.

Acute heart failure may be a presenting problem in a CCU and heart failure following myocardial infarction is a poor prognostic sign. The manipulation of medication will form a major part of therapy for the patient admitted to hospital with an acute exacerbation of heart failure.

It is estimated that the average life expectancy of a patient with chronic heart failure is 4–5 years, and a reduced quality of life and concurrent depression are common (Mårtensson et al 2005). Patients and their families will need information

and support to help them retain their independence for as long as possible. Nurse-led multidisciplinary intervention in chronic heart failure has the potential to yield substantial benefits for patients and family members, including reduced hospital admission rates and cost savings (McMurray & Stewart 1998). There is some evidence that nurse-led care of heart failure patients can increase quality of life for these patients (Mårtensson et al 2005).

The British Heart Foundation, the Department of Health and other national bodies (BHF et al 2003) have set out key aims for the local improvement of heart failure services and provide sources of information and examples of service models designed to help achieve the CHD National Service Framework (NSF) standards (DH 2000), the National Institute for Clinical Excellence (NICE) heart failure guidelines (NICE 2003) and the Scottish Intercollegiate Guidelines Network (SIGN) guidelines (1999).

For further reading about nurse-led care of the patient with heart failure, see Jaarsma & Stewart (2004).

Maintaining a safe environment

The prime concern for patients with heart failure is to restore haemodynamic stability, using a combination of medications to optimise cardiac function and control fluid loss through the kidneys. The effects of this therapy should be regularly assessed and practice nurses may be involved in monitoring the patient's weight, heart rate and rhythm. People living with heart failure should be taught how to monitor their pulse and to check their ankles for signs of oedema.

Breathing

The patient will often describe breathlessness, especially on exertion, as the main symptom. Difficulty in breathing can be a frightening and frustrating experience. Acute left ventricular failure leading to pulmonary oedema results in marked respiratory distress, agitation and production of copious frothy sputum. The priority is to reduce both the psychological and respiratory distress, using i.v. morphine, diuretics and oxygen therapy. Being with the patient and explaining what is being done in a reassuring way can allay anxiety and help the person through the alarming experience. The patient should be helped to sit upright and given high concentrations of oxygen to breathe. Reducing and spacing out energy demands may help to minimise difficulty in breathing. In hospital, the nurse is responsible for:

- ensuring that respiration is recorded regularly
- assessing the patient's subjective feelings about their breathing
- reporting acute episodes of dyspnoea
- administering oxygen therapy to help reduce anoxia, cautiously, in the patient with COAD (see Ch. 3)
- assessing the nature and amount of sputum
- working in partnership with the physiotherapist to apply chest physiotherapy and nasopharyngeal suctioning to help with sputum clearance.

At home the patient may need further advice around planning activities and symptom management. They should be supported to stop smoking.

Sleeping

Respiratory distress is often worse at night when the patient lies flat, and paroxysmal nocturnal dyspnoea is a very frightening experience. Sleeping supported with extra pillows helps. Patients with congestive failure may not sleep for long periods. Many doze for periods during the day. Some people stay in a chair at night, instead of going to bed, because of their respiratory distress. These factors should be remembered when patients are admitted to hospital. A restless patient awake in bed at 02.00 h may get more rest if they follow their normal pattern and are not constricted by hospital policy.

Elimination

Accurate estimation of fluid losses, in conjunction with daily weights, provides information on the effectiveness of diuretics; output should be in excess of 30 ml/h. Input of fluid and sodium should be restricted. Reducing sodium intake also often reduces the patient's thirst, which is very important if fluid intake is to be restricted to around 1 L/day. The use of loop diuretic therapy, such as furosemide, will cause loss of potassium. Potassium supplements are given and serum levels of potassium closely monitored to ensure they remain within normal limits, 3.5–5.5 mmol/L (see Ch. 20). To assist in the accurate assessment of haemodynamic status, a central venous catheter or pulmonary artery pressure catheter may be inserted.

Constipation should be avoided.

Oedema

Daily assessment of the extent of oedema will indicate the effectiveness of therapeutic intervention. All dependent areas should be assessed, including the spine and sacrum, if the patient is bed-bound. Patients at home should be taught how to monitor weight and the signs of oedema.

Nutrition

The patient should be encouraged to avoid salt at the table and to reduce the amount used in cooking. Herbs or salt substitutes can be used instead. In hospital, a low-salt diet may be rigidly enforced if the oedema is severe. Obese patients should also be on a reduced-calorie diet, to prevent further strain on the heart. Iron intake may need to be assessed if the person is anaemic.

Mobility

Rest is important for patients with congestive heart failure in order to reduce the cardiac workload and oxygen demand. In the acute phase, complete bed rest is advocated until pulmonary oedema is controlled. Activity is gradually increased until tolerated without signs of physical difficulty. A patient confined to bed or chair rest requires pillows for support to keep their breathing comfortable. With cardiac beds, both foot and head ends can be altered, helping to relieve respiratory distress, while aiding the peripheral drainage of fluid. Ankle swelling can be significantly reduced by walking and elevating the feet when sitting.

Work and leisure

People with heart failure may require help to live within their activity limits and to come to terms with the fact

that they have a progressive disease for which there is no cure. Many people consider they are doomed to, and a few adopt, the role of invalid and dependant. The response to gradually increased activity is assessed to calculate the patient's functional capacity (see also the section on mobility for people with acute coronary syndrome, p. 31).

Personal hygiene

A patient with heart failure can usually retain independence in this area by taking certain precautions. Showers demand less energy expenditure than a bath, and a seat in the shower is helpful. A common difficulty is in drying the lower half of the body, because bending affects respiration, but by sitting, all parts of the body can be reached.

Someone with oedema will have very fragile, papery skin in the affected areas and great care must be taken not to break the skin by too much rubbing. Soap also has a drying effect on the skin; emulsifying oils may be better.

Communication

The importance of information being exchanged between the patient, family and health professionals cannot be overemphasised. It should be remembered that heart failure is a progressive disease which affects many people. The restrictions on mobility may confine these people to their home, further isolating them. Community cardiac specialist nurses, health visitors and practice nurses are increasingly involved in health assessment and screening. This assessment needs to take careful account of the social and psychological consequences, as well as the physical consequences, of disease processes and disability. It may be possible to arrange for attendance at a day hospital for those who wish it, or for a charity group such as Age Concern to provide transport to social events or day centres.

Sexuality

The patient's role within the family may have to alter as the disease increasingly restricts activities. Women may have to give up some household tasks to partners or to a home help. This can further demoralise them and requires tactful support from family and health professionals. Sexual activity may need to be modified if the individual's activity levels decrease or shortness of breath becomes a problem. The nurse needs to be equipped to offer realistic, non-judgemental advice (Westlake et al 1999).

VALVULAR DISORDERS

Adult valvular disease is either congenital or acquired. The effects of congenital problems largely manifest themselves in childhood and so are not discussed here.

The major causes of valve pathology are rheumatic heart disease (RHD), infective endocarditis and, to a lesser extent today, syphilis. Disease can cause narrowing (stenosis) of the valve, or regurgitation as a result of failure of the one-way valve, leading to blood back-flow through the valve. Major disruption can also result from papillary muscle dysfunction following myocardial infarction or penetrating chest wounds, when onset of symptoms can be sudden and severe.

Rheumatic heart disease

Rheumatic heart disease tends to be the result of rheumatic fever which is caused by group A streptococcal infection of the pharynx. It is usually a childhood ailment and shows seasonal variation, with a peak in colder months. Outbreaks of rheumatic fever are now more common in developing countries than they are in the West, especially within communities that are becoming progressively urbanised. In industrialised countries, the annual incidence is around 0.5 cases per 100 000 school-age children. However, in developing countries the annual incidence ranges from 100 to 200 children per 100 000 school-aged children (Olivier 2000). Poor housing and socioeconomic conditions exacerbate the problem. It may take up to 10 years before the signs of heart disease appear.

PATHOPHYSIOLOGY

The connective tissue of heart, joints and skin responds to infection by a proliferative and exudative inflammatory response with oedema and fragmentation of collagen fibres. The arthritic pain 'flits' from joint to joint and there is low-grade pyrexia. All layers of the heart can be affected. Endocarditis is most common, usually affecting the left side and involving the mitral valve, although any valve is at risk. The valve leaflets become inflamed and oedematous with small, firmly attached 'vegetations'. In the acute stages, this results in incompetence of the valve. Subsequent fibrosis deforms and thickens the leaflets and shortens the chordae tendineae, leading to stenosis with or without incompetence. Clinical outcome includes the need for surgical valve replacement, recurrence of rheumatic fever, endocarditis and thromboembolic events.

MEDICAL MANAGEMENT

Prophylactic antibiotic cover is instituted following the first occurrence of rheumatic fever and if this prevents recurrence then most of those who develop endocarditis will have a normal heart in the long term.

Infective endocarditis

The majority of cases are streptococcal or staphylococcal infections, although an increasing number of infective agents are being isolated, due to increasingly invasive medical techniques, such as in dental treatment or urinary investigation. Intravenous drug users also introduce bacteria into their body through use of contaminated needles.

PATHOPHYSIOLOGY

As well as being a cause of valvular disorder, those who have pre-existing valve disease or congenital lesions are at greater risk of developing bacterial endocarditis, as the underlying structures are already damaged and the blood flow is more turbulent. Certain sites are more favoured than others for bacterial proliferation. When blood flows from a high-pressure to a low-pressure system via a narrow orifice, the organisms tend to gather on the low-pressure side. If a high-pressure jet or regurgitant stream is created due to, for example, valve dysfunction, then satellite colonies will be seeded in the endothelial wall where the jet hits. In aortic

regurgitation, for example, blood flows back from the high-pressure aorta via the supposedly closed aortic valve to the low-pressure left ventricle. Colonisation by bacteria would most likely occur on the ventricular surface of the aortic valve. Similar patterns can be elicited for other areas of dysfunction.

The vegetations of infective endocarditis, in contrast to those in rheumatic heart disease, are large and can aggregate to form up to 6 cm masses. This poses a double threat to the patient in that they:

- are more likely to embolise
- may cause ventricular insufficiency themselves by prolapsing into the valve orifice and obstructing flow.

Common presenting symptoms

Presentation may be slow and insidious, with general malaise, weight loss, lethargy, intermittent, often low-grade pyrexia, profuse sweating and joint pain. Microembolisation may manifest as splinter haemorrhages of the nail beds. If the infection has eroded tissue close to the valves where the conduction system lies, there may be evidence of rhythm and conduction disturbances. Evidence of embolisation may be seen in renal, cerebral, pulmonary and gastrointestinal systems. Myocardial infarction may also result from septic embolisation of the coronary arteries. Heart failure secondary to valve failure varies in its severity, depending on the valve affected and the acuteness of onset, and may give rise to shortness of breath and ankle oedema.

MEDICAL MANAGEMENT

Investigations

should include ECG, chest X-ray and echocardiography. Cardiac catheterisation is also necessary for those referred for surgery to assess valve function, ventricular function and the patency of coronary arteries. Intravenous routes are normally used for long-term administration of antibiotic therapy. Patients should be advised about the importance of regular dental hygiene and prophylaxis when undergoing surgical procedures.

Valve stenosis and incompetence

Aortic stenosis

PATHOPHYSIOLOGY

The left ventricle becomes progressively hypertrophied, working at a higher pressure to eject blood past the stenosed valve. The chamber size of the ventricle is reduced by the increased muscle mass, which may itself contribute to outflow obstruction. This state is asymptomatic until the orifice is reduced to 0.5–0.7 cm^2 (normal 2.6–3.5 cm^2) when the patient may experience angina, as oxygen supply does not meet demand.

The other major effect is syncope, as cardiac output fails to rise in response to exercise. Hypertrophy may progress to decompensation and heart failure with rising LVEDP and pulmonary oedema. There is a link between aortic stenosis and gastrointestinal bleeding, known as Heyde's syndrome. However, the incidence of this is low (Pate & Mulligan 2005) and the problem usually subsides with valve replacement.

Mitral stenosis

PATHOPHYSIOLOGY

In this condition, the left atrium has to eject blood through a resistant valve. Left atrial pressure rises, and the atrium distends and eventually decompensates, with fibrous tissue interspersed between cardiac muscle. Conduction becomes aberrant and atrial fibrillation results, decreasing cardiac output as there is no atrial contribution to ventricular filling. If sinus rhythm persists, evidence of atrial hypertrophy can be seen on ECG. Since conduction takes longer to spread across the enlarged left atrium, the P wave becomes broadened and bifid. Left atrial pressure rises further with the stasis of blood within the chamber. This pressure increase is transmitted to the pulmonary vasculature, where vascular resistance rises with resultant greater right-sided afterload and possible failure. Acute elevations of pressure with exercise, for example, will precipitate pulmonary oedema. Stasis of blood allows the formation of mural thrombus within the atria. The obvious danger is that this may be dislodged and carried forward into the systemic circulation with profound ischaemic consequences for the area supplied by the embolised vessel (see Case History 2.2).

CASE HISTORY 2.2

K — living with mitral stenosis

K is an infant-school teacher in her early 30s. When she was 12 she developed rheumatic fever, thought to have resulted from a streptococcal throat infection, although it was not a common disorder and no-one else in her family had ever suffered from it. At that time she was in hospital for several weeks and left with inflammation of her mitral valve (valvulitis) which caused a progressive narrowing (stenosis) of her mitral valve over the years. On auscultation, K's mitral stenosis was identified by the characteristic diastolic murmur.

Until the age of 25, K felt quite healthy and often wondered just why she had to have regular medical checks and be prescribed antibiotics so quickly when some minor infection occurred. However, in her late 20s she began to experience breathlessness after various activities with the children at school. She often had to sit down, feeling light-headed, and developed a persistent, irritating cough. At first she dismissed it, but eventually she contacted her GP. Investigations showed that K's stenosis of the mitral valve was becoming worse and that she was developing the early signs of heart failure.

As a result of K's mitral stenosis, the pressure in the left atrium, pulmonary veins and capillaries increases. The left atrium dilates, fluid may accumulate in the alveoli, the pulmonary artery pressure rises, and the right ventricle hypertrophies. Systemic effects become apparent in the form of peripheral oedema, ascites and hepatic engorgement. Atrial fibrillation can occur which may potentiate pulmonary oedema and systemic emboli.

Managing such symptoms will include the use of anti-arrhythmic agents to control atrial fibrillation, diuretics, a low-sodium diet and anticoagulant therapy. K will have to adjust her lifestyle to accommodate her valvular disorder but she will be at home.

Aortic incompetence

PATHOPHYSIOLOGY

LVEDP is approximately one-eighth of the concomitant aortic pressure, and therefore any breach of the valve allows large amounts of blood to flow back into the ventricle. The ventricle dilates to accommodate this volume, LVEDP rises and stroke volume increases, as does systolic pressure. Diastolic pressure within the aorta is low because of regurgitation, and therefore there is a wide pulse pressure, often approximately 140 mmHg (190/50 mmHg). Chronic gradual aortic incompetence (AI) is well tolerated, but if there is an acute onset, left ventricular failure (LVF) quickly develops. AI also occurs when the valve annulus becomes dilated so that the cusps cannot coapt, e.g. in connective tissue disorders, syphilis and aortic dissection.

Mitral incompetence

PATHOPHYSIOLOGY

This allows back-flow of blood to the left atrium in systole, where regurgitated blood and the normal atrial volume mix and return to the ventricle during atrial systole. In order to cope with this increased load, the ventricle hypertrophies and then dilates. Forward flow diminishes, with progressive failure of the ventricle and with back-flow into the atria at systole. Weight loss and lethargy are marked as the heart can no longer provide the nutrition the blood usually carries. The left atrium dilates, and changes in conduction and rhythm occur.

Tricuspid stenosis and incompetence

PATHOPHYSIOLOGY

These result in increased right-sided pressure, with evidence of stasis and engorgement of the portal and peripheral circulations, e.g. ascites, liver dysfunction and peripheral oedema. If the right atrium becomes hypertrophied due to tricuspid stenosis, the P wave on the ECG will become peaked. The majority of right-sided failure is usually secondary to failure on the left; however, there is an increase in bacterial endocarditis of the right heart, with the increasing use, or abuse, of intravenous medication (see Ch. 36).

MEDICAL MANAGEMENT OF VALVULAR DISORDERS

The aim is to improve the haemodynamics by improving any aberrant rhythm, e.g. atrial fibrillation (AF), by digitalisation or cardioversion. This reduces the heart rate, allowing more time for filling the coronary arteries in the longer diastolic period. Atrial contribution to cardiac output is thereby regained. Congestive failure is relieved by diuretics and by reducing physical demands. Oxygen therapy may be of use for those with pulmonary congestion. Pyrexia should be investigated and treated appropriately. Anticoagulation may be commenced for those with evidence of previous embolisation, i.e. those in AF and those in low output states with left and right failure. The latter may require inotropic support to increase cardiac output and renal perfusion. Sudden onset with pulmonary oedema, e.g. with papillary muscle rupture post-AMI, requires artificial ventilation, full monitoring, afterload reduction and the possible aid of an intra-aortic balloon pump (IABP) as in cardiogenic shock (see Ch. 18) to gain time prior to urgent surgery.

Those with chronic disease processes may be maintained on long-term medication.

Valvuloplasty

This involves a catheter being introduced across the stenotic valve, the balloon is then inflated and the calcified stenosis cracked and opened up.

In the mitral position, the approach is across the septum, while with the aortic valve the catheter is introduced retrogradely. Problems include:

- bradycardias
- profound hypotension when the balloon is inflated
- embolisation
- tamponade
- possible myocardial rupture.

The aim of valvuloplasty is to increase the functional area of the valve and therefore cardiac output. It is particularly appropriate for older people with aortic stenosis, for whom a full operation would hold too many risks but whose life expectancy would be short without it. It has the advantage of a short hospital stay and the prompt resumption of normal life. An alternative would be prosthetic valve replacement. This surgery is used for patients where valvuloplasty is unsuitable or unsuccessful. Valve repair may be considered early on in the disease process before valve replacement is an option. Valve replacement with a mechanical or bioprosthetic valve, made from animal or human tissue, must be performed before the patient is too unwell to tolerate the operation. The choice of valve tends to be determined by the patient's age and the surgeon's preference. The patient undergoes a median sternotomy and valve replacement or repair using cardiopulmonary bypass. The patient who has had a mechanical device fitted needs to become accustomed to hearing it click during each cardiac cycle.

NURSING PRIORITIES AND MANAGEMENT: The patient with valvular disease

Breathing

Shortness of breath, often initially on exertion, is the hallmark of progressive heart failure and ongoing respiratory assessment is important. In some patients, sudden valvular failure may result in an alarming onset of breathlessness. In others, it is a slow progressive problem which starts with breathlessness on exertion and eventually also breathlessness at rest. Orthopnoea (breathlessness in the supine position) may also occur and the increasing number of pillows people require in order to breathe comfortably is an indicator of the progression of their disease. Diuretic therapy is used to reduce fluid in the pulmonary interstitium. Sudden valve failure can be very alarming and these patients may require an urgent operation. They should be within sight of the nursing staff and have means of summoning help. An upright position, well supported by pillows, helps chest expansion.

Nutrition

General fatigue may be the major limiting factor in maintaining adequate nutrition. Small, frequent meals may be more easily digested. They should be high in protein and carbohydrate, especially if the metabolism is raised by fever. Long-term mitral valve insufficiency does not allow sufficient forward flow of oxygenated blood to nourish the peripheries. The nutritional state of people with valvular disorders should be optimised prior to surgery, and liver failure may be a problem due to right-sided heart failure, secondary to the primary left-sided failure (see Ch. 4).

The advice of the dietitian will be valuable. High-protein, commercially available drinks can be given to supplement the diet; however, fluid restriction might also be necessary to prevent pulmonary oedema. Fluid restriction and oxygen therapy often leave the mouth dry, and sucking ice or frozen fruit juice helps to keep the mouth as fresh as possible, while minimising fluid intake.

Personal hygiene

The ability to look after personal hygiene may be limited by fatigue and breathlessness. The community nursing team can help at home with bathing and can arrange, through the occupational therapist, to provide aids that make getting in and out of the bath or shower easier. Helping patients in this way allows nurses to assess perfusion of the peripheries. Those who experience sweating associated with aortic insufficiency may need more frequent attention to personal freshness.

Sleeping

It can be difficult to sleep due to shortness of breath, even when sitting upright. Each person may have to amend daily activities to allow for periods of rest. Nursing care should be similarly planned.

Mobility

Movement may be limited by the symptoms of the individual. If restricted to bed rest, deep breathing and leg exercises should be encouraged. People whose activities are limited at home might benefit from a home help or may be eligible for mobility allowance. Advice can be sought from the social services department.

Local authorities issue car stickers for disabled people to allow greater access to public amenities and car parking.

Wheelchair use

Access to public buildings is slowly improving; public planning incorporates wheelchair access, and many older buildings have been adapted to cater for the less mobile. Lists of places that are suitable for access are available at tourist information centres, city council offices and certain website addresses. Wheelchairs can also be provided to enable people to tour exhibitions or to travel more easily between trains and aircraft, and most large travel organisations provide this service. Holiday brochures often specify which hotels are easily accessible. The Red Cross also hires out wheelchairs and aids for limited periods.

The government website www.direct.gov.uk has links to information on disabled access in the home, employment and for leisure pursuits.

For patients who have had surgery, mobility is regained gradually. Each person should set themselves the daily goal of walking a little further. Strenuous exercise should be avoided until the sternum heals; for example, any sport involving swinging movements of the arms, such as golf, could prevent the bone edges from knitting together. Some surgeons restrict strenuous exercise for longer, since they feel too great a pressure gradient can be developed across the prosthetic valve with the increased cardiac output brought about by exercise.

Work and recreation

Some lines of work may prove too strenuous, necessitating a change of job. After cardiac valve surgery, the patient will be unable to return to work for at least 3 months. Returning part-time is desirable, as people often tire easily at first. This can gradually be increased to full-time. Heavy physical work should be avoided for 6 months. The employer may be able to provide lighter work initially but still involve the person in the working environment. Some work is no longer possible after cardiac surgery, e.g. an HGV licence cannot be held. Advice from the social worker about claiming social security allowance and information about retraining schemes can be given, if appropriate. Worry about loss of income can add to the stress of undergoing major surgery.

Maintaining a safe environment

Once a prosthetic valve is in situ, the recipient should be aware of how to avoid putting the valve and themselves at risk. Anticoagulation with warfarin is required for life in those with metal valves, and for a shorter time for those with tissue valves. The person should understand the action of the drugs and their potential risks. They should also be aware of the risk of infection and should inform other health professionals, e.g. dentists, that they have a prosthetic valve and are taking warfarin. Antibiotic cover is given for dental treatment and any other invasive investigation.

Driving is to be avoided until the sternum heals, as sudden movement, e.g. to avoid an accident, could disrupt sternal wire sutures, as could sudden impact to the chest. A small pillow between the seat belt and the chest can reduce friction on the wound, but does not necessarily absorb impact. Eyesight, especially of those who wear glasses, and concentration span are both affected for some weeks after cardiopulmonary bypass.

Sexuality

In relation to sexual activity, avoiding strain on the sternal suture line is the most important limitation until the bone heals, but after that, resumption of relationships should not be excluded. Intimacy between couples can be maintained without full intercourse prior to this. Fear that the valve will fail under exertion should be allayed. Currently, there is no clear consensus on the optimal type of cardiac valve prosthesis that should be placed in women of childbearing age (Mihaljevic et al 2005). The risks of reoperative surgery for bioprosthetic valves must be weighed against those of anticoagulation therapy required for mechanical valves. Some surgeons recommend that young women with prosthetic valves do not become pregnant, because of the increase in circulating volume and cardiac workload. Although successful pregnancies have been completed, this should be

as planned an event as possible. Women of childbearing age tend to be given tissue valves, as this allows the period of anticoagulation to be relatively short. Warfarin taken during pregnancy can cause birth defects, especially if taken during the first trimester of pregnancy. Oral contraceptives also inhibit the effects of warfarin. Some may find the prospect of sharing a bed with a partner who 'ticks' off-putting, especially as increases in heart rate can be clearly heard, which can increase fears that catastrophic events will take place during intercourse. These people can be reassured that the metallic noise becomes softened with time. For some patients, tissue valves might be considered, although they have a shorter life span and would require replacement within a few years.

For further information on valve disease, see Otto (2003).

2.7 The continuing care of patients with valvular disorders is essentially carried out in the community. The desired outcome for someone like K in Case History 2.2 is that:

- she enjoys a full and happy life within the limitations imposed by her disorder
- she can cope with the medication and dietary restrictions
- she maintains nursing advice and support.

Which members of the primary health care team will support K? What will their priorities be in caring for K at home?

Grown up congenital heart (GUCH) disease

Whilst the demand for health care for children born with congenital heart disease is likely to remain relatively stable, the numbers of adults with complex congenital heart disease is predicted to increase significantly. The British Cardiac Society Working Party on grown up congenital heart disease estimated that by the year 2010 there will over 185 000 adults living with congenital heart disease in the UK (British Cardiac Society 2002). These patients may require admission to hospital for the control of arrhythmias, cardiac catheterisation and the treatment of heart failure. An accessible and dedicated ward area for these patients is recommended. Patients in the community may need support and advice on issues such as contraception and pregnancy, the risks of infective endocarditis and general lifestyle advice.

HYPERTENSION

Hypertension is difficult to define and there is controversy as to what level of pressure, systolic or diastolic, constitutes hypertension. In adults, the considered upper limit of normal is 130–139/85–89 mmHg and pressures consistently above this are defined as hypertension. The optimal blood pressure targets are a systolic blood pressure of less than 120 mmHg and a diastolic blood pressure of less than 80 mmHg (Williams et al 2004). The technique of measuring blood pressure can also vary, resulting in differences, principally in diastolic definition. The scope of the problem may well be underestimated since the majority of people are without symptoms until target organs are affected. They then present with major consequences such as renal failure, ischaemic heart disease, cerebral emboli or infarction.

Being aware of associated predisposing factors may enable health workers to target screening towards at-risk groups.

Associated factors

Several factors associated with hypertension have been identified:

- obesity
- sodium intake
- alcohol
- genetic factors
- smoking
- stress.

Obesity

The interaction between obesity and hypertension is not fully understood. Overweight adolescents are at significant risk of later hypertension. Those involved in health education and school nursing may play an important part in educating children about diet and exercise in general. An increased intake of sodium will result from general overeating and it is thought that the sodium pump may become impaired in this group. However, this is a reversible situation. Blood pressure has been shown to decrease with weight loss, particularly with a weight reduction programme that incorporates moderate sodium, high potassium and a low fat diet (Nowson et al 2005).

Sodium intake

The link between sodium and hypertension may result from increased sodium and water retention by the kidneys in response to an increased sodium load. Sodium accumulates within the arterial walls of hypertensive people. These vessels then become more responsive to substances that cause vasoconstriction. People who reduce their sodium intake also reduce their blood pressure. High sodium intake is a feature of Western lifestyle and more isolated peoples with a lower intake have a lower incidence of hypertension; once they adopt a Western diet the incidence rises. Adherence to low-sodium diets is poor, as they are so unpalatable. Emphasis is now laid on not adding salt after cooking and salt substitutes are widely available. There is a generally increased awareness of the contents of packaged foodstuffs; clear product labelling helps people at risk to identify substances that contain sodium.

An increase in potassium intake through consumption of fruits, vegetables and beans is reported to be beneficial in lowering blood pressure (Lydakis et al 1997).

Alcohol

The contribution of alcohol is difficult to assess, as there is a tendency to under-report alcohol consumption due to social pressures. However, blood pressure rises with increasing intake and a reduction in intake reverses this.

Genetic factors

A family history of hypertension predisposes individuals to the same condition. Certain ethnic groups are more

susceptible to the condition: the black population in the USA has a 50% greater prevalence than their white counterparts. It appears that the mean resting renal blood flow of normotensive individuals with hypertensive parents is greater than in those with normotensive parents. The kidneys' ability to handle sodium is also thought to be genetically influenced.

Smoking
Nicotine promotes catecholamine release and so increases heart rate and blood pressure.

Stress
This is presumed to relate to increased sympathetic outflow (see Ch. 17). Certain occupations are associated with a higher risk of developing hypertension, e.g. crane drivers and air traffic controllers. People who work in noisy overstimulating environments also run a higher risk of occupational stress, especially if the tasks are repetitive and monotonous.

PATHOPHYSIOLOGY
Although difficult to define in terms of elevated blood pressure, hypertension is commonly classified according to cause:

- Primary or essential hypertension refers to a raised blood pressure where no cause can be found.
- Secondary hypertension is a result of the underlying conditions, most commonly:
  - — renal disease (see Ch. 8)
  - — an adrenaline-secreting tumour, e.g. phaeochromocytoma in the adrenal medulla
  - — diseases of the pituitary or adrenal cortex, where there is an elevation of glucocorticoids, e.g. Cushing's disease (see Ch. 5)
  - — coarctation (narrowing) of the aorta
  - — hyperthyroidism (see Ch. 5).

Hypertension can also be classified according to severity:

- mild — when elevation of blood pressure is only moderate and occurs over a long period of time
- malignant — when there is a sudden and severe blood pressure elevation.

The malignancy does not refer to cellular changes but to the fact that this is a life-threatening condition. Whatever form of hypertension is diagnosed, the concern is always the effect of this high blood pressure:

- on the heart, where the increased demand on its pumping capacity can lead to ventricular hypertrophy
- on the brain, where any elevation of blood pressure could precipitate a cerebral catastrophe (see Ch. 9).

Other organs that give rise to concern are the kidneys, where the delicate function of the nephrons can be impaired by constant high pressure, and the eyes, where fine retinal vessels may rupture and significantly impair vision.

Common presenting symptoms
People who are aware that they have a condition that predisposes them to hypertension will have been alerted to this potential problem and the symptoms may be more readily appreciated. However, many may be completely unaware of their hypertensive state, either having no symptoms at all or dismissing complaints such as headaches, vertigo, nosebleeds and fatigue.

MEDICAL MANAGEMENT
Examination
The elevated blood pressure may only be noticed at a routine examination for another reason, such as insurance cover. A single elevated reading does not justify a diagnosis of hypertension since anxiety about the examination itself may be the temporary cause; however, the person should be reassessed at a later date. Examiners should also be aware of the possible contribution their own technique and instrument calibration may make to errors in estimation, e.g. using inappropriately sized cuffs.

Generally, hypertension is defined by grading, with arbitrary cut-off points according to diastolic pressure.

Grade 1 hypertension is defined as a systolic blood pressure 140–159 mmHg or diastolic 90–99 mmHg or both. Grade 2 hypertension is a blood pressure greater than or equal to 160/100 mmHg (Williams et al 2004). The higher the diastolic pressure, the greater the risk of cerebrovascular accident (CVA), renal failure, coronary artery disease and heart failure.

Treatment of hypertension has been shown to reduce the relative risks of cardiovascular mortality and morbidity by 30% (Collins & Peto 1994). The management of the patient with hypertension is generally the responsibility of the primary health care team and hospitalisation is not usually required.

Investigations
include:

- blood pressure monitoring
- chest X-ray and ECG to determine the degree of left ventricular hypertrophy and heart failure
- full blood count, electrolytes, urea or nitrogen and creatinine, to exclude secondary causes and renal effects of the disease process
- urinalysis with microscopy, 24-h collections for creatinine clearance and vanillylmandelic acid (VMA)
- intravenous urogram (IVU) to assess renal perfusion.

Treatment
depends largely on how elevated the blood pressure is and the total risk of CVD. All adults should have their blood pressure measured routinely at least every 5 years. Those with 'high normal' systolic blood pressure (130–139 mmHg) or diastolic blood pressure 85–89 mmHg and those with previously elevated readings, should have their blood pressure measured annually (Williams et al 2004). All hypertensive patients should have a thorough history and physical examination. Medication is recommended in all patients with grade 2 hypertension. All patients with grade 1 hypertension should be offered treatment with antihypertensive medication if there is any complication of hypertension, target organ damage, diabetes mellitus or significant risk of CVD. Most people require more than one type of medication to control blood pressure. Care needs to be taken not to lower the blood pressure too far as this may cause feelings of light-headedness and fainting. Beta-blockers and ACE inhibitors are the first choice for younger patients. Calcium

channel blockers and diuretics are more effective for older patients. The formulation used should ideally be effective for 24 h when taken as a single daily dose and titrated up to the manufacturer's recommendations.

2.8 Using the *British National Formulary*, look at how the different antihypertensive medications exert their effect and why different agents might be used for different patients.

Certain lifestyle measures can reduce blood pressure (Williams et al 2004), including:

- maintaining a body mass index of 20–25 kg/m^2
- limiting alcohol consumption to three units a day or less for men and two units a day or less for women
- reducing intake of total and saturated fat
- eating at least five portions of fruit and vegetables a day.

Investigation for secondary causes of hypertension should ensue promptly. Tests should include assays for evidence of renal disease, primary aldosteronism, hypothyroidism and phaeochromocytoma, while urgent assessment and control of blood pressure take place. It may be that the hypertension is a side-effect of other treatment, e.g. oral contraception. Only 4–5% of women taking 'the pill' develop overt hypertension due to oestrogen ingestion, but it may take several months for it to settle. Other forms of contraception should be advised. Hypertension is also one of the signs of pre-eclampsia of pregnancy.

Overzealous treatment to achieve good blood pressure figures, rather than a good effect for the individual, should be avoided. Many people with hypertension have coexisting CHD, even if asymptomatic, and since the extraction of oxygen within the coronary circulation is close to maximum at rest, lowering the blood pressure may further compromise the coronary circulation, causing myocardial ischaemia.

Malignant elevation At any point in primary hypertension, sudden acute elevation of pressure can occur. This malignant hypertension can rapidly become life threatening. Death can ensue from CVA or from the cerebral oedema of hypertensive encephalopathy. Hypertension generally promotes the progression of atherosclerosis. Sudden increased pressure in vessels already compromised may lead to rupture or embolisation of existing thrombus. The importance of this depends on where the emboli occlude. Further occlusion of the afferent arterioles exacerbates the situation by stimulating increased renin release, which in turn contributes to the hypertensive state. Increased pressure may result in internal haemorrhage or infarction of the kidneys.

The progress of the increasing pressure is mirrored in changes to the vessels of the optic fundi, termed hypertensive retinopathy (see Ch. 12). Once papilloedema occurs, intracranial pressure has increased and the individual may complain of blurring of vision.

Management of hypertensive crisis

The aim of medical and nursing management of this life-threatening condition is a controlled reduction in blood pressure, with monitoring of other systems in order to minimise further damage or to prevent it from occurring (Shayne & Pitts 2003). Cerebral function should be assessed continuously. Blood pressure should be monitored, preferably by direct arterial cannulation, at least every 15 min to assess the efficacy of medication. Cardiac demand should be reduced as much as possible by bed rest and sedation. Straining at stool should be avoided. The patient should have urinary catheterisation and frequent observation of urine output. A 24-h urine collection should be commenced for excretory products of catecholamines, such as VMA, levels being twice that of normal in the presence of the adrenal tumour, phaeochromocytoma. The nurse should also be alert for haematuria or any other sign of blood loss. Complaints of ischaemic chest pain should be investigated and treated as already described.

Anxiolytic medication may benefit people whose condition is exacerbated by anxiety.

NURSING PRIORITIES AND MANAGEMENT: Hypertension

Where hypertension is secondary to an underlying condition, nursing priorities will reflect treatment of the primary problem. Hypertension will affect lifestyle and sense of well-being in many ways. However, since people with hypertension present in various ways, it is difficult to generalise about their management plans.

The experience of pain

Pain control is necessary for those experiencing headaches or anginal pain, with or without palpitations. Oral analgesics can be prescribed to combat headaches although the prescription may have to be tailored to the individual to find an effective agent. This symptom may only lessen once the level of hypertension is controlled and this may motivate the patient to comply with other treatments. Angina will be approached as previously discussed and will also be helped by other treatments aimed at lowering blood pressure, e.g. beta-blockade.

Nutrition

Dietary changes are aimed at the reduction of obesity, the control of any underlying problem such as diabetes mellitus, and the reduction of the salt content. A diet rich in fruits, vegetables and low-fat dairy food with reduced saturated total fat can substantially lower blood pressure (Cutler et al 1997). It is best to involve the whole family, as it is less socially disruptive if everyone can continue to sit down to the same meals together. Also, the hereditary aspect of hypertension would indicate that it is in the whole family's interest to prevent the problem developing. No salt added at table, or salt substitutes, are advised (see p. 51). The nurse may be able to assist patients in interpreting labels on food products.

Moderating alcohol intake is advised. This may be difficult for some, where entertaining forms a great part of their work; however, low-alcohol wines and beers are increasingly available.

Elimination

Diuretic medication can result in the need to pass urine at socially inconvenient times. This can often be avoided if the medications are taken first thing in the morning, so that their effect is largely over by the time the person leaves home. Discussing the person's daily routine and flexibility

in the timing of treatment to adapt to the person's lifestyle can result in greater adherence to treatment. It is often difficult for an asymptomatic individual to realise the importance of continuing with medication, especially if there are undesirable side-effects. It is often best to broach the subject of side-effects before they occur and to point out that other medication can be tried if one medication does not suit.

Diuretics — apart from the aldosterone antagonist, potassium-sparing varieties — promote the excretion of potassium in the urine. Low levels of potassium can result in muscle weakness, fatigue and cardiac arrhythmias. It is therefore important that potassium supplementation is also adhered to by those taking diuretics. Many products combine both diuretic and potassium. A list of foods rich in potassium, e.g. bananas, can be supplied.

Sleeping

Relaxation and rest are important. Daily routines should be examined in order to find appropriate periods for rest. Night sedation may be necessary to ensure adequate sleep, although the patient should be encouraged to maintain their own relaxation habits, e.g. soaking in a warm bath. Referral to agencies that practise relaxation and stress management techniques may be of benefit to some (see Ch. 17).

Work and leisure

Some working environments may add to the stress experienced by individuals. Work routines should be re-examined to see if more opportunity exists for delegation of work and for rest. Smoking may be a habit engendered by stress and reinforced by working with a group of people in similar positions. Finding interests other than work may help the 'workaholic'. Sporting hobbies should be encouraged, as exercise will increase cardiac fitness as long as strenuous exercise is not embarked on without advice.

Breathing

Every effort should be made to stop smoking. Various approaches exist, from cigarette substitutes to hypnosis, acupuncture and sheer willpower. People should be encouraged to find their own way and, as in changing eating habits, the whole family can also be involved here.

Beta-blockade, using the non-cardioselective varieties, e.g. propranolol, may result in bronchospasm. This side-effect could be extremely alarming if the patient is not aware of the possibility.

Sexuality

Anxiety and tension between couples may lead to sexual dysfunction. Openness on the part of health professionals may help couples to feel they can discuss their fears with these professionals and with each other. Beta-blockade may also cause impotence.

For more information on hypertension, see Wilkinson et al (2002).

AORTIC ANEURYSMS

An aneurysm is a permanent dilatation of the aorta with a diameter at least 50% greater than would be expected. The aneurysm can be localised or extend along the length of the aorta.

The aorta is divided into three segments:

- the ascending aorta
- the arch
- the descending aorta, which consists of abdominal and thoracic portions.

Aneurysms are also classified by shape, as being:

- fusiform — involving a complete circumferential section
- saccular — an outpouching from one weakened area.

Saccular aneurysms can be tied off surgically at the neck of the sac, while fusiform types require excision and replacement with a tubular graft. If the graft is required close to the aortic valve, a composite prosthetic valve and tube graft may be employed, with reimplantation of the coronary arteries if necessary.

There are several causes of aneurysm formation:

- *Atherosclerotic disease.* This is the major cause of aneurysms, especially of the descending portion, 75% of the aorta being below the level of the diaphragm. Plaque formation reduces the nutritional supply to the aortic wall by hampering diffusion of nutrients from blood in the lumen.
- *Turbulence around bifurcations.*
- *Hypertension and medial degeneration.* The medial layer of the vessel wall undergoes degenerative changes associated with ageing. Since this is the layer that, due to its elasticity, withstands the most pressure, degeneration allows the wall to dilate. This often occurs without symptoms and may be found on routine examination. The patient is often hypertensive. Increased blood pressure, especially diastolic pressure, reduces the blood flow to the medial layer, which becomes ischaemic and weakened.
- *Cystic medial degeneration* also occurs as a consequence of connective tissue diseases, e.g. Marfan's and Ehlers–Danlos syndromes. These affect the ascending aorta and may cause the annulus of the aortic valve to dilate. This may result in an incompetent valve, as the cusps cannot completely cover the larger area. First presentation may be as a consequence of valvular failure.
- *Infection.* Aneurysms due to syphilis and other infectious causes are less prevalent today; they largely affect the ascending aorta.

Abdominal aortic aneurysms (AAAs)

The abdominal aorta is the most frequent site of aneurysm formation, affecting 2–5% of the male population over 60 years with a male:female ratio of 4:1 (Sternbergh et al 1998).

PATHOPHYSIOLOGY

Common presenting symptoms

The majority of AAAs are without symptoms, but a pulsating abdominal mass may be felt when lying in bed. Pain relates to compression of neighbouring organs. It is severe, unrelated to movement and radiates through to the low back, and possibly down into the thighs and buttocks. Presentation may be due to ischaemia of the end organs whose arterial supply originates within the aneurysmal section. Ischaemia may also be the result of embolisation of

thrombus that gathers in the dilated portion due to sluggish blood flow and turbulence around atherosclerotic plaques. Diagnosis is made by ultrasonography, magnetic resonance imaging (MRI) and computed tomography (CT) scanning. Half of the dilatations greater than 6 cm will rupture within a year, so prompt surgical management is called for. Surgical repair involves either a midline incision for a retroperitoneal approach or a transverse approach above the umbilicus if the aneurysm is above the renal arteries and there is renal involvement. The aneurysm is clamped above and below the swelling and the thrombus removed. A synthetic graft is laid within the aneurysmal sac and sutured in place. The sac is trimmed and sewn over the graft. Older or cardiorespiratory-compromised patients may be unsuitable for surgical repair. Endovascular repair involving stent insertion into the affected lumen may be more appropriate for these patients (Ransome 1996). The risk of spontaneous dissection is that severe blood loss, hypotension and death will supervene. Emboli may enter the inferior vena cava and result in pulmonary infarction. Mortality in patients with a ruptured aneurysm is high. Emergency management aims to stabilise blood pressure by large volume infusion of colloid or other volume expanders and by pharmacological support with inotropic medication. Surgical repair should not be delayed.

For further information on the care of the patient undergoing surgical repair of an abdominal aortic aneurysm, see Collins (2003).

MEDICAL MANAGEMENT

Investigations

prior to planned surgery include abdominal X-ray, which will highlight any vessel calcification, echocardiography, ultrasound and CT scanning, all of which are non-invasive. Some centres also perform angiography; however, this may precipitate embolisation. Full cardiac investigation is required since atherosclerosis is a diffuse disease. Correction of any coronary insufficiency is recommended prior to surgical non-emergency aneurysm repair, since postoperative mortality is largely due to myocardial infarction.

Thoracic aneurysms

The aetiology is similar to aneurysms in the abdomen. False thoracic aneurysms can be secondary to blunt or penetrating injury to the chest in road traffic accidents, although they are more often associated with true rupture of the aorta, from which mortality is high. Some thoracic aneurysms are stabilised by surrounding tissue which can allow time for the patient to present at cardiothoracic services.

PATHOPHYSIOLOGY

Atherosclerosis affects the arch and descending thoracic aorta, while cystic medial degeneration and infections are found as causative agents in the ascending portion.

Common presenting symptoms

depend on the site of occurrence. Chest X-ray shows a widened mediastinum. Dilatation causes pressure on other structures: bronchospasm may result from deviation of the trachea, secretion retention and alveolar collapse from obstruction, shortness of breath and haemoptysis, if erosion occurs into the left main bronchus. Obstruction of the oesophagus may present as dysphagia, while fainting may be the result of reduced cardiac output due to obstruction of the superior vena cava.

Dissecting aortic aneurysms

PATHOPHYSIOLOGY

Tears in the intima due to the forces of hypertension, and the degenerative changes already discussed, allow a column of blood to enter and disrupt the media, creating a false lumen. Classification is by site of the tear. In addition to previously discussed predisposing diseases, there is a higher, but as yet unexplained, incidence of dissection among pregnant women.

Common presenting symptoms

depend upon the site and severity of the rupture. Severe anterior chest pain can be mistaken for acute myocardial infarction, but it is often described as tearing in nature. Pain may migrate as the dissection progresses. Alterations of neurological function may reflect involvement of the vessels originating from the arch of the aorta. As the dissection progresses, loss of peripheral pulses and palpable blood pressure will track its course. Renal artery dissection or occlusion will result in acute renal failure, exacerbated by the effects of profound hypotension. Alterations in rhythm or degrees of heart block may result from septal disruption as a consequence of aortic valve regurgitation. Leakage into the pericardium manifests as compression known as tamponade. The signs of cardiac tamponade are:

- hypotension
- tachycardia
- raised central venous pressure/jugular venous pressure
- oliguria
- peripheral vascular constriction
- fall in peripheral temperature.

If uncorrected, i.e. by pericardial aspiration of blood, this will lead to the state of pulseless electrical activity (PEA), cardiac arrest and death.

MEDICAL MANAGEMENT

Investigations

are identical to those used in AAAs.

Treatment

Operative correction is urgently required. If hypertension persists, this should be controlled by the use of arterial vasodilators, intensively and invasively monitored. If hypotension and collapse have supervened, then intervention is as for AAAs.

NURSING PRIORITIES AND MANAGEMENT: Aortic aneurysms

Pain control

The pain is often described as ripping or tearing in nature. Its location varies according to the section of artery

affected and may progress as the dissection progresses. Intravenous opioids are the analgesia of choice because of their associated sedative effect and the slight vasodilatation achieved, both of which encourage a reduction in blood pressure.

Anxiety and fear of dying

The prospect of surgery is extremely frightening, whether emergency or elective, and this should be acknowledged by nurses. Operations carry high risks, but there is often no alternative intervention. Those going for elective procedures may wish access to legal advisors. The need for spiritual care should also be recognised. There may be times when a dignified, peaceful death is more appropriate than surgery.

Maintaining a safe environment

Rupture of an aneurysmal vessel is a potentially catastrophic and unpredictable event. Those with known aneurysms that do not yet merit surgery should be aware of signs that indicate a progression of their disease. Control of hypertension by medication is indicated (see p. 52).

Breathing

Shortness of breath may be experienced by those with aneurysms of the thoracic aorta as the vessel impinges on the trachea. This may also result in bronchospasm. Rupture of the vessel can create a fistula into the bronchus, with resulting haemoptysis. Changing the person's position to allow maximal lung expansion may help. Oxygen therapy will be required. Bronchodilators may be of limited use, as the problem is mechanical rather than irritant. Chest infection due to atelectasis, as the lung may collapse under the weight of the expanding aorta, is to be expected. Since maintaining the airway is a potential problem, an airway, suction equipment, an Ambu-bag and other resuscitation equipment should be available.

Mobility and rest

Anxiety may prevent the patient from sleeping, so sedation may be helpful if the blood pressure is not adversely affected. The patient's condition can be so unstable that even performing minimal care can be exhausting. Care should be planned so that people are left in peace for periods. Nurses sometimes have to accept that their patient's condition will not allow care that would otherwise be thought essential, e.g. pressure area care. Consider the use of aids to dissipate pressure on what is often already poorly perfused skin.

Elimination

Since approximately 25% of cardiac output perfuses the kidneys, urine output is an important indicator of cardiac function. Accurate observation and recording of fluid balance are essential.

Personal hygiene

Because of poor general status and poor tissue perfusion, this is an area where the patient becomes dependent on a nurse to maintain standards of personal hygiene.

Sexuality

People attending electively for resection of abdominal aneurysms may be offered counselling before surgery. There is a possibility of impotence and paraplegia postoperatively if the arterial supply to the spinal cord is interrupted. It is possible to arrange storage of sperm against this eventuality. These issues need to be handled with sensitivity by the nursing and medical staff.

Surgical intensive care

If the patient's condition has deteriorated and surgery is necessary, they are completely dependent on hospital staff for circulatory support. Accurate haemodynamic assessment is essential. Careful observation and documentation of the response to medication and large-volume colloid infusion are essential. This may require invasive monitoring and the specialist nursing skills of the intensive care unit, and the patient should be moved to such a unit as soon as is feasible. This may mean a journey of several hours by road or air, a daunting prospect for patient and escorting staff alike. It often necessitates the separation of the patient from their family at a time of great stress, so every effort should be made to ensure effective communication. The management of cardiogenic shock is described in Chapter 18. Postoperative care is similar to that following cardiac surgery (see Nursing Care Plan 2.1).

For further information on the care of the patient with an abdominal aortic aneurysm, see Collins (2003).

PERIPHERAL VASCULAR DISEASE

Peripheral vascular disease includes pathological processes affecting both the arterial and venous circulations. Arterial and venous peripheral disease can occur alone or together and it is important to be able to differentiate between the two.

Revise the vascular anatomy of the lower limbs (Waugh & Grant 2001). For information on the aetiology and pathology of vascular disease, see Ockenden (2003); for information on the assessment of patients with vascular disease, see Stubbling & Chesworth (2003).

ARTERIAL DISEASE

Arterial occlusions

Atherosclerosis is the commonest cause of arterial disease. It is characterised by the development of atherosclerotic plaques within the intima of the artery wall which inhibit arterial blood flow. Symptoms of impaired blood supply may be slow to appear if collateral circulation has had time to develop.

Arteriosclerosis obliterans

PATHOPHYSIOLOGY

This is the state of chronic occlusive atheroma of the arteries supplying the extremities. Turbulence at bifurcations, as occurs in larger vessels, predisposes to intimal changes. There is also a degenerative element in its development. The same process is found in the cerebral and visceral arteries. The factors influencing its development have been discussed in the section on CHD. It is typically a disease of middle-aged to older men, who may be hypertensive,

Nursing Care Plan 2.1

G is a 54-year-old unemployed welder who had an abdominal aortic aneurysm repair 36 h previously. This was an elective operation and involved the insertion of a synthetic graft. Since the operation G has been cared for in an intensive care unit. He had artificial respiratory support on a ventilator up until 12 h ago. A urinary catheter, nasogastric tube and central venous pressure line were inserted in theatre. G's wife and family are very concerned about his condition and his wife is spending most of the day at his bedside.

Nursing considerations	Action	Rationale	Expected outcome
1. Potential problem of hypovolaemic shock	• Continue to monitor vital signs, noting for: – fall in blood pressure – increase in heart rate • Observe for fall in hourly urine output • Observe for changes in mental state: restlessness, confusion • Note and report significant changes in temperature • Observe for signs of peripheral oedema and cold, pale peripheries • Observe wound site for excessive leakage • Give intravenous fluids as prescribed: colloids, crystalloids and inotropic support as necessary • Continue with central venous pressure recordings, noting and reporting trends	Hypovolaemic shock may arise due to excessive blood loss/inadequate fluid replacement or rapid warming	Stable vital signs Urine output >30 mL/h Stable neurological function
2. Possibility of developing hypertension	• Regular measurement of blood pressure • Monitor effects of any hypertensive medication • Ensure that G knows to report any pain/discomfort Assess and plan intervention, and evaluate pain relief measures • Observe wound site regularly for any sign of suture line being under stress due to increased blood pressure • Attempt to limit anxiety by providing information and support, and creating a calm, relaxed atmosphere for G and his family	May have been hypertensive prior to operation Systemic vascular response may increase as a result of: – decreased circulatory volume – increased sympathetic tone as a stress response High blood pressure may cause bleeding around the graft site and is controlled with i.v. GTN To control/relieve pain and anxiety	Vital signs within normal limits Is pain-free, comfortable and relaxed
3. Risk of infection	• Monitor temperature recordings at regular intervals • Give prophylactic antibiotics • Observe sites of intravenous and arterial access for redness/inflammation • Observe colour and consistency of urine	Risk of infection due to: – surgical procedure – immobility – urinary catheterisation – venous and arterial convolution	Remains apyrexial and free from infection

Continued ▶

Nursing Care Plan 2.1 *(Continued)*

Nursing considerations	Action	Rationale	Expected outcome
4. **Possibility of gastrointestinal disturbance**	• Note nature of stools, especially diarrhoea and bloody stools • Observe for increase in abdominal girth • Maintain position and patency of nasogastric tube, gradually introducing fluids orally • Ensure that G knows to report abdominal pain • Ensure G is aware of the planned timescale for resuming eating and drinking • Mouth care	May develop as a result of handling the colon during surgery with resultant oedema May develop as a result of antibiotics Nasogastric tube to remain in place for 3–4 days, during which time oral fluids are gradually introduced	Remains free from gastrointestinal disturbance
5. **Possibility of cardiac arrhythmias**	• Monitor continuously heart rate and rhythm	Sinus tachycardia and atrial fibrillation are the most common arrhythmias	Heart rhythm stable
6. **Wound care**	• Check dressing with vital signs • Observe for signs of haemorrhage: may need to measure abdomen for increase in girth • Check drainage: vacuum drains may be used for 24–48 h		Wound healing problems identified promptly
7. **Possibility of difficulty in breathing**	• Administer 40–60% warm humidified oxygen • Ensure G knows to report any difficulty breathing • Observe respiratory rate and chest expansion • Offer oxygen therapy • Encourage turning 2-hourly to promote postural drainage • Encourage deep breathing and coughing • Liaise with physiotherapist regarding chest physiotherapy	Wound may limit deep breathing Abdominal distension may raise the diaphragm, reducing breathing capacity Signs of heart failure may suggest a rupture into the vena cava	Aim for oxygen saturation of 95% or above Is comfortable when breathing Displays no evidence of cyanosis or heart failure
8. **Potential problem of pain/discomfort**	• Ensure G knows to report any pain/discomfort • Give prescribed analgesics on a regular basis for abdominal pain at incision site • ECG if G experiences chest pain • Observe for signs associated with ischaemic pain: shortness of breath, nausea and vomiting	May experience abdominal pain at wound site May experience ischaemic chest pain as a result of decreased coronary artery blood flow Need to be aware of epidural anaesthesia masking haemorrhage or paralysis	Is pain-free and comfortable

Continued ▶

Nursing Care Plan 2.1 *(Continued)*

Nursing considerations	Action	Rationale	Expected outcome
9. Potential problem of renal impairment	• Measure urine output hourly via urinary catheter • Maintain record of fluid input and output • Record weight at the same time daily • Give intravenous fluids at the rate prescribed • Note trends in urine output in relation to blood pressure and rates of medication infusion	May develop renal impairment as a result of embolisation; fall in blood pressure; trauma to the renal artery during surgery; or preoperative renal ischaemia due to renal artery involvement in development of aneurysm	Urine output >30 mL/h
10. Reduced mobility	• Record limb perfusion observations hourly • Complete pressure ulcer assessment tool preoperatively and immediately postoperatively • Use pressure-relieving mattress appropriately • Give subcutaneous heparin to prevent DVT	Epidural can lead to reduced sensation in lower limbs and prolonged pressure on vulnerable areas	
	• Assist to maintain desired activities of living: hygiene, personal grooming, mouth care, etc. • Place objects within reach Offer access to radio, papers, books as requested • Liaise with physiotherapist • Formulate plan for gradually increasing mobility, beginning with sitting out of bed for short periods on day 1 • Involve family members in care, if acceptable to them • Encourage frequent changes in position whilst in bed • Advise how to support wound when moving about	Mobility is reduced as a result of monitoring equipment, intravenous lines, urinary catheter, abdominal discomfort and uncertainty as to permitted safe level of movement	Effects of limited mobility will be minimised Mobility levels will be gradually increased
11. Anxiety and lack of information	• Explain all treatment and expected course of hospital stay to G and his family • Encourage B's family to visit when they can, promoting a welcoming and open atmosphere • Develop one-to-one relationship between nurse and G to foster open communication and individualised support and information giving • Provide realistic outlook for future and recovery • Avoid heavy lifting for 12 weeks • Return to work in 6–12 weeks	G and his family are likely to be anxious about the outcome of the operation and the future The ITU environment may exacerbate these feelings	G and his family will appear to be coping effectively with the operation and recovery G and his family will express that they feel able to cope and state that they understand the operation, treatment and plans for recovery

diabetic, have a diet high in lipids and who smoke, resulting in greater risk of atherosclerosis.

The result of increasing occlusion of the vessels, with medial calcification and loss of elastic fibres, is the slowing of blood flow. The blood becomes hypercoagulable. Thrombosis of the deep veins may occur, secondary to sudden arterial thrombosis. The ischaemia of surrounding tissue is evidenced by skin and muscle atrophy, loss of subcutaneous fat deposits and ischaemic neuropathy.

Severe occlusion can result in gangrene, usually first seen at the toes, then extending into the foot and leg. At the boundary between viable and necrotic tissue, an area of inflammation is often seen. The extent of the ischaemia will depend on how quickly occlusion developed and how extensive collateral circulation has become. Gangrene occurs when insufficient oxygen is conveyed to the tissue to sustain its life. This can be exacerbated by any other superimposed demand, e.g. infection, when oxygen demand rises but cannot be sustained by an impaired blood flow. Diabetic patients are more prone to infected ulceration in association with gangrene (see Ch. 5). Vasoconstriction should be avoided if at all possible.

Common presenting symptoms

may occur gradually or with sudden acute thrombosis, which may be the first indication of a process that has been silently progressing for some time (see Table 2.7).

Pain: intermittent claudication The term 'claudication' comes from the Latin 'claudicare' meaning to limp. Intermittent claudication is the commonest symptom of vascular disease and describes exercise-induced pain in muscle groups distal to the occluded vessel. Its nature varies from a numb cramp to severe pain. It is a manifestation of increased oxygen demand with exercise and the subsequent accumulation of metabolic wastes. It is relieved by rest. The calf muscles are the most commonly affected, but thigh and buttock muscles can also be involved, depending on the site of occlusion. The distance the individual can walk on the flat before onset of symptoms, the claudication distance, is an indication of the progress of the disease. Pain may eventually occur at rest, most often in the toes and foot and particularly at night, when limbs become warm and oxygen demand increases, thus interfering with sleep. Pain may become severe and difficult to contain if the patient develops gangrene. Neuropathy reduces sensation and may make the person unaware of the progressive gangrenous changes. Any exercise that can be tolerated should be encouraged.

MEDICAL MANAGEMENT

Investigations

Pulses should be assessed at rest in a warm room. They will remain intact until two-thirds of the lumen is occluded. Posterior tibial, popliteal and femoral pulses should be

Table 2.7 Presenting features of arterial and venous peripheral vascular disease

Assess	Arterial disease	Venous disease
Pain	Acute: sudden, severe pain, peaks rapidly Chronic: intermittent claudication; rest pain	Acute: little or no pain; tenderness along course of inflamed vein Chronic: heaviness, fullness
Impotence	May be present with aortoiliac femoral disease	Not associated
Hair	Hair loss distal to occlusion	No hair loss
Nails	Thick, brittle	Normal
Skeletal muscle	Atrophy may be present; may have restricted limb movement	Normal
Sensation	Possible paraesthesia	Normal
Skin colour	Pallor or reactive hyperaemia (pallor when limb elevated; rubor [red] when limb dependent)	Brawny (reddish-brown); cyanotic if dependent
Skin texture	Thin, shiny, dry	Stasis dermatitis; veins may be visible; skin mottling
Skin temperature	Cool	Warm
Skin breakdown (ulcers)	Severely painful; usually on or between toes or on upper surface of foot over metatarsal heads or other bony prominences	Mildly painful, with pain relieved by leg elevation; usually in ankle area
Oedema	None or mild; usually unilateral	Typically present, usually foot to calf; may be unilateral or bilateral
Pulses	Diminished, weak, absent	Normal
Blood flow	Bruit may be present; pressure readings lower below stenosis	Normal

Adapted from Bright & Georgi (1992).

included in the examination; dorsalis pedis pulses are not consistently present in all people. The volume of the pulses should be compared, as well as simple presence or absence. Many people find it difficult to differentiate between their own pulse and the patient's, and increasing the examiner's rate by exercising can help in this situation. The noise of turbulent blood flow (bruit) may also be heard as a murmur or abnormal sound when a stethoscope is placed over areas of turbulence in arteries that are still pulsating.

Colour and temperature As occlusion develops, the feet, and especially the toes, may be red in colour. This can later develop into bluish mottled areas or areas of pallor. With sudden occlusion, pallor may be marked. Elevation of legs with severe occlusion results in deathly pallor. Once legs return to the dependent position, colour normally returns. Superficial veins normally refill within 15 s, but in these cases it may take a minute or more. In severe cases, the limbs may become a cyanotic red colour (rubor). Temperature changes accompany reduced blood flow with cool pale extremities.

X-rays will show calcification of the vessel wall.

Doppler ultrasound When low-intensity sound is directed through the tissue towards a blood vessel, sound waves strike moving blood cells and are transmitted back. The frequency of these sound waves reflects changes in proportion to the velocity of the blood. Sound waves diminish in arterial occlusion and stenosis. Doppler ultrasound is used to assess the ankle brachial pressure index (ABPI) which decreases with arterial occlusion. Duplex scanners offer a sensitivity of 80% and are more reliable than angiography for detecting femoral and popliteal disease (see Fig. 2.14).

Helical or spiral computed tomography is a minimally invasive technique for vascular imaging which scans large areas in a short period of time, thereby reducing motion artefact.

Exercise testing will assess the functional limitations of arterial stenosis and differentiate occlusive arterial disease from other causes of exercise-induced lower limb symptoms.

Arteriograms are usually performed in order to assess occlusion prior to surgery.

Other examinations include ECG, a full blood count, urea, electrolytes and blood sugar estimation.

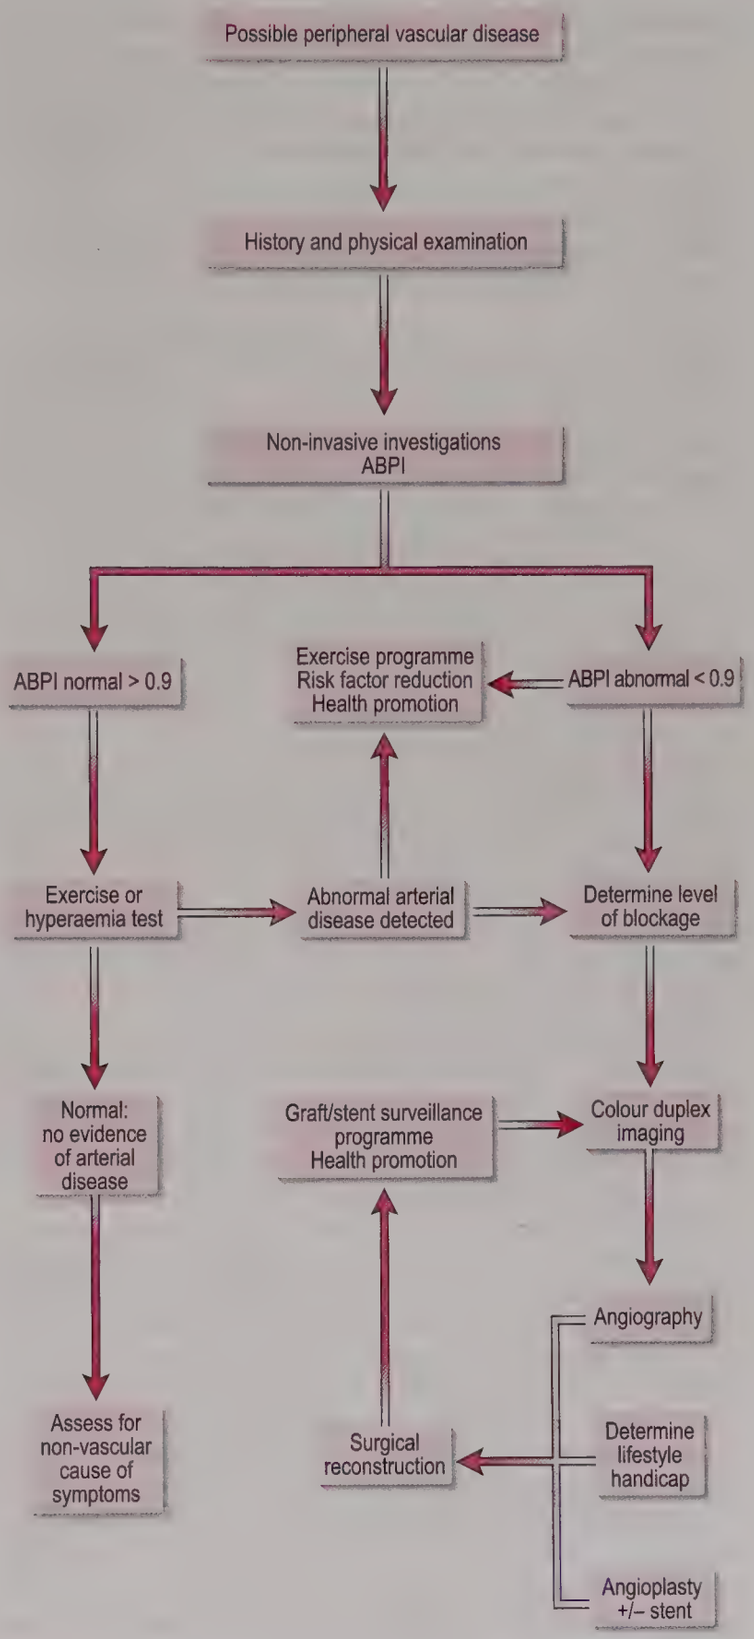

Fig. 2.14 The management of peripheral vascular disease. (Adapted from Murray 2003.)

Treatment

Underlying disease states, e.g. diabetes mellitus and infection, should be as well controlled as possible. Advice aimed at minimising symptoms and the risk of extending atherosclerosis should be given, as follows:

- Modify the diet to reduce lipid intake and reduce weight.
- Avoid the following which lead to vasoconstriction:
  — cigarette smoking
  — tight clothing
  — cold temperature.
- Avoid direct use of heat because of the risk of burns in a limb with decreased sensation.
- Avoid using hot water bottles, sitting too close to fires or radiators, taking hot baths and soaking the feet in hot water.
- Promote increased blood supply by a generally warm environment and elevation of the head of the bed.
- Avoid maintaining a completely dependent position since the resultant oedema will further reduce circulation.
- Encourage exercise up to the limit of pain, partly to maintain joint and muscle function and to promote

collateral circulation (Leng et al 2005). By walking three to four times a day, ischaemic time will decrease and pain control can also be improved by increasing blood flow; however, ischaemic pain is notoriously difficult to manage and may require opiate analgesics and night sedation.

- Avoid trauma to the impaired limb.
- Avoid wearing ill-fitting shoes; referral to a chiropodist may be required.

Patients will be prescribed regular aspirin or other antiplatelet medication to reduce the risk of coronary or cerebrovascular events.

For more information on the conservative management of intermittent claudication, see Murray (2003); on promoting health in vascular nursing, see Litchfield (2003); and on patients' experiences on living with peripheral vascular disease, see Gibson & Kenrick (1998).

Following assessment, sympathectomy may be considered to increase blood flow by obliterating neural control of vasoconstriction.

Percutaneous transluminal balloon angioplasty (PTBA) is a minimally invasive treatment for patients with atherosclerotic peripheral vascular disease. This surgical technique involves placing an intra-arterial balloon within an obstructing arterial lesion and forcibly dilating the balloon under fluoroscopy. In selected patients, the use of an intravascular stent may be an alternative to traditional bypass. Intravascular brachytherapy, whereby radiation is applied directly to the lesion, can inhibit re-stenosis (narrowing) of the vessels (Hansrani et al 2005).

If the occlusion is sudden and acute and the viability of the limb is in question, then surgical intervention, using either saphenous vein or prosthetic material, e.g. a femoropopliteal bypass, will be required to bypass the occlusion. Endarterectomy of the vessel may be performed first to core out the atheroma of the vessel.

Prior to surgery, the patient may undergo arteriography and should be rehydrated and have blood coagulation status assessed. There is a strong association with CHD, so full cardiac assessment is required prior to operation.

If the lesion is localised and accessible, embolectomy under local anaesthesia may be sufficient to reperfuse the limb. In this procedure, a catheter is inserted into the artery up to the level of the occlusion when the balloon at the end is inflated, aiming to fracture the plaque. Inflammation and re-endothelialisation occur secondary to this. Fibrinolytic drugs can be infused at the site of the occlusion. The advantage of embolectomy is that general anaesthesia can be avoided; however, reocclusion occurs more frequently than with bypass grafting.

For further information on peripheral artery bypass, see Galloway et al (2005).

Pain may become so severe and gangrene so advanced that the limb is no longer viable and amputation may become unavoidable. Bypass grafting may minimise the extent of amputation by restoring circulation, e.g. to a foot, but losing some of the toes. Amputation of a limb is traumatic for anyone but may be accepted as a means of relief from intolerable pain. It may, however, require skilled counselling before this fact can be faced by the patient and the full support of rehabilitation and limb-fitting services postoperatively is accepted (see Ch. 10).

2.9 Find out about the rehabilitative care for any patient who has an amputation of a lower limb and is adapting to the use of a prosthesis.

For more information on the care of a patient faced with the prospect of an amputation, see Donohue (1997a–d).

Thromboangiitis obliterans or Buerger's disease

This chronic occlusive inflammatory disease has no known cause. It manifests in a younger population than atherosclerosis, is predominant in men and is strongly associated with smoking. It is postulated that carbon monoxide has a toxic effect on the arterial wall and nicotine has vasoconstrictive effects. In contrast to atherosclerosis, it affects small and medium vessels of the extremities. It is not a diffuse disease since only segments of arteries develop lesions. Thrombosis is a secondary feature. The lumen may become occluded and the intima thickened but the medial wall structure remains intact, in contrast to atherosclerotic disease. The diagnosis can often be made on the basis of a careful history and physical examination. A patient may present with cold hypersensitive fingers and toes on two or more limbs. Investigations aim to exclude other causes of ischaemia. Occasionally, arteriography is warranted to confirm the diagnosis. The patient is strongly advised to stop smoking. Besides the general treatment approaches used in ischaemic diseases of the limbs, including antibiotics, antirheumatics and corticosteroids, some specific surgical procedures may be considered.

Raynaud's disease

This is episodic vasospastic ischaemia of the small arteries and arterioles in the most distal part of the extremities in response to cold or, less commonly, emotional stress. It usually occurs in young women and is more prevalent in cool, damp climates. A distinction should be made between Raynaud's phenomenon, which results in no permanent damage, and Raynaud's disease, the more advanced condition associated with permanent damage. The fingers become pale and cold, but pulses are intact. Cyanosis may also be a feature. Pain is not always present, but function may be lost. Similar episodes of vasospasm can be found secondary to scleroderma, some neurological conditions and in some occupational groups, e.g. those that use pneumatic vibrating tools. Treatment includes avoiding situations that trigger the problem. This may mean a change in occupation, giving up smoking and keeping warm. Vasodilating medication, including calcium channel blockers, e.g. nifedipine, prostaglandin therapy and sympathectomy have been tried as means of improving the circulation. The nurse's primary role is patient education so that the onset of symptoms associated with this disease can be identified and minimised.

NURSING PRIORITIES AND MANAGEMENT: Arterial disease

Almost all the activities of life are affected by the distress of arterial disease.

Maintaining a safe environment

Possible loss of sensation increases the risk of trauma to tissue that has reduced ability to combat infection and to heal. The person's home and work circumstances can be considered, and hazards minimised. Useful advice includes the following points:

- Toenails may be best cut by the chiropodist in case soft tissue injury is inflicted, especially as some people with atherosclerotic disease, with or without diabetes, may also have poor sight.
- Caution should be exercised with electric blankets, hot water bottles, open fires and hot baths, as burns may not be felt.
- Cold can also be damaging.
- Constrictive clothing, e.g. tight underwear, is best avoided.
- Sitting cross-legged causes constriction of lower limb circulation.
- Remaining in one position for any length of time puts pressure on one area of tissue, allowing ischaemic changes to occur.

2.10 Drawing on your experiences of visiting older people at home, identify the range of possible hazards for those susceptible to arterial disease. Think of your own home and work environment. How aware are you of actual and potential damage to your lower limbs from knocks, friction, pressure and cuts?

Pain control

The pain of claudication is relieved by rest; however, exercise to the limit of pain is to be encouraged in the hope of developing increased perfusion and collateral circulation. Controlling ischaemic pain is essential and will often require the use of opiate analgesics, which may cause drowsiness as a side-effect. Keeping warm, especially for people affected by vessel spasm, and positioning the affected limb in a dependent position from time to time are also advised. Anti-inflammatory medications are used in diseases with an inflammatory response. Distraction techniques can also be helpful (see Ch. 19).

Nutrition

Excessive weight increases circulatory demand, and people with diabetes need to be particularly careful about what they eat (see Ch. 5, Part 2). Dehydration contributes to the process of clot formation because of increased blood concentration, so taking plenty of liquids is recommended. A balanced diet, including the vitamins and trace elements that aid tissue healing and integrity, can help to prevent aggravation of symptoms (see Ch. 23). People with hyperlipidaemia could be encouraged to follow the diet suggested for those with CHD and may also be prescribed medication to reduce their lipid levels.

Sleep

This is often impaired by pain. Elevating the head of the bed is suggested to increase flow (see also Ch. 25).

Breathing

Smoking reduces the amount of oxygen the haemoglobin can carry and nicotine results in venous spasm. Encouraging the patient to give up smoking may therefore produce benefits.

Mobility

Maintaining as great a degree of mobility as possible can help to prevent general stiffness of all joints, which can develop if they are underused. Muscle wasting and weakness are associated problems; the patient can be encouraged to carry out a wide range of joint exercises.

Personal hygiene

Careful attention to hygiene helps to prevent infection, especially if the person is diabetic. After bathing, the skin should be thoroughly dried, especially between the toes. This gives the opportunity to assess the skin for any signs of ischaemia. Points to note are:

- bath water should be neither too hot nor too cold
- tight socks with elastic tops cause constriction
- clean clothing, daily, is preferred
- plastic shoes encourage sweating and maceration of the skin as water cannot evaporate.

Work

Consideration should be given as to the physical demands and environmental hazards at the person's work. The more potent analgesics may also impair work performance and safety.

Discharge planning

After successful surgery, it is important to consider how vascular improvement can be maintained to ensure a reasonable quality of life and prevent further hospital admissions.

2.11 What type of discharge planning would be appropriate following femoropopliteal bypass grafting?

VENOUS DISEASE

Venous insufficiency

Venous disease results from:

- obstruction, by thrombus or thrombophlebitis
- incompetence of valves in the veins.

2.12 Read Case History 2.3 and consider the following questions:

a) What is meant by the term gangrene?
b) Mr L was suffering from the pain of ischaemia prior to surgery. What is meant by the phantom limb pain that might occur after amputation and how do you think such pain could be alleviated?
c) Can you explain, in physiological terms, why his aching legs were relieved by rest?
d) Describe the tests Mr L might have undergone to assess his arterial insufficiency.
e) How does smoking affect the feet?
f) What vasodilatory medicine might have been prescribed?
g) What was the surgery that Mr L underwent?
h) It was clear that Mr L found it almost impossible to change his lifestyle. What role do you think

CASE HISTORY 2.3

Peripheral vascular disease: Mr L's memories

Mr L lay back on his hospital pillow, wishing he was at home. The powerful analgesic was at last easing the pain in his gangrenous foot. Tomorrow he would have surgery that would rid him of the limb, but losing a limb had been difficult to come to terms with — and what was this phantom pain he had heard so much about?

Thirty years ago Mr L had been strong and fit, fond of long country walks and watching football. His first complaint had been aching legs after his long walks, but it had not lasted long and was easily relieved by sitting down. However, the aching became a great deal worse and his walks became shorter and shorter. Fond of his food, he had gained weight and spent more of his leisure time smoking.

His GP had described his symptoms as intermittent claudication or limping. He had said it was due to impairment of the blood supply to his lower limbs and had organised several tests to confirm this. At first the treatment had seemed quite easy. Mr L had to cut down on his smoking, alter his diet to avoid rich and fatty food that could 'clog up' his arteries and avoid extremes of temperature, which would make the symptoms worse.

It had been hard to stick to his diet and give up smoking and, seeing no visible evidence of it working, he had soon abandoned this. The ache in his legs eventually became worse, developing into excruciating pain. At night he had to sit up in bed and hang his legs down to cool them and ease the pain. The GP had given him tablets to help dilate the blood vessels but they had not helped and not long afterwards he had found himself facing an operation to improve the blood supply.

Mr L had not minded the operation too much. One of his veins had been used to bypass the occlusion in the artery of his thigh. He had thought this rather clever at the time and he had quickly felt the benefits. After the operation he had felt much more enthusiastic about changing his lifestyle. The surgeon had stressed that the success of the operation in the long term would depend on his ability to stop smoking, and he had, for a while. Friends and family had said he looked so much better but somehow it did not last. He had lost weight but just could not stop smoking. He had known the pain was coming back. His toes were looking discoloured and often felt either very sensitive or numb. The skin on his right leg, particularly, was thin and dry and there had seemed to be less muscle. Once again, he had found himself in hospital, the circulation to his lower limbs being thoroughly assessed.

The night before his operation he was unable to sleep and feared both the immediate and long-term future.

hospital and community nurses can play in helping someone like Mr L?

i) Outline a plan of care for Mr L for the immediate postoperative period after his above-knee amputation of his right leg.

Some diseases, such as varicose veins, may seem trivial but can contribute to day-to-day discomfort and absence from work. Other venous diseases are associated with chronic health problems, such as venous ulcers, or a sudden medical emergency, such as pulmonary embolus following deep vein thrombosis.

Deep vein thrombosis (DVT)

Clot formation is more likely to occur when flow is reduced within the veins. This can occur due to obstruction and stasis but is also associated with increased blood viscosity, slower flow and damage to the endothelial wall of the vessel. Hypercoagulability may be a feature of dehydration or malignant disease. It seems that there is also an imbalance between fibrinolysis and coagulation in the postoperative patient, which predisposes them to DVT. Trauma may be mechanical or chemical. The increasing use of vascular cannulae predisposes the patient in hospital to the irritant effects of pharmacological preparations, the plastic of the cannula itself and the possibility of intimal trauma at insertion.

Stasis allows clotting factors that normally would be cleared from the circulation to remain active for longer. The effects of the muscle pumps of the leg and negative intrathoracic pressure during inspiration normally promote venous return. Any situation that obliterates their action predisposes to stasis of the venous circulation. Immobility and the recumbent position are frequently features of the postoperative patient and the older person. There has also been much debate about the risks of arising from sitting still for long periods during long-haul flights and passengers are now encouraged to exercise their limbs regularly. Muscle relaxant medications used during surgery abolish the muscle pump, and breathing is under positive pressure when ventilated mechanically. Stasis is more common in the dilated portions of varicosities. Mechanical obstruction to flow can be seen in pregnancy and abdominal tumours.

Prophylaxis is important and simple measures such as regular physical activity, avoidance of dehydration, elevation of the legs without calf compression, minimising periods of immobilisation and the use of graduated compression stockings are important (Kolbach et al 2005).

Other measures include intermittent pneumatic compression (IPC) devices and electrical muscle stimulation. Low dose subcutaneous unfractionated heparin is the most widely used form of prophylactic anticoagulation. Warfarin and dextran are also used.

For further information on assessing patients at risk of DVT, see Autar (1998).

MEDICAL MANAGEMENT

Clinical assessment includes the use of Homan's sign which involves sharply dorsiflexing the foot when the patient is lying flat with their legs straight. The test is positive if pain is felt in the calf. Alternatively, the knee can be slightly flexed and the gastrocnemius muscle compressed against the tibia. Again if pain is felt, the test is positive. More than 25% of DVTs produce no symptoms and are only detected on screening. In other cases, the affected area will be tender, swollen and hot. Compression ultrasonography has become a first line investigation with the measurement of circulating D-dimer concentrations. D-dimer, a by-product of fibrin production, is a useful adjunct to ultrasonography, with a 98% sensitivity for DVT and a high negative predictive value (Gorman et al 2000). Venography, plethysmography (use of infrared light to assess relative changes in blood volume) and isotope scanning may also be used. Once diagnosed, treatment includes pain relief and anticoagulation, first with heparin and later with warfarin. Prophylactic subcutaneous heparin is almost a routine postoperative

prescription. Leg elevation, with some flexion at the knee, will be necessary until swelling and pain subside. Avoidance of dehydration, external pressure, immobility in those at risk and careful observation are all part of the preventive management. Home management is cost effective and likely to be preferred by patients (Schraibman et al 2001).

Chronic venous insufficiency

Of those suffering from chronic venous insufficiency, most will have had episodes of DVT previously. Pressure within the venous system remains high, resulting in increased capillary pressure and allowing chronic oedema to develop. The valves and elastic fibres of the vein wall are also destroyed by thrombophlebitis, aggravating the situation. Accumulation of interstitial fluid increases pressure locally. Eczema may occur secondary to this, possibly with pruritus. Owing to stasis, red blood cells may be trapped and haemolysed. This manifests as areas of brown pigmentation (haemosiderin). Melanin may also be deposited. Prolonged oedema reduces the nutrition available to subcutaneous tissue, which then fibroses. This induration further prevents drainage of any oedema.

Venous ulcers

Ulceration may follow trauma or dermatitis of such an area. Ulcers are commonly seen around the internal malleolus and tend to recur in the same place, as the scar tissue is atrophic.

Infection of ulcers is common. Venous ulceration is a major problem, particularly in older people, with district nurses spending a significant amount of time treating them. Compression therapy is considered to be the most appropriate non-invasive treatment of leg ulcers, although appropriate patients may benefit from surgery.

MEDICAL MANAGEMENT

Prompt and correct treatment of thrombophlebitis helps to prevent chronic venous insufficiency. Pain is worse in the dependent position, so elevation of the limb when seated and regular walking should be advised. Prolonged standing should be avoided.

Oedema is treated by elevation during bed rest. Once it is reduced, support stockings should be fitted. Any infection should be isolated and treated with appropriate medication. If varicose veins contribute to ulceration, they may be dealt with surgically. Chronic ulcers may have to be skin-grafted.

For information on the care and management of leg ulcers, see Chapter 23 (this volume) and Moffatt (2003).

Varicose veins

Varicosities are tortuous, dilated and incompetent veins, partly due to the effects of gravity. Dilatation causes the valves to become incompetent and retrograde flow is no longer prevented. It has a genetic component: about half the sufferers will have a family history of varicosities. The hormonal changes in pregnancy also reduce venous tone, while the obstruction to venous return by the gravid uterus combines to increase pregnant women's susceptibility. Simple obesity has a similar obstructive effect. Standing for prolonged periods maximises the force of gravity. Thrombophlebitis of the deep veins increases venous pressure, while inflammation destroys valve tissue. This increase in pressure is transmitted to the superficial veins which, being relatively less supported by surrounding structures, dilate. Most people complain of dull aching in their legs. Trauma may result in significant blood loss and should be guarded against. Ulcers are rare. Some individuals are concerned by appearance. Elevation and use of support stockings may reduce the aching and oedema.

MEDICAL MANAGEMENT

Diagnosis involves history taking, examination and investigation for reflux, including the Brodie–Trendelenburg test, i.e. selective clinical testing for reflux, which can identify sites of perforation or junctional incompetence in either the long or short saphenous system. Continuous wave Doppler or colour flow duplex ultrasonography is also used (see Fig. 2.15). Conservative treatment involves patient education, control of risk factors, advice on camouflage techniques and cosmetic treatments, e.g. laser therapy, microsclerotherapy. Support hosiery should be worn as routine. If symptoms persist, the most common management is the surgical stripping and ligation of the varicosed vein. For some, the injection of a sclerosing agent would be considered. Treatment is increasingly being carried out on a day surgery basis and this has an impact on nursing care priorities both in hospital and at home. There is potentially less time for providing accurate information to patients about the disease process, treatment options and interventions for its prevention. For further information on surgical intervention, see Chapter 26. Patients can usually return to driving in a week and to work between 1 and 3 weeks after the procedure. Some 20–30% of patients will develop recurrent varicose veins within 10 years (London & Nash 2000).

For a review of the treatment and prevention of varicose veins, see Vowden & Vowden (2003).

NURSING PRIORITIES AND MANAGEMENT: Venous insufficiency

Pain control

Bed rest or limb elevation reduces the throbbing pain of venous insufficiency. Walking rather than standing is advisable. Supportive anti-embolism stockings, by aiding venous return, reduce the feeling of pressure in the legs. However, they can be hot and uncomfortable. Once any oedema has reduced, the patient should be measured again, to ensure that the stockings fit properly and are still therapeutic. Similarly, swollen legs should not be squeezed into elastic stockings that have become too small. Anti-inflammatory medication may be prescribed to settle the inflammatory process of thromboembolism.

Mobility

Mobility should be maintained as much as possible. Patients should be advised to elevate the legs when sitting, in order to increase venous return and reduce oedema, and to avoid standing for long periods. After an operation for ligation of

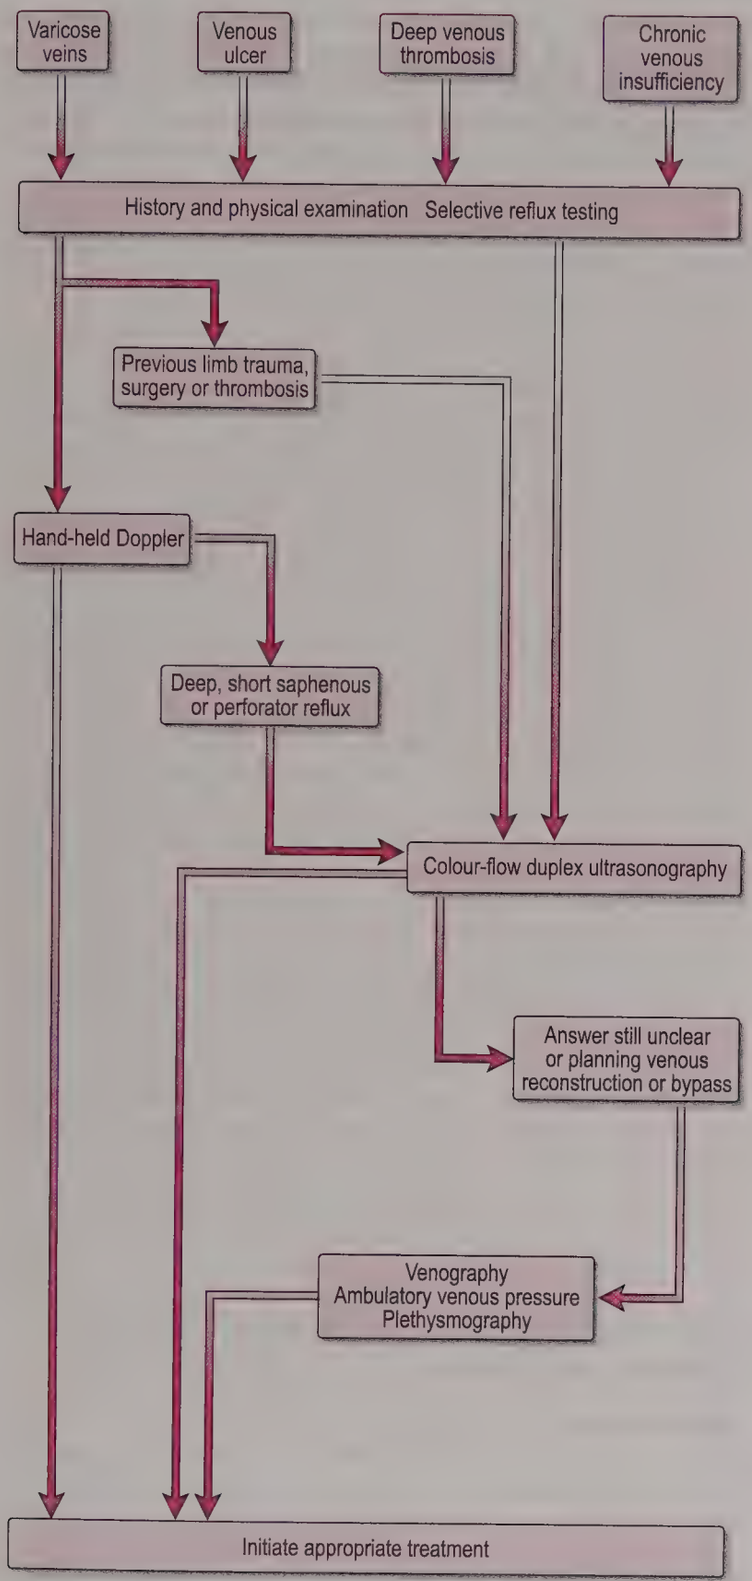

Fig. 2.15 Investigation pathway for patients presenting with venous disease. (Adapted from Murray 2003.)

varicosities, measures to prevent DVT should be considered. The patient will be advised to:

- walk a prescribed distance of perhaps 2 miles daily
- avoid standing for long periods
- always elevate the feet when sitting.

See Nursing Care Plan 2.2.

Nutrition

Adequate hydration and balanced nutrition assist flow and maintain vessel integrity. A diet deficient in fibre has been thought to predispose to varicose veins. Constipation and straining at stool can cause compression and dilatation of both the superficial and deep veins in the leg. Some supplementation of vitamins, trace elements and iron may have to be considered in the older person.

Maintaining a safe environment

Avoidance of trauma and infection is important, as in arterial disease. Blood loss can be severe, even from venous circulation.

Work

Occupations that involve standing for long periods, e.g. shop assistants, may present a problem. Prophylactic use of support hose by at-risk groups may be advised by the occupational health nurse.

Lifestyle issues

Women taking oral contraception run a slightly increased risk of DVT, especially if there is a family history of thrombosis. If a DVT was to develop, then oral contraception would be discontinued and another form adopted. Pregnant women are also more prone to DVT and varicose vein formation. The cosmetic effect of these problems can prove very upsetting, as wearing thick white stockings is far from attractive. Trousers and opaque-coloured tights may make them more acceptable. The perfect compression stocking, which would be easy to put on, comfortable to wear, give adequate graduated compression and look fashionably sheer, has not yet been invented!

2.13 Health education leaflets related to cardiovascular disease are widely available. Where do these leaflets come from? Who uses them? Do health professionals and the public find them useful? Explore these questions during your placements in the community and in hospital.

Nursing Care Plan 2.2

J is a 68-year-old lady admitted to hospital 2 days previously for surgical stripping and ligation of varicose veins in her left leg. J lives alone and is concerned about how she will cope after discharge.

Nursing considerations	Action	Rationale	Expected outcome
1. Pain/discomfort	• Explain normal pains/ sensations likely to be felt over forthcoming days/weeks • Ensure support stockings are fitted correctly • Give analgesics to promote pain-free movement of affected extremities • Inspect bandages regularly for bleeding: a compression bandage is usually kept on the leg for 1–2 weeks	It is normal for the leg to feel painful and be very bruised. There may be a small amount of bleeding through the dressing. This may be a problem in the groin, particularly if the support bandage ends over a bruise Complaints of patchy numbness are to be expected, but these disappear over a year Sensation of pins and needles or hypersensitivity to touch in the involved extremity may indicate a temporary or permanent nerve injury as a result of surgery; the saphenous vein and saphenous nerve are in close proximity Local anaesthetic infiltration of groin and popliteal wounds can significantly reduce postoperative discomfort	Ultimately, is pain-free and comfortable Feels informed about the pains/sensations to expect Wears support stockings correctly
2. Leg needs to be supported	• Elevate leg 30° to provide adequate support for whole leg • Leg to be encased in pressure bandage from toe to groin for about a week, followed by knee-level stockings for 3–4 weeks after surgery • Ensure J has adequate supply of stockings	Long-term elastic support after discharge will promote circulation and limit likelihood of recurrence	Is aware of the importance of supporting the leg
3. Fear/difficulty in walking	• Encourage J to walk with normal gait, offering support if necessary • Encourage short frequent walks to regain confidence and promote circulation • Give analgesics to ease movement of affected extremity • Advise to continue leg exercises after discharge	Early ambulation needs to be encouraged to promote circulation	Feels confident about walking and is able to walk without discomfort

Continued ▶

Nursing Care Plan 2.2 *(Continued)*

Nursing considerations	Action	Rationale	Expected outcome
4. Potential for recurrence of varicosities	• Advise J to continue to avoid activities that cause venous stress by obstructing blood flow: – avoid wearing tight socks or tight girdle – avoid sitting or standing for long periods of time – avoid dangling legs (causes stasis of blood in lower leg) – avoid crossing legs at the knee for long periods whilst sitting (decreases circulation by 15%) • Elevate foot of bed 15–20° at night • Avoid excessive weight gain • Wear elastic support tights • Attend outpatient follow-up visits every 6 months • Avoid knocking/damaging leg	It is possible that varicosities may recur in approximately 20% of patients. Therefore conservative measures learned perioperatively need to be continued	Recurrence of varicosities will be avoided Will feel confident about practising preventive measures
5. Coping after discharge	• Ensure that she knows what to expect after discharge • Discuss availability of support from family and neighbours after discharge; assist in coordinating these resources • Discuss feelings about wearing support bandages; arrange to talk to someone who has previously had this operation to talk through feelings • Arrange for district nurse to visit to remove sutures • Advise about keeping bandage dry when washing • Ensure she is aware of outpatient follow-up	May feel isolated after support of hospital May have difficulty coping with activities of living at home May feel embarrassed about having to wear support stockings Sutures are removed after 2 weeks Phlebotomy stab incisions are usually closed with adhesive strips and larger wounds with subcuticular sutures	Feels more confident about coping after discharge home

INTRODUCTION

The respiratory system is one of the most vital systems in the human body. In health, it functions automatically and usually without our awareness. There are, however, few disease processes that do not have some disruptive effect on the respiratory system. There are also many respiratory disorders relating to environmental pollution, trauma, infection, genetic susceptibility and primary disease, as well as conditions secondary to other diseases. Although causative agents differ, the aetiology of each condition follows certain common patterns. To know the anatomy and physiology of the respiratory system is to understand how respiratory disorders inevitably relate to breakdown in ventilation, gaseous exchange or pulmonary perfusion. Symptoms differ only in degree and effect, and the treatment of symptoms will always have certain basic aims.

The effects of respiratory disorders range from the minor discomforts of the common cold to the distressing and life-threatening symptoms associated with respiratory failure. All are disabling to some extent to the individual and their family. As respiratory conditions and diseases cover such a broad spectrum and are common in both community and hospital settings, it is essential that nurses have a broad knowledge base relating to the basic concepts of normal respiration and an understanding of the factors that can lead to respiratory dysfunction.

Research indicates that some of the more serious respiratory disorders are related to lifestyle and are preventable. This chapter will therefore emphasise and outline various approaches to health promotion and disease prevention and the nurse's expanding role, opportunities and challenges in this field. It will also explore some of the more common disorders and, in discussing them, draw out the basic principles of management for all respiratory disorders. Although the emphasis is on nursing management, implicit in all discussions is the assumption that nurses work in close collaboration with other health care professionals and, in many instances, are responsible for coordinating the work of the whole team.

As you read this, you are probably unaware that you are breathing quietly and effortlessly; once you become attentive to the process of breathing, however, you can voluntarily vary the depth and pace of your respirations. You can sigh, cough or hold your breath for a time, and you can force air out through your vocal chords and sing or shout. When you go to sleep tonight, you can be reasonably confident that you will continue to breathe automatically and wake up in the morning feeling refreshed and well.

However, if for any reason your respiratory system were to break down, this whole picture would change. Case History 3.1(A) gives some insight into a patient's perspective on an acute episode of respiratory distress caused by a severe asthma attack (see p. 89).

3.1 What is the critical response time in cardiopulmonary resuscitation (CPR) if you are to prevent irreparable brain damage? Refer to your first aid manual and, with appropriate guidance, be sure to practise CPR regularly throughout your nursing career: it is an essential procedure.

3.2 As well as following suggested reading and activities, you may find it useful to compile an information folder on essential procedures relating to respiratory care. It is also important when you are in the clinical area to observe the patients undergoing these procedures, to note their reactions and the effects of the procedures on them, and to talk to them about how they feel. Analyse the context. Reflect on your experiences. Make notes of critical incidents, and discuss them with your mentor or teacher.

The essential elements of life support are the essential elements of respiration. Airway, breathing (ventilation) and circulation are the ABC of life support. If any one of the three is cut off or becomes dysfunctional, the others are equally so, and an emergency situation exists which requires instant action if irreparable brain damage and death are to be prevented. An airway must be established and the individual's breathing and circulation restored in order to get oxygen to the vital organs and tissues.

ANATOMY AND PHYSIOLOGY

The reader is advised to review the anatomy and physiology of the respiratory system as a whole and to use a model of the thoracic cage to establish the relationship between all the structures illustrated in Figure 3.1. This section is intended as an overview of the most relevant points relating to normal respiratory function. Texts that can be consulted in conjunction with the present discussion are suggested below.

For further reading, see Waugh & Grant (2001) and Kindlen (2003).

Physiology of respiration

A continuous supply of O_2 and the elimination of CO_2 are necessary for the survival and functioning of body cells. The respiratory system in conjunction with the red blood cells (RBCs) of the circulatory system is responsible for this vital exchange. The process of respiration involves both external and internal respiration: external respiration involves oxygenation of the pulmonary capillary blood supply and elimination of CO_2 by diffusion across the alveolar and capil-lary membranes; internal respiration involves the exchange of O_2 and CO_2 at the cellular level and the use of O_2 and production of CO_2 in the tissues.

External respiration

External respiration involves ventilation, gaseous exchange and perfusion of the lungs with blood.

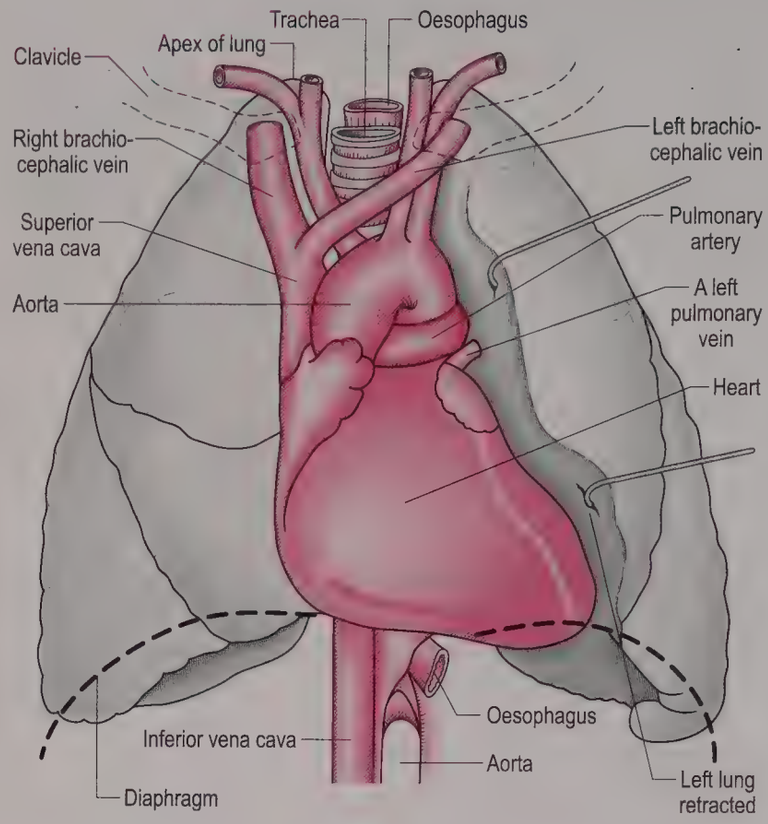

Fig. 3.1 Organs associated with the lungs.

Ventilation is the process by which air is moved in and out of the lungs via the airways. This process is powered by the respiratory muscles, mainly the diaphragm and the intercostal muscles, which work together to increase and decrease the size of the thoracic cavity. They are responsive to both voluntary and involuntary central nervous system (CNS) control. The thoracic cavity is lined with parietal pleura and the lung surfaces have a covering of visceral pleura. The negative pressure and serous lubricant between the parietal and visceral pleura have the effect of 'sticking' the lungs to the thoracic wall so that they expand and contract with these ventilatory movements. In health there is only a potential space between the pleural layers.

Central control Normally, the involuntary system maintains the regular automatic breathing cycle and is controlled by respiratory centres in the brain (see Fig. 3.2). These centres receive information from sensory receptors throughout the respiratory system and from chemoreceptors located in the carotid arteries, aorta and medulla.

The sensory receptors in the respiratory system itself monitor local irritants and lung expansion. A cough, for example, is a reflex response to airway irritants and a natural defence mechanism to clear the airways. The chemoreceptors monitor the levels of CO_2, O_2 and H^+ in the blood and of H^+ in the cerebrospinal fluid (CSF), and alter ventilation of the lungs to restore a normal balance of gases (see Table 3.1).

For a detailed explanation of gaseous exchange, see Chapter 7 in Kindlen (2003).

Pulmonary function — lung volume capacity and compliance It is important to bear in mind the basic principles relating to lung volume capacity and compliance and

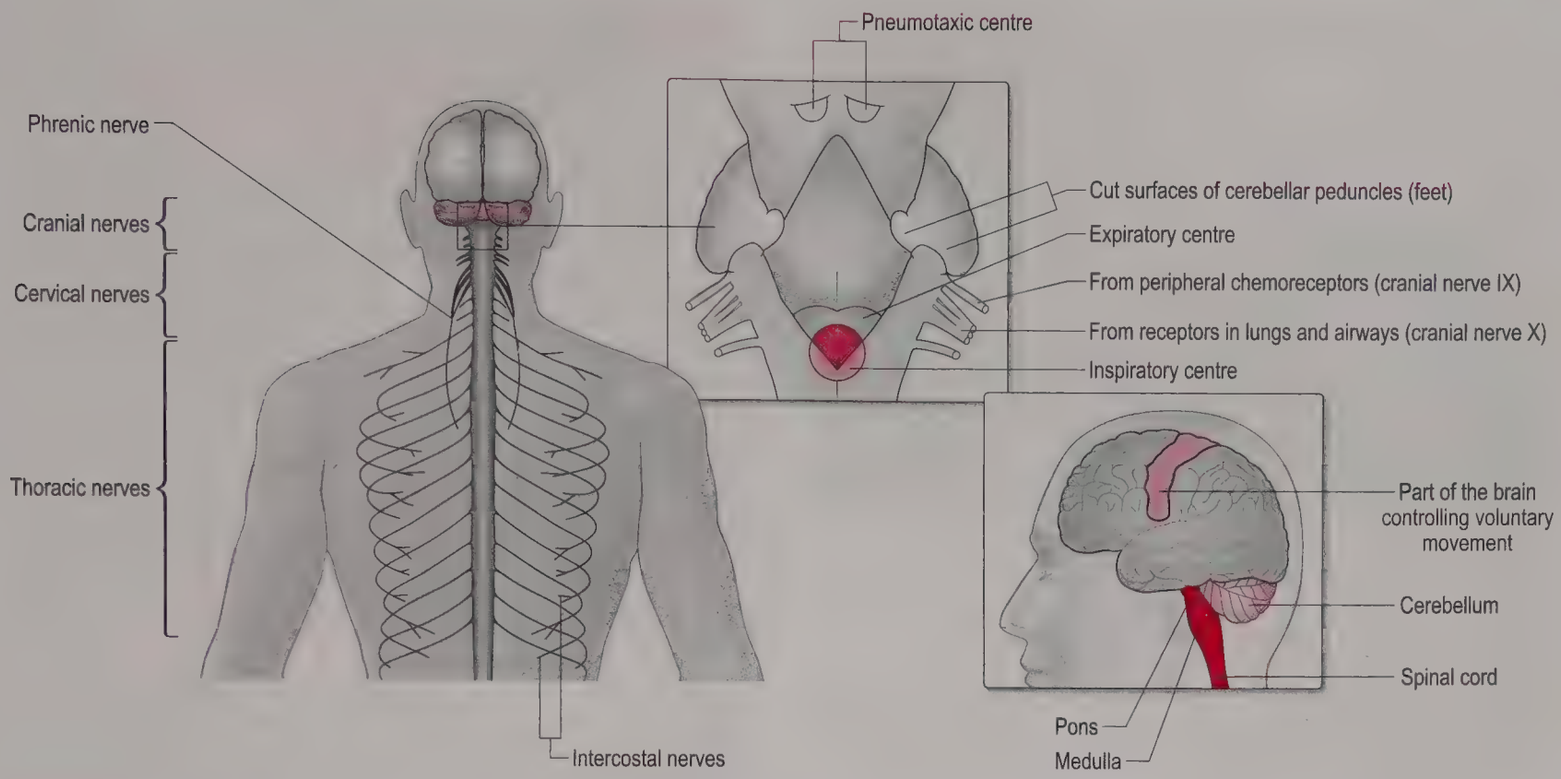

Fig. 3.2 Parts of the nervous system involved in controlling breathing: brain, brain stem, spinal cord and nerves. The enlarged inset shows the position of the respiratory centres in the medulla and pons of the brain stem as viewed from behind (the cerebellum, which sits on top of this, is not shown).

Table 3.1 Sensory receptors involved in the control of breathing

Type	Location	Stimulus	Effect on breathing
Within the respiratory system			
Irritant receptor	Airway epithelium: Nose, Trachea, Bronchioles	Inhaled particles and vapours	Sneeze Cough Increased rate and depth
Stretch receptors	Airway smooth muscle	Inflation	Slowed down
J receptors	Alveolar wall	Interstitial oedema Pulmonary emboli	Rapid and shallow
Muscle spindles	Respiratory muscles	Elongation of the muscles	Made smoother and more efficient
Elsewhere			
Chemoreceptors	Carotid artery Aorta	↑ CO_2 ↓ O_2 ↑ H^+ } in blood	Increased rate and depth
	Brain (medulla)	↑ H^+ in CSF	

Reproduced with permission from Kindlen (2003).

to recognise the significance of their measurement. They are important factors in ventilation and are often affected by respiratory disorders. Lung volumes can be measured by spirometry (see Fig. 3.3).

The volume of air breathed in and out and the number of breaths per minute vary from one individual to another according to age, size and activity. Normal, quiet breathing gives about 15 complete cycles per minute in the adult. Lung volume can be assessed in the following terms:

- *Tidal volume (TV)* — this is the amount of air that passes in and out of the lungs during each cycle of quiet breathing (approximately 500 mL in the adult). Exchange of gases takes place only in the alveolar ducts

Fig. 3.3 Measurement of breathing flow and lung volumes by spirometry. The subject is instructed to breathe normally then fully inspire, put lips firmly around mouthpiece and blow out as hard, fast and completely as possible before returning to normal breathing. The spirometer records the FEV_1 and FVC. The standard test procedures are performed by trained technicians to ensure the quality of results. (Reproduced with kind permission of Medical Illustration Services, North Glasgow University NHS Hospitals Trust.)

Box 3.1

Assessment of air flow

Vital capacity
This is the sum of inspiratory reserve volume, tidal volume and expiratory reserve volume, approximately 4800 mL.

Peak expiratory flow rate (PEFR), or peak flow
This is an expression of the maximum rate of air flow when the individual is breathing out as hard and fast as possible, starting with full lungs. The normal range is 400–600 L/min. PEFR is measured with a simple instrument called a peak flow meter. Patients with diseases such as asthma are taught to record their own peak flow at regular intervals. A fall in PEFR provides a warning of bronchospasm before breathlessness occurs and therefore alerts patients to use prescribed bronchodilator medications or to seek medical advice before the condition worsens. PEFR measures are also recorded before and after administration of bronchodilatory medications to assess their effectiveness.

Forced expiratory volume (FEV)
FEV_1 (forced expiratory volume in 1 s) is the volume of air exhaled in the first second of a forced maximal expiratory manoeuvre. The FEV_1/VC ratio is the ratio between the volume exhaled in 1 s to the total volume of air exhaled. It will be reduced in an obstructive disorder, i.e. it will be less than 75%.

and sacs. The rest of the air passages are known as 'dead space' and contain about 150 mL of air.

- *Inspiratory capacity* — this is the amount of air that can be inspired with maximum effort. This consists of tidal volume plus the inspiratory reserve volume (IRV).
- *Functional residual capacity (FRC)* — this is the amount of air remaining in the air passages and alveoli at the end of quiet respiration; it is composed of expiratory reserve volume (ERV) and residual volume (RV). The RV prevents collapse of the alveoli and makes continuous gaseous exchange possible as the alveolar gas mix remains constant.
- *Vital capacity (VC)* — this is the TV plus the IRV and ERV.
- *Total lung capacity (TLC)* — with maximum effort the adult lungs can hold 4–6 L of air. Most of this can be forcibly expelled, leaving a RV of about 1 L (see Box 3.1).

Lung expansion and recoil Elastic fibres in lung tissue and the surface tension of the fluid lining the alveoli give the lungs their natural recoil tendency. Ease of expansion and recoil depends on normal compliance and elasticity and on the presence of surfactant in the fluid lining the alveoli. Compliance can be reduced by the stiffening of normally soft alveolar tissue due to pulmonary oedema or to the ageing process. Conversely, compliance can be increased by extreme softening due to loss of lung tissue, as in emphysema.

Surfactant is a mixture of substances, mainly lipoproteins, secreted by cells of the alveolar epithelium, which lowers the surface tension of the alveolar fluid, making it easier for the alveoli to expand. Lack of surfactant in premature infants results in alveoli that remain collapsed (atelectasis) and leads to a ventilatory problem known as infant respiratory distress syndrome. A surfactant deficiency can also occur in adults as a response to severe shock, trauma or massive blood transfusion. This leads to increasing ventilatory difficulty, with rapid, shallow breathing and ineffectual respiration, a critical condition known as adult respiratory distress syndrome (ARDS) which may require artificial ventilatory support.

Ventilation, then, depends on CNS control, functioning respiratory muscles and adequate volume capacity of the lungs. Conditions which affect ventilation include some neurological diseases, diaphragmatic compression from constricting dressings or appliances, injuries to the chest wall, lungs or diaphragm, obstructive airways diseases such as asthma, space-occupying lesions, thoracic deformities and severe pain. In addition, certain opioid medications, such as morphine, are known to depress the central respiratory centre.

Gaseous exchange is the second vital component in the respiratory process. By a process of diffusion, O_2 passes from the alveoli into the bloodstream and CO_2 passes from the bloodstream into the alveoli. This exchange is dependent on adequate perfusion by the pulmonary blood supply.

Perfusion, i.e. the volume of blood passing through the lungs, determines the amount of O_2 taken into the body and the amount of CO_2 eliminated. In health, regulatory mechanisms ensure a balance between ventilation and perfusion such that well-ventilated parts of the lung receive an adequate blood supply and blood does not pass through the pulmonary circulation without being oxygenated (termed 'shunting'). Shunting occurs where there is an area of consolidation, as in pneumonia; although there is adequate perfusion, there is no ventilation.

3.3 Revise the properties of gases.

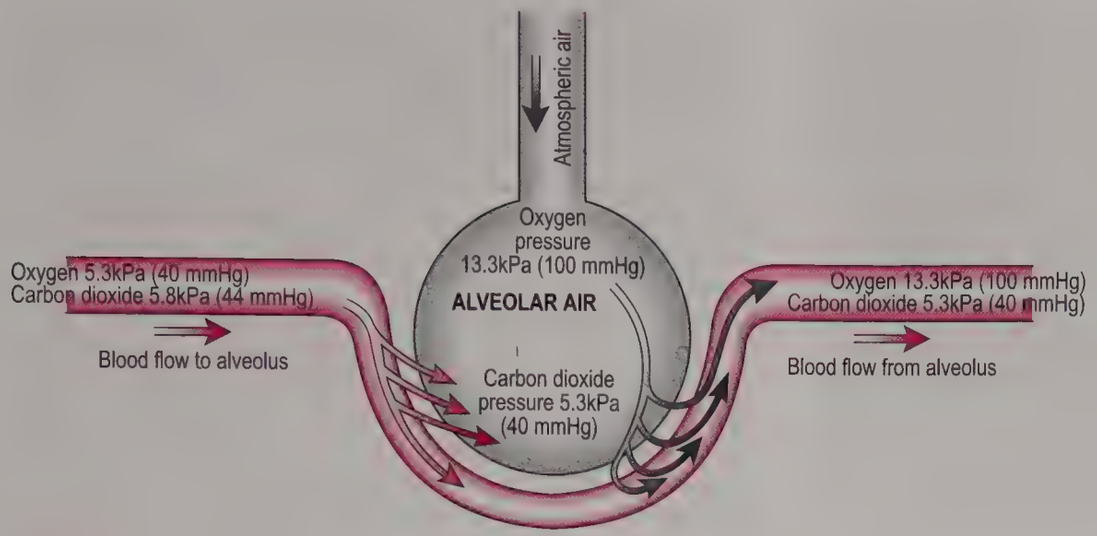

Fig. 3.4 The interchange of gases between air in the alveoli and the blood capillaries.

Gaseous exchange and lung perfusion Each microscopic, grape-like alveolus is surrounded by an intimate structural network of capillaries which together provide the lungs with an enormous capacity for gaseous exchange. This exchange is smooth and uninterrupted because the composition of the alveolar air remains constant due to the tidal ebb and flow of inspired air and the residual volume (RV) which is warmed and saturated with water vapour. As indicated in Figure 3.4, the gases in the blood leaving the lungs are in equilibrium with the air in the alveoli.

The total pressure exerted in the walls of the alveoli by the mixture of gases in air is the same as atmospheric pressure (100 kPa). Each gas in the mixture exerts a part of that total pressure proportional to its concentration; this is known as its partial pressure (P).

Arterial blood gas (ABG) levels Nurses may be involved in interpreting blood gas results, administering oxygen and monitoring respirators. A working knowledge of the properties of gases, of partial pressure and of gaseous exchange is therefore essential (see Table 3.2).

Table 3.2 Composition of air

	Dry atmosphere		Alveolar air (37°C)	
	%	kPa[a]	%	kPa[a]
Oxygen	21	21	13.2	13.2
Carbon dioxide	0.04	0.04	5.3	5.3
Nitrogen[b]	79	79	75.2	75.2
Water vapour	?[c]	?[c]	6.3	6.3

[a]Assuming barometric pressure is 100 kPa.
[b]Includes <1% rare gases (argon, helium, etc.).
[c]Amount of moisture in atmosphere depends on humidity and temperature. If moisture is present, percentage of other constituents will then be correspondingly decreased.
Reproduced with permission from Kindlen (2003).

Internal (cellular) respiration

Cellular respiration is an essential part of the whole process of respiration.

The haemoglobin of the red blood cells (RBCs) carries O_2 to the tissues where, by the process of diffusion, gaseous exchange takes place between the arterial end of the capillaries and the tissue fluid. CO_2, which is one of the waste products of carbohydrate and fat metabolism in the cells, transfers to the venous capillary blood, where it is carried to the lungs in three ways, i.e.:

- dissolved in the blood plasma
- combined with haemoglobin
- in combination with sodium as sodium bicarbonate.

These processes are described more fully in Kindlen (2003, pp. 136–138), where a clear description of both the oxygen–haemoglobin dissociation curve and the carbon dioxide dissociation curve is given.

PRINCIPLES OF NURSING MANAGEMENT IN THE PREVENTION AND TREATMENT OF RESPIRATORY DISORDERS

There are two main nursing priorities:

- health promotion and disease prevention
- developing clinical skills in order to ensure competent care.

The first priority will be addressed in relation to preventing serious respiratory diseases caused by environmental pollution and cigarette smoking; the second will be addressed in relation to specific respiratory disorders later in the chapter.

Conceptual framework

It is assumed in care planning for patients with respiratory disorders, whether in the hospital or in the community, that the care is underpinned by an appropriate driving philosophy and model of nursing care. It is suggested that a modified version of Orem's (2001) philosophy of promoting

independence and balancing self-care deficit with nursing compensatory intervention could be appropriate in the care of an asthma patient. For example, on admission, during an acute attack of asthma (Case History 3.1(A), p. 89), C is unable to meet his self-care needs and requires major compensatory intervention by both medical and nursing staff. As he recovers, the deficit is reduced and nursing intervention, always in collaboration with other members of the health care team, moves through partly compensatory to supportive–educative as he is prepared for discharge home and is more able to control his asthma and maintain a higher degree of independence (see Case History 3.1(B), p. 94).

The nurse's role in health promotion and disease prevention

Promoting health and preventing disease are vital to the social and economic well-being of our society and their importance is reflected in government legislation and the development of large-scale screening and health education programmes (Donaldson 2004). With the cost of health care soaring, it makes good sense to prevent disease where possible rather than treating the consequences. This is particularly true of some respiratory diseases and nurses are well placed in their many roles in the hospital and community to plan an active and expanding role in the area of primary health care (Buck 1997).

Downie et al (1996) describe three basic orientations for health education: disease orientation, risk factor orientation and health orientation (see Box 3.2). The evidence suggests that while each of these models has a valid place, a comprehensive and collaborative approach is necessary to tackle the complexities of most health-related issues. Government initiatives are aimed at preventing specific diseases and eliminating risk factors while health-orientated programmes initiated by the health professionals reinforce government policies by offering a more positive focus and satisfying health outcome for the individual. Information should be presented in an innovative and effective way, which means that nurses must make sure they have accurate information, good teaching skills and adequate resources.

Box 3.2

Orientations for health education

Downie et al (1996) describe the following orientations for health education:

1. *Disease-orientated education.* This approach aims to prevent specific diseases. The emphasis is on measuring success in terms of progress towards target rates for morbidity and mortality.
2. *Risk factor-orientated education.* Efforts are aimed at eliminating particular risk factors to prevent associated diseases.
3. *Health-orientated education.* The aim is to enhance positive health as well as to prevent ill-health. This orientation recognises the physical, mental and social facets of both positive and negative health and acknowledges that:
   - Provision of information is not enough. The educational process needs to be participatory, to help people clarify their values, e.g. how they see themselves and their health, and acquire and develop life skills, e.g. decision making and assertiveness. The educator seeks to understand people's perspectives and opinions, to respect them rather than correct them or blame them for their behaviour
   - There are major constraints to freedom of choice in health-related behaviour, e.g. sociopolitical factors.

Environmental pollutants and cigarette smoking are two of the major risk factor areas which can affect the health of the respiratory system. When the lungs are continually exposed to such irritants there is, initially, an increase in mucus secretion. The cilia, which normally clear the air passages of mucus, become coated and dysfunctional and eventually die. The presence of irritants and excess mucus causes inflammation and narrowing of the airways, disrupting gas diffusion. Cigarette smoke also contains carbon monoxide (CO), which binds easily to haemoglobin and displaces oxygen. Other chemicals in tobacco smoke cause vasoconstriction and constriction of the airways (West et al 2000). Constant inflammation leads to the formation of fibrous tissue and permanent narrowing of the airways of chronic bronchitis. Alveolar tissue is destroyed, reducing lung area and resulting in emphysema (see p. 84). These destructive changes are irreversible, although further destruction can be avoided by eliminating the cause: a concept simple in theory but difficult to put into practice.

Environmental pollution and health

Exhaust fumes from motor vehicles are a major source of air pollution in cities in the UK and other heavily populated countries in the world. Government intervention is needed to control this and other environmental pollutants such as dust, smoke, chemical fumes, agricultural pollutants and cigarette smoke. Nurses can actively and usefully support such intervention through early detection of risk factors, innovative local intervention and health education in the hospital, the workplace, the school and the home.

Many industrial workplaces expose employees to pollutants such as dust, chemicals and toxic fumes. Miners of nickel, coal, cobalt and radium are exposed to fluorocarbons, which have been shown to be related to an increased incidence of serious lung disease, including carcinoma. Agricultural workers are exposed to biohazards such as grain dust, bacteria and their metabolites (endotoxins and exotoxins), fungi and their metabolites (glucans) and storage mites; they are also exposed to airborne insecticides, fungicides and pesticides and to animal parasites and debris. Epidemiological and clinical studies have identified strong associations between agricultural exposure and rhinitis and asthma. More serious diseases, although less common, are hypersensitivity, pneumonitis and respiratory infection (Linaker & Smedley 2002).

Occupational health and community nurses have a responsibility to educate employees and managers about environmental hazards and to press for the use of appropriate protective clothing and respiratory masks and for improved working conditions and leisure facilities.

The home can also be a source of respiratory risk factors. Use of aerosol hair and body sprays and household cleaning

products, together with sidestream cigarette smoke, can be a constant source of respiratory irritation for the whole family. Again, it is the community nurse who can advise and educate families.

Cigarette smoking and health

The hazardous health effects of tobacco have been known for over 50 years (WHO 2002a). Although the prevalence of smoking has fallen in developed countries, it is increasing in many low and middle income countries, especially among young people and women. In 2000, an estimated 4.9 million deaths (8.8% of the global total) were attributable to use of tobacco, 45% higher than the number in 1990 (Shibuya et al 2003). Without additional interventions to reduce use of tobacco, the health burden will continue to increase. At current levels of consumption, the burden is estimated to double by 2020 (WHO 2002b).

The tobacco epidemic requires international action and, in 2003, the World Health Organization (WHO) for the first time used its constitutional authority to develop an evidence-based global public health treaty, the *WHO Framework Convention on Tobacco Control* (Shibuya et al 2003). This sets out a range of measures to reduce both the demand and the supply of tobacco. Governments have a key role in encouraging risk reduction strategies, for example, through taxation and restriction on tobacco advertising, promotion and sponsorship, but it is known that getting governments to agree on strategies for prevention or treatment is difficult. In the UK, legislation to ban advertising was only introduced in 2003 (Eaton 2003).

3.4 Scan current journals and websites for articles relating to smoking and health. What is the current UK position regarding the following:

(a) tobacco advertising, promotion and sponsorship
(b) tobacco packaging and labelling
(c) protection from exposure to environmental tobacco smoke
(d) restriction of tobacco sales to and by minors?

Smoking tobacco is considered to be the most preventable cause of ill-health and early death in the UK. Reducing smoking and the harm it causes are major government health-related priorities (Scottish Executive 2004). It is estimated that every year in the UK, approximately 114 000 people die as a result of smoking which contributes significantly to disease of the heart, blood vessels, lungs, upper respiratory tract, oesophagus, stomach, bladder and other organs (Tobacco Advisory Group of the Royal College of Physicians 2000, British Heart Foundation 2004). In Scotland, adult smoking rates remain consistently higher than in the UK as whole for both genders, and there are marked differences by post-code sector; the highest smoking rates are found in areas of highest economic deprivation (Office for National Statistics 2002, NHS Health Scotland/ASH Scotland 2003).

The sidestream smoke inhaled in passive smoking has a higher concentration of some toxic and carcinogenic substances than has mainstream smoke, which is significant for families and workmates of smokers (Moher et al 2004). There is evidence that active or passive smoking during pregnancy is associated with increased health risks to the unborn child (Acharya et al 2002). Maternal smoking has been linked to sudden infant death syndrome (SIDS) and passive smoking to a high incidence of childhood asthma (Dezateux et al 1999). Passive smoking can also be linked to a high incidence of acute coronary syndromes (Pitsavos et al 2002) (see Research Abstract 3.1; see also Ch. 2).

RESEARCH ABSTRACT 3.1

Passive smoking increases the risk of developing acute coronary syndrome (ACS)

The purpose of this study by Pitsavos et al (2002) was to investigate the association between passive smoking and the risk of ACS. Patients with a first event of ACS (n = 848) and cardiovascular disease-free matched controls (n = 1078) completed a detailed questionnaire regarding their exposure to environmental smoke. From this, 297 (35%) of the patients and 259 (24%) of the controls were defined as non-smokers and passive smokers, respectively. The results showed that non-smokers exposed to cigarette smoke increased their risk of ACS by 51% when compared to non-smokers not exposed to smoke. It was estimated that 34 coronary events per 134 subjects would occur as a result of passive smoking during their lifetime.

Pitsavos C, Panagiotakos D B, Chrysohoou C et al 2002 Association between passive cigarette smoking and the risk of developing acute coronary syndrome: the CARDIO2000 study. Heart and Vessels 16(4): 127–130

Smoking cessation and nursing intervention

Although most adult smokers say they would like to give up smoking and are aware of its dangers, each year only 2% who try to give up will manage by will-power alone. There are a number of interventions that increase quit rates. These range from low intensity support, such as self-help materials and telephone helplines, to more intensive interventions including individual and group counselling. In general, the more intensive the intervention, the greater the increase in quit rate. When combined with pharmacological aids, i.e. nicotine replacement therapy (NRT) or bupropion (Zyban), quit rates double irrespective of the intervention (West et al 2000). However, even the most intensive interventions result in modest quit rates. Nevertheless, compared with other medical interventions, smoking cessation interventions are cost-effective and if widely available and properly applied, will contribute to a reduction in smoking prevalence. All NRT products are on the *Nurse Prescribers' Formulary* (British Medical Association 2002) and community nurses are now making an increasing contribution to smoking cessation (Percival 2003) (see Research Abstract 3.2).

3.5 Design a smoking-related health education programme for early teenage children. What activities would you include? What teaching aids would you use? Access current websites that cover health promotion initiatives and look for local advertisements regarding one-to-one helplines.

RESEARCH ABSTRACT 3.2

Nursing interventions for smoking cessation

Health care professionals, including nurses, frequently advise patients to improve their health by stopping smoking. Such advice may be brief, or part of more intensive interventions. To determine the effectiveness of nurse-delivered smoking cessation interventions, the Cochrane Tobacco Addiction Group register was searched for studies of interventions using nurses or health visitors and an additional search made on CINAHL. Randomised trials with follow-up of at least 6 months were selected. Sixteen studies comparing nursing intervention to a control or usual care found intervention to significantly increase the odds of quitting. There was no evidence from indirect comparison that interventions classified as intensive had a larger effect than less intensive ones. There was limited evidence that interventions were more effective for hospital inpatients with cardiovascular disease than for inpatients with other conditions. Five studies of nurse counselling on smoking cessation during a screening health check found that under these conditions nursing intervention had less effect.

The results indicate the potential benefits of smoking cessation advice and counselling given by nurses to their patients, with reasonable evidence that interventions can be effective. The challenge will be to incorporate smoking cessation intervention as part of standard practice so that all patients are given an opportunity to be asked about their tobacco use and to be given advice to quit, along with reinforcement and follow-up.

COMMON RESPIRATORY DISORDERS

Respiratory disorders reflect a breakdown in the integrity of the alveolar walls. They either cause, or are caused by, oedema, the presence of exudate or by inflammation, resulting in scarring and alteration in the process of gaseous exchange. Causes of respiratory inflammation are varied and range from common diseases such as influenza and colds, to bronchitis, pneumonia, tuberculosis, cystic fibrosis and the opportunistic infections of AIDS and other immunosuppressive conditions. While causative factors, organisms or irritants differ, the aetiologies of respiratory disorders are similar and they are, in varying degrees, similar in their clinical manifestations. Assessment of respiratory function is central to all clinical care (see Box 3.3).

For a detailed account of respiratory assessment, see Field (1997).

The incidence of COPD and malignancy due to environmental pollutants and cigarette smoking appears to have increased significantly in recent years (Office for National Statistics 2000). Additionally, the lungs are often involved in terminal or critical illness where pulmonary oedema, bronchitis, pneumonia or atelectasis, i.e. collapse of alveoli, may develop.

Box 3.3

Respiratory assessment: a clinical skill central to all patient care

- Visual observation — cyanosis, perfusion
- Respiratory rate, rhythm and depth
- Breath sounds
- Use of ancillary muscles
- Sputum and secretions
- Causes of variation from normal, e.g. pain, anxiety, disease
- Respiratory history
- Arterial blood gases
- Pulse oximetry
- Chest X-ray
- Pulmonary lung function tests
- Bronchoscopy
- Imaging, e.g. CT scan, MRI

Common clinical manifestations of all of these disorders include varying degrees of breathlessness, cough, sputum production and dyspnoea (difficulty in breathing), tachypnoea (increased respiratory rate), cyanosis (blue discoloration of the skin), hypoxia (low O_2 concentration in the tissues) and hypercapnia (high concentration of CO_2 in arterial blood).

Wherever there is disruption of the respiratory process, there is the probability that oxygen therapy will be necessary to relieve breathlessness and improve tissue perfusion (see Box 3.4).

Each of the processes involved in external respiration — ventilation, gaseous exchange and circulatory perfusion — is a critical component in maintaining the life and function of body cells. Disruption in any of these processes results in respiratory disorders of varying severity.

INFECTIONS OF THE RESPIRATORY SYSTEM

Infections of the upper respiratory tract are addressed in Chapter 14. This chapter will focus on bronchitis, pneumonia and tuberculosis.

Acute bronchitis and tracheobronchitis

Acute bronchitis is the inflammation of the mucous membranes of the bronchial tree. Tracheobronchitis, as the name implies, affects the trachea as well as the bronchi. Both conditions are associated with infections of the upper respiratory tract (see Ch. 14) but may also occur as a result of atmospheric pollutants, cigarette smoking or when some other chronic respiratory disorder already exists. They can affect people of all ages and are usually only of real concern in the very young, the very old and the debilitated. A normally healthy person will usually recover quite quickly. The concern in terms of health promotion is to ensure that acute bronchitis does not develop into bronchopneumonia and that acute attacks do not become so frequent that the condition becomes chronic (see p. 84).

For information on pulmonary pathophysiology, see West (2003).

Box 3.4

Oxygen (O_2) therapy

The need for O_2 therapy arises when oxygen transport to the tissues is insufficient due to breakdown in either the respiratory or the circulatory system. Clinical signs and blood gas levels are the main indicators of degree of hypoxia. Profound hypoxaemia will cause death in minutes, whereas death from carbon dioxide (CO_2) narcosis is a more lengthy process (see Box 3.6).

The aim of O_2 therapy is to administer sufficient oxygen to maintain tissue oxygenation at a functional level and eliminate detrimental compensatory responses to hypoxaemia, and to prevent serious or irreparable damage to vital organs and tissues.

The percentage of oxygen that is to be delivered is carefully determined, either by circumstances, as in life-threatening emergencies, where 100% pure oxygen may be given initially, or by carrying out arterial blood gas (ABG) measurement or pulse oximetry, and prescribing oxygen accordingly. A pulse oximeter is a small, non-invasive device which can register arterial oxygen saturation through the skin using a clip-on sensor (Cowan 1997).

For therapeutic purposes, the range of prescription is usually between 24 and 60% of O_2. Hyperbaric oxygen (oxygen given at greater than 1 atmosphere absolute) may be used to improve oxygen perfusion of the tissues by increasing the dissolved oxygen in the blood, as in treatment of CO poisoning or deep-sea divers' 'bends' (Bateman & Leach 1998).

In certain conditions, the amount of oxygen given is determined by prior knowledge of adverse effects. For example, in patients with known COPD (see p. 84) it is dangerous to give too much oxygen. In premature babies high oxygen tensions in the arterial blood may cause damage to immature retinal vessels and in severe cases may result in blindness. This condition is known as retrolental fibroplasia.

Oxygen is commonly administered via nasal cannulae or oxygen masks. Supplemental oxygen may also be delivered during mechanical ventilation or non-invasive ventilation (NIV). Hyperbaric oxygenation can be achieved in specialist centres using hyperbaric chambers.

Humidification chambers attached to the oxygen equipment ensure that the oxygen is moistened before being inhaled. In mechanical ventilators it is also warmed and therefore enters the respiratory tract as vapour, fully saturated and at body temperature.

Oxygen toxicity

Retrolental fibroplasia may develop in premature infants as described above. Mature lungs may be damaged if high concentrations of oxygen are given over several days. This is thought to increase alveolar permeability so that capillary walls break down and fluid and blood accumulate. Severe cases may progress to pneumonia, fibrosis, pulmonary hypertension and right-sided heart failure.

PATHOPHYSIOLOGY

Common presenting symptoms The individual feels generally unwell with, initially, a dry painful cough and a moderate pyrexia. The cough becomes increasingly productive as the inflamed mucosal cells pour out mucus and the sputum produced becomes increasingly mucopurulent. Bronchospasm can occur, causing wheezing and a degree of dyspnoea.

MEDICAL MANAGEMENT

Investigations For otherwise healthy individuals, investigations are usually unnecessary. However, if marked mucopurulent sputum is produced, a sputum culture will be taken to identify the causative organism and a chest X-ray will be required.

Treatment The treatment is aimed at relieving the symptoms. Bed rest is advocated until the pyrexia has resolved. Moist inhalations, as prescribed, can relieve the bronchial symptoms and a high fluid intake is encouraged. Expectorants will also help to relieve the congestion, and antibiotic therapy will be prescribed as appropriate.

NURSING PRIORITIES AND MANAGEMENT: Acute bronchitis and tracheobronchitis

The nurse's priority will be for those vulnerable individuals for whom acute bronchitis could prove serious. Overexertion must be avoided and such patients may need support with expectoration and sputum clearance and maintaining oral hygiene. Optimal nutritional and fluid intake will aid recovery and help to prevent further infection.

When the individual is well enough, advice should be given as to how further attacks can be prevented. Avoidance of cigarette smoke, dust and ill-ventilated, cold or crowded environments is encouraged but is not always easy to achieve. The advice given and the outcomes aimed for must be realistic and tailored to the lifestyle and socioeconomic circumstances of the individual. An influenza vaccination may prove an effective preventive measure in high-risk individuals. Currently it is recommended for people with underlying respiratory, heart and renal disease or impaired immune systems, for those over 65 years of age and for health care workers (Joint Committee on Vaccination and Immunisation 2003).

Pneumonia

Pneumonia is an infection of lung tissue and is most usefully classified according to the causative organism, which may be bacterial or viral.

Bronchopneumonia

PATHOPHYSIOLOGY

Bronchopneumonia is characterised mainly by patchy areas of consolidated lung tissue. Causative organisms are bacterial and fungal and include staphylococci, pneumococci, streptococci, *Haemophilus influenzae* and *Candida*. It usually occurs in individuals weakened by other conditions and often in the very old, the very young, the unconscious, and as a result of a pre-existing disease, such as chronic bronchitis, atelectasis or carcinoma in adults, or infectious diseases in infants.

Clinical features vary in severity depending on the overall condition of the patient but include varying degrees of pyrexia, cough with copious purulent sputum, exhalatory

râles, dyspnoea and tachypnoea. On auscultation, consolidation of the lower lobes is found.

MEDICAL MANAGEMENT

The causative organism is isolated by sputum culture and sensitivity, and appropriate antibiotic therapies are commenced. The patient's general condition is improved by attention to nutrition, hydration and physiotherapy (Kleinpell & Elpern 2004).

NURSING PRIORITIES AND MANAGEMENT: Bronchopneumonia

The patient with bronchopneumonia will be very ill and both patient and family will need a great deal of comfort and reassurance. Attention to personal hygiene and physical comfort is important. The patient should be turned or encouraged to move regularly. An upright sitting position, where possible, will make breathing easier and, if oxygen is prescribed, this therapy should be monitored carefully. Aids to prevent pressure ulcers developing should be selected judiciously (see Ch. 23).

Bronchopneumonia can be prevented in many hospitalised high-risk patients by thorough nursing assessment and meticulous nursing care.

Lobar pneumonia

PATHOPHYSIOLOGY

This is an acute bacterial infection which sometimes involves a whole lobe. It occurs mainly in young adults, usually males, but its full-blown effects are uncommon now because of the early and effective use of antibiotics. However, if left untreated, lobar pneumonia can progress to further areas of consolidation as well as to pleurisy, pericarditis, bacteraemia and possibly death.

Viral pneumonia

PATHOPHYSIOLOGY

The main difference between viral pneumonia and other types of pneumonia is that the inflammatory reaction is localised within the septal walls of the alveoli and there is no exudate. Many cases are caused by agents such as *Mycoplasma pneumoniae*, *Legionella* and *Chlamydia*. This group was formerly known as primary atypical pneumonia (PAP). Although these diseases differ from pneumococcal pneumonia, there may be overlap in clinical presentation. Other highly contagious viruses which can begin as a 'common cold' and progress to more severe respiratory tract infections include influenza types A and B, respiratory syncytial virus (RSV), rubella and varicella, *Rickettsia* and echoviruses.

Clinical features Symptoms include pyrexia, muscular pains, headaches and a dry, hacking cough. Treatment is symptomatic, with attention given to general nutrition, hydration and antibiotic treatment of any intercurrent bacterial infections. The disease runs its course and, except in the more vulnerable individual, resolution is expected. However, the patient may be left feeling weak and exhausted for some time afterwards.

NURSING PRIORITIES AND MANAGEMENT: Viral pneumonia

Susceptible individuals — older people, the debilitated and health workers at high risk of infection — should be encouraged to attend the practice nurse clinic for influenza vaccinations in preparation for the winter months or where epidemics are forecast (Joint Committee on Vaccination and Immunisation 2003, Willcox 2003).

Most individuals can be treated at home. Some may need nursing advice or assistance to carry out the activities of daily living and to ensure they are properly nourished and hydrated. Individuals nursed at home will be referred back to their GP if medical treatment becomes necessary.

For further information, see British Thoracic Society (2001a). For information on severe acute respiratory syndrome, see Box 3.5.

Tuberculosis (pulmonary)

Tuberculosis (TB) is a chronic infectious disease mainly of the lungs (pulmonary tuberculosis) but, when infecting other parts of the body, it is known as miliary tuberculosis. In the early part of the 20th century, it was common in developed as well as developing countries. With the advent of compulsory chest X-ray, bacille Calmette–Guérin (BCG) vaccination and effective medication, the incidence in developed countries became almost negligible. However, the UK is now experiencing an increase in the incidence of TB due to increased immigration from Eastern bloc and developing countries and the rise of HIV (WHO 2004) (see also Ch. 37). The occurrence and rise in multidrug-resistant TB (MDR TB) has also been closely associated with HIV infection (Pozniak 2001).

For further information, see Joint Tuberculosis Committee of the British Thoracic Society (2000).

PATHOPHYSIOLOGY

Tuberculosis is a disease caused mainly by *Mycobacterium tuberculosis*, although *Mycobacteria avium* and *bovis* can also cause the respiratory form. The disease is characterised by two types of lesions: exudative and productive.

The exudative lesion arises from the inflammatory process in which the bacterial organism is surrounded by fluid containing polymorphonuclear leucocytes and monocytes. If the lesion fails to heal, it may become necrosed and develop into a productive lesion (tubercle).

A tubercle consists of a fibrous or a soft outer cover with a core of giant cells, lymphocytes, monocytes, fibroblasts and epithelioid cells. The mycobacterium can live in the centre of this tubercle for years. The soft tubercle can rupture and spread its contents into surrounding tissue. Spread of infection is by direct contact with the infected tissue, by the bloodstream or by the lymphatics. In pulmonary tuberculosis, spread to others is by droplet infection from coughing or saliva.

Clinical features vary in severity, depending on the virulence of the organism and the susceptibility of the

Box 3.5

Severe acute respiratory syndrome (SARS)

In 2003, the World Health Organization (WHO) reported the existence of a new atypical pneumonia called severe acute respiratory syndrome (SARS). SARS is defined as a serious respiratory illness, with patients exhibiting the following signs and symptoms:

- pyrexia (>38°C)
- cough, shortness of breath or difficulty in breathing
- changes on X-ray indicative of pneumonia.

The cause of SARS is the SARS coronavirus (SARS CoV). Corona viruses have a halo or crown-like (corona) appearance when viewed under the microscope. This group of viruses commonly cause mild to moderate upper respiratory illness in humans and are associated with respiratory, gastrointestinal, liver and neurological diseases in animals. Most SARS infections appear to be less infectious than influenza but the corona viruses can survive in the environment for as long as 3 h.

It is thought that the SARS CoV is closely related to the animal corona viruses and has jumped species. There is evidence that the SARS CoV may be able to survive longer than other forms of the virus. The incubation period is thought to be between 7 and 10 days.

The first outbreak of this life-threatening syndrome was in the province of Guangdong in China in mid-November 2002. From there it was spread to Hong Kong by an infected doctor. The exact means of transfer was unconfirmed. He seeded a cluster of cases among guests in the hotel where he stayed. The virus spread to other parts of China and to Canada, Singapore and Vietnam. It was then reported in Malaysia, the Philippines, Taiwan, Thailand and South Africa.

By 2003, the number of deaths reported as being due to SARS was: China, 348; Hong Kong, 298; Taiwan, 84; Canada, 38; Singapore, 32; Vietnam, 5; Malaysia, 2; the Philippines, 2; Thailand, 2; S Africa, 1 (BBC 2003).

Management of SARS CoV cases

Isolation is essential to limit the spread of the disease. It is recommended that patients are managed at home, if their condition permits, in order to limit cross-infection. Standard infection control precautions should be taken when examining or taking samples from a potential SARS case (see Ch. 16). Suspected SARS patients should be advised to cover their mouths with a tissue when coughing or sneezing. If respiratory status permits, the patient should wear a respirator or surgical mask when in close contact with a non-infected person. The health care worker or carer should wear a surgical mask.

At present there is no specific treatment for SARS, although antibiotics and antiviral drugs are being used to try to treat the symptoms.

For up-to-date information, see the WHO website: www.who.int/health.

individual. Manifestations include a productive cough, sometimes with bloodstained sputum, fatigue, weight loss, low-grade evening fever, night sweats and pleuritic pain. Advanced cases will manifest wheezing and râles, deviation of the trachea, pulmonary consolidation and haemoptysis, i.e. frank bleeding from the lungs.

MEDICAL MANAGEMENT

Investigations Mantoux/Heaf skin tests may be performed (see below). Specimens of sputum, bronchial washings or a lymph node biopsy may be sent for bacteriology. Chest X-ray will indicate the condition of the lungs. All forms of TB are compulsorily notifiable under the Public Health (Control of Disease) Act 1984. This allows contact tracing and provides surveillance data.

Treatment The patient is isolated until there is complete adherence to the medication regimen, usually 2–4 weeks. Medications include isoniazid, rifampicin, streptomycin, ethambutol and pyrazinamide. Until the specific sensitivity is determined, the patient is usually on a rotating regimen of several of these medications because of the high probability of bacterial resistance to some combinations. Therapy will then continue with long-term treatment with at least two of the medications. Regular clinic attendance and supervision of treatment are mandatory. Contacts are traced, tested and treated if necessary.

NURSING PRIORITIES AND MANAGEMENT: Pulmonary tuberculosis

Prevention

Prevention is based upon public health education and on screening and vaccination to protect those at risk. Specialist TB nurses, working closely with health visitors, public health nurses, school nurses, GPs, microbiologists and Consultants in Communicable Disease Control (CCDCs), are key in the prevention and control of TB.

Schoolchildren, health care workers and contacts of people identified as having TB are screened by the Mantoux/Heaf skin tests. These tests use a single intradermal injection of purified protein derivative (PPD). The result is read within 24–72 h.

Mantoux test With Mantoux testing, if the area of induration is >5 mm, the test is positive, which indicates either that a past subacute infection stimulated present immunity or that present infection exists which needs treatment. In the case of past infection, the result signifies that there is effective immunity and vaccination is not necessary. An area of 5 mm in a person recently exposed to tuberculosis indicates that a course of prophylactic treatment should be given. A negative Mantoux test, i.e. no reaction, indicates that there is no natural immunity and the BCG vaccination is necessary.

Heaf tests are similarly graded according to the reaction. Screening may prove difficult, especially in the homeless group. Education of carers working with homeless people is essential in detection of suspected cases. Currently, BCG is offered to children aged between 10 and 14 years and to certain groups at high risk of exposure to TB, including infants and children of certain immigrant populations known to be of high risk (Joint Tuberculosis Committee of the British Thoracic Society 2000).

Management of a newly diagnosed patient

The patient is isolated for 2–4 weeks and expanded infection control precautions are adopted (see Ch. 16). The patient will need reassurance that treatment will be effective, as well as rest, diversionary therapy, good nourishment and administration of prescribed medications. On discharge home, although treatment is standardised, the level of care required will vary from monthly review to directly observed therapy (DOT) three times per week. DOT is a treatment control strategy where health workers observe and record the patients swallowing the prescribed antituberculosis medication (WHO 2003). WHO (2004) recommends that in order to achieve global targets, government and national TB control programmes need to take a strategic approach to planning and match budgets more closely with plans.

OBSTRUCTIVE DISORDERS OF THE AIRWAYS

'Chronic obstructive pulmonary disease' (COPD), sometimes referred to as 'chronic obstructive airways disease' (COAD), is a term used to describe a group of disorders which cause obstruction to air flow. Included in this group are chronic bronchitis, emphysema, asthma and bronchiectasis:

- In chronic bronchitis, the inflammation and constant productive cough obstruct air flow
- In emphysema, the overdistended alveoli with reduced permeability result in impaired gaseous exchange
- In asthma, there is both inflammatory reaction and bronchospasm
- In bronchiectasis, there are chronic copious secretions filling the lungs.

Bronchiectasis is usually a separate condition, but the others often coexist and complicate each other in presenting as the set of symptoms commonly termed COPD (National Collaborating Centre for Chronic Conditions 2004).

Chronic bronchitis

The accepted definition of chronic bronchitis is the presence of a persistent productive cough for at least 2 months over 2 consecutive years. It can occur in any age group but is more common in middle-aged men, cigarette smokers and people exposed to high levels of environmental pollution.

PATHOPHYSIOLOGY

Chronic irritation causes hypertrophy and hyperplasia of the mucous glands of the tracheobronchial tree, which results in excessive mucus production and impaired ciliary action. The bronchi and bronchioles are usually the most severely affected and may become blocked with purulent mucus. This, together with the resultant oedema and congestion, can affect respiratory defence mechanisms and predispose to recurrent bacterial and viral infections.

Clinical features A chronic productive cough with muco-purulent sputum may persist for years, accompanied by gradual and increasing airway resistance and functional impairment. Untreated, this will lead to increasing dyspnoea, hypoxia and hypercapnia.

MEDICAL MANAGEMENT

Management is to advise the patient to avoid the causal irritant, if this is possible, and to treat the symptoms. This may involve prescribing physiotherapy, bronchodilatory medications, antibiotics and oxygen therapy.

NURSING PRIORITIES AND MANAGEMENT: Chronic bronchitis

Prevention of deterioration

The patient is advised and supported in avoiding causative agents.

When identifying patient problems and nursing priorities, it is useful to consider chronic bronchitis and emphysema together, as the two conditions often coexist (see p. 85).

Pulmonary emphysema

Pulmonary emphysema is a chronic destructive disease of the respiratory bronchioles, alveolar ducts and alveoli. It is most common in those aged over 40 and is often associated with other chronic lung disorders. There are two main types of pulmonary emphysema, which may coexist and which are exacerbated by persistent and severe coughing: alveolar emphysema and centrilobar emphysema.

Alveolar emphysema

PATHOPHYSIOLOGY

In this form of emphysema, the walls between adjacent alveoli break down, the alveolar ducts dilate and there is loss of interstitial elastic tissue. This results in distension of the lungs and loss of normal elastic recoil and therefore trapping and stagnation of alveolar air. As alveoli merge, there is loss of surface area for gaseous exchange, and this is further reduced by loss of permeability of the stretched and damaged alveolar walls. Predisposing factors include cigarette smoking, genetic deficiency of α_1-antitrypsin, which makes the individual more susceptible to environmental pollutants, acute lower respiratory inflammatory conditions and chronic coughing, which puts pressure on the already stretched tissues.

Centrilobar emphysema

PATHOPHYSIOLOGY

This type of emphysema involves irreversible dilatation of the bronchioles in the centre of the lobules, which affects airway pressure and ventilation efficiency. Predisposing

conditions include recurrent bronchiolitis, pneumoconiosis and chronic bronchitis.

Clinical features Emphysema becomes symptomatic when approximately one-third of the lung parenchyma is affected. The patient is dyspnoeic, and in advanced cases the slightest physical activity can cause severe respiratory distress and cyanosis. Ventilation is forced and exhalation is particularly lengthy and difficult. The patient learns to push the air out through pursed lips, which automatically brings the upper abdominal muscles into play and helps maintain positive pressure in the airways. The hyperinflation of the lungs makes the chest barrel-shaped and rigid and exerts pressure on thoracic structures so that neck and facial veins are distended. There is a chronic, productive cough and wheezing.

Abnormal ventilation:perfusion ratios result in chronic hypoxia (low O_2 in tissues), hypercapnia (high CO_2) and polycythaemia. The clinical picture representing this is of peripheral cyanosis (due to low O_2) and facial flushing (because CO_2 is a vasodilator). Respiratory acidosis may occur in acute exacerbations of the disease, although the body may adapt its buffer system to some extent, given the chronic nature of the condition.

The patient is weakened by constant respiratory effort and becomes unable to tolerate normal basic activities of living.

MEDICAL MANAGEMENT

Investigations History, symptoms and clinical examination are diagnostic. Pulmonary function tests — spirometry (see p. 76) — indicate the type and extent of restricted function: reduction in all parameters indicates obstructive disease because of the prolonged exhalation time, and reduced FEV_1 (forced expiratory volume in 1 s) and FVC (forced vital capacity) indicate restrictive disease. Blood gas analysis and chest X-ray will confirm the stage and effect of the disease and influence treatment.

Treatment Oxygen is prescribed according to individual need and blood gas results (see Box 3.4). It is given in strictly controlled percentages because of the importance of the 'hypoxic drive' in COPD patients and the fact that too much oxygen can reduce this drive, resulting in CO_2 narcosis and respiratory arrest (see Box 3.6). Oxygen may be required constantly, both in hospital and at home.

Bronchodilator medication, corticosteroids and antibiotics are usually prescribed, and physiotherapy is essential.

3.6 Maintaining a clear airway by regular aspiration of tracheal secretions is a common nursing procedure. As a rule of thumb, the procedure should not be carried out for more than 10–15 s at a time, with adequate periods of rest in between. What is the reason for this? Refer back to residual volume and the composition of alveolar air.

A full description of tracheal suctioning can be found in Jamieson et al (2003).

3.7 How would you explain the concept of hypoxic drive and its importance for self-treatment to a patient with COPD who is about to be sent home on O_2 therapy?

Box 3.6

Carbon dioxide narcosis

In healthy people, when CO_2 levels rise, the respiratory rate increases. This increase allows excess CO_2 to be blown off by the lungs. However, in chronic obstructive pulmonary disease (COPD), where chronic ventilatory problems result in constantly high levels of arterial CO_2, this mechanism becomes blunted and eventually PCO_2 has no effect on the respiratory centre in the brain.

With severe CO_2 retention, the respiratory drive is created by the low PO_2 stimulating the carotid and aortic bodies. This is known as the 'hypoxic drive'. A high concentration of O_2 will suppress this hypoxic drive, and if PO_2 is raised even to normal, breathing becomes shallow and more and more CO_2 is retained, further depressing the respiratory centre, and a condition known as carbon dioxide narcosis develops. This is characterised by increasing drowsiness and eventual death.

The hypoxic drive must always be considered when O_2 is prescribed for patients with COPD. Usually this is not more than 24% of O_2 — slightly more than the 21% in room air — which is enough to improve oxygenation without eliminating the hypoxic drive. Prior to and during O_2 therapy, it is essential to determine arterial blood gas levels and to prescribe O_2 accordingly. The correct percentage is ensured by using controlled-flow O_2 masks and other appliances.

NURSING PRIORITIES AND MANAGEMENT: Emphysema and chronic bronchitis

Major considerations

During acute exacerbation the patient may be very ill. The nurse will be involved in administering prescribed therapy, monitoring the patient's condition and detecting any deterioration.

In advanced cases of emphysema, even when stable, the patient will constantly strive for breath and will need maximum reassurance and calm support. Lifestyle will be drastically curtailed and every effort should be made to make a realistic assessment of the patient's capabilities and need for assistance in designing a care plan. Limitations may be extreme and affect even minor activities such as eating, drinking, combing hair, brushing teeth and moving about the room. Time should be spent helping, observing and listening.

Nursing Care Plan 3.1 describes the case of M, a 70-year-old lady admitted to hospital with exacerbation of COPD. She lives at home with her husband as sole carer. Over a period of 4 days she has developed increasing shortness of breath, chest pain on coughing and purulent sputum. She stopped smoking 5 years ago. She is very anxious regarding admission.

Oxygen therapy

Oxygen should always be administered strictly according to the prescribed amount, because of the danger of switching

Nursing Care Plan 3.1 M: exacerbation of COPD

Nursing considerations	Action	Rationale	Expected outcome
1. Potential problem of deterioration in M's condition following admission	• Monitor vital signs for: – increase in heart rate and respiratory rate – decrease in S_aO_2 • Observe for: – increasing oedema – changes in mental state: confusion, restlessness – increasing dyspnoea with use of accessory muscles	Despite optimal medical therapy patients with respiratory failure may develop respiratory acidosis or worsening hypercapnia, requiring consideration for invasive or non-invasive ventilation	Stable vital signs S_aO_2 remains above 90% (or at level stated by medical staff) No evidence of deterioration
2. Dyspnoea	• Administer oxygen therapy as prescribed and humidify where appropriate	Maintain adequate oxygenation	Minimise level of distress from dyspnoea
	• Administer prescribed medications (antibiotics, steroids, bronchodilators)	Maximise therapy	Gradual return to 'normal' level of dyspnoea
	• Refer to physiotherapist to assist with sputum clearance	Active cycle of breathing techniques can be taught to aid secretion clearance	
	• Position sitting upright in bed supported by pillows or leaning forward on the overbed table	To enable maximum expansion of the lungs and increase movement of the thoracic cage	
	• Provide nurse call bell near to hand and assist with personal hygiene	Minimise dyspnoea by minimising exertion/effort	
3. Pyrexia	• Administer antipyretic as prescribed • Nurse in cool room	Maintain temperature within normal range	Patient is apyrexial and comfortable
4. Anxiety	• Give support and reassurance • Explain care being administered and realistic expected progress • Avoid medical jargon	Information giving will improve patient knowledge and understanding	As a result of improved understanding patient will be less anxious
5. Maintaining adequate hydration and nutrition	• Commence fluid balance chart and carry out nutritional assessment • Refer to dietitian to set individual goals and provide high energy supplements • Provide nutritious and easily eaten diet • Change to nasal cannulae during meals	Monitoring and adjusting diet and fluid intake ensures optimal nutrition and avoids need for intravenous fluids	Patient will be well nourished and hydrated

Continued ▶

Nursing Care Plan 3.1 M: exacerbation of COPD *(Continued)*

Nursing considerations	Action	Rationale	Expected outcome
6. Suitability for early discharge	• Refer to acute respiratory assessment team (or equivalent) for assessment for early supported discharge	M may be discharged home early under the care of Hospital at Home schemes, which provide continued monitoring and support for a limited period. Suitability depends on presence of other disease and level of physical functioning, social circumstances and M's preference	M is safely discharged home as early as possible
7. Potential problem of further hospital admissions with exacerbation of COPD	• Prior to discharge M and husband understand and are able to carry out medication and therapy regimens		
	• M has received advice on prompt response to symptoms of an exacerbation and on vaccines (flu/pneumococcal)	M is able to carry out treatment therapies and recognise when her respiratory function is compromised	Potential for admission with exacerbation of COPD will be reduced

off the patient's hypoxic drive. In hospital, a controlled ventimask is usually used. It is vital that the nurse understands this and can explain it in simple terms, especially if the patient is to use and control the oxygen supply at home. The patient and family will need both verbal and written information and plenty of opportunity for discussion (see Box 3.7). Nasal cannulae are often preferred when the patient is on long-term oxygen therapy (LTOT). At home, an oxygen concentrator machine is often used instead of oxygen cylinders with oxygen set at prescribed litres/min; use of nasal cannulae allows normal speaking, eating and drinking.

Non-invasive ventilation (NIV), delivered from a small ventilator via a mask, has been found to have significant beneficial effects for patients with acute exacerbations of COPD. In decompensated respiratory failure, the application of NIV can lead to improvement and prevent the need for intubation and mechanical ventilation. It is not suitable for individuals with impairment of swallow, cough or gag reflexes or excessive bronchial secretions (see Fig. 3.5 and Research Abstract 3.3).

Arterial blood gas (ABG) analysis

ABG analysis is the most reliable way to monitor blood gas levels and the nurse should be prepared to follow the required procedure for obtaining the blood sample (see Box 3.8). A basic understanding of normal levels is also assumed.

The nurse must be aware that cyanosis may be a late sign of hypoxia and should not be relied upon as an early indicator. As a rule of thumb, cyanosis is usually noticeable

Box 3.7

Patient teaching in O_2 therapy

Increasingly, patients go home on O_2 therapy and will need information on how to get a supply of medical O_2 and how to set it up at home. The following instructions, which should accompany the patient, should be discussed fully and reinforced on every contact.

Instructions for home use of oxygen

- Oxygen is highly combustible. Do not use it near a fire or open flame. Post a 'no smoking' sign on the cylinder and explain to relatives and friends the reason for so doing. Electrical appliances and kinetic toys that may produce a spark are also a source of danger.
- Adjust the flow meter to the flow rate the doctor prescribes and do not change it without the doctor's consent.
- Keep water in the humidifier to the correct level and change it daily.
- NOTIFY DOCTOR if any of the following occur:
  - — you have increased difficulty breathing
  - — you feel unusually restless or upset
  - — your breathing becomes irregular
  - — you feel abnormally drowsy
  - — your lips or fingernails look blue
  - — you have trouble concentrating or you become confused.

Do not assume that you will feel better if you take more oxygen. This may not be the case and you should consult your doctor or go to the nearest Emergency Department immediately if you experience any of these symptoms.

RESEARCH ABSTRACT 3.3

Positive benefits of non-invasive ventilation (NIV)

NIV can improve gas exchange, optimise lung volumes and reduce the work of breathing. NIV is indicated in acute exacerbation of COPD when respiratory acidosis (H^+ >45 mmol/L) persists despite medical treatment on controlled oxygen therapy. NIV is also indicated in respiratory failure due to chest wall deformity or neuromuscular disease.

British Thoracic Society (BTS) 2002 Standards of Care Committee. BTS Guideline: Non-invasive ventilation in acute respiratory failure. Thorax 57(3): 192–211

Box 3.8

Monitoring arterial blood gas levels

In the clinical situation, arterial blood gas levels can be monitored by laboratory blood gas analysis. Blood is drawn from the radial or femoral artery, or from an established arterial line, using a heparinised syringe. Care is taken not to draw air into the syringe, which is capped and sent for immediate analysis.

Following the procedure, unless blood has been obtained from an arterial line (A-line), firm pressure must be applied to the puncture site for at least 5 min to ensure haemostasis under arterial pressure.

If on oxygen therapy, it is important to make sure that the patient has been receiving the prescribed amount for at least 15 min before and during the time when the sample is drawn. If the patient has been on a mechanical ventilator for a session of intermittent positive pressure breathing (IPPB), the nurse should wait at least 20 min before taking a sample and 20 min after commencing ventilation or post-tracheal suctioning. The prescribed amount of oxygen or the IPPB should be noted on the laboratory request form.

when the concentration of deoxygenated haemoglobin in blood exceeds 50 g/L. The distinction between central and peripheral cyanosis is an important one: central cyanosis is due to low oxygen content of the arterial blood (hypoxic hypoxia) and can be determined by inspecting the tongue and mucous membranes of the eye in addition to the skin; peripheral cyanosis is due to a sluggish circulation (stagnant hypoxia) where release of oxygen from the blood is slowed down even though the arterial oxygen content may be normal, as for example in cardiac failure and shock.

For further information, see Margereson & Esmond (1997a,b,c).

Positioning and breathing

The patient will be more comfortable sitting up and well supported by pillows. Breathing may be easier leaning forward on an overbed table with elbows extended to the side. Emphysematous patients tend to take short, shallow breaths and should be taught diaphragmatic breathing to improve and slow down ventilation. Pursed-lip exhalation is helpful because it improves positive airway pressure and brings the abdominal muscles into play.

Chest physiotherapy

The physiotherapist will teach the patient deep breathing and coughing exercises and postural drainage techniques and may perform frappage, patterns of clapping the chest wall, to loosen tenacious secretions. Deep breathing and coughing exercises should be reinforced by nursing staff and the patient should be taught to perform them independently and to continue them after discharge home.

Patient education

The patient should understand the disease process and the aims of treatment. If the disease is in the early stages, removal of predisposing factors such as cigarette smoking will help to prevent further deterioration. If the condition is advanced, the patient may need help to adapt to a severely compromised lifestyle and to preserve what pulmonary function remains.

Structured pulmonary rehabilitation programmes that include exercise, education, physiotherapy, nutritional support, smoking cessation and psychological support can be a way of ensuring that the patient achieves an optimal level of independence and functioning in the community. Structured programmes require an organised multidisciplinary approach, involving respiratory nurses and other members of the health care team. Trials have shown that such programmes have a positive effect on the person's quality of life (British Thoracic Society 2001a, Lacasse et al 2003).

Asthma

Asthma is a common chronic inflammatory condition of the airways, characterised by bronchospasm, severe dyspnoea, wheezing, chest tightness and expiratory exertion. As a result of inflammation, the airways are hyperresponsive and narrow easily in response to a wide range of provoking stimuli. Although much is known about asthma, it is a complex condition about which much remains to be understood.

CASE HISTORY 3.1(A)

C

C was brought into the Emergency Department one night by his wife, and this is the account of his first severe asthma attack:

'I just couldn't get my breath ... I was panicking and really scared. My chest felt it was in a steel vice ... I was wheezing and gasping for air and just couldn't get my breath. The nurse took one look and got into action straight away. The room was swirling ... I thought I was a gonner ... and I passed out.

When I came to, they'd put some powerful medication through a drip in my arm and an oxygen mask on my face.

I began to feel the panic again but then realised that the breathing was getting easier, and that calmed me down. That was my first bad attack of asthma and I never want to go through that again. I ended up in the Intensive Care and my family were worried sick.

Two years before this we'd been through a rough time ... I was made redundant from my regular job ... been unemployed then got this other job which I'm not happy with ... there's a lot of dust and fumes around. I'd started to wheeze and cough a fair bit and the GP said it was asthma ... which was a bit of a shock at my age — 40 years old! It must run in the family, though. Dad has asthma but I thought I'd got away with it. Anyway, the doctor had given me some pills and a puffer, which helped at times but I must admit I wasn't really good at taking them. This severe attack, though, made me want to know more about it so that it doesn't happen again.'

Broadly speaking, there are two types of bronchial asthma: extrinsic and intrinsic. The extrinsic form occurs in children and young adults who are hypersensitive to foreign proteins such as dust mites, pollens, animal dander and feathers. Familial allergic tendencies can often be traced. Intrinsic or chronic asthma occurs later in life and is often associated with chronic respiratory inflammatory disease. Although there may be no history of childhood asthma, there may be a family history of asthma and allergic tendencies (see Case History 3.1(A)). In many cases the role of allergens is still suspected.

A large group of asthma sufferers are found to be vulnerable to stimuli of both extrinsic and intrinsic origin. There is increasing evidence that the psychosomatic element is negligible and can no longer be regarded as a major causative factor in most cases (British Thoracic Society/Scottish Intercollegiate Guidelines Network 2003).

Research suggests that there is a critical trigger time early in the development of asthma when, if steroid therapy is introduced, the process can not only be controlled but also 'turned off' so that the condition does not progress or recur. However, there continues to be some resistance to steroid therapy from the general public, especially in relation to treating children. This is because of the misconceived fear of side-effects, which in fact are minimal with inhaled steroids (British Thoracic Society/Scottish Intercollegiate Guidelines Network 2003).

For current incidence of asthma in the UK, visit www.asthma.org.uk.

PATHOPHYSIOLOGY

Immunoglobulin E (IgE) is present in small amounts in normal sera but in increased amounts in asthma sufferers. In allergic extrinsic asthma, the disease process involves inhalation of antigens (allergens) which are absorbed by the bronchial mucosa and trigger production of IgE antibodies. These antibodies bind to mast cells and basophils around the bronchial blood vessels. When the allergen is encountered again, the antigen–antibody reaction releases histamines and bradykinin, resulting in bronchial muscle spasm, oedema and excessive secretion of thick mucus. In many cases, the severity of attacks lessens with age and good treatment, unless other factors are involved.

There are various theories of the pathogenesis of intrinsic asthma. Allergens may be implicated. Whatever the cause, the bronchi and bronchioles are chronically inflamed, oedematous, full of mucus and subject to bronchospasm. Air is trapped in the alveoli and expiration is difficult. The disease can be progressive and impaired ventilation can result in hypoxia, hypertension and right-sided heart failure.

Clinical features Asthma attacks can last for minutes, hours or days (status asthmaticus). They manifest as paroxysms of severe ventilatory difficulty with rapid, laboured breathing accompanied by wheezing. Expiration is forced and prolonged due to bronchospasm, hyperinflated lungs and trapped alveolar air. This may be accompanied by a dry or moist cough. There may be extreme anxiety, sweating, dyspnoea, orthopnoea and peripheral cyanosis with hypoxia and hypercapnia. Tachycardia is common because of anxiety and hypoxia and may be increased by bronchodilatory medication such as salbutamol (Hoskins et al 2000). If there is no response to treatment, exhaustion will occur rapidly and may be followed by respiratory failure.

MEDICAL MANAGEMENT

Investigations Diagnosis is by typical clinical presentation and past history. After an attack has subsided, lung function tests such as FEV_1 will be helpful in establishing the degree of impairment and in monitoring response to treatment. Prolonged FEV_1 indicates loss of elasticity of lung tissue. Chest X-rays will indicate clarity of lung fields and size of the heart. Skin sensitivity tests and a history of exposure to specific allergens may help in isolating and avoiding triggering factors.

Treatment Management of a patient with asthma is best coordinated by referring to the British Thoracic Society (BTS) guidelines (2003a,b,c) (see Figs 3.6–3.8). The guidelines are readily available to all GPs, Emergency Departments (EDs) and respiratory units and provide step-by-step guidance on treatment.

Depending on the severity of the asthma attack, the patient may be managed at home or be admitted to the local hospital Emergency Department. Respiratory status will be assessed by recording the peak expiratory flow (PEF), the type and rate of respirations and ability to complete a sentence without becoming breathless. The patient's general appearance and pulse rate will also indicate the level of respiratory distress.

Management of acute severe asthma in adults in general practice

Many deaths from asthma are preventable, but delay can be fatal.
Factors leading to poor outcome include:
- Doctors failing to assess severity by objective measurement
- Patients or relatives failing to appreciate severity
- Under use of corticosteroids

Regard each emergency asthma consultation as for acute severe asthma until it is shown to be otherwise.

Assess and record:
- Peak expiratory flow (PEF)
- Symptoms and response to self treatment
- Heart and respiratory rates
- Oxygen saturation (by pulse oximetry, if available)

Caution: *Patients with severe or life threatening attacks may not be distressed and may not have all the abnormalities listed below. The presence of any should alert the doctor.*

	Moderate asthma	Acute severe asthma	Life threatening asthma
INITIAL ASSESSMENT			
	PEF > 50% best or predicted	PEF 33–50% best or predicted	PEF < 33% best or predicted
FURTHER ASSESSMENT			
	• Speech normal • Respiration < 25 breaths/min • Pulse < 110 beats/min	• Can't complete sentences • Respiration ≥ 25 breaths/min • Pulse ≥ 110 beats/min	• SpO_2 < 92% • Silent chest, cyanosis, or feeble respiratory effort • Bradycardia, dysrhythmia or hypotension • Exhaustion, confusion or coma
MANAGEMENT			
	Treat at home or in surgery and ASSESS RESPONSE TO TREATMENT	**Consider admission**	**Arrange immediate ADMISSION**
TREATMENT			
	High dose $ß_2$ bronchodilator: - Ideally via oxygen-driven nebuliser (salbutamol 5 mg or terbutaline 10 mg) - Or via spacer or air-driven nebuliser (1 puff 10–20 times) If PEF > 50–75% predicted/best: • Give prednisolone 40–50 mg • Continue or step up usual treatment If good response to first nebulised treatment (symptoms improved, respiration and pulse settling, and PEF > 50%) continue or step up usual treatment and continue prednisolone	• Oxygen 40–60% if available • High dose $ß_2$ bronchodilator: - Ideally via oxygen-driven nebuliser (salbutamol 5 mg or terbutaline 10 mg) - Or via spacer (1 puff $ß_2$ agonist via a large volume spacer and repeat 10–20 times) or air-driven nebuliser • Prednisolone 40–50 mg or IV hydrocortisone 100 mg • **If no response in acute severe asthma: ADMIT**	• Oxygen 40–60% • Prednisolone 40-50 mg or IV hydrocortisone 100 mg immediately • High dose $ß_2$ bronchodilator and ipratropium - Ideally via oxygen-driven nebuliser (salbutamol 5 mg or terbutaline 10 mg and ipratropium 0.5 mg) - Or via spacer (1 puff $ß_2$ agonist via a large volume spacer, repeated 10–20 times) or air-driven nebuliser
	Admit to hospital if any: • life threatening features • features of acute severe asthma present after initial treatment • previous near fatal asthma **Lower threshold for admission if:** afternoon or evening attack, recent nocturnal symptoms or hospital admission, previous severe attacks, patient unable to assess own condition, or concern over social circumstances	**If admitting the patient to hospital:** • Stay with patient until ambulance arrives • Send written assessment and referral details to hospital • Give high dose $ß_2$ bronchodilator via oxygen-driven nebuliser in ambulance	**Follow up after treatment or discharge from hospital:** • **GP review within 48 hours** • Monitor symptoms and PEF • Check inhaler technique • Written asthma action plan • Modify treatment according to guidelines for chronic persistent asthma • Address potentially preventable contributors to admission

Fig. 3.6 Management of acute severe asthma in adults in general practice. (Reproduced from British Thoracic Society 2003a, with permission from the BMJ Publishing Group.)

Treatment in the Emergency Department will be in accordance with the BTS guidelines (2003b; see Fig. 3.7). Reference to the chart indicates that the treatment plan extends over a 2-h period, but the first 5 min are crucial. Response to treatment will determine whether the patient is admitted to hospital or discharged home. If discharged, the GP will follow the BTS guidelines for general practice (2003a; see Fig. 3.6). If admitted, the medical staff will follow the BTS guidelines for management of acute asthma in hospital (2003c; see Fig. 3.8).

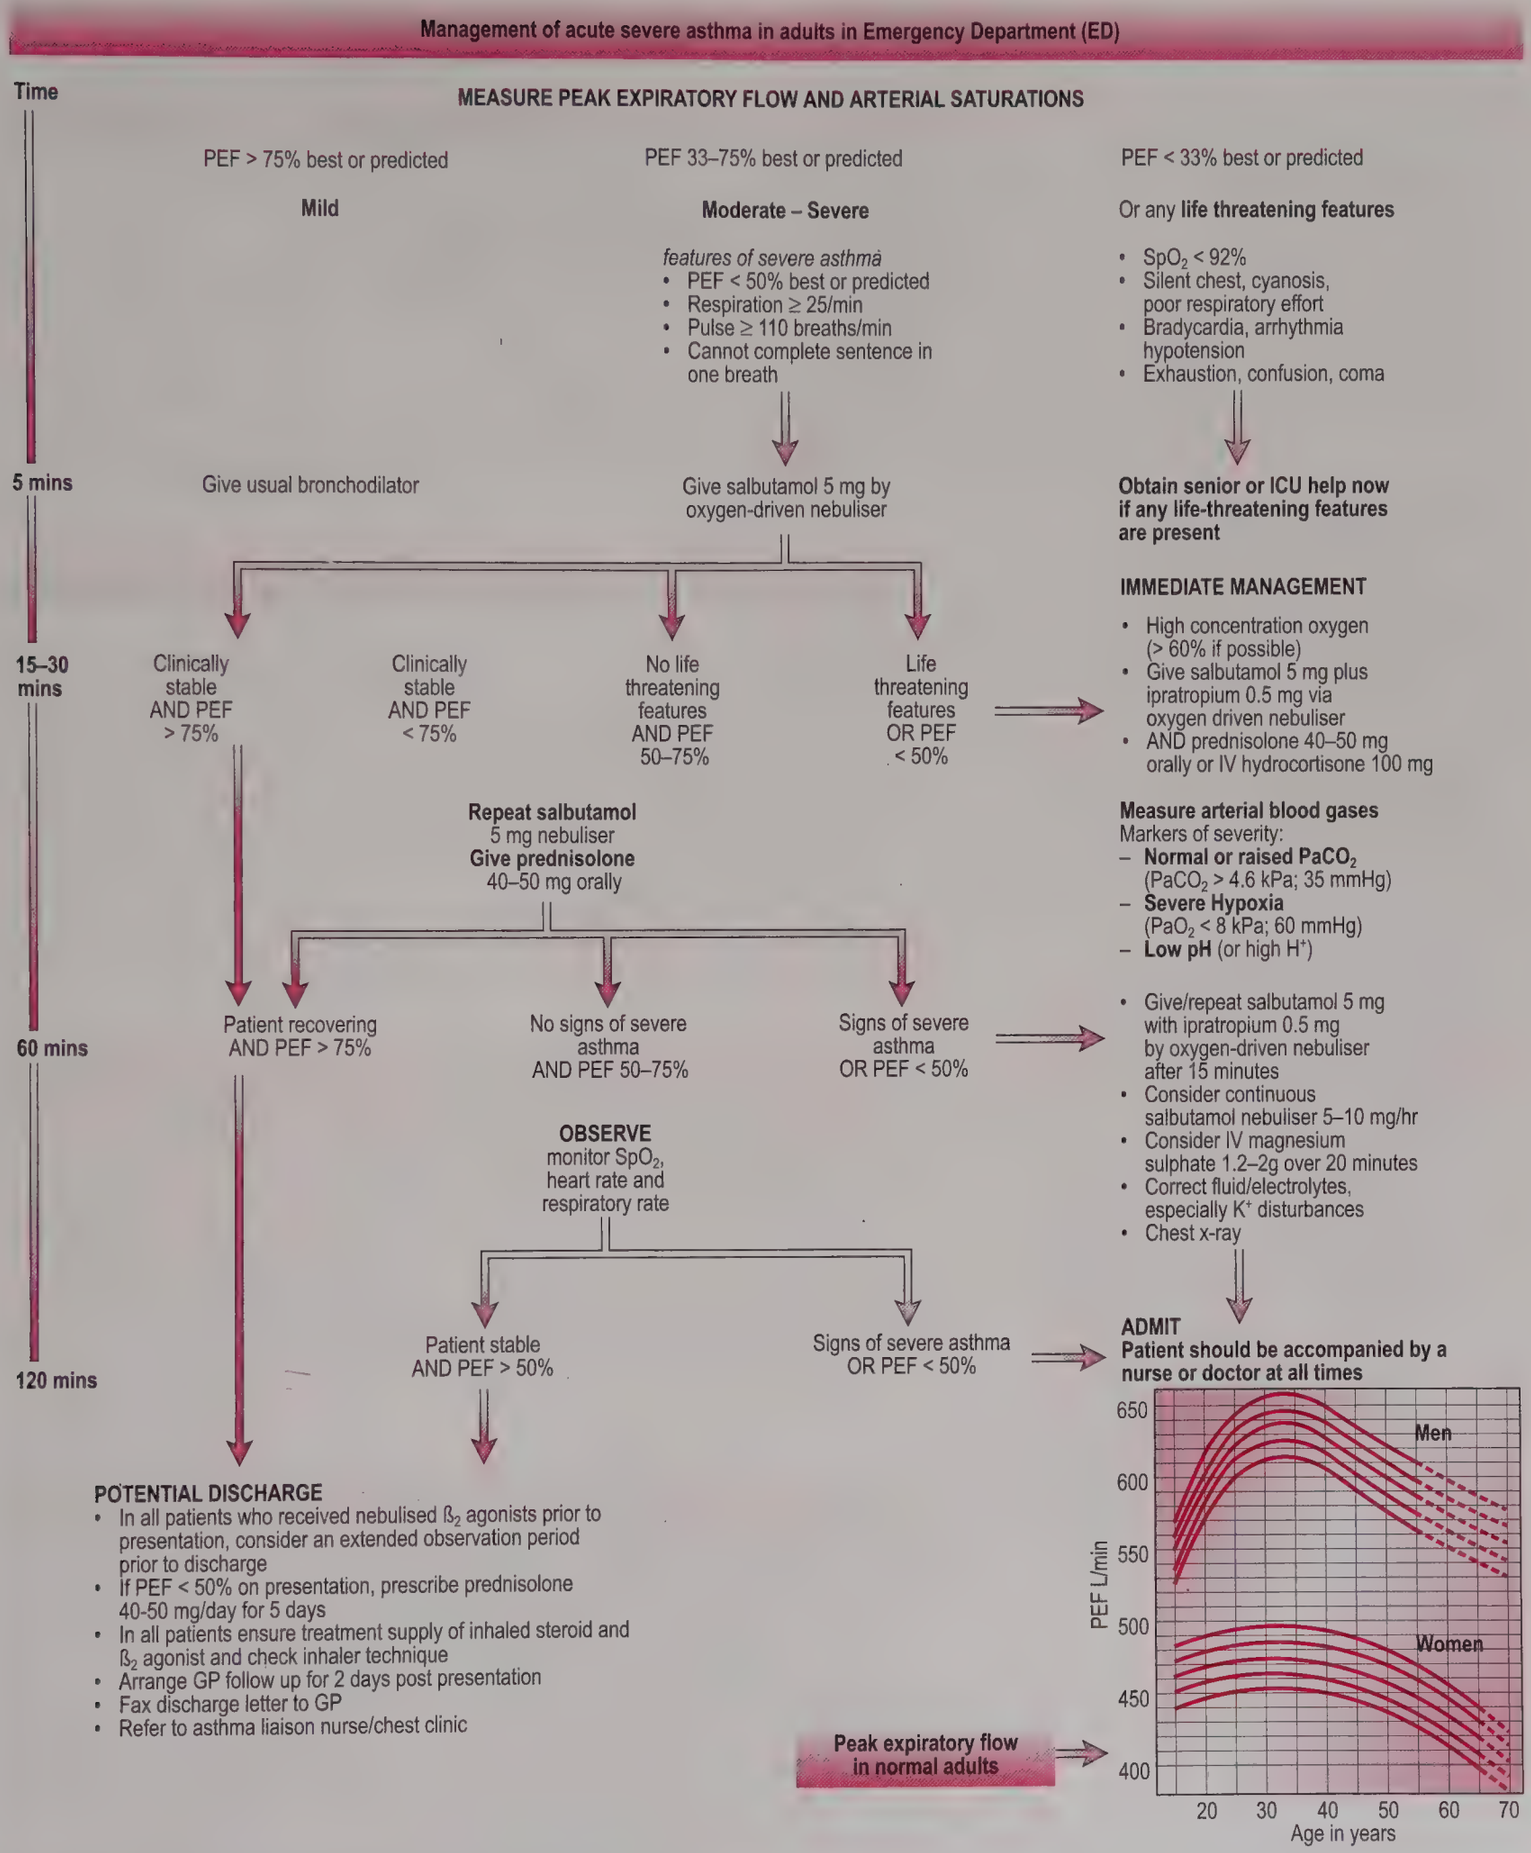

Fig. 3.7 Management of acute severe asthma in adults in the Emergency Department. (Reproduced from British Thoracic Society 2003b, with permission from the BMJ Publishing Group.)

Management of acute severe asthma in adults in hospital

Features of acute severe asthma
- Peak expiratory flow (PEF) 33–50% of best *(use % predicted if recent best unknown)*
- Can't complete sentences in one breath
- Respirations ≥ 25 breaths/min
- Pulse ≥ 110 beats/min

Life threatening features
- PEF < 33% of best or predicted
- SpO_2 < 92%
- Silent chest, cyanosis, or feeble respiratory effort
- Bradycardia, dysrhythmia, or hypotension
- Exhaustion, confusion, or coma

If patient has any life threatening feature, measure arterial blood gases. No other investigations are needed for immediate management.

Blood gas markers of a life threatening attack:
- Normal $PaCO_2$ (4.6–6 kPa, 35–45 mmHg)
- Severe hypoxia: PaO_2 < 8 kPa (60 mmHg) irrespective of treatment with oxygen
- A low pH (or high H^+)

Caution: Patients with severe or life threatening attacks may not be distressed and may not have all these abnormalities. The presence of any should alert the doctor.

Near fatal asthma
- Raised $PaCO_2$
- Requiring IPPV with raised inflation pressures

IMMEDIATE TREATMENT

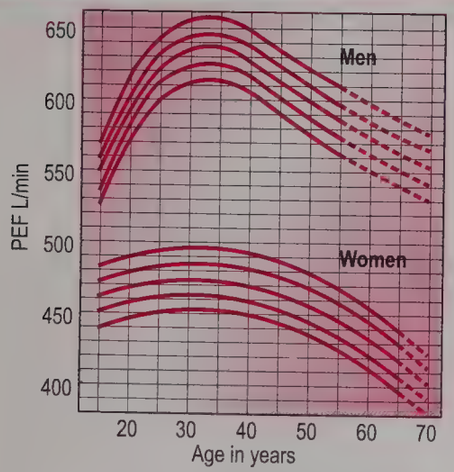
- Oxygen 40–60% (CO_2 retention is not usually aggravated by oxygen therapy in asthma)
- Salbutamol 5 mg or terbutaline 10 mg via an oxygen-driven nebuliser
- Ipratropium bromide 0.5 mg via an oxygen-driven nebuliser
- Prednisolone tablets 40–50 mg or IV hydrocortisone 100 mg or both if very ill
- No sedatives of any kind
- Chest radiograph only if pneumothorax or consolidation are suspected or patient requires IPPV

IF LIFE THREATENING FEATURES ARE PRESENT:

- Discuss with senior clinician and ICU team
- Add IV magnesium sulphate 1.2–2 g infusion over 20 minutes *(unless already given)*
- Give nebulised $ß_2$ agonist more frequently e.g. salbutamol 5 mg up to every 15–30 minutes or 10 mg continuously hourly

⇓

SUBSEQUENT MANAGEMENT



IF PATIENT IS IMPROVING continue:
- Oxygen 40–60%
- Prednisolone 40–50 mg daily or IV hydrocortisone 100 mg 6 hourly
- Nebulised $ß_2$ agonist and ipratropium 4–6 hourly

IF PATIENT NOT IMPROVING AFTER 15–30 MINUTES:
- Continue oxygen and steroids
- Give nebulised $ß_2$ agonist more frequently e.g. salbutamol 5 mg up to every 15–30 minutes or 10 mg continuously hourly
- Continue ipratropium 0.5 mg 4–6 hourly until patient is improving

IF PATIENT IS STILL NOT IMPROVING:
- Discuss patient with senior clinician and ICU team
- IV magnesium sulphate 1.2–2 g over 20 minutes *(unless already given)*
- Senior clinician may consider use of IV $ß_2$ agonist or IV aminophylline or progression to IPPV

⇓

Peak expiratory flow in normal adults

MONITORING

- Repeat measurement of PEF 15–30 minutes after starting treatment
- Oximetry: maintain SpO_2 > 92%
- Repeat blood gas measurements within 2 hours of starting treatment if:
  - initial PaO_2 < 8 kPa (60 mmHg) unless susequent SpO_2 >92%
  - $PaCo_2$ normal or raised
  - Patient deteriorates
- Chart PEF before and after giving $ß_2$ agonist and at least 4 times daily throughout hospital stay

Transfer to ICU accompanied by a doctor prepared to intubate if:
- Deteriorating PEF, worsening or persisting hypoxia, or hypercapnoea
- Exhaustion, feeble respirations, confusion or drowsiness
- Coma or respiratory arrest

⇓

DISCHARGE

When discharged from hospital patients should have:
- Been on discharge medication for 24 hours and *have had inhaler technique checked and recorded*
- PEF >75% of best or predicted and PEF diurnal variability < 25% *unless discharge is agreed with respiratory physician*
- Treatments with **oral and inhaled steroids** in addition to bronchodilators
- Own PEF meter and **written asthma action plan**
- GP follow up arranged *within 2 working days*
- Follow up appointment in respiratory clinic *within 4 weeks*

Patients with severe asthma *(indicated by need for admission)* **and adverse behavioral or psychosocial features are at risk of further severe or fatal attacks**
- Determine reason(s) for exacerbation and admission
- Send details of admission, discharge and potential best PEF to GP

Fig. 3.8 Management of acute severe asthma in adults in hospital. (Reproduced from British Thoracic Society 2003c, with permission from the BMJ Publishing Group.)

The best treatment for asthma is avoidance of known causal factors and provision of patient education.

The majority of patients are treated by their GP and can administer their own treatment at home and avoid asthma attacks. Severe cases are referred to specialist respiratory units. Once diagnosed, if patients do not respond to the usual prescribed treatment and notice a significant drop in their peak flow readings or experience increasing difficulty, they may present and self-admit to the respiratory unit where they are known or to the nearest Emergency Department.

NURSING PRIORITIES AND MANAGEMENT: Asthma

Major considerations

The first priority is to ensure that the individual experiencing an asthma attack is seen by a doctor as quickly as possible. The condition can deteriorate rapidly.

Giving psychological support

An attack of asthma is extremely frightening. The patient will be fighting for breath and is often panic stricken. It is vital for the nurse to maintain a calm and reassuring manner and to stay with the patient throughout the attack. A sound knowledge base will enable the nurse to anticipate the course of the attack and the likely reactions to it and so help the patient to remain calm. Nebulised therapy is the method of choice in an acute episode of asthma (see Box 3.9 and Fig. 3.9).

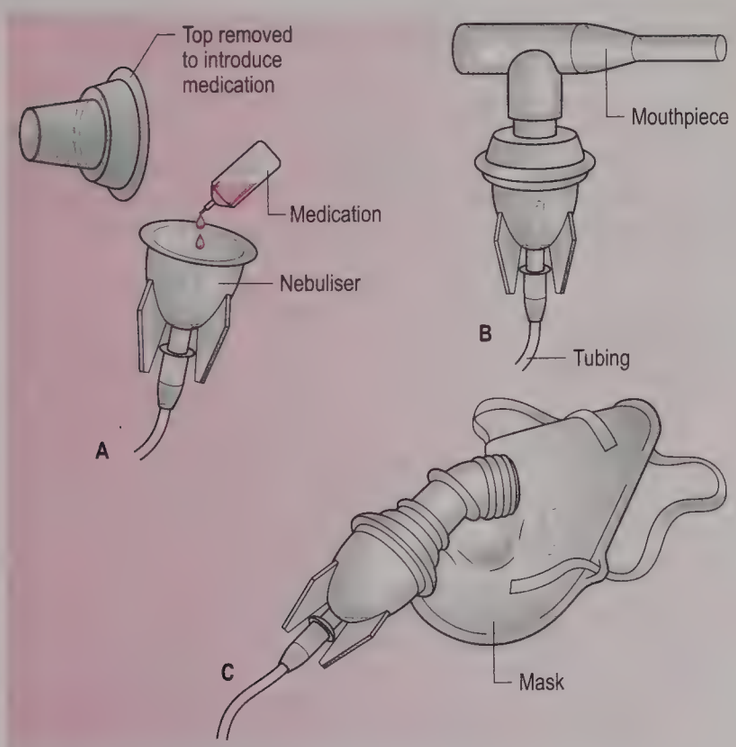


Fig. 3.9 Nebulisers. A: Nebuliser taken apart to introduce medication. B, C: Nebuliser attached to mouthpiece or face mask depending on drug to be used and/or patient preference. (Based on an original drawing by Nicole Rooth, Moreton Bay Design Co., Australia, with permission.)

Box 3.9

Assisting a patient to use a nebuliser

A nebuliser attached to a flow of oxygen or air converts a liquid into an aerosol mist. The medication is prescribed by the doctor. The procedure may be coordinated with chest physiotherapy, and peak flow of tidal volume may be measured and recorded before and after the treatment. The equipment is assembled according to the procedure illustrated in Figure 3.9.

The medication is checked and, if two medications are prescribed, they should not be mixed together. Separate nebulisers should be used and the bronchodilator medication given first.

- The equipment and purpose of the medication is explained to the patient. The medication is put into the nebuliser, which is assembled and attached to the air supply. If oxygen is ordered, a 'no smoking' sign is displayed and the reason explained. If the patient has chronic obstructive pulmonary disease (COPD), air is used instead of oxygen because of the danger of disrupting the patient's hypoxic drive (see Box 3.6).
- Peak flow is measured if required and the best of three attempts is charted.
- The patient sits up in a comfortable position.
- The air flow meter is adjusted to 5 L to ensure vaporisation of the medication.
- The nurse ensures that there is a fine vapour coming from the nebuliser and encourages the patient to breathe it in through the mouthpiece if possible. If this is too difficult, the patient may use an oxygen mask instead. The patient is instructed to breathe normally, taking an occasional deep breath. If the patient is on a respirator, a nebuliser can be introduced into the ventilator circuit.
- The nurse should stay with the patient until all the medication is nebulised and observe the respirations, checking how the patient feels and encouraging them to cough and expectorate if there is mucus in the lungs. A clean sputum container should be ready to hand.
- Half an hour after the treatment, peak flow readings are taken again and the best of three is charted.
- The procedure is documented and the equipment washed and dried and stored in the patient's locker until needed again.

Positioning and monitoring

The patient should sit up well supported by pillows or lean forward on an overbed table. Vital signs, oxygen therapy and ABGs should be monitored constantly and interpreted intelligently. The nurse should be alert for any sign of deterioration.

Prevention and treatment of non-acute asthma

Medication to prevent and treat asthma is also given via inhaler devices. The nurse, preferably with specialised education in asthma, should ensure that the patient is assessed for the correct inhaler device, understands the therapy and receives training in the correct use of the device. The choice may be influenced by the choice of medication or the patient's ability to use it. Figure 3.10 illustrates a selection of devices available.

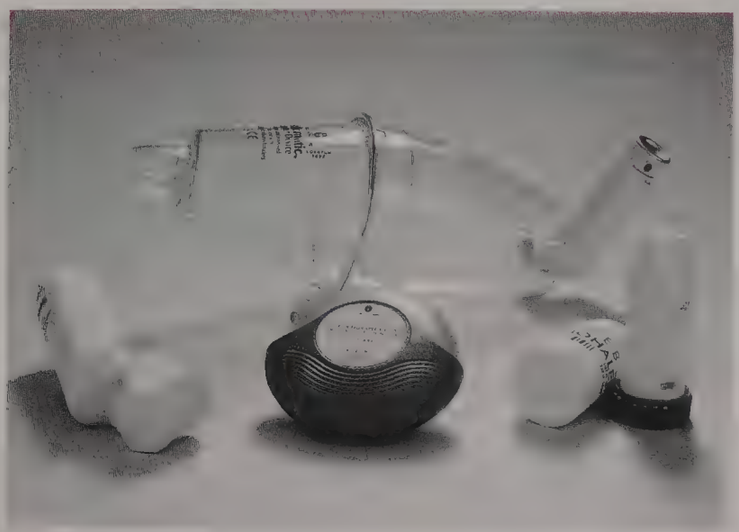

Fig. 3.10 Inhaler devices. Front row left to right: Easy Breathe Inhaler; Accuhaler; Turbohaler. Behind these is the Volumatic device with metered dose inhaler (MDI) attached. (Reproduced with kind permission of Medical Illustration Services, North Glasgow University NHS Hospitals Trust.)

Assisting with inhalation therapy

A common cause of failed home treatment is that the patient does not use the inhaler correctly and therefore does not get the full dose of the medication (Sayer 1999).

Adherence to prescribed treatment may be difficult to assess. Emphasis in therapy is on the concept of concordance which implies a negotiated agreement between nurse and patient. Non-adherence may be due to failure of the nurse to provide a treatment regimen which is acceptable and understood by the patient.

Health education

Practice nurses, community nurses and hospital nurses are in a good position to make a realistic assessment of patient capabilities and inhaler technique and to give advice accordingly. The effectiveness of received medication can be determined by measuring lung function (peak flow) before and after inhalation. Patients can be taught to do this themselves and to record the results.

For the hospitalised patient, a multidisciplinary care plan and critical pathway based on the latest British Thoracic Society's asthma guidelines (2003c) should be developed to ensure research-based practice, consistency of care and cost-effectiveness (see Case History 3.1(B) and Multidisciplinary Care Plan 3.2).

Specialist training

Audit has shown that specialist care of adult patients admitted with asthma is associated with improved outcome. The BTS recommends that health care personnel such as ambulance officers, ED staff, practice nurses and school nurses should have specific education in asthma care and be enabled to follow the guidelines that they recommend (see Figs 3.6–3.8).

LUNG CANCER

Lung cancer can be of primary origin or can occur as secondary metastatic spread from other primary sources.

CASE HISTORY 3.1(B)

C's story (cont'd)

At the team meeting just before C was discharged from hospital, he made the following comments:

'I just did not realise how important it was to know about asthma — and in particular to know about how it affects me and how the medications work. I hadn't given it much thought really before this severe attack and usually just had a few more puffs with the inhaler when I thought I needed them.

When I first came to this ward I remember how surprised I was that the other patients seemed to know so much and take such an active part in their own treatment. I thought you came into hospital to have things done to you, not to learn how to do it yourself, but I see now. They treated the unit a bit like a "club". Mostly they'd been in before and their good-natured "advice" was a great help, especially when I got depressed about being stuck with asthma. I realised it wasn't the end of the world.

Knowing about asthma makes me feel more in control; and now I've learnt how to use the inhaler properly and the peak flow meter, and you've explained what my safe limits are, I shall know what to do in future. Having it all written down, too, is somehow reassuring. I certainly don't want another episode like this last one, so it's worth taking a bit more time to understand things and look after myself. I don't intend to let asthma rule my life, though, but I will change my job and try to look after my general health more.'

PATHOPHYSIOLOGY

Lung cancer is classified according to basic cell type, i.e. squamous cell adenocarcinoma (the most common), undifferentiated carcinoma, and large- and small-cell carcinoma. The tumour may present as a cauliflower-shaped mass which slowly infiltrates the lung parenchyma. Because this form of cancer is difficult to detect in the early stages, it has a high potential for metastatic spread before being discovered.

Common presenting symptoms The patient presents with a persistent cough of several months' duration which may be accompanied by haemoptysis (bloodstained sputum), chest pain, hoarseness and breathlessness. There may also be weight loss, anaemia, pleural effusion and bone pain. The patient will look generally unwell.

Box 3.10

Cancer support

Patients with cancer move through a number of health care settings in the course of their cancer journey, during which time they will become involved with a number of health care professionals who will address their needs. For this, there needs to be a collaborative effort from all the teams involved and clear, effective lines of communication.

There should be regular evaluation and modification of the care plan to ensure that individual care requirements are implemented and that the appropriate nursing, medical and allied health professionals (AHP) and hospice support are being accessed to provide this package of care. Support will be available from oncology specialist nurses, the palliative care team, the pain control team, Macmillan nurses, district nurses, physiotherapists, dietitians, occupational therapists and social workers (see Chs 31 and 33).

Multidisciplinary Care Plan 3.2 C: acute asthma

Problem focus	Medical	Nursing	Patient	Physiotherapy	Social work
Transfer from ICU for stabilisation and establishment of self-care treatment regimen following an acute severe asthma attack	• Priority if called to review patient's condition	Coordinate team care • educative-supportive role • priority to any sign of deteriorating condition. Action STATIM • monitor vital signs and respiratory status		• Ensure clear airway – deep breathing, coughing exercises, use of ancillary muscles	• Problem with work environment
Patient involvement and understanding essential regarding: • disease process • symptoms • management • interpretation of symptoms and PEF • specific medication actions and side-effects • written self-care plan and action to be taken when pre-arranged signs of deterioration are evident	• Select and prescribe treatment and medications • Discuss with patient and care team: – asthma disease process – treatment and action of medications – taking and monitoring peak expiratory flow (PEF) – significance – nebuliser technique • Monitor ABGs • Establish individual acceptable range PEF • Establish written self-care plan for patient and action to be taken	• Reassurance • Reinforce and repeat doctor's explanations in lay terms • Teach use of peak flow meter. Repeat significance of PEF readings • Teach use of nebuliser and inhaler • Coordinate physio and medication times • Assist with ABGs • Medications as prescribed • Monitor effects • Assist C to work out role in care team and express questions and concerns • Contact Asthma Campaign • Assist with written self-care plan	• Cooperate with health care team to learn more about: – asthma – treatment – management – using nebuliser/inhaler – recording PEF and what readings signify Work out action to take at set points • Ask questions – discuss results • Practise use of equipment • Talk to social worker and get advice on work and family problems • Help to work out written self-care plan • Aim to control asthma and avoid further severe attacks	• Coordinate physiotherapy with inhalation regimen. Assist with nebuliser technique • Discuss general fitness • Teach C respiratory mechanics and exercises	• Advise on family benefits • Funding for peak flow meter • Advise on job change

MEDICAL MANAGEMENT

Investigations Diagnosis is confirmed by auscultation (listening to the chest with a stethoscope), chest X-ray or CT scan and sputum cytology. A bronchoscopy (direct visualisation of the trachea and bronchi using a bronchoscope, i.e. a flexible tube with a light source) may be performed. A small piece of lung tissue (biopsy) may be taken via the bronchoscope and sent for pathology.

Treatment A full explanation of the diagnosis and prognosis will be given to the patient and family so that an informed decision can be made regarding treatment.

Approximately 15% of primary lung tumours can be treated successfully by surgical removal. This will involve either lobectomy (removal of the affected lobe) or pneumonectomy (removal of the whole lung) followed by cytotoxic chemotherapy. Where there is invasive and metastatic spread, the treatment is usually conservative, involving chemotherapy, deep X-ray, intervention to alleviate symptoms and pain control (see Chs 19 and 31, and Box 3.10).

NURSING PRIORITIES AND MANAGEMENT: Care of the patient following lobectomy

General perioperative care is as described in Chapter 26. The reader should also review the position and function of the structures illustrated in Figure 3.1.

Specific considerations

The following points are of particular importance in postoperative management following lobectomy:

- The physiotherapist will manage the pre- and postoperative chest physiotherapy; however, the role of nursing staff in giving assistance and ensuring continuity is extremely important.
- Chest surgery can be very frightening and the patient and family will need careful explanations and constant reassurance.
- In order to allow full expansion of the operated lung, the patient must be nursed in a semi-upright position, well supported with pillows, following a lower lobectomy. Following an upper lobectomy, the patient must be nursed in the position requested by the surgeon; this will be detailed in the postoperative instructions.
- If oxygen therapy is required it will be prescribed by the doctor. The nurse will monitor the equipment, the amount given and the effect of the therapy on the patient.
- There are usually two chest drains in situ, one anterior to the apex and one posterior to the base. These are attached to underwater seal drainage and pleural suction (see Fig. 3.11). Their purpose is to allow air to escape from the lobectomy space and to allow drainage of haemoserous fluid caused by the surgical procedure. Management of underwater seal drainage is discussed in detail in Box 3.11.
- The patient can sit out of bed and walk short distances while the drains are in place, but care must be taken not to put traction on the tubes and to keep the drainage system below the level of the chest. Two pairs of chest drain clamps should accompany the patient at all times.

NURSING PRIORITIES AND MANAGEMENT: Care of the patient following pneumonectomy

Specific considerations

Postoperative positioning

It is vital to find out whether the pericardium has been opened during the operation or not. If it has been opened, the patient must not be allowed to lie on the operated side because of the danger of herniation of the heart through the pericardium and mediastinal shift, i.e. shifting of the heart

Box 3.11

Care of underwater seal drainage

Basic principles

The drainage system is sterile throughout. It is completely assembled prior to the chest drain being inserted. Connections are airtight and sealed with transparent tape to allow inspection. Water level in the drainage device is determined using the manufacturer's instructions. The water acts as a valve and prevents air re-entering the pleural space. The outlet tube allows expelled air to escape. Drainage may be by gravity and respiratory movements or may be assisted by attaching low grade suction to the outlet tube. Single-, two- and three-bottle systems are available.

The chest drain is sutured in place and has an additional purse-string suture around the skin entry site. A sterile dressing surrounds the entry site.

Nursing management

- Give a full explanation and reassurance to the patient to allay anxiety and gain cooperation.
- Assess for and provide appropriate pain relief.
- Keep the patient sitting up, well supported by pillows whilst in bed, and encourage deep breathing and coughing exercises as discussed with the physiotherapist.
- Ensure that two pairs of chest drain clamps accompany the patient at all times in case of accidental disconnection. If the system becomes disconnected, air will be drawn into the interpleural space, extending the pneumothorax.
- When clamping is necessary, it is critical that the clamps are not left on for more than the essential period as a tension pneumothorax may develop. The patient must never be left unattended while the tubing is clamped.
- Ensure that the drainage system is always kept below the level of the chest to prevent back-flow into the interpleural space.
- Check regularly to ensure that the system is airtight and the water level is correct.
- Note the presence of bubbling. If the tube is bubbling, air is being evacuated from the pleural space. If there are no bubbles, there should be a swinging movement of fluid in the down-tube which reflects the pressure changes in the pleural cavity with respiration. The amount of fluid swing should lessen as the lung re-expands. If there are no bubbles and there is no fluid swing, this may mean that either the drainage tube is blocked or that the lung is fully expanded. Chest X-ray will confirm.
- Prevent accidental disconnection by:
  - — supporting the chest drain on the chest wall with adhesive tape, taking care to loop the tube and not bend it
  - — securing the tubing to the bedclothes or the patient's clothes with tape and pins, taking care not to pierce the tubing
  - — stabilising the drainage device by housing it in a special cradle on the side of the bed or the floor.
- Maintain patency by gently lifting sections of the tubing at regular intervals to facilitate the gravitational drainage of blood and viscous fluid.
- Maintain sterility when changing the down-tube and drainage device.
- Measure and record the amount and consistency of drainage. There is a chart to record this on the side of the drainage device.

and greater vessels into the pleural space, causing kinking of the vessels and acute circulatory failure.

Unless otherwise indicated by the surgeon, the best practice is to nurse the patient upright, well supported by pillows.

Chest drains

Usually there are no drainage tubes in position, the main aim being for the space to fill with haemoserous fluid. This will slowly become organised into fibrous tissue and, together with contraction of the intercostal and diaphragmatic muscles and gradual slight shift of the mediastinum, will eventually fill the residual space.

However, if chest drains are in position, they will be attached to an underwater seal drainage system and double-clamped. There may be a request that the clamps be released for brief periods at given times to allow escape of excess fluid and air. If this is the case, the nurse must stay with the patient during the unclamped period and be prepared to clamp the tubings immediately if the patient is about to cough. Because a cough is a full inspiration followed by forced expiration, it will force air from the lung space out through the drainage tube, allowing a sudden mediastinal shift, which could be fatal (Allibone 2003).

Other considerations

The knowledge of loss of an entire lung, together with a degree of post-anaesthetic collapse of the alveoli, atelectasis, in the remaining lung, can cause a patient to panic and become extremely agitated. It is vital for the nurse to remain with the patient as much as possible and to maintain a calm and reassuring manner. Pain can be severe following pneumonectomy and prescribed pain relief should be given prophylactically. It should be borne in mind that effective pain control will help to promote calm, relaxed breathing and is therefore important to the patient's recovery. Oxygen will be given as prescribed. The nurse may need to explain that the lung space will be allowed to fill slowly with blood and serum which, over the following few weeks, will undergo fibrosis (see Ch. 19).

For further information on the management of pleural disease, see British Thoracic Society (2003).

RESPIRATORY EMERGENCIES

This section begins with a brief consideration of chest injuries, pulmonary oedema and respiratory failure. An introduction to endotracheal intubation and mechanical ventilation is also given. Pulmonary embolism, a fairly common and potentially lethal complication of surgery and trauma, is discussed in Chapter 26.

CHEST INJURIES

Fractured ribs and flail chest

PATHOPHYSIOLOGY

Any injury to the thoracic cavity has the potential to disrupt ventilatory mechanisms and compromise respiratory function. Penetrating injuries caused by sharp objects, bullets or fractured ribs may result in collapse of the lung or abnormal collections of blood or air in the pleural cavity. Non-penetrating injuries caused by blunt trauma or crushing can also disrupt ventilatory mechanisms, especially if the diaphragm or other structures are ruptured or contused. Both types of injury will involve disabling pain, and both will restrict surface area for gaseous exchange.

Clinical features Signs and symptoms common to all chest injuries include varying degrees of dyspnoea, chest pain, cyanosis, hypoxia, tachycardia and possibly haemoptysis.

MEDICAL MANAGEMENT

Investigations Diagnosis is confirmed by chest X-ray and the degree of hypoxia is determined by blood gas analysis.

Treatment Simple fractured ribs are usually stable and heal without intervention. Compound fractured ribs may cause a pneumothorax (see below).

When several successive ribs are fractured and become dissociated completely from the rest of the rib cage, the condition is known as flail chest and is characterised by paradoxical breathing. This is where the dissociated ribs rise and fall in opposition to the rest of the rib cage.

NURSING PRIORITIES AND MANAGEMENT: Fractured ribs and flail chest

Providing there are no complications or other serious injury, the patient with fractured ribs can be nursed at home. Flail chest, however, is often associated with more serious chest trauma requiring hospital care.

The main aim of nursing care is to promote rest and relieve pain until the intercostal muscles have had a chance to stabilise the fractured ribs. In the case of flail chest, the patient will need bed rest and probably opioid pain relief. In some cases, patient-controlled analgesia (PCA) may be appropriate.

On discharge, the patient should be advised to avoid heavy lifting or exertion until the fractures are healed.

Pneumothorax and haemopneumothorax

PATHOPHYSIOLOGY

The term 'pneumothorax' refers to the presence of air in the pleural space, and 'haemopneumothorax' to the presence of blood and air in the pleural space. Both conditions may cause partial or complete collapse of the lung on the affected side. However, tension pneumothorax is a more serious condition.

In 'tension pneumothorax', the opening into the pleural space from either the lung or the outside chest wall acts as a one-way valve and sucks air into that space during inhalation but does not allow it to escape during exhalation. Gradually there is a build-up of air in the affected side and a mediastinal shift occurs with resultant cardiopulmonary compromise.

Clinical features An open pneumothorax is characterised by the presence of an open wound and a sucking sound as air is drawn into the pleural cavity. In closed pneumothorax,

air enters the space from torn lung tissue and there is little or no movement on the affected side.

MEDICAL MANAGEMENT

First aid The patient is kept in an upright position or lying on the affected side. Penetrating foreign bodies are not removed until intensive care facilities are available, in case their removal causes massive haemorrhage or mediastinal shift. Open wounds can be covered by a clean occlusive dressing; this must be released at intervals to avoid a tension pneumothorax developing.

On admission to the Emergency Department, the patient will have a chest X-ray. An apical intercostal chest drain will be inserted and connected to an underwater drainage system. If there is a haemopneumothorax, the patient will require a second chest drain in the basal chest wall. Opioid analgesics will usually be necessary to control the patient's pain and to relieve anxiety.

NURSING PRIORITIES AND MANAGEMENT: Pneumothorax and haemopneumothorax

Specific considerations

General principles of care for the initial period will be as described in Chapter 27. Specific considerations are as follows.

Observation and monitoring

Constant vigilance must be maintained in observing for any change in respiratory status. These injuries are potentially life threatening and the patient should never be left unattended. Changes in respiratory patterns, symptoms and vital signs should be monitored frequently and action taken accordingly.

Assisting with insertion of a chest drain

The patient will usually be given an opioid analgesic for sedation and pain relief. This will also result in slower, deeper and more effective breathing. The nurse assisting should offer simple explanations and reassurance. If possible, the patient should be assisted to sit up and lean forward with arms resting on an overbed table. This will help to expand the thoracic cavity and provide good support for the patient. The pressure needed to pierce the chest wall may be unpleasant but should not be painful. A complete, sterile chest drain set is kept pre-packaged in the Emergency Department. Before the chest drain is inserted, the drainage system should be opened, connected and the drainage chamber filled with sterile water to the requisite level. The whole system should be carefully checked to ensure that it is airtight. A local anaesthetic is then given at the chosen site. Once anaesthesia is achieved, a small incision is made and the chest drain is inserted into the pleural cavity. The chest drain is connected to the underwater drainage system and sutured in place (see Fig. 3.11). A chest X-ray is carried out to confirm the correct position. If low suction is required, a controlled underwater drainage system is connected between the suction source and the end drainage system.

Assisting with removal of a chest drain

This procedure must be carried out by two people, usually a doctor and an experienced nurse. A pre-procedural analgesic will be administered. A careful explanation of the procedure should be given to the patient, who should be shown how to practise the Valsalva manoeuvre which

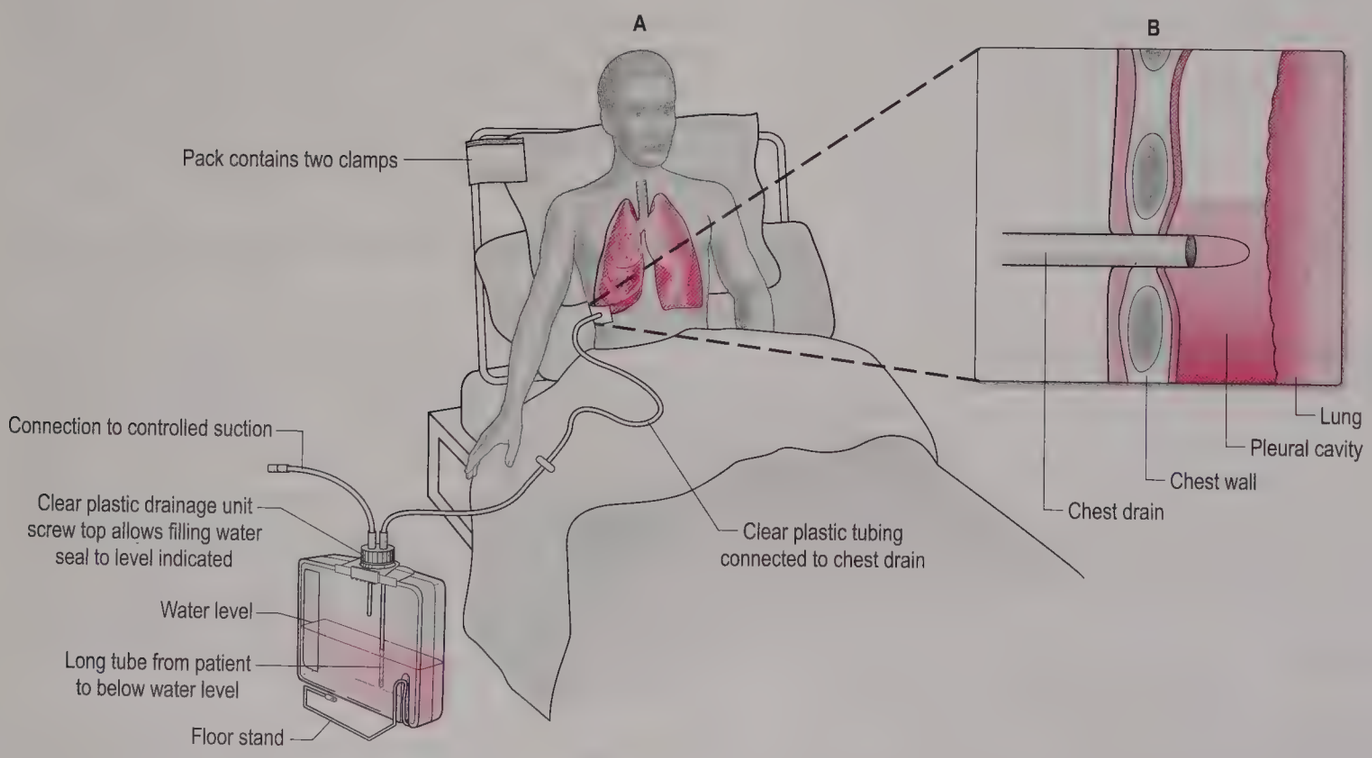

Fig. 3.11 Underwater seal chest drainage. A: Drainage system in position. B: Detail of the position of the chest drain in the pleural cavity. (Based on an original drawing by Nicole Rooth, Moreton Bay Design Co., Australia, with permission.)

involves forcible exhalation against a closed glottis. Alternatively, the patient can be asked to take a deep breath and hold it, as this prevents a rush of air into the puncture site and is more easily controlled than the Valsalva manoeuvre. An occlusive dressing and airtight tape must be ready to be applied to the insertion site. The purse-string suture holding the drain in position is located and the retaining suture removed. The drain is steadied and, as the patient performs the Valsalva manoeuvre, the drain is quickly removed and the purse-string suture tied to close the insertion hole. The dressing and airtight tape are then applied firmly and the patient observed carefully following the procedure. A check X-ray may be performed.

PULMONARY OEDEMA

Pulmonary oedema, excess fluid in lung tissue, is associated with many conditions, including inflammatory response to infections, shock, cardiac failure, nephrotic syndrome and severe allergic reactions.

PATHOPHYSIOLOGY

The lungs are susceptible to oedema because of the minimal tissue resistance offered by the thin alveolar and capillary cell walls. The condition is akin to drowning in that the lungs may be full of water, blood and mucus. Pulmonary oedema is usually acute and potentially life threatening, as it disrupts gaseous exchange.

Clinical features The patient presents with a moist cough that produces copious, frothy, pink sputum and is dyspnoeic, tachycardic and extremely distressed.

MEDICAL MANAGEMENT

Diagnosis is based on presenting signs and symptoms, auscultation, chest X-ray and medical history. The main principles of treatment are to remove the water from the alveolar sacs and to assist the respiratory process. Treatment consists of sitting the patient upright, giving oropharyngeal suction, diuretic therapy, opioid analgesics, bronchodilator medication and oxygen. In severe cases, it may be necessary to intubate and mechanically ventilate the patient.

NURSING PRIORITIES AND MANAGEMENT: Pulmonary oedema

As pulmonary oedema is usually associated with cardiovascular disease, specifically left ventricular failure, the principles of nursing management are discussed in Chapter 2.

RESPIRATORY FAILURE

If impending respiratory failure is recognised early, the actual state can be avoided; nurses should be alert for the following clinical signs:

- the patient appears restless and confused
- there is an increase in respiratory rate with laboured ventilatory effort and use of ancillary respiratory muscles (sternomastoid and abdominal muscles)
- forced and abnormal movement of the diaphragm
- pronounced flaring of the nostrils with each breath
- pale or deeply cyanosed and clammy skin.

Where impending respiratory failure is suspected, sedation must be withheld as it will further depress respiratory function. ABGs will confirm the diagnosis.

Respiratory failure is indicated when there is respiratory acidosis with a falling pH, PO_2 below normal and raised PCO_2 (see p. 91). Untreated, the condition will worsen steadily, and increasingly difficult ventilatory effort will leave the patient exhausted and hypoxic, and will eventually lead to a comatosed state and death. However, patients with impending respiratory failure are normally intubated and mechanically ventilated and are nursed in ITU. Only then can sedation be given with safety.

In order to cut down on dead space and improve respiratory efficiency, a tracheostomy, an opening directly into the trachea, is usually performed (see Ch. 14).

EMERGENCY AIRWAY MANAGEMENT, ENDOTRACHEAL INTUBATION AND MECHANICAL VENTILATION

Nursing priorities and management

The nurse must be prepared at all times to perform emergency airway procedures and to assist in endotracheal intubation and mechanical ventilation. These procedures are reviewed in Boxes 3.12 and 3.13 (see also Fig. 3.12).

For further information, see Armstrong & Salmon (1997).

3.8 When a patient is mechanically ventilated, and in certain other instances, it is necessary to flood the lungs with pure oxygen both before and after carrying out aspiration. What is the reason for this? (See Ch. 29.)

GENETIC DISORDERS OF THE RESPIRATORY SYSTEM

There is considerable evidence of genetic predisposition and susceptibility to some of the more common respiratory diseases such as asthma. Of the classic genetic disorders, cystic fibrosis has the most dramatic and distressing impact on the respiratory system. This is a disease which disturbs the mucus-producing glands throughout the body, particularly those of the respiratory tract.

For a full description of the disease process and its nursing management, see Chapter 6.

CONTINUITY OF CARE: HOSPITAL AND COMMUNITY

Communication between hospital and community health care teams is vital for continuity and ultimate effectiveness of care, and issues relating to discharge planning, accountability and ethical implications are outlined in Box 3.14.

3.9 During your community placement, ask your community nursing team leader to discuss the practice profile with you.

Select two respiratory care patients from the profile and collect as much relevant information about the

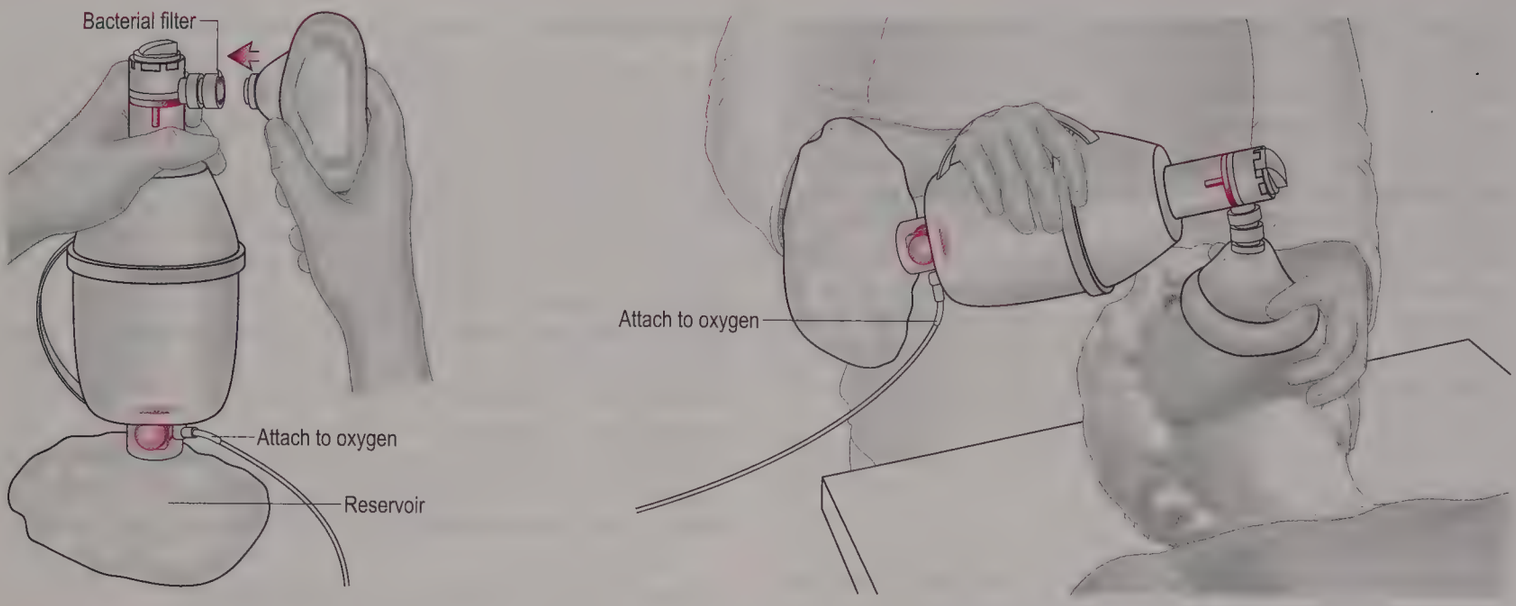

Fig. 3.12 Assembling and using the AMBU bag resuscitator. A: Attaching the face mask and bacterial filter. B: AMBU bag may be attached to oxygen supply if time permits. Patient's neck is hyperextended and mask placed firmly over mouth and nose. Jaw is supported forward. The bag is compressed every 5 s for an adult. (Based on an original drawing by Nicole Rooth, Moreton Bay Design Co., Australia, with permission.)

Box 3.12

Endotracheal intubation and mechanical ventilation

Endotracheal intubation and mechanical ventilation are both specialist procedures and will be performed and monitored by doctors and nurses specially educated in this area. However, it is necessary for the generalist nurse to be familiar with the relevant procedures and equipment in order to be prepared to assist in emergency situations and to better understand the needs of the patient who has been intubated and ventilated during general anaesthesia.

Endotracheal intubation

Maintenance of equipment

Equipment on resuscitation trolleys and in the anaesthetic room must be checked regularly to ensure that it is complete and functional. Equipment must include an appropriate range of sizes of both nasal and oral endotracheal (ET) tubes, at least two laryngoscopes with a supply of new batteries, universal connectors, catheter mounts, 20 mL syringes, artery forceps, Magill intubating forceps, introducers, masks, oral airways, laryngeal spray, suction, lubricant and scissors.

Assisting the anaesthetist

During induction of general anaesthesia, the anaesthetist will select the appropriate tube for the patient and will test and lubricate it. The nurse will ensure that suction is available and have the prepared tube ready for the anaesthetist. The patient is given a full explanation and the nurse should continue to reassure the patient until the i.v. anaesthetic, muscle relaxant and anaesthetic gas have taken effect. The anaesthetist will visualise the vocal chords with the laryngoscope, introduce the ET tube, inflate the cuff and connect the ET tube to the anaesthetic machine. The nurse may be asked to apply cricoid pressure during induction of the anaesthetic in order to prevent regurgitation of stomach contents, especially in emergency cases. This procedure involves using the thumb and forefinger to apply pressure to the patient's cricoid cartilage until anaesthetised and the cuff of the ET tube has been inflated.

Extubation

Following extubation, removal of the ET tube, the nurse must be alert for complaints of sore throat due to damage to the tracheal mucosa, or problems related to oedema of the larynx leading to tracheal obstruction. The nurse should raise the head of the bed unless this is contraindicated and report the symptoms to the surgical team.

Mechanical ventilation

There are many reasons why a patient may need mechanical help with respiration. Extrapulmonary causes which affect the respiratory process include:

- those which affect the respiratory control centres in the brain, e.g. CNS disease, brain contusion or haemorrhage, drug overdose or anaesthesia
- those of neuromuscular origin which cause respiratory paralysis, e.g. Guillain–Barré syndrome, myasthenia gravis, poliomyelitis, organic phosphate poisoning and cervical spine injury
- those which restrict expansion of the thoracic cavity, e.g. musculoskeletal injuries such as extensive flail chest and ruptured diaphragm.

In addition, disorders which affect gaseous exchange can result in severe hypoxia. These include adult respiratory distress syndrome (ARDS), cardiac disease resulting in pulmonary oedema, smoke inhalation and respiratory infection in a patient with chronic obstructive pulmonary disease (COPD).

If help with breathing is needed, the patient may be intubated and attached to a mechanical ventilator. The ventilator will simulate the bellows action normally provided by the diaphragm and thoracic cage and will deliver oxygen-enriched air to the lungs. The type of ventilator used will depend on the specific needs of the individual and will be prescribed by the respiratory specialist. The patient will be nursed in the intensive therapy unit (ITU) and will need specialist nursing care, the principles of which are described in Chapter 29.

Box 3.13

Emergency airway management

Emergency airway management is an essential clinical procedure. The nurse must be familiar with the assembly and use of the hand-held resuscitator known as the AMBU bag and should always be aware of its location in the work area. In cases of respiratory arrest, the AMBU bag will ensure more effective ventilation. The procedure for its use is as follows:

- First, clear the airway of any obstruction, mucus or vomitus. Position the patient to open the airway and insert an oral pharyngeal airway, e.g. Guedel airway.
- Position the face mask to seal the mouth and nose and compress the AMBU bag with the other hand every 5 s. This will deliver approximately 1 L of air with each compression. A smaller bag is used for a child. Oxygen may be attached to the AMBU bag if available.
- If it is necessary to aspirate mucus from the patient's airway, do so via the oropharyngeal airway. Avoid nasotracheal suctioning where possible because this can stimulate the sensory receptors of the vagus nerve, causing disordered heart rate and rhythm — usually bradycardia (slowing).

type of statutory and voluntary services available for these particular patients and add this to your resource folder; use pseudonyms for the patients to ensure anonymity.

Compare your findings with those of your colleagues who may have had placements where the emphasis and case load were different.

Suggested resource people: Local Council of Social Services Directory of Statutory and Voluntary Services, GP surgeries, local libraries, health education libraries, day hospitals, community nursing services.

CONCLUSION

In health we are seldom aware of the functioning of the respiratory system, but disorders and diseases that affect respiration have the potential to affect every aspect of daily living. Airway, breathing and pulmonary circulation are the ABC — the essential elements — of survival.

This chapter has emphasised the importance of a thorough understanding of the anatomy and physiology of the respiratory system — particularly its physiology, because to understand the function of the system is to understand the profoundly disrupting effects that respiratory disorders can have for the individual's health and well-being. A sound knowledge base in respiratory care must inform nursing interventions in every field of practice. Whether working in community settings or a hospital ward, in educational programmes or in an industrial setting, the nurse must be prepared to recognise and act upon any compromise, whether chronic or acute, in respiratory function. Nursing intervention will range from resuscitative procedures in an emergency to giving day-to-day advice on the prevention or management of respiratory disease.

Nursing today encompasses both community-based primary health care and the specialised 'high-tech' skills

Box 3.14

Principles of nursing management: dimensions of community respiratory care

Recent trends have highlighted certain basic issues involved in management of respiratory disorders in the community. These trends include early discharge home from hospital, a higher incidence of severe and chronic respiratory disorders being cared for in the home, and respiratory consultants visiting patients in the community and working alongside GPs, practice nurses and clinical nurse specialists (British Thoracic Society/Scottish Intercollegiate Guidelines Network 2003).

The discharge process

Patient education

Teaching self-care and teaching relatives to assist with care should begin early during hospitalisation so that an acceptable level of proficiency is achieved before discharge and problems are identified and addressed.

Liaison between hospital and home

When a patient is discharged home following acute hospital care, it is vital that there is close liaison between the hospital and the community health care teams. Ideally, the community nurse or another member of the multidisciplinary community care team is allocated time to visit the patient while they are still in hospital and to participate in planning for discharge. At the very least, the community nurse should have direct patient and family contact before discharge and may already know them and be able to provide valuable input into discharge planning. The earlier this is done, the better, so that arrangements can be made to have the necessary equipment and services in place.

In addition to basic aids to daily living, special equipment such as that required for oxygen therapy, inhalation and nebulisation therapy, airway suctioning or mechanical ventilation can be installed before the patient is discharged, and the patient and carers taught to manage it efficiently.

Linking

Knowing and utilising all the statutory and voluntary support bodies that are available and appropriate to the patient and family are crucial in ensuring effective community care.

Practice profile

A descriptive and statistical record, the practice profile is compiled by each community nurse and is a vital tool in overviewing case type, frequency and workload, and in planning maximum and effective use of resources and skill mix.

Documentation

Respiratory disorders and their management in the home can carry a fair degree of risk and hazard.

Documentation is important in all areas of nursing as a basis for accountability and quality assurance; however, for community nurses, detailed and accurate records are even more essential as they often practise alone and are especially vulnerable to the complex legal and ethical dimensions involved in entering a person's home and administering treatment and advice. Great care must be taken to ensure that entry and treatment are achieved with that person's consent and cannot be construed as intrusion or assault or, conversely, that the care given cannot be described as negligent.

required in acute care. Nurses are developing new interdependent and independent roles to meet the demands of new approaches to health care delivery. Increasingly, they are being employed in community and specialist clinics to screen, advise, immunise and treat patients and to promote disease prevention and health education. At the same time, technological and medical advances are demanding a higher level of clinical nursing skills.

This chapter has illustrated two of the major principles in nursing management of respiratory disorders: disease prevention and health promotion, and the active, reflective acquisition of a sound knowledge base and clinical skills. Although the emphasis has been on nursing management, the implicit assumption is always that nurses work in close collaboration with other health care professionals and, in many instances, will be responsible for coordinating the work of the whole team.

INTRODUCTION

The study of the gastrointestinal (GI) system is essential to nursing practice, as the digestive processes are the means by which foods and liquids are digested and absorbed and then transported by the blood for cellular metabolism. Nutrition and dietary factors are integral to the care of individuals receiving treatment for diseases affecting either the digestive system itself or other systems of the body.

Because the GI system comprises a large number of organs with a range of interrelated functions, disorders can produce diverse and often distressing symptoms, some of which may cause people considerable embarrassment, leading them to restrict their social lives. Symptoms include pain, dysphagia, anorexia, loss of weight, heartburn, vomiting, constipation and diarrhoea.

Disorders of the GI system may be acute, presenting as life-threatening emergencies, or chronic, requiring long-term management and sometimes admission to hospital for more intensive treatment and/or surgical intervention. The specific needs of patients with GI disorders will vary, although in GI surgery there are general principles of perioperative care, which can be followed. Although many advances in pharmacological treatment have been made over the years, surgery is still the treatment of choice for some conditions, allowing many patients to make a complete and rapid recovery. For those patients whose condition is such that palliative surgery is the only option, skilled nursing care will be required both in the hospital and in the community.

Essential to human health and well-being is the ability to maintain a regular intake of a balanced diet, and the nurse working in a community or hospital setting is in a key position to advise individuals on the constituents of such a diet and how it may be achieved. The nurse is also in a good position to provide explanations of any investigations, treatments, diagnoses and prognoses, and to follow up any information given by medical colleagues. The principles of holistic care should be adhered to and a process of

continuous assessment, planning, intervention and evaluation followed. This process should be flexible, allowing priorities to be changed as the patient's condition and circumstances evolve.

This chapter begins with a review of the basic anatomy and physiology of the GI tract and its related structures, describing the basic functions of that system and how the specialised organs and tissues which it comprises contribute to its effective functioning. The disorders of the GI system, liver and biliary tract that will most commonly be encountered by nurses in hospital or community settings are then described. A separate chapter has been devoted to disorders of the mouth and its related structures (Ch. 15) and it is vital that nurses caring for patients undergoing surgery, the terminally ill or those with GI and related disorders should appreciate the importance of giving careful attention to mouth care.

ANATOMY AND PHYSIOLOGY

The gastrointestinal or digestive tract runs from the mouth to the anal canal and includes the oesophagus, the stomach, the duodenum and the small and large intestines. The ancillary organs of digestion which are connected to, but do not form part of the digestive tract include the liver, the pancreas and the gall bladder. In this chapter, the spleen will also be considered alongside the GI system.

The digestive tract is responsible for taking in food and fluids at the mouth (ingestion), breaking up the food into pieces of a manageable size, extracting the nutritional content of the food and expelling residues and waste products from the rectum via the anus (defaecation). This section will briefly describe the structure and function of the different components of the digestive tract in order to help the reader understand the adverse effects of diseases of this organ system.

The mouth

The mouth carries out three functions in the process of digestion (see Ch. 15 and Fig. 15.1): mechanically breaking down food (chewing or mastication), initiating the chemical breakdown of food (salivation), and swallowing food (deglutition) to allow it to proceed on its journey through the digestive tract.

Movement of food within the mouth is achieved mainly by the tongue, which is largely composed of skeletal muscle. The tongue is also a sensory organ, allowing the taste, texture and temperature of food and fluids to be perceived. The sensation of taste is enabled by the fungiform papillae, or taste buds, which house the relevant sensory nerve endings. The filiform papillae give the tongue a roughness that allows it to be used for manipulating semi-solid food (see Ch. 15).

Saliva is released from three pairs of glands located around the lower jaw. These are, moving anteriorly, the parotid, the submandibular and the sublingual glands. A constant stream of saliva is released into the mouth, of which the submandibular glands contribute about 70% in the absence of a food stimulus. However, the sight, smell or presence of food in the mouth will stimulate the parotid glands to make the major contribution.

Saliva is a mildly alkaline and slightly viscous fluid that serves to keep the mouth moist and clean. It is mildly antibacterial. In digestion, it helps to lubricate food prior to swallowing and, since it contains the enzyme amylase, it also initiates the digestion of starch.

The final process in which the mouth participates is that of swallowing, whereby food is passed into the oesophagus. After food has been sufficiently chewed, which is partly a subjective decision and partly determined by the texture of the food ingested, it is formed into a ball (bolus) between the palate and the tongue and pushed to the back of the mouth by the tongue. The swallowing reflex is initiated by the bolus touching the oropharynx and involves the following steps:

- the temporary cessation of breathing
- the soft palate shuts off the nasal passage
- the raising of the larynx and the lowering of the epiglottis to protect the trachea
- the opening of the upper oesophageal sphincter to receive the bolus of food.

The oesophagus

The oesophagus is a hollow, muscular tube connecting the pharynx to the stomach. It exists solely to enable the passage of food between these two areas and performs no digestive or absorptive roles. The oesophagus is composed of three layers of tissue: an inner mucosal layer with an underlying submucosal layer, a middle muscular layer and an outer connective tissue layer. The mucosal layer contains glands that secrete mucus for the lubrication of food as it passes down the oesophagus. The submucosal layer provides a nerve and blood supply. The muscles of the middle layer are arranged both circularly and longitudinally. The composition of this layer changes throughout the length of the oesophagus in such a way that there is more striated, or voluntary, muscle at the pharyngeal end. Towards the stomach end, the muscle becomes predominantly and then entirely smooth, or involuntary.

The propulsion of food towards the stomach is achieved by peristalsis, which can be described as follows:

1. A descending wave of contraction of circular muscle narrows the lumen of the oesophagus, thereby compressing the bolus of food
2. This is preceded by contraction of the longitudinal muscles to widen the lumen in order to receive the bolus.

Peristalsis is entirely under involuntary control. Relaxation of the lower oesophageal sphincter allows food to enter the stomach (see Fig. 4.1).

The stomach

Digestion continues in the stomach when the bolus of food enters through the lower oesophageal sphincter. The basic structure of the stomach is illustrated in Waugh and Grant (2001). On the inner surface of the stomach, a mucosal, secretory, layer of tissue is supplied with blood vessels and lymph glands by an underlying submucosal layer. Between the mucosal layer and the outermost, peritoneal layer lies a

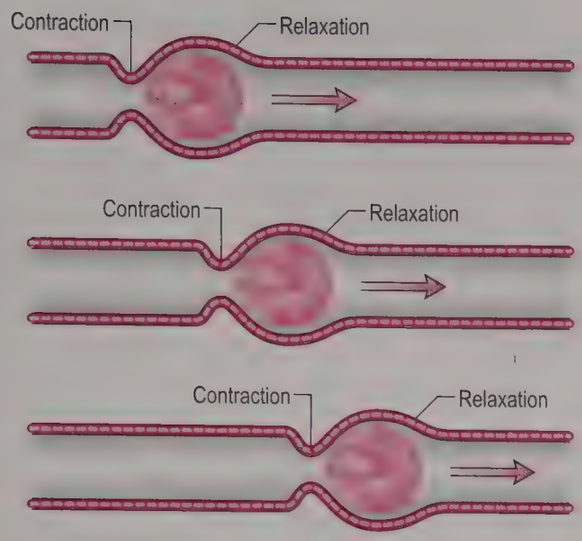

Fig. 4.1 Illustration of the movement of the bolus through the oesophagus by peristalsis.

muscular layer, which is itself composed of three layers: an inner layer of oblique fibres, a middle layer of circular fibres and an outer layer of longitudinal fibres. These layers of muscle allow increasingly stronger waves of contraction in three directions to mix the food in the stomach and allow maximum contact with gastric juice. Innervation of the stomach is from a branch of the Xth cranial (i.e. vagus) nerve, which provides parasympathetic nerve endings that stimulate the secretory cells of the stomach. The internal surface area of the stomach is increased by the arrangement of folds (rugae) in the lining.

Cells in the mucosa of the stomach produce mucus, hydrochloric acid and pepsinogen. This mixture is referred to as 'gastric juice' and, when combined with food in the stomach, as 'chyme'. Hydrochloric acid helps to maintain the acidity of the stomach at a pH of about 2. At this level of acidity, pepsinogen, an inactive precursor, is converted to pepsin, a protein-digesting enzyme that works optimally at this pH. The stomach, therefore, is mainly responsible for initiating protein digestion, although some carbohydrate digestion can continue inside a bolus of food by the action of any salivary amylase that has not yet become inactivated by the acidity of the stomach.

Release of gastric juice by the stomach mucosa is stimulated by the sight, smell and thought of food. This is known as the cephalic phase of digestion. The gastric phase of digestion begins when food reaches the stomach and continues until chyme enters the duodenum, where the intestinal phase of gastric digestion begins. The length of time taken to empty the stomach is variable and depends on the composition of the meal eaten. An average time for emptying of the stomach after a meal is about 4 h. Emptying takes place through the pylorus. The pyloric region holds about 30 mL of chyme; with each wave of contraction in the stomach about 3 mL of chyme is released into the duodenum. This process is regulated by the pyloric sphincter.

Digestion in the stomach is controlled by several factors. The presence of food in the stomach stretches the stomach wall, activating stretch receptors and stimulating the release of gastric juice. A hormone called gastrin is released by the stomach walls; this also stimulates the release of gastric juice. The presence of food substances such as protein and caffeine also stimulates gastrin release. Waves of contraction in the stomach are increased by stretching of the stomach wall and by the presence of protein. On the other hand, low pH inhibits gastrin release. Both the cephalic and gastric phases of digestion can be inhibited by emotional factors. The stomach is not involved in the main process of absorption, although some water, alcohol and certain medication, such as aspirin, are absorbed in the gastric phase.

The intestinal phase of digestion begins when chyme enters the duodenum. The main effect on gastric digestion of the entry of food into the duodenum is inhibitory. The enterogastric reflex, mediated via the medulla, leads to the inhibition of gastric secretion. In addition, the presence of food in the duodenum stimulates the release of three hormones — secretin, cholecystokinin and gastric inhibitory peptide — all of which inhibit gastric juice secretion and reduce gastric motility (see Fig. 4.2).

The small intestine

Extending from the pyloric sphincter to the ileocaecal valve, the small intestine is responsible for the completion of digestion, the absorption of nutrients and the reabsorption of most of the water that enters the digestive tract. The duodenum, which takes up the first 25 cm or so of the small intestine, plays a key role in the process of digestion. It collects chyme from the stomach and is the site where the secretions of the gall bladder and the pancreas are mixed with chyme. These secretions enter the duodenum through the ampulla of Vater, the joining of the common bile duct and the pancreatic duct, which meets the duodenum at the duodenal papilla. The emptying of the gall bladder is regulated by the sphincter of Oddi at the duodenal papilla.

In common with the remainder of the small intestine, the duodenum has a mucosal layer, a submucosal layer, a muscular layer and a peritoneal layer. Unlike the remainder of the small intestine, however, the duodenum is relatively immobile. Its regulatory role is fulfilled when the stimulus of chyme entering the duodenum triggers the enterogastric reflex as well as stimulating the release of gastrin, secretin, cholecystokinin and gastric inhibitory peptide. The effects of cholecystokinin and secretin on the functioning of the stomach have been mentioned above. Secretin also stimulates the cells of the liver to secrete bile, and cholecystokinin stimulates the release of digestive enzymes by the small intestine.

Chyme is very acidic because of its high concentration of hydrochloric acid. When it enters the duodenum, it is brought to a neutral pH by the effect of alkaline bicarbonate released by the pancreas. The effect of bile is to emulsify fats in the chyme, i.e. to break up fat globules into smaller particles more amenable to the effects of fat-digesting enzymes. The enzymes of pancreatic juice can then begin to digest their respective food substances in the duodenum; this action is continued as the chyme is passed down the small intestine.

The first two-fifths of the small intestine following the duodenum is called the jejunum and the remaining three-fifths the ileum. Two types of movement, segmentation and peristalsis, take place in the small intestine; these, respectively, mix and move the food along the tract.

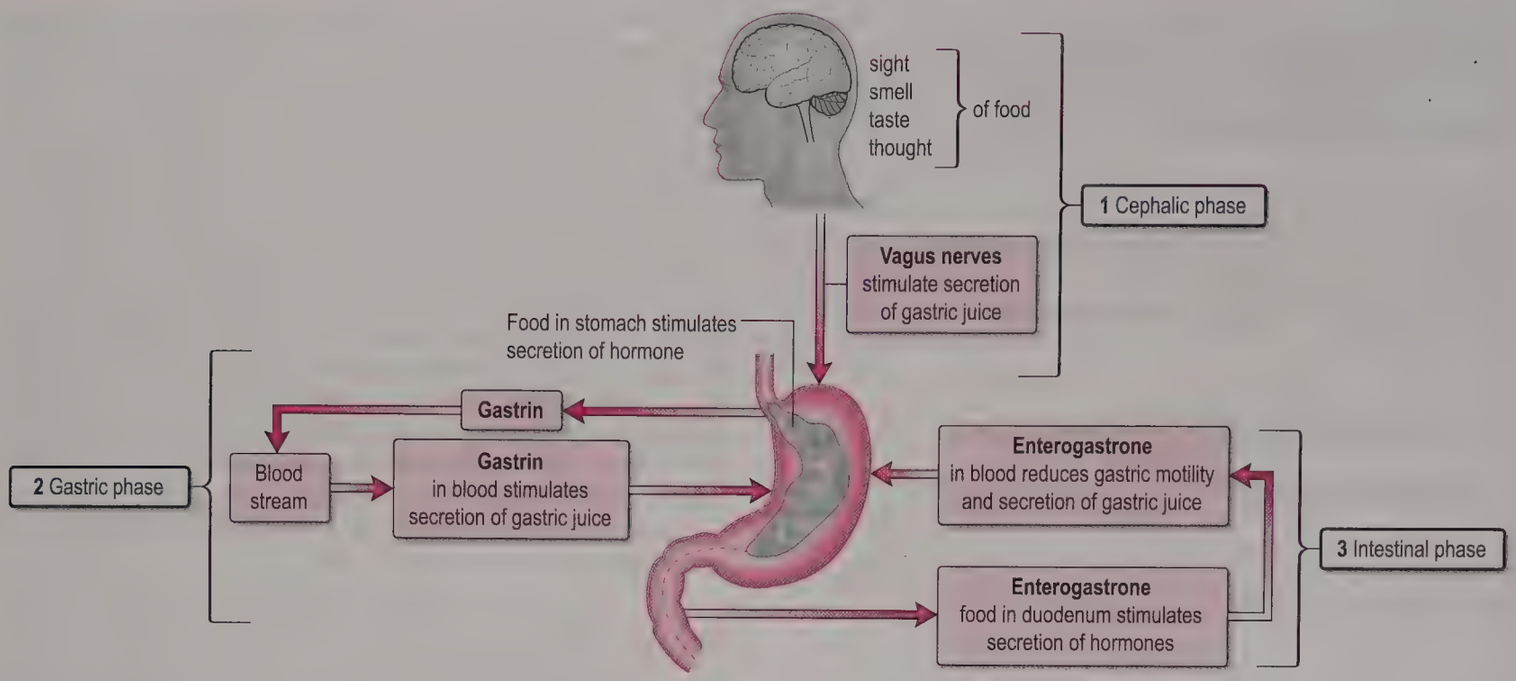

Fig. 4.2 The phases of secretion of gastric juices.

Secretory cells of the mucosa of the small intestine release a slightly alkaline juice containing mainly water and mucus. The remaining enzymes of digestion in the GI tract are located on the microvilli, which are microscopic finger-like projections of the cell membrane. The enzymes of the small intestine complete the digestion of all components of the diet, including protein, fat, carbohydrate and nucleic acids.

Absorption takes place along the full length of the small intestine, and 90% of all the products of digestion are absorbed here. The products of digestion are amino acids and peptides from protein, fatty acids and monoglycerides from fats, hexose sugars from carbohydrates, and pentose sugars and nitrogen-containing bases from nucleic acids. About 7.5 L of water are secreted into the small intestine daily and 1.5 L ingested. As only about 1 L enters the large intestine, the major portion of the water is reabsorbed in the small intestine. Absorption takes place at the villi, which greatly increase the digestive and absorptive area of the small intestine. Each villus contains an arteriole and a venule connected by a capillary network, and a central lacteal, which is a projection of the lymphatic system. Short-chain fatty acids, amino acids and carbohydrates are absorbed directly into the bloodstream. Triglycerides, which form structures called chylomicrons, are absorbed into the lacteals and then enter the bloodstream where the thoracic lymphatic duct empties into the left subclavian vein (see Fig. 4.3).

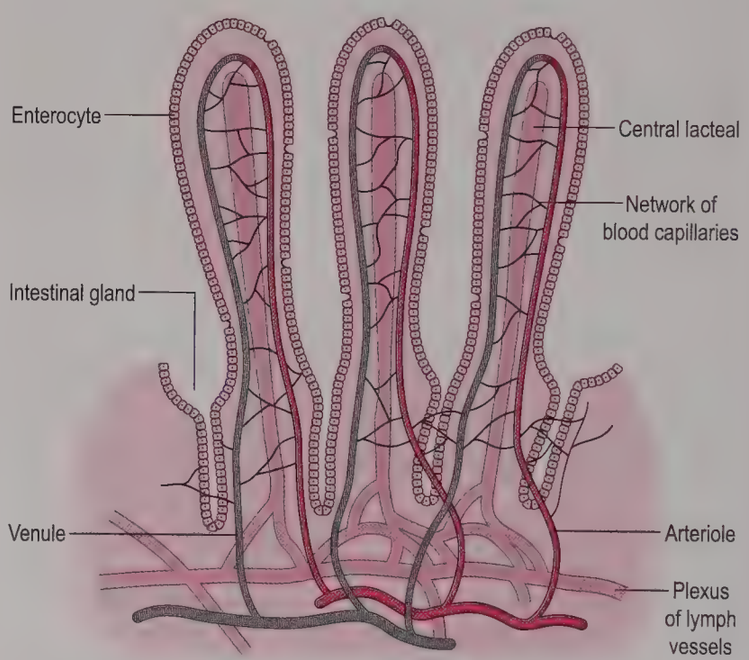

Fig. 4.3 Highly magnified view of the villi in the small intestine.

The large intestine

With most of the nutrients removed, the indigestible residue of food from the small intestine passes through the ileocaecal valve and enters the large intestine. The mesentery attaches both the small and large intestines to the rear wall of the abdomen and provides both with their blood supply.

The large intestine can be divided into four portions: the ascending, the transverse, the descending and the sigmoid colon. The curves joining the ascending with the transverse colon and the transverse with the descending colon are referred to as the hepatic and splenic flexures respectively. Near the ileocaecal valve, two features can be identified: the caecum, which is a pouch below the ileocaecal valve, and the appendix, which is a finger-like projection of the caecum. The descending colon leads to the sigmoid colon, which terminates in the rectum. Three muscular bands called the taeniae coli run the length of the large intestine. These maintain a slight longitudinal tension in the large intestine and give it its characteristic segmented appearance (haustration). The rectum stores food residue as faeces before expulsion via the anus. The anal canal, which opens externally at the anus, controls evacuation and has an internal anal sphincter of smooth muscle and an external anal sphincter of skeletal muscle.

In common with the small intestine, the large intestine has mucosal, submucosal, muscular and peritoneal layers, but it differs in appearance from the small intestine in that there are no villi. The large intestine is designed mainly for the absorption of water and the lubrication of food residue as it is passed, by the mass action of food entering at the ileocaecal valve, to the rectum. Any nutrients that do enter the large intestine are broken down by commensal bacteria, causing the gases methane, hydrogen, carbon dioxide and sulphur dioxide to be produced. Food can take up to 24 h to pass through the large intestine.

When faeces reach the rectum, a reflex is initiated whereby stretch receptors in the wall of the rectum send signals to the brain informing it of the presence of faeces. However, the desire to expel faeces (defaecation) can be suppressed until the time and place are appropriate. When it is appropriate to defaecate, the internal anal sphincter automatically relaxes and the external anal sphincter, under voluntary control, is relaxed. Intra-abdominal pressure is increased as the individual breathes in and holds the breath against a closed glottis (Valsalva's manoeuvre), and faeces are expelled from the rectum via the anal canal (see Fig. 4.4).

The hepatobiliary system, pancreas and spleen

The liver

With the exception of the skin, the liver is the largest single organ in the body. It is located mainly in the upper right quadrant of the abdomen, just below the diaphragm, and weighs about 1.5 kg. It is a compact lobular organ with large right and left lobes and two smaller caudate and quadrate lobes. Blood is supplied to the liver by the hepatic artery, as well as by the hepatic portal vein, which carries blood containing the products of digestion from the small intestine directly to the liver. The hepatic portal system also collects blood from the lower oesophagus, the stomach, the spleen and the large intestine.

Each lobe of the liver is subdivided into functional units called lobules. In these lobules, branches of the hepatic artery, the hepatic portal vein and a bile duct run concurrently in a structure known as the portal triad. All of the blood entering the liver mixes in spaces called sinusoids and is then drained into a central vein.

Due to its size and unique structure the liver has many diverse functions. These include the detoxification of blood by phagocytic, chemical and other processes, carbohydrate, protein and fat metabolism, protein synthesis and the manufacture and secretion of bile.

For further reading, see Waugh & Grant (2001).

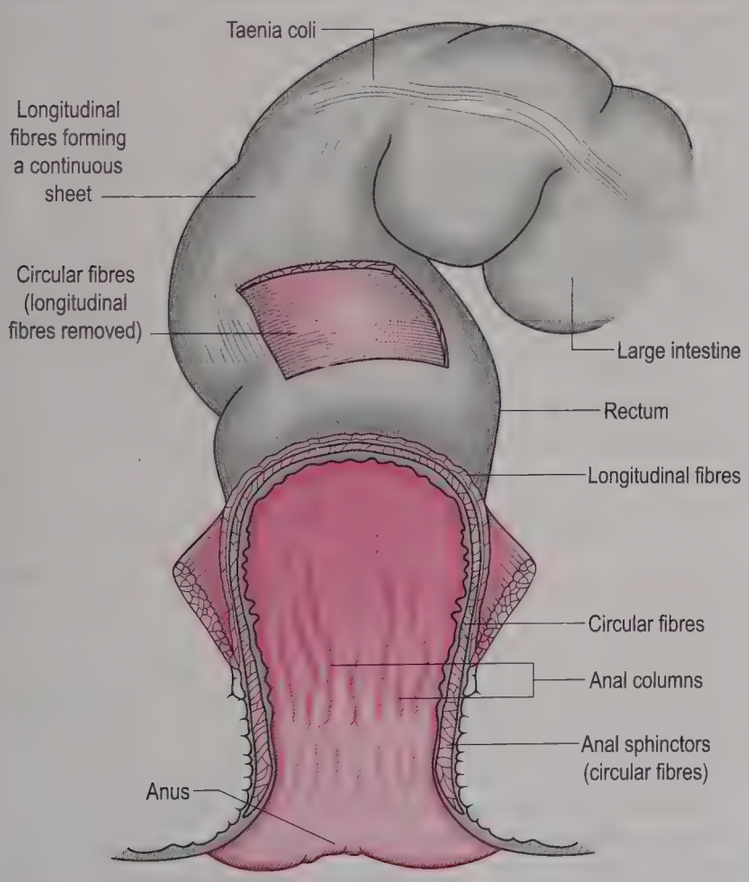

Fig. 4.4 The arrangement of muscle fibres in the colon, rectum and anus (sections have been removed to show layers).

The gall bladder

Lying beneath the liver, the gall bladder has the function of storing and concentrating bile, which is composed principally of bilirubin, derived from the breakdown of haemoglobin from erythrocytes, and bile salts, formed from excess steroid hormones. The gall bladder is a pear-shaped sac about 10 cm long. It lacks a submucosal layer but, in common with other parts of the digestive system, has a middle muscular layer comprising smooth muscle under vagal and hormonal control. Vagal stimulation causes the gall bladder to contract. The mucosal surface area of the gall bladder is increased by the presence of rugae; this promotes the reabsorption of water and a 10-fold concentration of the bile that enters from the cystic duct. The liver secretes bile at a rate of about 1 L per 24 h, but the capacity of the gall bladder is only 30 mL. Bile ducts in the right and left lobes of the liver empty their contents into the right and left hepatic ducts, respectively, which join to form the common hepatic duct. Bile is taken by the cystic duct from the common hepatic duct to the gall bladder, where it is stored and water is reabsorbed. When the gall bladder is stimulated, it contracts and the bile travels to the duodenum down the common bile duct. The release of bile is stimulated by cholecystokinin and secretin.

The pancreas

The pancreas, which lies below and behind the stomach, manufactures and releases pancreatic juice containing enzymes, including enzymes which digest protein, carbohydrate, fat and nucleic acids, and bicarbonate. These constituents of pancreatic juice are produced in the acinar cells of the pancreas.

The exocrine function of the pancreas is discrete from its endocrine function whereby insulin and glucagon are secreted into the bloodstream in response to fluctuating blood glucose levels. The exocrine secretory functions of the pancreas are under vagal and hormonal control. The initial stimulus for the release of pancreatic juice is food entering the duodenum and stimulating the release of cholecystokinin and secretin. Cholecystokinin is responsible for

stimulating the release of the pancreatic enzyme portion of pancreatic juice and secretin is responsible for the release of bicarbonate. The pancreatic duct, which delivers pancreatic juice to the duodenum, and the common bile duct join at the ampulla of Vater. Release of bile and pancreatic juice into the duodenum is controlled by the sphincter of Oddi. This sphincter, a ring of smooth muscle, is relaxed by cholecystokinin.

The spleen

The spleen is composed of lymphatic tissue and lies in the upper left quadrant of the abdomen, between the stomach and the diaphragm. It is richly supplied with blood via the splenic artery. Blood flow through the spleen is slowed down by the fact that it must pass through sinuses in which the monophage/macrophage system scavenges old erythrocytes and pathogenic particles and passes the breakdown products on to the liver via the hepatic portal system.

DISORDERS OF THE GASTROINTESTINAL TRACT

DISORDERS OF THE MOUTH

The mouth and tongue are often examined by the physician during clinical examination, as local abnormalities or indications of disease elsewhere can often be detected in this manner. For example, a dry, furred tongue can indicate the presence of a digestive problem or dehydration.

Patients with gastrointestinal and liver disease require meticulous attention to oral hygiene as the mouth can be affected both directly, as in Crohn's disease, and indirectly, as in vitamin and iron deficiency in malabsorption and GI haemorrhage. Patients on steroid and immunosuppressive therapy are also prone to infections of the mouth and oesophagus.

The principles of mouth care and the treatment of a range of disorders affecting the mouth and related structures are described in detail in Chapter 15.

For further reading on oral care, see Evans (2001).

DISORDERS OF THE OESOPHAGUS

Because the oesophagus has a relatively narrow lumen, any obstruction rapidly affects the passage of food. The two most common symptoms that are experienced by patients with disease of the oesophagus are dysphagia and pain. The term dysphagia refers to difficulty in swallowing. This can present in varying degrees, ranging from slight and intermittent difficulty in swallowing solid food to total occlusion of the oesophagus, preventing the patient even from swallowing saliva. Oesophageal pain can be extremely severe and should not be underestimated. There are three main presentations:

- A burning pain (known as 'heartburn') felt high in the epigastrium and behind the sternum. This is usually due to the reflux of gastric contents and sometimes radiates to the neck and to one or both arms.
- A deep, boring, gripping pain across the front of the chest which may radiate to the back, neck or arms. This is usually due to spasm of the oesophageal muscle and is similar in nature to the pain of angina pectoris.
- Pain behind the sternum on swallowing, especially hot liquids. This is usually due to oesophagitis.

Oesophageal moniliasis

This condition is caused by the yeast-like fungus *Candida (Monilia) albicans*. Those who may be vulnerable to this condition are:

- patients with chronic oesophageal obstruction — oesophageal dysfunction causes stasis of saliva and food particles, which predisposes to infection
- patients with immunosuppressive disorders, e.g. diabetes mellitus, leukaemia, lymphoma, AIDS
- patients taking immunosuppressive therapy, e.g. chemotherapy or corticosteroids
- debilitated patients receiving long-term antibiotic therapy.

PATHOPHYSIOLOGY

Common presenting symptoms These will vary according to the severity of the infection, but may include dysphagia, heartburn and retrosternal pain. *Candida* affecting the mouth will show as white patches on the mucosa. A mild fever may be present.

MEDICAL MANAGEMENT

Diagnosis will be made using endoscopy, when biopsies and brushings will be taken. Treatment is with antifungal oral antibiotics such as nystatin suspension, amphotericin lozenges or parenteral fluconazole.

NURSING PRIORITIES AND MANAGEMENT: Oesophageal moniliasis

The priority of nursing care is to minimise the dysphagia and pain experienced on eating and drinking. The patient should be given a soft diet tailored to their likes and dislikes. Supplemental drinks should also be given to ensure weight loss does not occur. Oral hygiene is, of course, extremely important. Patients who prefer to wear their dentures at all times may have to be persuaded of the benefits of removing them at night, as the constant pressure and friction from the presence of dentures could exacerbate the problem.

Hiatus hernia and gastro-oesophageal reflux

A hernia is the protrusion of an organ through the wall of the cavity that contains it. It may apply to any part of the body but is most commonly thought of in terms of abdominal hernias, which are discussed later in this chapter (see p. 127).

A hiatus hernia results from herniation of a portion of the stomach through the oesophageal hiatus in the diaphragm. The opening of the diaphragm normally encircles the oesophagus tightly, and therefore the stomach lies within the abdominal cavity. When the opening through which the

oesophagus passes becomes enlarged, part of the stomach protrudes into the thoracic cavity.

PATHOPHYSIOLOGY

Hiatus hernia disrupts the lower sphincter function and impairs oesophageal clearance (Quigley 2003). Hiatus hernias occur most frequently from middle age onwards. They are four times more common in women than in men and are often found in association with obesity. Such hernias can also result from a congenital abnormality presenting in early infancy. Hiatus hernias can be described as 'sliding' or 'rolling', the former being the more common. In sliding hernias, the oesophageal sphincter mechanism is defective, causing reflux of acid-peptic stomach contents.

Clinical features Although many individuals with a hiatus hernia are symptomless, the most common and significant symptom is heartburn as a result of the reflux oesophagitis. It occurs after eating and can be initiated by bending over and lying down. Waterbrash (pyrosis) and a feeling of fullness are common, but dysphagia is a relatively uncommon symptom. Bleeding may also be a feature, involving a chronic, small loss leading to anaemia. This may occur particularly in the older patient with reflux oesophagitis.

MEDICAL MANAGEMENT

Investigations Diagnosis is by medical history, barium swallow and meal or endoscopy.

Treatment In mild cases, it may be sufficient simply to advise the individual to make certain lifestyle adjustments, e.g. losing weight if appropriate, taking small meals at more frequent intervals, wearing loose clothing and avoiding bending over from the waist. Sleeping well supported by pillows is also helpful. It is essential for the individual not to smoke. Medication may include antacids and/or acid-inhibiting drugs.

Failure of medical treatment still remains a significant indication for surgery to reduce the hernia and re-form the angle between the oesophagus and stomach. The procedure is fundoplication (Griffin & Raimes 1997), commonly performed by laparoscopic technique. During the operation, a cuff of stomach is wrapped around the lower end of the oesophagus to tighten up the junction between the oesophagus and the stomach, thereby reducing the risk of reflux.

NURSING PRIORITIES AND MANAGEMENT: Gastro-oesophageal reflux

In many individuals, reflux occurs, without associated hiatus hernia, due to obesity, pregnancy or the use of drugs that may relax the gastro-oesophageal sphincter, e.g. anticholinergic drugs. Reflux can be most distressing and is often mistaken for angina. Most people are able to manage their symptoms by conservative means. For example, raising the head of the bed may be all that is needed to relieve symptoms at night. However, if reflux is chronic or severe, the inflammation of the oesophagus can lead to fibrosis and narrowing of the oesophagus, the development of dysphagia and a predisposition to malignant change (see p. 112).

Preoperative preparation

Preparation for surgery will be as for elective abdominal surgery on the GI tract (see p. 907 and Nursing Care Plan 26.1, p. 916).

Postoperative management

This is the same as that for patients undergoing laparoscopic surgery.

Adequate analgesia using opiate analgesics by patient-controlled analgesia (PCA) or i.m. administration must be given to ensure that the patient is pain-free and hence able to cooperate in deep breathing and coughing exercises. Causes of postoperative pain are described in Table 26.7 (p. 932). Analgesics commonly used in postoperative pain control are listed in Table 26.6 (p. 930).

The i.v. infusion must be monitored to ensure adequate hydration. Oral fluids may be withheld for 24 h. As bowel sounds return, sips of water can be given, increasing to 30 mL of water hourly and then greater amounts as they are tolerated. The nasogastric tube, if used, is removed at the discretion of medical staff, usually as the volume of gastric aspirate decreases.

Following this operation, patients will often have some difficulty in swallowing solid foods, but these symptoms usually settle within approximately 1 month of surgery. Approximately 5% of patients will have persistent problems with flatulence orally following surgery. This is termed 'gas bloat' and can be significantly reduced by encouraging the patient not to swallow air while eating or drinking and to reduce the intake of carbonated drinks. Prior to discharge the patient should be advised to take small, regular meals and to avoid heavy lifting. Return to normal activities will be possible as soon as the discomfort from the abdominal wound has settled, normally 5–10 days following laparoscopic surgery and 2–6 weeks following conventional surgery.

Achalasia

PATHOPHYSIOLOGY

This is a relatively rare motility disorder of the oesophagus (incidence = 1:100 000) (Heading & Tibaldi 1998). The cause is unknown but the pathophysiology is a loss of inhibitory innervation of the oesophageal body and the lower oesophageal sphincter (LOS). This impairment results in a loss of oesophageal peristalsis and failure of the LOS to relax. Unopposed cholinergic innervation can then compound the increased LOS pressure.

The condition can be complicated by respiratory pneumonitis and, very rarely, by oesophageal carcinoma.

Clinical features are as follows:

- dysphagia for solids and often liquids
- intermittent retrosternal chest pain
- regurgitation of oesophageal contents (especially at night)
- aspiration of oesophageal contents
- weight loss.

MEDICAL MANAGEMENT

Treatment There is no cure for achalasia and medical treatment is aimed at reinstating acceptable swallowing for the patient.

The principal treatment at present is pneumatic dilatation of the LOS and this seems to be effective in 60% of patients (Heading & Tibaldi 1998). Oesophageal perforation is a serious, but rare, complication of this procedure. Where dilatation is unsuccessful, a Heller's myotomy, i.e. laparoscopic division of the muscular fibres of the lower oesophagus to aid swallowing, may be performed.

Smooth muscle relaxants such as nitrates or nifedipine can be used in the short term to provide some relief from dysphagia whilst awaiting treatment.

Studies have shown that endoscopic injection of botulinum toxin is a safe and effective treatment for achalasia (Annesse et al 1996, Cuilliere et al 1997). This treatment inhibits the cholinergic effect on the LOS.

NURSING PRIORITIES AND MANAGEMENT: Achalasia

Nursing input is aimed at helping the patient come to terms with, and cope with, an imperfect swallow, although to many patients the fact that they can swallow at all is a significant improvement on their pretreatment condition.

The patient should be encouraged to eat slowly and drink fluids to ease the swallowing process. Dietetic referral may be necessary for patients with extreme weight loss prior to treatment and who require dietary supplementation.

For further reading on disorders of oesophageal motility, see Heading (1999).

Carcinoma of the oesophagus

The majority of carcinomas of the oesophagus occur in older people. Men are affected more frequently than women. This form of cancer is extremely unpleasant and distressing. The patient will rapidly become emaciated due to difficulty in eating and drinking, and skilled nursing care is essential to comfort and support the patient in coping with these and other effects of the illness. Several predisposing factors for oesophageal cancer have been identified:

- *Smoking* — this form of cancer is more prevalent among individuals who smoke (Kjaerheim et al 1998)
- *Alcohol consumption* — individuals who have had a high intake of alcohol are more likely to develop a malignant tumour; in England, a high incidence of oesophageal cancer among publicans and brewers has been noted
- *Achalasia* of the cardia, gastro-oesophageal reflux, Paterson–Kelly (Plummer–Vinson) syndrome and previous trauma are all associated with an increased risk of oesophageal cancer.

PATHOPHYSIOLOGY

Squamous cell carcinoma and adenocarcinoma form the majority of malignant oesophageal tumours. Globally, squamous cell carcinoma remains the most common, although the incidence of adenocarcinoma has been rising in the developed world since the 1970s. According to Pisani et al (2002) in squamous cell carcinoma, 10% occur in the upper oesophagus, 45% in the mid-oesophagus, and 45% in the lower oesophagus. Most adenocarcinomas occur in the lower third of the oesophagus and at the gastro-oesophageal junction, accounting for approximately 40–50% of all oesophageal cancers. The primary tumour can spread locally, up or down the oesophagus, and through its wall to the trachea, bronchi, pleura, aorta and lymph vessels. Distant metastases may occur in the liver and lungs.

Common presenting symptoms The most prominent presenting feature is dysphagia. In the initial stages, this symptom will occur only occasionally and the individual will probably not seek medical help. As the disease progresses and the tumour enlarges, dysphagia will increase and become a constant feature. There will be regurgitation of food, and vomiting and pain will become intense, indicating a spread of the cancer to surrounding tissues. Because of the dysphagia the patient will be anorexic and lose weight rapidly. Many patients develop a cough due to pressure on the bronchus, and a chest infection due to aspiration of oesophageal contents. Haematemesis and melaena occasionally occur as a result of bleeding from an ulcerated tumour.

MEDICAL MANAGEMENT

Investigations Diagnosis is confirmed by oesophagoscopy (see Box 4.1), during which biopsies will be taken. Computed tomography (CT) scan may be used to help identify local and metastatic spread to surrounding tissues. Bronchoscopy may be performed if the tumour is in the upper zone. This will identify whether the bronchus has been invaded and will have a bearing on treatment and care.

Endoscopic ultrasonography (EUS) is a recognised diagnostic tool for the staging of oesophageal and gastric carcinomas.

Treatment As the prognosis is poor, treatment is directed mainly towards the relief of symptoms. Each patient is carefully assessed as to the extent of the disease before a treatment plan is chosen and commenced. Time is also

Box 4.1

Endoscopy in GI medicine

Endoscopy refers to the visualisation of the interior of the body cavities and hollow organs by means of a flexible fibreoptic instrument (endoscope). The use of this technique has contributed greatly to diagnosis and therapy in many areas of medical practice. For use in the gastrointestinal tract, the endoscope is variously designed to view the oesophagus, the stomach, the duodenum, the colon and the rectum. It is also possible, by a modification of the gastroduodenoscope, to visualise the pancreatic and common bile duct; this is called endoscopic retrograde cholangiopancreatography (ERCP). Although most endoscopes are flexible, a rigid instrument may be used for a sigmoidoscopy. For further information, see Cotton and Ackerman (2003).

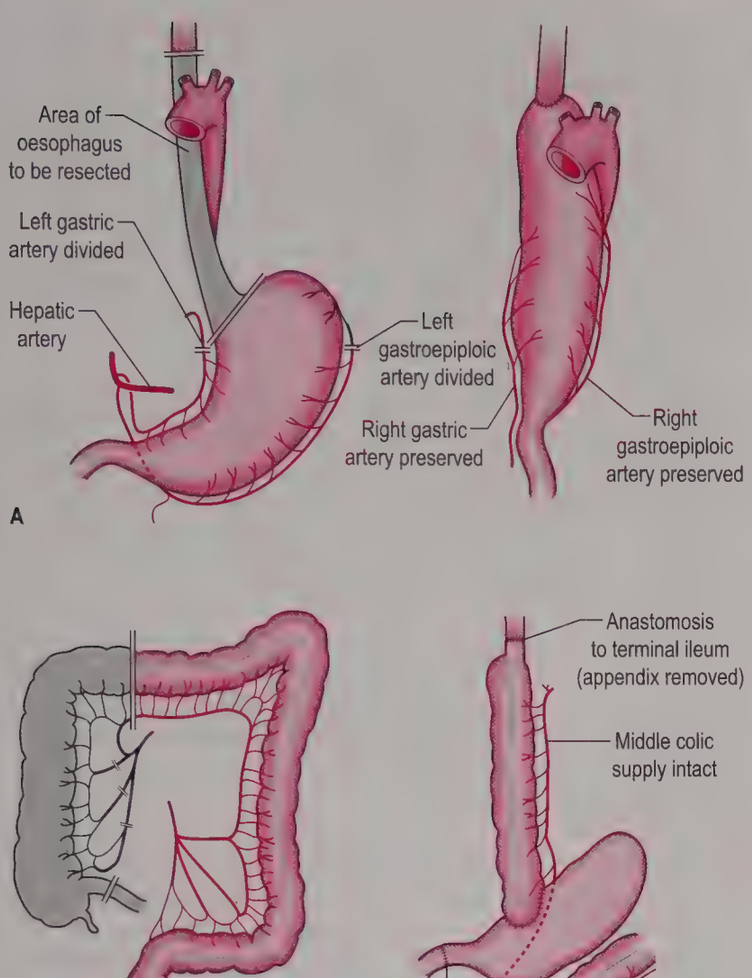

Fig. 4.5 Oesophagectomy and methods of reconstruction. A: Replacement by stomach. B: Replacement by colon.

spent on improving the general nutritional state of the patient by either nasogastric or parenteral feeds.

Surgical intervention will be attempted if the tumour is resectable and if there is no local spread or metastases (see Fig. 4.5).

Radiotherapy may be used if the tumour is radiosensitive, i.e. a squamous cell carcinoma. This treatment is usually used for tumours of the upper third of the oesophagus, but is also sometimes used for the relief of pain.

Malignant dysphagia may be relieved by oesophageal dilatation, endoscopic or open insertion of a stent, or tumour ablation with laser, heat, diathermy or injection of cytotoxic substances (Griffin & Raimes 1997).

NURSING PRIORITIES AND MANAGEMENT: Carcinoma of the oesophagus

Most patients with this form of cancer will be very distressed and emaciated, their life dominated by the symptoms of the disease and by the thought that there is no cure. However, by adopting a caring and sensitive approach, the nurse can do much to alleviate the patient's physical and emotional suffering (Lindars & Sergeant 1994).

4.1 Mr J is a 65-year-old, newly retired accountant, with a wife and two married sons. He has recently been diagnosed as having oesophageal cancer with metastases in the bronchus and lungs. What would you consider to be the main priorities of his nursing care?

Major patient problems

Dysphagia

Some patients experience significant weight loss, for example, several kilograms over a period of months (Nicklin & Blazeby 2003). Weight should be recorded weekly and noted in relation to their pre-illness weight. An accurate account of daily dietary intake should be recorded with the dietitian's help. Consistency of food is important and the patient should avoid large pieces of meat, 'stringy' foods such as oranges, and 'stodgy' foods such as scones and pastries, as these food choices may lead to blocking of the oesophageal lumen.

The patient should be encouraged to take fluids with meals and to chew foods thoroughly, for example, twice as long as normal. In order to ensure adequate nutrition it may be necessary to provide a liquidised diet.

As the disease advances, the patient will be able to swallow liquids only and should be supplied with a variety of nutritionally supplemented liquids. Supplementary drinks are now available in a variety of sweet and savoury flavours.

Eventually, total dysphagia will occur. It cannot be overemphasised what a distressing condition this is for the patient and family. Nursing management is discussed on page 802.

In the case of a bolus obstruction, it may be necessary to perform an endoscopy to relieve the obstruction. The insertion of a stent is often used to relieve dysphagic symptoms. The oesophagus is dilated at endoscopy and the tube inserted. Following this procedure, the patient will lose the action of the gastro-oesophageal sphincter and will therefore suffer from reflux. The head of the bed should be elevated at all times. The patient will be prescribed an H_2 blocking agent, e.g. cimetidine, to help prevent reflux oesophagitis; this should be given in syrup form. Encouragement should be given to eat a semi-solid diet and to chew food well. The patient should take carbonated drinks, e.g., soda or tonic water, with every meal as this helps keep the stent clear.

Immediately after the insertion of a stent, the patient may suffer quite severe discomfort and it may be necessary to give an analgesic injection. A chest X-ray will be performed and the patient should not be allowed any food or fluid until this has been done in case of perforation of the oesophagus.

For further information, see Donahue (1990) and Owen (2001).

Pain

In the earlier stages of oesophageal cancer, if pain is present, mild analgesics such as paracetamol given in dispersible form may be all that is necessary. As the disease advances, opiates may be required. Initially, the patient may be able to swallow a morphine suspension, but if total occlusion of the oesophagus occurs, it may be necessary to give the

morphine by injection. The most effective and convenient way of administering this is by the s.c. route via, for example, a Graseby syringe driver. This delivers a constant level of opioid and readily allows for a 'booster' dose to be given as necessary, to avoid the distress of breakthrough pain. The patient will be able to be at home, if circumstances allow, with a community nurse visiting daily to change the syringe. If necessary, an antiemetic can also be added to the syringe driver.

For further information, see Schofield & Dunham (2003).

Psychological distress

Time must be set aside to allow these patients to express their thoughts, fears and anger, which may be directed towards either the distressing nature of their symptoms or the poor prognosis of the disease, or perhaps both. In the final stages of the disease, every effort should be made to allow the patient to die in the environment of their own choosing. If the patient's choice is to remain at home, a Macmillan or Marie Curie nurse can provide the support and care required.

Oesophageal perforation

PATHOPHYSIOLOGY

Instrumental perforation may occur during endoscopy, especially if the oesophagus is friable due to disease. There is an increased risk of perforation with oesophageal dilatation and the insertion of an oesophageal tube in the palliative management of patients with oesophageal carcinoma.

Spontaneous perforation may occur following a sudden increase in oesophageal pressure caused by vomiting, straining, convulsions or blunt abdominal pressure, e.g. steering wheel pressure in a car accident.

Clinical features The individual will experience severe pain, which may be accompanied by dyspnoea, cyanosis, dysphagia and fever, due to leakage into the mediastinum.

MEDICAL MANAGEMENT

Treatment will be centred on managing potential shock, providing analgesics and prescribing antibiotic therapy. If perforation is severe, surgery may well be required. Such a patient may be acutely ill and require intensive nursing support (see Ch. 29).

Conservative management includes the administration of broad-spectrum antibiotics and ensuring the patient does not take food or fluid orally. These patients are fed either parenterally or via a feeding jejunostomy.

DISORDERS OF THE STOMACH AND DUODENUM

Disorders of the stomach and duodenum are the most common organic disorders of the GI tract. They are considered together here because disorders of one organ commonly affect the other. The overall incidence of acute upper GI haemorrhage in the UK is 103/100 000 adults per year. The incidence rises with age and the overall mortality is 14% (Rockall et al 1995).

Gastritis

PATHOPHYSIOLOGY

Gastritis is an inflammatory condition of the stomach that may be acute or chronic. Acute gastritis is commonly caused by the ingestion of an irritant substance such as aspirin or an anti-inflammatory drug, or by the excessive intake of alcohol. Chronic gastritis develops over many years and is found in patients with pernicious anaemia, autoimmune disorders, chronic alcohol abuse, peptic ulceration and gastric cancer, and following gastric surgery.

Clinical features The outstanding presenting symptom in gastritis is abdominal pain, accompanied by a feeling of distension, nausea, vomiting and anorexia. However, in chronic gastritis, the patient is often asymptomatic. Where symptoms are present, these are the same as those found with acute gastritis, pain being associated with eating and often being described as 'indigestion'.

MEDICAL MANAGEMENT

Investigations Diagnosis is made endoscopically by gastric biopsy. *Helicobacter pylori* is found in the biopsy of many patients with chronic gastritis and, if confirmed, antibiotic therapy will be prescribed.

Treatment An antacid may be prescribed to relieve discomfort and an H_2 blocker such as cimetidine prescribed to prevent histamine from stimulating the gastric parietal cells to secrete hydrochloric acid. Most important is dietary advice, as the patient should avoid causative agents such as alcohol and highly spiced foods.

NURSING PRIORITIES AND MANAGEMENT: Gastritis

In the very acute stage, when vomiting is present, an antiemetic will be given and i.v. fluid replacement therapy may be necessary for a short time. Frequent mouthwashes are given and an appropriate diet gradually reintroduced. The opportunity should be taken to explore the patient's dietary habits and to promote a healthy eating pattern. This is particularly important where the problem of alcohol abuse has been identified.

Peptic ulcer

A peptic ulcer occurs in those parts of the digestive tract that are exposed to gastric secretions, namely the stomach and duodenum.

In the past, peptic ulcer disease was thought to be a chronic relapsing condition that required long-term acid suppression therapy and often major surgical intervention. There was also an associated mortality due to major gastrointestinal haemorrhage and development of gastric cancer.

The identification of the *Helicobacter pylori* bacterium by Marshall and Warren in 1984, and its association with peptic ulcer disease, radically altered the management of this condition from the 1990s, especially with the shift in focus in the NHS from secondary to primary care.

PATHOPHYSIOLOGY

Peptic ulcer formation requires both the presence of gastric acid and damage to the mucosal defence barrier. *H. pylori* is known to be a major factor in causing this damage and is present in over 90% of all patients with duodenal ulcers and 75–80% of those with gastric ulcers (Chua et al 1997). Gastric irritant medication such as aspirin and non-steroidal anti-inflammatories (NSAIDs) are also known to cause mucosal damage. Cigarette smoking is considered to be a causative influence in the development of peptic ulcers and there is growing evidence that smoking prevents the healing of gastric and duodenal ulcers (Haslett et al 2002). The exact mechanisms by which this occurs are not clear, but it is known that long-term smoking increases gastric secretion and interferes with the actions of H_2-receptor antagonists.

The gastric mucosa is, in part, protected by being buffered by food, and erratic dietary habits may contribute to ulcer formation. There is also some conflicting evidence as to whether emotional factors such as stress and anxiety are also causative factors (see Box 4.2).

In *H. pylori* infection, the bacteria burrow beneath the mucosal layer and release a toxin that results in a local inflammatory and systemic immune response. Consequently there is inhibition of the release of somatostatin, a gastric hormone that inhibits gastric acid formation, and oversecretion results. *H. pylori* survive in this acid climate by enzymatically creating an alkaline microenvironment.

It was once believed that ulcers could not develop in the absence of gastric acid (achlorhydria) found in some conditions such as pernicious anaemia and gastric mucosal atrophy (Schwarz's dictum: 'no acid, no ulcer'). Research has shown that while this dictum holds for duodenal ulcers, gastric ulcers can be found in non-acid states (Bynum 1991).

Chronic peptic ulcers penetrate through the mucosa to the muscle layers and may damage blood vessels, causing bleeding. In the duodenum, they are found immediately beyond the pylorus and in 10–15% of cases are multiple. The resulting fibrosis can lead to pyloric stenosis, which in turn can lead to gastric outlet obstruction. Gastric ulcers are found on the lesser curvature of the stomach in 90% of cases.

Box 4.2

Stress ulceration

Unlike other forms of peptic ulceration, stress ulcers are superficial in nature and are often referred to as erosions, since they do not penetrate muscle layers. The pathogenesis is multifactorial and includes hypovolaemia, reduced cardiac output, increased vasoconstriction and splanchnic hypoperfusion. This contributes to acid back-diffusion and reduced bicarbonate secretion, mucosal blood flow and gastrointestinal motility. Within a clinical setting, these ulcers tend to occur after major surgery, trauma, burns or severe illness and commonly present with bleeding (which may be dramatic). The occurrence of stress ulcers will be less likely if prophylactic treatment is given. This is usually an i.v. H_2 antagonist, but proton pump inhibitors are being increasingly used (Daley et al 2004).

Common presenting symptoms The individual with a chronic peptic ulcer will describe a pattern of episodic pain and dyspepsia. Pain is a classic symptom and is described as a burning or boring pain in the epigastrium; often the patient points directly to where the pain is felt. The pain is sometimes more diffuse or radiates through to the back.

While studies show the relationship to food and mealtimes to be variable, the person with a duodenal ulcer is more likely to feel pain and 'hunger feelings' about 2–3 h after a meal, whereas with a gastric ulcer, pain is felt about 30–60 min after a meal and is not relieved by more food. Sometimes patients admit to inducing vomiting in an attempt to relieve the pain. Persistent non-induced vomiting of large amounts indicates an obstruction to the pylorus: pyloric stenosis. Other common features are belching and regurgitation which causes heartburn.

MEDICAL MANAGEMENT

Investigations A full medical history will be taken. An accurate diagnosis is made by endoscopy and/or barium meal. A full blood count is taken for haemoglobin estimation.

Diagnosis of *H. pylori* infection can be made by blood or serum tests for antibodies, and at endoscopy by taking a biopsy from the stomach lining and subjecting it to the rapid urease test, which detects the enzyme that *H. pylori* produces (also known as the 'campylobacter-like organism' (CLO) test). The CLO test, developed by Warren and Marshall in 1984, uses a well of urease indicator gel sealed inside a plastic slide. The gel is amber in colour and turns cherry red if *H. pylori* are identified in the tissue sample.

'Breath test' This is a non-invasive test that detects isotopic carbon dioxide after ingestion of radiocarbon-labelled urea. The *H. pylori* enzyme splits the carbon from the urea. It is then carried as carbon dioxide via the blood to the lungs, where it can be detected in exhaled breath. These tests are specific, as no other bacterium is known to produce the urease enzyme.

Treatment is dependent on the cause and severity of the ulcer. Removal of the causative factor followed by healing of the ulcer is the main aim of treatment, e.g. eradication therapy in *H. pylori* or discontinuation of NSAIDs or aspirin, followed by acid-suppressing medication.

Advice should also be given about avoiding known aggravating factors, such as smoking and erratic dietary patterns. Patient adherence to medication regimens is crucial to the success of *H. pylori* eradication and ulcer healing, and therefore patient education is essential. In some cases, surgical intervention may be necessary.

Medication may include:

- Antacids for the relief of dyspepsia. Many preparations are based on magnesium and may result in a degree of diarrhoea.
- H_2-receptor antagonists, e.g. cimetidine and ranitidine. These assist in ulcer healing by preventing histamine from stimulating the gastric parietal cells to secrete hydrochloric acid.
- A proton pump inhibitor, i.e. omeprazole, to inhibit the release of hydrochloric acid from the parietal cells.
- Eradication therapy which is now the standard treatment for *H. pylori*.

First-line treatment lasts for 1 week and consists of:

- proton pump inhibitor (lanzoprazole/omeprazole) twice daily
- amoxicillin 500 mg three times daily
- metronidazole 400 mg three times daily.

In patients with penicillin allergy, it is common practice to substitute clarithromycin 500 mg twice daily for amoxicillin. However, long-term acid-lowering therapy may be required if there are complicating factors, e.g. NSAID therapy.

Repeat endoscopy is essential to confirm that healing has occurred.

For further information, see University of York (1995), Cottrill (1996) and MacConnachie (1997).

Surgical intervention Indications for surgery for patients with peptic ulcer are as follows:

- failure of response to medical therapy
- recurrence
- development of complications, i.e. perforation, haemorrhage, pyloric stenosis.

The aim of surgical intervention is to reduce acid and pepsin secretion. This is achieved by interrupting the vagus nerve or by resection of the gastric acid-producing section of the stomach. The options for surgical intervention in peptic ulceration are summarised in Table 4.1.

NURSING PRIORITIES AND MANAGEMENT: Peptic ulcer

Preoperative preparation (see Case History 4.1)

The patient who is to undergo an elective procedure may be admitted 1 day prior to surgery or, if the patient is otherwise healthy, may be requested to attend a pre-admission clinic. This allows time for medical examination to be made regarding the individual's fitness for the operation and a general anaesthetic. A blood sample is required for grouping and cross-matching.

A full nursing assessment is made and a care plan formulated to meet the specific needs identified and to fulfil standard preoperative nursing requirements (see Ch. 26). Explanations are given of the timescale for the preparation that will take place. If the patient is a smoker, the importance of stopping smoking and support to do so is offered.

Preparation of the GI tract will include nil orally for 4–6 h preoperatively (see Ch. 26, p. 912). On the morning of the operation, the patient is prepared for theatre. A nasogastric tube is passed perioperatively.

Prior to emergency surgery, regular observations are made of blood pressure and pulse in order to detect any deterioration in the patient's condition. Analgesics are given for pain relief, and clear, concise explanations are given to the patient and the relatives regarding treatment.

4.2 In the light of Mr R's identified needs in Case History 4.1, create a plan for this patient's preoperative care in hospital.

Postoperative management

On the patient's return to the ward, the nurse will monitor and/or observe the following:

- airway, respiratory rate, blood pressure and pulse and pulse oximetry
- nasogastric aspirate
- bleeding and drainage from the wound and the wound drain if present
- skin colour
- i.v. infusion and site
- urinary output.

These observations are maintained during the first 24–48 h, decreasing in frequency as haemodynamic stability is regained.

The nasogastric tube is usually left on free drainage between aspirations to allow air to escape. The aspirate should be observed for colour and amount. Normally the aspirate diminishes and bowel sounds are heard within 24–48 h. Should large amounts of aspirate continue, this would indicate that absorption from the stomach is not

Table 4.1 Surgical procedures used in the treatment of peptic ulceration

Site	Elective	Emergency
Gastric	Partial gastrectomy, or truncal vagotomy and pyloroplasty, or gastrojejunostomy	Partial gastrectomy Excision of gastric ulcer with truncal vagotomy and pyloroplasty or gastrojejunostomy Simple closure
Duodenal	Highly selective vagotomy Truncal vagotomy and pyloroplasty, or gastrojejunostomy Partial gastrectomy	Simple closure with truncal vagotomy and pyloroplasty, or gastrojejunostomy

After Whitehead (1988) and Forrest et al (1995).

CASE HISTORY 4.1

Mr R

Mr R has been diagnosed as having a duodenal ulcer with pyloric stenosis. He is 54 years old. He has lost a lot of weight over the last few months as a result of vomiting and does not eat much now. He is very thin and is also very anxious. He admits that he smokes 30–40 cigarettes a day and has difficulty sleeping. He has difficulty in hearing but does not use a hearing aid. His particular identified care needs are:

- relief of pain
- relief of anxiety caused by difficulty in hearing the doctor's explanations
- breathing exercises pre- and postoperatively, especially in view of his smoking
- pressure area care due to weight loss
- optimal maintenance of nutritional status
- getting adequate sleep.

occurring; it may also indicate the onset of paralytic ileus (see Ch. 26, p. 926).

Fluids are withheld for at least 24 h, after which period, if bowel sounds have returned, sips of water or ice chips may be given. Fluids may then be given at hourly intervals, beginning with 30 mL and gradually increasing until free amounts of fluid are well tolerated. Light, easily digested food is gradually introduced and the patient is encouraged to eat, but is asked to avoid drinking fluids for at least 30 min after meals (see 'dumping syndrome' below).

Care should be taken that the nasogastric tube is positioned comfortably and well supported. Nasal care is given as required. Oral hygiene is also important and the patient's mouth should be kept clean and moist using mouthwashes or by brushing the teeth if the patient can tolerate this.

The i.v. infusion must be maintained as prescribed, to preserve fluid and electrolyte balance and to prevent dehydration while oral fluids are not being taken.

4.3 What observations could the nurse make of the patient that would indicate whether adequate fluid intake is being maintained? (See Ch. 20.)

Following surgery, patients should be encouraged to sit up, get out of bed and take a few steps as soon as possible. They should also be encouraged to breathe deeply and cough regularly to clear the lungs of anaesthetic gases and excess mucus. These measures will help to prevent chest infection. Regular gentle leg activity, even when in bed, can also help to prevent the development of deep vein thrombosis. Adequate analgesia and holding the wound firmly when moving or coughing will encourage the patient to cooperate actively with postoperative therapy.

Dumping syndrome

Dumping syndrome is a postoperative complication of gastric surgery that may occur following eating. Symptoms are varied and may consist of a feeling of epigastric fullness and discomfort, sweating, an increase in peristalsis, a feeling of faintness and sometimes diarrhoea.

These symptoms occur within 10–15 min of eating and usually settle within 30–60 min. Patients frequently have to lie down until symptoms subside. The symptoms are caused by the sudden emptying of hyperosmolar solutions into the small bowel, resulting in rapid distension of the jejunal loop anastomosed to the stomach and a withdrawal of water from the circulating blood volume into the jejunum to dilute the high concentration of electrolytes and sugars.

The symptoms of dumping may be alleviated by eating smaller portions of food more frequently, reducing carbohydrate intake and avoiding drinking fluids during meals. If symptoms persist, changes in dietary intake and further surgery may eventually be indicated.

Discharge planning

Patients who have undergone surgery for peptic ulceration are generally fit to be discharged within a week of the operation. However, older patients and those with intercurrent disease may need a longer period in hospital. Therefore, it is important for the nurse to be fully aware of the patient's social circumstances so that from the time of admission adequate preparation for discharge can be made and potential problems anticipated, e.g. Will the patient need transport home? Is a home help required? Does the patient have young children? Early communication with the patient's family or friends is essential in planning for discharge.

4.4 In view of the patient profile given in Case History 4.1, what advice should be given to Mr R prior to his discharge?

An outpatient follow-up appointment may be arranged to ensure that a satisfactory recovery has been achieved, to discuss any ongoing management and to monitor the patient's rehabilitation. The GP is always given details of the patient's surgery and discharge and of any special aftercare that may be required. If continuing care of the wound is required, this will be arranged with the community nursing team or practice nurse prior to discharge.

Complications of peptic ulcer

The three major complications of peptic ulcer are:

- haemorrhage
- perforation
- pyloric stenosis.

Haemorrhage

Severe abdominal bleeding is a life-threatening emergency. Immediate measures must be taken to replace blood loss and arrest the bleeding (see Ch. 18, p. 725).

MEDICAL MANAGEMENT

Careful assessment of the extent of the bleeding is made, and fibreoptic endoscopy may be used to identify the exact site. In the first instance, an i.v. infusion is started and blood transfusion given if the patient is shocked. Intravenous ranitidine is given to reduce gastric secretion. Hourly oral fluids and a light diet are commenced when bleeding has stopped. Surgery is undertaken as an emergency if the bleeding does not cease. Elective surgery at a later date may be advised for patients who do not respond to conservative treatment.

NURSING PRIORITIES AND MANAGEMENT: Abdominal haemorrhage

Major nursing considerations

Nursing and medical staff must implement resuscitative techniques promptly as necessary. Oxygen therapy should be commenced and maintained at the prescribed rate. Blood pressure, pulse and respirations should be checked and recorded frequently to assess the patient's general condition and to observe for continuing haemorrhage. Central venous pressure monitoring may also be instituted.

Any vomit should be observed for amount and for the presence of fresh blood or a 'coffee ground' appearance. If the bleeding is severe and vomiting is continuous, a nasogastric tube will be passed to determine blood loss and to prevent further vomiting. Stools should be observed for melaena.

Pain is usually severe, requiring opiate analgesic relief. The patient should be monitored for response to analgesics (see Ch. 19, p. 742).

Urinary output must be monitored, as hypotension can affect renal function, diminishing filtration. A urinary catheter should be passed to assist in monitoring output.

Intravenous plasma protein substitutes or whole blood and plasma should be given promptly to restore circulating blood volume. Continuous monitoring must be maintained.

Efforts should be made to allay the patient's anxiety. Ongoing explanations will help to reassure both the patient and the relatives that appropriate treatment is available and that everything possible is being done to arrest the bleeding.

When the patient's condition has stabilised, preparation for surgery can be finalised. Alternatively, if conservative treatment has been successful, surgery may not be necessary.

Perforation

PATHOPHYSIOLOGY

Perforation of an ulcer allows the duodenal and gastric secretions to leak into the peritoneal cavity, resulting in peritonitis.

Perforation of a duodenal ulcer is two to three times more common than perforation of a gastric ulcer (Burkitt et al 2002).

Common presenting symptoms Haemorrhage is not a constant feature and the patient may have very few symptoms. The major presentation is the onset of severe epigastric pain, which becomes generalised abdominal pain and tenderness, made worse by any movement. Therefore, the patient typically stays remarkably still, as a result of which the abdomen develops a 'board-like' rigidity — a classic sign.

MEDICAL MANAGEMENT

Diagnosis is usually confirmed by plain erect X-ray of the upper abdomen. In a positive diagnosis, this will show air collected under the diaphragm. If the diagnosis is uncertain, barium examination may be undertaken. Gastroscopy, which requires inflation of the stomach, is contraindicated. Emergency surgery is the usual course of action, either to repair the perforation or to make a more extensive intervention.

NURSING PRIORITIES AND MANAGEMENT: Perforation

Nursing care will include the following:

- administering resuscitative therapy as necessary
- administering oxygen therapy
- monitoring blood pressure and pulse for shock
- administering i.v. fluids to correct electrolyte imbalance
- administering prescribed analgesics
- passing a nasogastric tube and performing regular aspiration to empty the stomach and prevent further peritoneal contamination
- commencing antibiotic therapy as prescribed
- preparing the patient for surgery
- giving careful explanations and calm reassurance.

Pyloric stenosis

PATHOPHYSIOLOGY

This complication of peptic ulceration is less common than haemorrhage or perforation, and most people associate the disorder with the congenital hypertrophy of the pylorus that sometimes occurs in babies. The stenosis occurs in the first part of the duodenum and in adults is due to repeated healing and breakdown of a chronic peptic ulcer. The build-up of fibrous tissues causes the stenosis, which results in partial or complete obstruction to the gastric outlet.

Common presenting symptoms include a feeling of fullness after meals, anorexia and occasional vomiting, which progresses to an overdistended stomach full of partly digested food, and projectile vomiting.

MEDICAL MANAGEMENT

Investigations Diagnosis is by clinical examination and a barium meal.

Treatment Dehydration and electrolyte imbalance, which may be severe due to the vomiting, are corrected by i.v. fluids. A nasogastric tube is inserted to alleviate vomiting. Once the patient is stable, surgical intervention may be necessary to prevent further ulceration and ensure gastric drainage. The most common procedures are vagotomy and pyloroplasty or vagotomy and gastrojejunostomy (Burkitt et al 2002, Garden et al 2002).

4.5 What would you consider to be the nursing priorities for a patient with pyloric stenosis prior to surgical intervention?

Carcinoma of the stomach

Gastric carcinomas are more common in men than in women and are usually found in 55- to 70-year-olds. The highest incidence is in Japan. A diet high in carbohydrates and low in fat, fresh fruit and vegetables is thought to predispose to gastric cancer. An increased risk is associated with pernicious anaemia, chronic gastritis and following gastric surgery. The incidence is greater in individuals with blood group A (Garden et al 2002).

PATHOPHYSIOLOGY

Gastric carcinomas are almost always adenocarcinomas derived from the mucus-secreting cells of the gastric glands; 60% occur at the pylorus or in the antrum, 20–30% in the body and 5–20% in the cardia. The tumour spreads along the gastric wall to the duodenum and oesophagus and through the wall to the peritoneum. Adjacent organs become infiltrated. Metastatic spread may occur locally to neighbouring organs, within the peritoneal cavity, or via the lymphatic or blood vessels to the liver, lungs and bones. In most countries, the overall cure rate for gastric cancer remains around 10%. However, the results from Japan present a more encouraging picture, with an overall 5-year survival rate of over 50% (Griffin & Raimes 1997).

Common presenting symptoms The most common symptoms are anorexia, loss of weight and epigastric pain. Often such symptoms are either rationalised as trivial or tolerated

despite the distress they cause; consequently, there may be considerable delay before the patient seeks medical help. By this time, the disease may be well advanced and may have spread to adjacent organs. Dysphagia indicates that the cardia of the stomach is involved. Vomiting suggests obstruction by a tumour at the gastric outlet.

MEDICAL MANAGEMENT

Investigations Diagnosis can be made by medical history, clinical examination and a barium meal, usually confirmed by CT scanning. Fibreoptic gastroscopy allows direct inspection and a biopsy to be taken.

Treatment The prognosis is poor. A partial or total gastrectomy — which is either palliative or so-called curative, depending on the extent of the tumour — may be undertaken. Details of surgery are given in Figure 4.6 (see also Griffin & Raimes 1997). Sadly, for some patients the carcinoma is so advanced that surgical intervention is inappropriate.

NURSING PRIORITIES AND MANAGEMENT: Carcinoma of the stomach

See Chapter 26 for details of perioperative nursing priorities in abdominal surgery.

Long-term care after palliative surgery

Major patient problems

After the patient has been discharged home, it is very likely that the symptoms of the cancer will gradually increase.

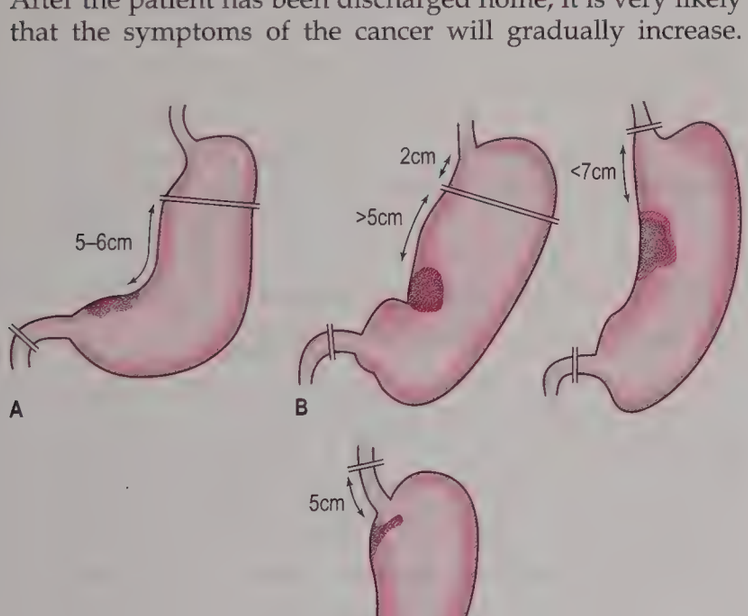

Fig. 4.6 Surgical resection for carcinoma of the stomach. A: Antral carcinoma — subtotal gastrectomy and resection of the first part of the duodenum. B: Carcinoma of the middle third — subtotal or total gastrectomy depending on the proximal margin of resection. C: Carcinoma of cardia — total gastrectomy and resection of lower oesophagus. (Reproduced with kind permission from Griffin & Raimes 1997.)

Skilful and sensitive nursing care will be required to help the patient to remain as comfortable and as free from anxiety as possible.

Pain from the tumour, metastases and ascites can be relieved initially by oral morphine sulphate (MST), progressing, as the need arises, to the judicious use of opioid analgesics, usually diamorphine, given subcutaneously via a syringe driver. Such delivery gives a consistent level of analgesia and is often the key factor in enabling the patient to be pain-free and to remain at home.

Dietary intake may prove a problem. Persistent nausea and vomiting may develop and be difficult to control. Regular and pre-emptive antiemetic medication can be most beneficial. Meals should be small and attractively served at times when the effect of antiemetics is at its optimal level. Nutritious drinks such as Ensure and Enlive can help to supplement nutrition without extra effort on the part of the patient.

Diarrhoea and constipation can both occur. A common side-effect of opiate analgesics is constipation, for which an oral laxative should be prescribed. Orally or rectally administered medications can help to control these symptoms, as can dietary advice.

Mouth infection As in all malignant disease, candidiasis is very common. Nystatin lozenges or suspensions may be given after meals and oral hygiene and dental/denture care must be meticulously maintained (see Ch. 15, p. 636).

Ascites For some patients, there may be the added distress of ascites, which is an accumulation of serous fluid within the peritoneal cavity that can cause pressure on other abdominal organs and the respiratory system. Abdominal paracentesis, whereby the ascitic fluid can be drained off, may be preferred to relieve the symptoms. Diuretics may also be used.

Psychological distress The support of the community nursing team and where possible the Macmillan or Marie Curie nursing services can prove indispensable in giving the patient the confidence to remain at home rather than in hospital. The daily visits of such a nurse, as well as ensuring that the practical aspects of care are achieved, gives the patient and the family the opportunity to talk about fears and worries. The visiting nurse is in an ideal position to monitor the well-being of both parties and to recognise when plans of care should be reviewed. Chapters 31 and 33 explore many ways in which a sensitive continuity of care can be achieved, whether in hospital, at home or in a hospice.

DISORDERS OF THE SMALL AND LARGE INTESTINES

Unlike disorders of the upper GI tract, in which the major problem is that of ingestion of nutrients, disorders of the small and large intestines result in problems of absorption of nutrients or the transit and elimination of bowel contents. People suffering from such problems complain of varying

degrees of abdominal pain and discomfort, diarrhoea and/or constipation. Often the symptoms are insidious and/or embarrassing, such that they are ignored or tolerated and not mentioned even to close relatives.

Many health education strategies are now aimed at encouraging the early reporting of symptoms before serious changes have occurred. An American colon cancer screening initiative (Anderson et al 2003) successfully increased screening for, and raised awareness of, this condition. However, although mortality from colorectal cancer can be reduced by 90% using existing screening methods, these are utilised by less than 50% of the US population. In the UK, baseline findings from a multicentre study have shown that 71% of people aged 55–64, who showed an interest in screening in a questionnaire, actually attended for flexible sigmoidoscopy (Mayor 2002).

Malabsorption syndromes

PATHOPHYSIOLOGY

Malabsorption is a consequence of impaired digestion or absorption of nutrients from the intestinal lumen and is caused by a number of conditions. These include:

- lack of digestive enzyme activity, as in chronic pancreatitis and hypolactasia
- lack of bile salts, as in common bile duct obstruction and liver disease
- loss or damage to the absorptive area, as in coeliac disease, extensive bowel resection or Crohn's disease
- failure of adequate removal from the interstitial fluid of absorbed nutrients, as in obstruction of lymphatic drainage.

Common presenting symptoms Whatever the cause, the presenting signs and symptoms of malabsorption are essentially the same. Patients may complain of frothy, greasy and bulky stools that are difficult to flush away (steatorrhoea), diarrhoea, weight loss and abdominal distension.

Vitamin and mineral deficiencies due to malabsorption may result in anaemia, lack of iron, folate and vitamin B_{12}, bleeding disorders and purpura due to lack of vitamin K, and peripheral neuropathy due to lack of vitamins A and B.

Protein deficiency can result in oedema and the musculoskeletal system may also be affected by osteopenia due to lack of calcium, vitamin D and phosphate, and tetany due to lack of calcium.

MEDICAL MANAGEMENT

Investigations When a careful history and clinical examination suggest malabsorption, the following diagnostic tests will be carried out to determine the cause:

- faecal fat estimation
- glucose and lactose tolerance tests
- haematological studies
- radiological and barium studies
- endoscopic examination and biopsy.

Treatment The form of treatment offered will clearly depend upon the cause of the malabsorption. In coeliac disease, where there is sensitivity to gluten, or in lactose intolerance, the advice seems simple: avoid foods containing the offending element. However, for the individual, such advice is not always easy to follow and the condition can potentially cause disruption and stress in everyday life, undermining the sense of well-being.

Where malabsorption is part of, or has resulted from, some other disorder, nutritional supplementation may be required on a temporary or permanent basis.

NURSING PRIORITIES AND MANAGEMENT: Malabsorption syndrome

Major considerations

The assessment and planning of care will necessarily focus on the problems of nutritional impairment, diarrhoea and any associated feeling of embarrassment, anger or despair. For some, pain will be a distinctive feature, in which case providing analgesics must be a priority.

A full nutritional assessment should be made (see Ch. 21) with the assistance of the dietitian. While assessing eliminatory function, efforts should be made to minimise the physical misery and embarrassment caused by diarrhoea. Attention to hygiene and the provision of soothing creams for any excoriation can make all the difference. Ensuring rest and relaxation can help general malaise. This is not always easy, as the investigations may be many and frequent. Supporting the patient through such tests and ensuring full understanding will help in maintaining a positive attitude.

Counselling and teaching will be a priority once the diagnosis and management have been determined. This is especially important as discharge approaches and the patient begins to take responsibility for dietary modification. The community nurse, GP and self-help groups can give support in the community, but probably the best support can be gained from those closest to the patient. The involvement of family and significant friends in any teaching and health promotion programme should be encouraged.

Inflammatory bowel disease: Crohn's disease and ulcerative colitis

Inflammatory bowel disease is the term used to describe two chronic and debilitating conditions: Crohn's disease (CD) and ulcerative colitis (UC). Both disorders are relatively common in developed countries and usually affect people in young adulthood. The incidence of both conditions has risen in Western populations over the last century, associated with better diagnostic techniques (Logan 1998). As yet no definitive cause has been found but it is currently believed that a combination of genetic susceptibility and environmental factors such as bacteria, drugs, smoking and perhaps diet, are implicated (Jewell 2002). It would seem that UC and CD are different manifestations of the same disease; UC, however, affects the colon and rectum, whereas CD can affect any part of the GI tract from the mouth to the anus.

PATHOPHYSIOLOGY

In UC, inflammatory changes occur in the mucosa and submucosa. These changes are diffuse, with widespread

superficial ulceration. In CD, the inflammatory changes affect isolated segments of all layers of the intestinal tract. The damaged mucosa develops granulomata, which give the bowel a cobblestoned appearance. Fibrosis and narrowing of the tract can occur and the transmural damage can lead to fistula formation whereby abnormal passageways develop between loops of the bowel.

In UC, the rectum is almost always involved (proctitis) and a variable amount of the rest of the colon. The entire colon can be affected. The inflammatory process affects primarily the mucosa and is continuous. Initially, there is reddening and oedema of the mucosa with bleeding points. This is followed by ulceration, which is usually superficial. In acute disease, especially of the transverse colon, there may be gross dilatation (toxic dilatation) causing the bowel wall to become thin and rupture. In chronic disease, the colon becomes shortened and narrowed. It should be noted that when Crohn's disease affects the colon or rectum, the presentation, treatment and prognosis are very similar to that of UC.

Common presenting symptoms Bloody diarrhoea with frequency, urgency and abdominal cramping are characteristic of UC. Pain may be relieved by defaecation. Pus and mucus may be present in the stool. Attacks vary in severity from being troublesome to life threatening.

The symptoms of CD depend on the site of inflammation, with large bowel CD presenting very similarly to UC. Small bowel CD may present with severe constant pain and weight loss. Oral and perianal lesions may also be present. As with UC, the severity of attacks varies. Both conditions may be associated with extra-intestinal symptoms that include arthritis, skin lesions and eye inflammation. Both UC and CD have minimal mortality rates but both have a substantial negative impact on quality of life (Love et al 1992).

Sometimes the disease is in quite an advanced state before help is sought. In such situations, the symptoms may reflect the more serious complications of rectal abscesses, fissures, fistulae or even obstruction and perforation, which will constitute an abdominal emergency.

MEDICAL MANAGEMENT

Investigations History and examination suggesting inflammatory bowel disease prompt hospital admission for diagnostic tests. Haematological studies will reveal a raised WBC, a raised ESR, a raised platelet count and lowered Hb, B_{12} and zinc. There is often hypoproteinaemia.

4.6 Can you explain these abnormalities in the blood picture?

Other investigations will include:

- examination of the diarrhoea for blood, fat and infective agents
- radiological and barium examination to reveal characteristic features of inflammatory bowel disease
- endoscopic examination — proctoscopy, sigmoidoscopy and colonoscopy; great care must be taken with such examinations, which are in fact contraindicated in fulminating disease due to the risk of perforation of the bowel
- ultrasound and CT scanning to determine the presence of abscess formation.

Treatment As there is no real cure for inflammatory bowel disease, with the exception of total colectomy in UC, the aim of medical intervention is to bring about remission of active disease and maintain this for as long as possible. This may involve the initial correction of fluid and electrolyte imbalance (see Ch. 20), malnutrition and anaemia. Close observation will be made for signs of obstruction or perforation.

Treatment strategies will have the following aims:

- Relieving abdominal pain by the judicious use of analgesics.
- Controlling the inflammation by the use of steroid therapy and 5-amino-salicylic-acid (5ASA) medications such as mesalazine and sulfasalazine. Anti-inflammatory treatment can be given orally or rectally. The aim is to bring the inflammation under control with steroids and then to maintain remission with 5ASAs, thus avoiding long-term steroid usage. The immunosuppressant medications azathioprine and mercaptopurine are used in severe cases and when the patient cannot tolerate steroids. The monoclonal antibody to tumour necrosis factor alpha, infliximab, is being used increasingly in refractory CD (Carty & Rampton 2003).
- Preventing thrombosis in the acute stage, due to thrombocytosis by the administration of s.c. heparin 5000 units twice daily.
- Restoring nutritional and fluid and electrolyte status. In fulminating disease, enteral nutrition may not be possible and parenteral nutrition will be required (see Ch. 21, p. 806). If enteral nutrition is possible, an elemental diet free of residue may be necessary for a short while before a low-residue diet can be reintroduced. As the inflammation settles, dietary restrictions can be reduced. During any quiescent phase, a 'normal' healthy diet is recommended. Such a diet should have sufficient kilocalories to restore and maintain weight, as well as being high in protein and carbohydrate and low in fat. Supplements of vitamins, iron, folic acid, zinc and potassium may be required.

Surgical intervention Surgery is required in 20–30% of patients with inflammatory bowel disease, but it is always preferred that any surgery be postponed for as long as possible. As a result, living with this condition can mean living with the constant anxiety that symptoms will become severe and complications arise. Surgery becomes unavoidable when:

- acute episodes become more frequent or fail to respond to medical treatment and there is a deterioration, leading to generalised debility, malnutrition, fluid and electrolyte disturbance and anaemia
- obstruction is acute and/or fails to resolve by conservative means
- perforation occurs
- toxic megacolon occurs — the colon hypertrophies, dilates and could rupture
- fistulae develop — these may be internal or enterocutaneous

Box 4.3

Ileoanal pouch anastomosis

The surgical management of chronic ulcerative colitis and familial adenomatous polyposis was revolutionised in 1978 by the introduction of the ileoanal pouch anastomosis, following proctocolectomy and avoiding the necessity of a permanent stoma. Factors such as age, concurrent medical conditions and, most importantly, anal sphincter function are to be considered. Patient selection is of paramount importance to achieve good results. The use of a temporary ileostomy is recommended in most patients to prevent pelvic sepsis. Small bowel obstruction, pelvic sepsis, fistula formation and pouchitis are the most common complications. Sexual dysfunction represents a major concern for younger patients in need of this kind of surgical treatment. The primary advantages of this technique are that the disease is removed completely, adequate reservoir is restored and transanal defaecation and faecal continence are re-established, avoiding the necessity of a permanent stoma (Moreno et al 1996).

This procedure is not used in Crohn's disease because of the risk of disease recurrence in the pouch.

- abscesses fail to respond to intensive treatment
- malignant changes are considered to be a risk.

The choice of operation will depend on the extent and severity of the disease. It is generally accepted that the emergency operation of choice is colectomy with terminal ileostomy and preservation of the rectum. This leaves open for the future the option of proctectomy, ileorectal anastomosis or ileoanal anastomosis. Elective surgery may include total proctocolectomy with permanent ileostomy, colectomy with ileorectal anastomosis or restorative proctocolectomy with ileoanal reservoir.

Great strides have been made in recent years to develop sphincter-preserving operations which avoid creation of a stoma (Moreno et al 1996, Williams 2002) (see Box 4.3). Williams (2002) discusses the possible alternatives to conventional stoma formation, recognising the undoubted impact which stoma formation can have on the patient's self-concept and body image.

In CD, the patient may undergo more than one operation over many years, as surgery may initially be limited to resection of the affected segments of the bowel. However, because the disease affects the total GI tract, alternatives to stoma formation are less easily achieved.

NURSING PRIORITIES AND MANAGEMENT: Inflammatory bowel disease

General considerations

The nursing care of patients with inflammatory bowel disease is essentially symptomatic and must be individualised. Assessment will focus on nutritional status, pain and discomfort, eliminatory patterns, how much the patient knows about the condition and their ability to cope with it. It will also be important to get to know the patient's lifestyle, likes and dislikes, and to identify any sources of stress in their daily life. For some patients, developing a treatment plan will be much easier if a trusting relationship is developed with the nurse. Having a 'named nurse' can be a great comfort and support in coping with the stress of being hospitalised and undergoing a range of often exhausting investigations for which fasting and bowel preparation is required (see Case History 26.4, p. 906).

Confirmation of diagnosis can be a great source of relief in some patients, many of whom may have thought they had a much more serious illness. However, they will now have to accept the reality of a condition that is with them for life. Time must be spent on a regular basis helping the patient to adjust and to plan positively for the future. The National Association for Colitis and Crohn's Disease (NACC) can offer a great deal of support to both patients and their families (see Useful websites, p. 157).

In addition, nursing priorities must include assessing and relieving pain, providing comfort measures that will promote rest, ensuring a high standard of personal hygiene, and providing emotional support to the patient and the family.

It is essential that privacy and ease of access to a toilet or commode is ensured, as the patient will be embarrassed and sensitive about the frequent bowel movements. The patient should be encouraged to maintain an adequate nutritional intake. Small snacks between meals will help to increase calorie intake. The provision of regular oral hygiene and antiseptic mouthwashes is essential to prevent moniliasis. The use of an oil-based barrier cream will help to prevent excoriation around the anal area. Fatigue will be a constant feature. A tactful approach when disturbing an exhausted patient in order to carry out essential care is helpful in gaining cooperation, despite appearing unappreciative of the nursing care being carried out.

Nursing care in acute episodes

During fulminating episodes, the patient may be acutely ill. Abdominal pain can be severe and diarrhoea unremitting, and the presence of fissures, fistulae and rectal abscesses may make the symptoms worse. Dehydration and electrolyte imbalance must be corrected and nutritional status maintained by the parenteral route. The patient will be prone to infection, and the nurse should be alert for signs of pyrexia and tachycardia that may indicate the presence of infection. Toxic megacolon, when the colon becomes grossly dilated, is a life-threatening medical emergency that can result in perforation, haemorrhage and septicaemia. A sudden reduction in either bowel motions or bowel sounds in the acutely ill patient should alert the nurse to the possible onset of this grave complication. Pain and abdominal distension are not always present. This complication will require immediate surgical intervention.

Monitoring

Specific monitoring of the patient's physical condition should include:

- recording of vital signs, particularly any elevation in temperature or pulse rate or signs of impending shock
- recording fluid intake and output. This would include all fluid replacement, whether i.v. or oral, and all fluid

losses: urine, liquid diarrhoea and/or via any fistula. A drop in urine output may indicate fluid depletion. However, if parenteral nutrition is necessary, signs of fluid overload could occur (see Ch. 20, p. 769)
- recording frequency and nature of diarrhoea on a stool chart.

Perioperative care

The essential principles of perioperative care are discussed in Chapter 26. In inflammatory bowel disease there are additional concerns of which the nurse must be aware. Many patients are physically debilitated and, should they present as an abdominal emergency, it may not be possible to improve this state prior to surgery (see Case History 26.2, p. 903). The psychological preparation for surgery that may involve stoma formation is essential, even if time is limited. If optimal time is available, such preparation, in which the stoma nurse specialist plays a key role (see Box 4.4), has been shown to have a very beneficial effect in helping the patient come to terms with and manage the stoma.

Box 4.4

The role of the stoma nurse specialist

Psychological preparation for ileostomy and colostomy is essential. The need for information, for emotional support and to develop new skills is vital for the total well-being of the patient (Porrett & Daniel 1999).

The stoma nurse specialist specialises in the care of patients who undergo stoma surgery. In the case of elective surgery, the stoma nurse will visit the patient and the family prior to the operation to give information and support. It is essential that the patient is fully informed of the surgical options available in order to give informed consent to treatment. Clear explanations can help to ensure that the patient understands the changes in body function that will take place and help in adjusting to the accompanying alteration of body image and self-concept. An opportunity should be given to voice feelings and concerns. The spouse or partner should be included in these discussions if the patient wishes, and topics such as sexuality and fertility should be addressed. Referral for specialist counselling may be made as required. Part of the stoma nurse's function is to liaise with other members of the health care team in hospital and in the community, in order to ensure that optimal care and support are given during the patient's treatment and rehabilitation.

The stoma nurse specialist is usually involved in helping to choose the stoma site; this decision should be made after observing the patient standing, walking and sitting, rather than just lying in bed (Black 2000). The chosen stoma site should be marked before the patient is transferred to theatre. The various appliances which are available should be demonstrated before the operation, and, if it seems appropriate, it may be helpful for an individual who has a stoma to visit the patient to talk about what it is like to cope with a stoma in day-to-day living and to reinforce the fact that general health will improve after the surgery.

Research has shown that adequate counselling and education prior to surgery have a positive effect upon the individual's ability to cope following the procedure.

For further information, see Porrett & Daniel (1999) and Black (2000).

Stoma care

Postoperatively, the nurse must maintain close observation of the stoma to ensure that it is viable and has a good blood supply. The stoma should be pink; if it darkens in colour this indicates that the blood supply is threatened. Initially the stoma will be oedematous, but this should reduce over a few days. A clear drainage stoma bag will be in position to allow good observation of the stoma. If an ileostomy has been formed, digestive enzymes will be present and fluid faeces will become copious; care must be taken that the skin is protected by the correct application of the stoma bags. The stoma is formed so that it is approximately 3.5 cm long, thus protecting the surrounding skin. However, care is still necessary to protect the skin and position the appliance. No pressure should be put on the stoma during care.

The patient should be reassured that the output from the stoma will reduce and will become more 'paste-like' in consistency, as the small intestine recovers and adjusts. The stoma nurse specialist can demonstrate the various appliances available so that the patient has a supply of the most suitable ones prior to discharge. Initial care of the stoma is given by the nursing staff, with the patient gradually taking over under supervision and then performing care independently before going home. Continuity of care is given in the community by the primary health care team and the stoma nurse specialist. Advice is also available from the ward staff as required.

Dietary advice should be given by the dietitian and the stoma nurse specialist before discharge, and the patient and family should be advised of the likely protracted recovery and adjustment time that will be required before a return to good health and a full lifestyle can be achieved.

For further information, see Black (2000).

4.7 Arrange to accompany a stoma nurse specialist on a follow-up visit if possible.

4.8 Ensure you are aware of the different stoma appliances that are available to ostomists. What are the arrangements for the supply and disposal of the appliances?

4.9 As part of your community studies, find out the allowances and benefits to which a person with Crohn's disease may be entitled.

Diverticular disease

Diverticular disease presents as small hernias or outpouchings of the mucosa through the muscular wall of the bowel. These occur predominantly in the sigmoid and descending colon. The presence of uncomplicated diverticulae with minimal or no symptoms is known as diverticulosis and is present in at least half the population aged 80 years and over (Tjandra et al 2001). If inflammation occurs, causing severe symptoms, the condition is referred to as diverticulitis and, if persistent, will be considered a chronic inflammatory disease. However, it is often impossible to distinguish one condition from the other on radiological examination, and hence it is useful to include

both active and asymptomatic disease in the term 'diverticular disease'.

It is thought that a diet low in fibre is a major factor in the development of the disease. Research has shown that people with diverticular disease have diets low in fresh fruit and vegetables, brown bread and potatoes, and high in meat and milk products. It is also thought that chronic constipation and the excessive use of purgatives may cause diverticular disease by raising intraluminal pressure.

PATHOPHYSIOLOGY

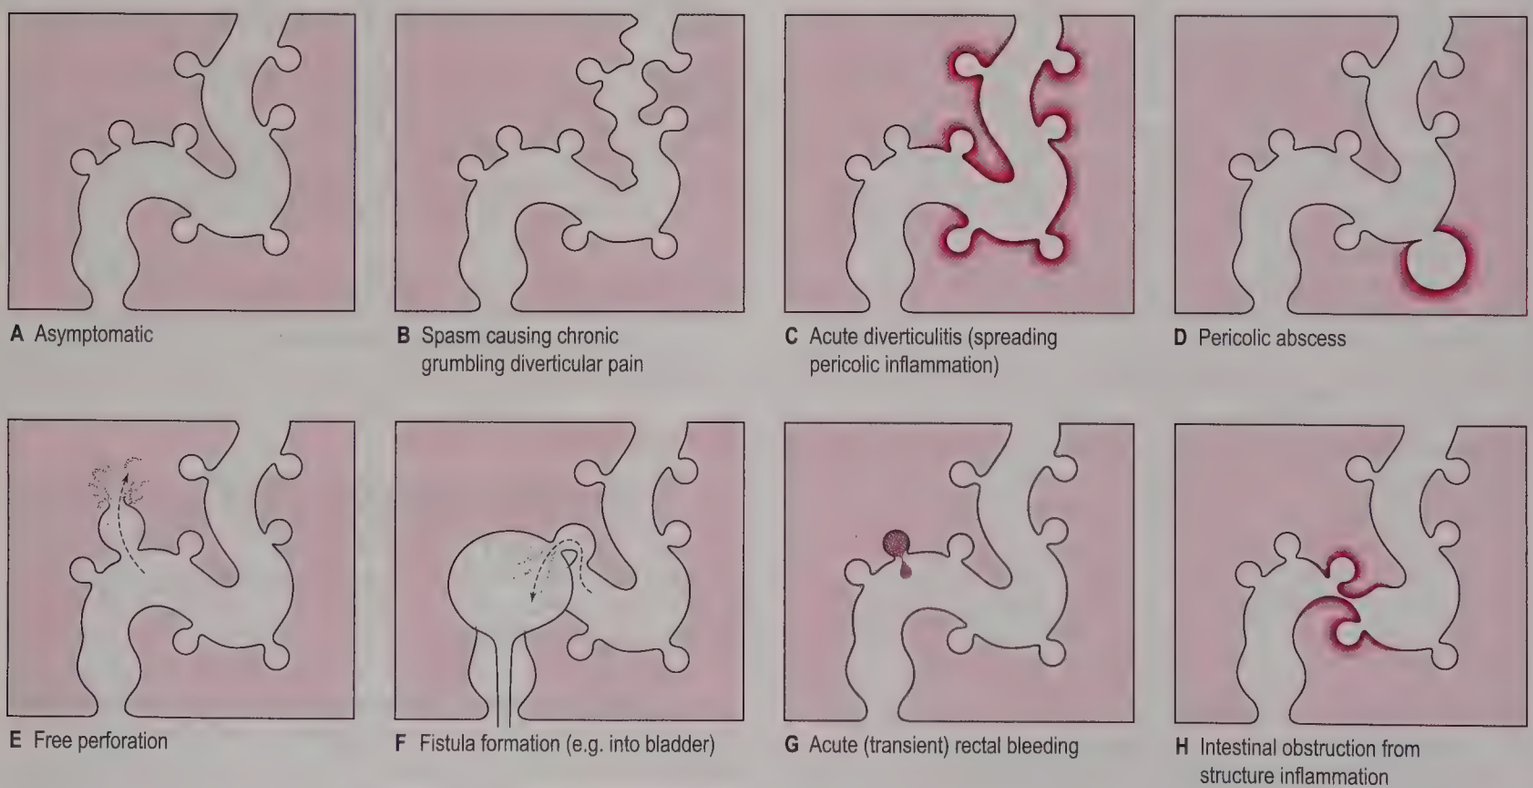
It is thought that a low volume of colonic content leads to a reduction in the diameter of the colon. Increased luminal pressure during segmentation causes herniation of the mucosa through the muscle wall. Faeces may collect in the hernia(e), causing inflammation, perforation and abscess formation, the formation of fistulae into the small intestine, bladder or vagina, and peritonitis. Repeated attacks can eventually lead to obstruction.

Common presenting symptoms include the presence of intermittent grumbling, spasmodic pain in the left iliac fossa or suprapubic region, and a mass may be palpable on abdominal or rectal examination. Constipation, intermittent constipation or intermittent diarrhoea are usual. The majority of patients with diverticular disease are asymptomatic, but Figure 4.7 shows the range of clinical presentations that can occur.

MEDICAL MANAGEMENT

Investigations Diagnosis is made by barium enema. Flexible sigmoidoscopy is undertaken to exclude cancer. Colonoscopy is indicated when there is rectal bleeding or where a carcinoma is suspected. Most individuals are treated in the community by their GP.

Treatment The main treatment is dietary. The individual should be encouraged to increase fibre intake, including unprocessed bran, wholemeal bread, fruit and vegetables, and should drink plenty of water. Antispasmodics such as propantheline bromide can be used. It must be emphasised that stimulant laxatives should not be used, as they increase the pressure in the muscular wall of the colon and can cause more herniation of the mucosa.



In severe exacerbations, admission to hospital may be necessary if there is marked abdominal pain and pyrexia. Treatment will include broad-spectrum antibiotics, i.v. infusion and nasogastric aspiration until the inflammation subsides. Although many people who live with diverticular disease feel able to cope and have no difficulty in adhering to dietary advice, for about 25% of sufferers complications do occur and surgical intervention will be required. Those complications that may necessitate surgery are shown in Figure 4.7(C–H). Depending on the nature and severity of the problem, resection and temporary or permanent stoma formation may be necessary.

4.10 Possible surgical procedures for diverticular disease might include:

(a) colectomy
(b) Hartmann's procedure (see Ch. 26)
(c) transverse loop colostomy.

An anxious older patient cannot remember what the surgeon actually said in describing these operations. How would you explain the nature and purpose of these procedures to the patient?

A Asymptomatic

B Spasm causing chronic grumbling diverticular pain

C Acute diverticulitis (spreading pericolic inflammation)

D Pericolic abscess

E Free perforation

F Fistula formation (e.g. into bladder)

G Acute (transient) rectal bleeding

H Intestinal obstruction from structure inflammation

 Fig. 4.7 Clinical presentations in diverticular disease (Burkitt et al 2002).

Irritable bowel syndrome

PATHOPHYSIOLOGY

Irritable bowel syndrome (IBS) is an interaction of three major mechanisms: psychosocial factors, altered gut motility and altered sensory gut function (Camilleri & Choi 1997). Organic bowel disease must be excluded when making the diagnosis. IBS accounts for up to 50% of all referrals to gastroenterology clinics and has a prevalence of between 3 and 22% in European adults with women representing 80% of patients (Delvaux 2003). In IBS, the disorders of gut motility and sensation are mediated by psychological stress factors such as anxiety and depression, although other gut irritants, some food types and alcohol can exacerbate symptoms. In addition up to 40% of IBS patients report physical or sexual abuse (Delvaux 2003).

Common presenting symptoms are:

- diarrhoea and/or constipation
- abdominal pain (often relieved by defaecation)
- abdominal distension
- sensation of incomplete evacuation (tenesmus)
- urgency of defaecation.

MEDICAL AND NURSING MANAGEMENT

Investigations include a careful history, noting details of the paient's physical symptoms, life stressors and reactions to these, and general personality. The type of investigation will depend on presenting symptoms and the patient's age. For example a young person with no 'alarm' symptoms, e.g. weight loss, anaemia and/or rectal bleeding which would raise the suspicion of a pathological problem rather than a functional problem, would require only blood tests and no invasive procedures. However, patients over the age of 40 and anyone with the above 'alarm' symptoms would require flexible sigmoidoscopy to exclude any more serious pathology.

Once the diagnosis is confirmed, time is spent discussing the symptoms and findings and reassuring the patient that there is no underlying pathology.

Treatment is aimed at control of the predominant symptoms. If this can be achieved by avoiding known aggravating factors such as certain foodstuffs or psychological stressors, then the need for pharmacological intervention can be avoided. However, if no particular factor can be identified then antidiarrhoeal agents, bulking agents and antispasmodics should be prescribed.

Alternative therapies such as hypnotherapy have been shown to have significant and long-term value in symptom control in IBS (Gonsalkorale et al 2003). However, nurses must remember to be realistic when discussing coping strategies with patients, as alternative therapies are not readily available on the NHS and can be very expensive.

Appendicitis

The appendix develops from the dependent pole of the caecum as a blind-ended, worm-like sac. It has a large amount of lymphoid tissue in its walls and is covered by the peritoneum. The appendix is described as vestigial in that it constitutes the remnant of a structure whose function is no longer required. In adulthood it is about the size of an adult little finger (5–6 cm).

Inflammation of the appendix is the most common cause of abdominal sepsis in developed countries. The concern is always that the inflamed appendix might rupture, causing peritonitis. Appendicitis is a life-threatening condition and constitutes a surgical emergency.

Although in many people the appendix has virtually disappeared by their middle years, appendicitis can occur at any age. It is rare in infancy and less common in later life, but in the UK can affect 12–15% of those aged 8–15 years. Its prevalence is thought to be closely related to refined Western diets where faecolith residues may be retained in and obstruct the lumen of the blind-ended appendix. The incidence of appendicitis does appear to have fallen significantly over the past 10 years, perhaps reflecting the promotion of a healthier diet that is high in fibre. Less commonly, viral infections, contaminated food and intestinal (tape) worms can precipitate appendicitis.

PATHOPHYSIOLOGY

When the lumen of the appendix becomes obstructed, bacteria proliferate and cause an acute inflammatory response. The local end-arteries become thrombosed and gangrene sets in. This in turn leads to perforation and localised peritonitis. If left untreated, this becomes generalised peritonitis (see Box 4.5 and Fig. 4.8).

Common presenting symptoms Often appendicitis occurs 'out of the blue'. Many an anecdote tells of individuals who at 21.00 h were happily enjoying an evening at the theatre or a restaurant and at 03.00 h found themselves in a hospital bed minus their appendix.

For others, symptoms of colic and fever may 'grumble' on for some time before an acute episode occurs. In such cases, the obstruction has perhaps been partial and the inflammation transitory. These recurrent episodes can result in adhesions forming which can cause further problems (see Box 4.6).

The classic and cardinal features are usually seen in the young person and readily 'diagnosed' even by family and friends (see Case History 4.2).

4.11 After reading Case History 4.2, try to answer the following questions:

(a) How do you account for the discomfort affecting P's right leg?
(b) Why would any delay in admitting P to hospital have been unwise?
(c) Why might P have experienced postoperative urinary retention? (See Ch. 26, p. 934.)

MEDICAL MANAGEMENT

Investigations Following a careful history and examination, only essential investigation will be carried out to confirm diagnosis. If this is in doubt, an ultrasound scan may be undertaken.

Treatment

Surgical intervention Appendicectomy is the treatment of choice. To remove the offending appendix, a small

Box 4.5

Peritonitis (inflammation of the peritoneum)

Acute peritonitis

Acute peritonitis is commonly caused by irritating substances, often bacterial in nature, entering the abdominal cavity due to:

- perforation of an organ by either trauma or disease, e.g. a penetrating injury, a perforated appendix, duodenal ulcer, or ruptured fallopian tube as a result of an ectopic pregnancy
- gangrene of an organ such as might occur in a strangulated hernia
- septicaemia, which may have originated in another part of the body.

The peritoneum becomes inflamed, inciting a dramatic increase in the production of serous fluid. This rapidly becomes infected and purulent in the presence of bacteria (typically *Escherichia coli* and *Bacteroides*). Toxins are absorbed from the inflamed and oedematous peritoneum and large amounts of fluid are lost into the peritoneal cavity, leading to paralytic ileus, abdominal distension, hypovolaemia, fluid and electrolyte imbalance and loss of protein.

Immediate and intense pain is felt at the site, followed by vomiting, pyrexia, extreme weakness and shock. Diagnosis is essentially clinical, supported by X-ray examination to detect the presence of free air, fluid levels, abdominal masses and perforations.

Treatment is by a combination of surgery, i.v. antibiotic therapy and specific intervention for the underlying cause. The peritoneal cavity may need to be opened to remove the toxic material and allow drainage of the peritoneal cavity. Supportive therapy includes i.v. fluids to maintain fluid and electrolyte balance, nasogastric aspiration to relieve distension, oxygen therapy and analgesics. If the patient continues to remain pyrexial, tachycardic and in pain, an abdominal abscess should be suspected as a complication.

Chronic peritonitis

This is far less common than acute peritonitis but may occur in association with tuberculosis (see Ch. 3) or as a complication of some long-standing irritant such as peritoneal dialysis or a foreign body. Symptoms are less severe and include low-grade fever, vague pain and malaise. Treatment will depend on the cause.

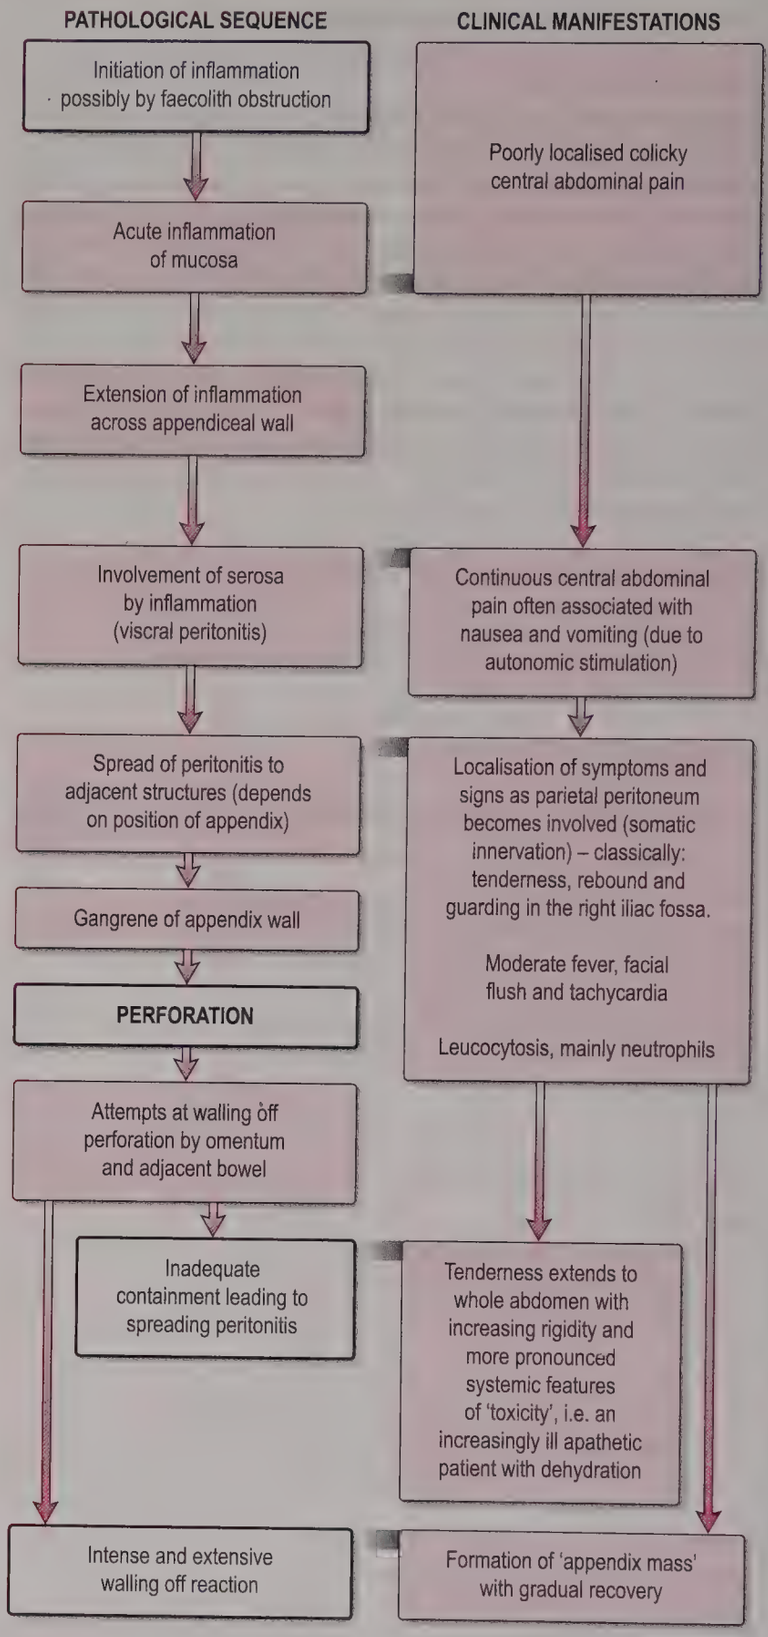


Fig. 4.8 The pathophysiology and clinical manifestations of acute appendicitis (Burkitt et al 2002).

incision is made, the appendix 'delivered' and the stump sutured. The cavity will be irrigated and a drainage tube inserted if any infected material is evident. Alternatively, the appendix may be removed using a less invasive laparoscopic technique.

NURSING PRIORITIES AND MANAGEMENT: Appendicitis

As appendicitis so often presents as an emergency, the patient may have to be prepared quickly. Every detail of safe physical preparation must be attended to, but psychological support must not be considered 'a luxury we can't afford'. The skilled nurse will blend clinical and interpersonal skills to support the patient and family during this crisis.

In the majority of cases, postoperative recovery will be uneventful and rapid. Pain relief should be ensured and vital signs monitored at regular intervals. Monitoring should be tailored to the patient's condition and continue until stability is restored (see Ch. 26, p. 921).

Box 4.6

Adhesions

An adhesion is the union of two surfaces that are normally separate. In the abdomen they are commonly the result of abdominal surgery, injury or inflammation. As healing occurs, fibrous scar tissue develops which may adhere to adjoining tissue, e.g. loops of bowel. These adhesions can distort tissue and, by so doing, impair function, e.g. the transit of intestinal contents. Adhesions may be asymptomatic, but they occasionally cause obstruction and require surgical division.

Such fibrous bands can also occur around pelvic organs, in the pleura, the pericardium and in damaged joints.

CASE HISTORY 4.2

P

P, an active 13-year-old boy, complained of having pains in his stomach and of feeling sick. He refused his breakfast and was reluctant to go to school. Kept at home 'just in case', he was listless and vomited the soup he tried at lunchtime. His friends came round after school; for a while he seemed to 'pick up' and laughter was heard from his room. However, by 20.00 h he could localise the pain to his right side. He curled up on the sofa and complained particularly when he tried to straighten out his right leg.

His mother, suspecting appendicitis, called the doctor. By the time the GP arrived, P was flushed, vomiting and in considerable pain, especially when the GP tried to examine his abdomen. He was immediately admitted to hospital, where a diagnosis of appendicitis was confirmed and he went directly to theatre for an appendicectomy. His designated nurse ensured that both he and his mother understood what was to happen. P's mother was relieved to know that an analgesic could now be given but understood that P's description of the pain had been important in aiding diagnosis. P was not given any bowel preparation, as it would only aggravate the condition. He had not eaten since lunchtime, but because he had vomited, and on examination appeared dehydrated, an i.v. infusion was started to correct any fluid and electrolyte imbalance (see Ch. 20). Intravenous antibiotics were administered in the perioperative period.

P appeared to cope well but was clearly comforted by his mother's presence; she helped him into his theatre gown and promised to safeguard his precious watch. Once prepared, P was taken to theatre, returning to the ward in the early hours of the next day. P's mother decided to go home, having reassured P that she would be back in the morning.

P recovered rapidly and there had been no evidence of perforation or peritonitis (see Box 4.5). He required little analgesic relief but the nurse remained alert to the possibility he was 'putting on a brave face'. The fluid balance record was maintained while the i.v. infusion continued, but this was discontinued after 24 h. By the next day, P was out of bed and taking a light diet and wanting to go home. His only problem had been an initial inability to pass urine that he found unpleasant and embarrassing. However, standing out of bed made things easier. The nurse running water from the tap, however, didn't impress him at all.

P was discharged on the third postoperative day. His sutures were dissolvable and would therefore not need to be removed. The discharge advice for this normally active boy was to ensure that he was not overly active too soon and his nurse took time to explain again that healing would not be fully complete for about 4–6 weeks.

Complications

Should perforation and peritonitis occur (see Box 4.5), the patient may become seriously ill. Intestinal peristalsis will be halted and the risks of dehydration, electrolyte imbalance and septic shock are very real. Treatment will involve the removal of the appendix and toxic material, drainage of any abscess and the administration of systemic antibiotics. Oxygen therapy may be necessary and vascular volume will be restored and maintained intravenously. Opiate analgesics will be given to ensure pain is not allowed to exacerbate an already serious situation. With effective and prompt intervention, the mortality rate of such complications is low.

Abdominal hernia

In the discussion on hiatus hernia (see p. 110), a hernia was defined as the protrusion of an organ through the structures that normally contain it. Abdominal hernias occur where there is an acquired or congenital weakness in the muscle wall of the abdomen, allowing an outpouching of peritoneum to form a sac (see Fig. 4.9). Acquired weakness can occur in any condition that may result in chronically

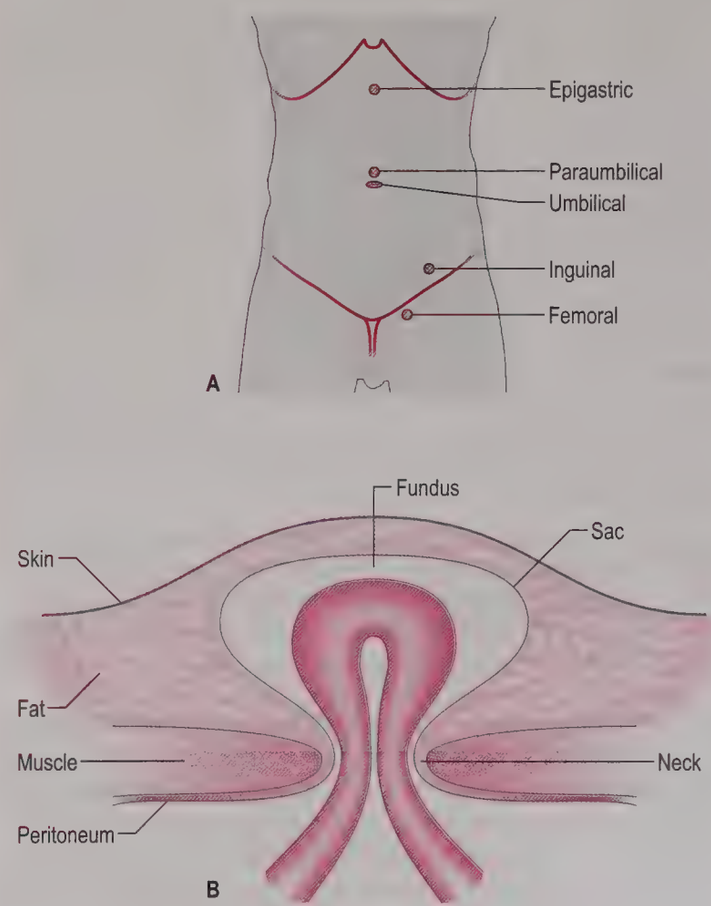

Fig. 4.9 A: Common abdominal wall hernias. B: The principles of the anatomy are the same in each case, although there are obviously individual differences. There is a protrusion of the peritoneum through a natural gap or weakness in the muscle wall of the abdomen. This gap narrows the sac of peritoneum into a neck before it opens out into the fundus. The sac may or may not contain some of the contents of the peritoneal cavity, e.g. omentum, small bowel. (Reproduced from Whitehead 1988, with permission from Edward Arnold.)

raised intra-abdominal pressure, e.g. chronic cough, constipation or heavy lifting, or where abdominal muscle weakness has developed, e.g. obesity, old age, illness or pregnancy.

An untreated hernia may progress to contain peritoneal contents, typically the small or large bowel. The major concern is that, due to twisting and/or constriction at the neck of the sac, the blood supply may become impaired at that site. Unless this is immediately resolved, all of the symptoms of intestinal obstruction will occur (see Box 4.7).

4.12 How would paralytic ileus be managed?

PATHOPHYSIOLOGY

Abdominal hernias The most commonly occurring types of abdominal hernia may be described as follows.

Inguinal hernia This type of hernia may be indirect or direct, the former being the more common. In indirect inguinal hernia, congenital abdominal weakness causes the hernial sac to protrude through the inguinal ring and follow the round ligament or spermatic cord. A direct inguinal hernia protrudes directly through the posterior ring. Inguinal hernias are far more common in men than in women.

Femoral hernia This type of hernia is considered to be acquired, resulting from herniation through the femoral canal. This canal is wider in women, making such herniation more commonly a female complaint. Femoral hernias also have a greater risk of complications.

Umbilical hernia Many infants are born with an umbilical hernia. This normally disappears in the first year of life without surgical repair. Acquired umbilical hernias can develop in overweight individuals or in those with abdominal ascites (see p. 138).

Incisional hernia Following abdominal surgery, the incision site is a point of potential weakness. This becomes a problem if the patient experiences postoperative problems such as impaired healing, especially if drainage of the wound has been required, abdominal distension or generalised debility.

4.13 It is often difficult to picture the anatomical features of inguinal or femoral hernias. Review again normal abdominal anatomy with the help of your physiology textbook and take time to understand for yourself how hernias develop.

Reducible and irreducible hernias In the early stages, a hernia may often be reducible, i.e. with manual palpation or a change to standing posture the sac will return to the abdominal cavity. However, as the hernia becomes larger and adhesions form, reduction becomes impossible and the hernia is described as irreducible or incarcerated. If the blood flow is then impaired and obstruction occurs, the hernia is described as strangulated.

Common presenting symptoms The term hernia is usually familiar to the public and the diagnosis, therefore, is often of no surprise. However, familiarity with the term must not be confused with full understanding of the condition. Many may live with the condition for some time, not appreciating the related problems that could occur. Often

Box 4.7

Intestinal obstruction

Intestinal obstruction occurs when the normal transit of intestinal contents is impeded due to mechanical obstruction, vascular occlusion or impaired innervation. Obstruction may be partial or complete.

Mechanical obstruction

Intraluminal causes
- Neoplasms
- Strictures
- Foreign bodies
- Faeces
- Intussusception: a telescoping of one part of the bowel into another part

Extramural causes
- Adhesions
- Strangulated hernia
- Volvulus: twisting of the bowel
- Neoplasms outwith the intestinal tract

When the obstruction occurs, the affected intestine becomes distended with GI secretions (as much as 8 L is formed each day). As the fluid accumulates, the pressure rises and the bowel responds by attempting to propel the contents forward. This serves only to increase secretions; eventually, the increase in pressure increases capillary permeability and fluid is forced out into the peritoneal cavity. The distension may cause respiratory embarrassment. Severe abdominal colic is experienced. If the obstruction is in the small bowel, vomiting occurs. Obstruction in the large bowel results in distension with air and faeces, and the eventual increase in pressure results in necrosis and the threat of perforation. The outcome of unresolved obstruction will be electrolyte imbalance, hypovolaemia and possibly peritonitis.

Vascular occlusion

Obstruction may occur if there is vascular occlusion of the major mesenteric blood supply by a thrombus or embolus. It is the resulting ischaemia that leads to obstruction. Although there is pain, there is no distension. As the condition deteriorates, the pain may actually decrease. If undiagnosed, gangrene and bacteraemia develop as toxins from the lumen invade the peritoneum and are absorbed into the bloodstream. If surgical intervention is not prompt, death may result. It should also be noted that any mechanical obstruction (e.g. strangulation) that impairs blood supply carries with it a significant mortality risk.

Impaired innervation: paralytic ileus

Paralytic ileus will occur when trauma, inflammation or pain in the thoracolumbar region interferes with the normal innervation of the bowel. It can therefore be a complication of such conditions as back and chest injury, renal pathology and peritonitis. Temporary (paralytic) ileus that follows the necessary handling of the bowel in certain abdominal surgical procedures usually resolves in 12–48 h (see Ch. 26, p. 926). Paralytic ileus will result in marked distension, causing discomfort and respiratory embarrassment.

Treatment

Treatment will involve the correction of fluid and electrolyte imbalance, the relief of the distension and pain, and surgical intervention to address the cause.

it is only when symptoms of local pain and tenderness arise that medical advice is sought. By that time the hernia will probably have become irreducible.

MEDICAL MANAGEMENT

The traditional treatment of choice is surgical repair, herniorrhaphy being the usual procedure. The abdominal contents are returned, the sac excised (herniotomy) and the abdominal wall repaired and strengthened with sutures. Laparoscopic techniques are now the more common approach to hernia repair. The minimally invasive nature of such surgery is proving increasingly beneficial to the patient. Follow-up in an outpatient clinic is not considered necessary unless there was an identified surgical problem.

On rare occasions, surgery is contraindicated due to pre-existing morbidity. In these situations a supporting truss may be worn to keep the hernia reduced and the patient free of symptoms. However, this option is not ideal. Surgery under epidural or local anaesthetic for those patients with chronic respiratory or cardiac problems has greatly improved patient outcome and obviated the need for many people to wear a truss.

Strangulation of a hernia This life-threatening complication presents with all of the symptoms of intestinal obstruction, i.e. vomiting, severe abdominal pain, distension and absolute constipation. The patient rapidly becomes shocked, dehydrated and pyrexial. Diagnosis is made by history and clinical examination. A plain X-ray may identify the location and the associated distended loops of bowel. Rapid preparation for surgery will be necessary and definitive therapy will include oxygen, opiate analgesics, i.v. correction of fluid and electrolyte balance, nasogastric aspiration and antibiotic administration. Surgery may well necessitate resection of the affected bowel and intensive nursing care will probably be required in the early postoperative period.

When such an occurrence is unexpected, relatives will find it especially hard to cope and will need regular contact with nursing staff for information, explanation and support. The patient is initially often too ill to appreciate more than clear and brief communications.

NURSING PRIORITIES AND MANAGEMENT: Abdominal hernia

Perioperative care

Ideally, the surgery will be elective and the patient fit. Care must be taken to ensure the patient is not suffering from a chest complaint, allergy or smoker's cough. In such situations, surgery should be postponed, as postoperative coughing could threaten the integrity of the hernia repair. Smoking is always discouraged, even if only for the perioperative period, and the physiotherapist and nurse should teach the patient how to support the wound and flex the hip on the affected side should coughing or sneezing occur. Postoperative recovery is usually uneventful and the patient is often discharged the next day. Potential problems that must be recognised are urinary retention, infection of the wound and pain, particularly scrotal discomfort when inguinal herniorrhaphy has been performed. A well-fitting scrotal support, used in conjunction with analgesics, usually eases any discomfort.

4.14 What specific nursing care is required if the patient has had a hernia repair under epidural anaesthetic?

Hernia repair should never be considered lightly. Often surgery is more complicated than anticipated and the patient may experience considerable postoperative pain and temporary loss of peristalsis. If this is the case, postoperative recovery will necessarily take a little longer (see Ch. 26).

Discharge advice

Time must be taken to ensure that the patient and the family understand the precautions that are necessary to ensure optimal recovery and well-being. Although activity is encouraged, lifting or straining must be avoided. Older men may be troubled by an enlarged prostate gland and may strain to pass urine. Equally, coughs, colds, known allergens and constipation, i.e. anything that might raise intra-abdominal pressure during the weeks of healing, should be avoided if at all possible. The time allocated to give advice and support prior to discharge presents an ideal opportunity for general health promotion, e.g. on smoking, diet and alcohol, and, in the vulnerable patient, for a sensitive reappraisal of home circumstances and community support. Driving should be avoided until the patient is confident of being able to perform an 'emergency stop' if required.

Colorectal cancer

Neoplasms, both benign and malignant, can occur in the large bowel. The concern with benign neoplasms such as polyps is that, if they are extensive, large and of prolonged duration, there is a propensity for malignant change to occur. As a result, if polyps are diagnosed, they are usually removed surgically. Malignant tumour of the large bowel — colorectal cancer — is second only to cancer of the lung in causing death from malignant disease in Western society. It is the second most common cause of cancer-related deaths in Scotland (SIGN 2003). Although it affects all age groups, it is uncommon under the age of 40.

Cancer can affect any part of the large bowel but is most common in the rectum and sigmoid colon (Keighley & Williams 1999). It affects men and women equally, but rectal carcinoma is more common in men and colonic carcinoma is more common in women.

The exact cause of colorectal cancer is unclear. As it is virtually unknown in rural communities in the developing world, its association with the Western diet is increasingly accepted. The early work of Burkitt (1971), relating low-fibre diets to disease, has proved very influential. Certainly, a low-residue diet prolongs transit time in the intestine, thus allowing any potential carcinogen increased contact with the intestinal mucosa. Colorectal cancer is also associated with other disorders of the bowel, e.g. ulcerative colitis, adenomatous polyps and, significantly, the hereditary disorder known as familial adenomatous polyposis (FAP) (see Ch. 6).

PATHOPHYSIOLOGY

The tumours arise from the epithelial cells of glandular tissue — adenocarcinomas. As they grow, they progressively

obstruct the bowel by extending into the lumen or spreading circumferentially to form a ring-like stricture (see Box 4.7). Metastatic spread is by direct infiltration of local tissues and organs via the lymphatic and portal circulation, or by implantation during surgery.

Common presenting symptoms Unfortunately, patients tend not to present until the disease is at an advanced stage. The symptoms are subtle, gradual and easily ignored or explained away. Symptoms will vary somewhat according to the site of the tumour but will essentially involve an alteration in bowel habit. Constipation alternating with diarrhoea is the presenting feature, combined with rectal bleeding and weight loss. Tenesmus and colic may well be present, as well as excess mucus in the stool. Pain is not a common feature and, perhaps due to this, medical advice is often not sought until either the patient is very anaemic and debilitated or the symptoms associated with obstruction are marked.

MEDICAL MANAGEMENT

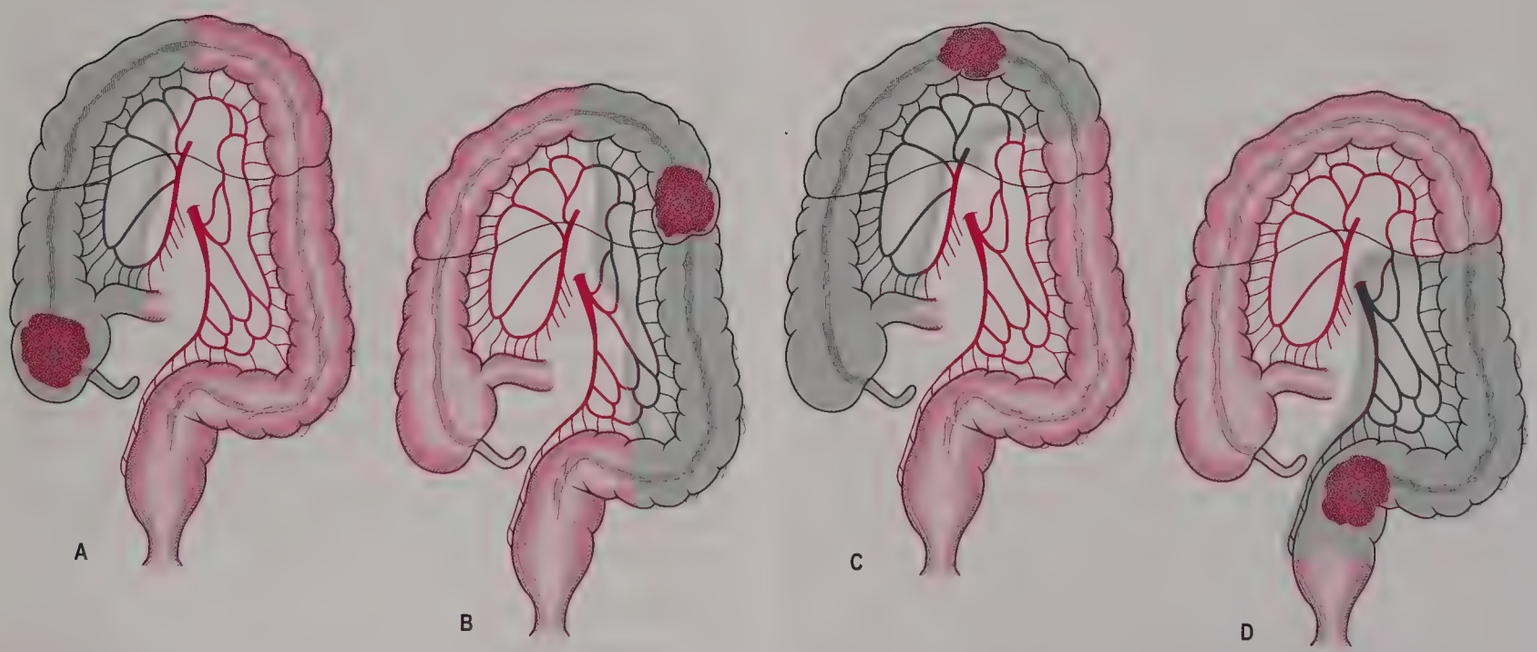
Investigations Many patients will present with a palpable mass that can be detected on abdominal or rectal examination. Specific investigations to confirm diagnosis will include barium studies, sigmoidoscopy, colonoscopy and biopsies. CT scan, chest X-ray and ultrasound scan will be necessary to seek out metastases, particularly in the lung and liver. For the latter, liver function tests will also be carried out.

Staging The staging of the carcinoma is based on histological examination of a resected specimen (see Ch. 31). For colorectal cancer, Dukes' staging is the most widely used (Keighley & Williams 1999). At its simplest, it describes four stages:

- A — the tumour is confined to the bowel mucosa and submucosa
- B — the tumour has invaded the bowel wall to serosa but there is no lymph node involvement
- C — spread to involve lymph nodes
- C2 — distant metastases or severe local or nodal spread, making surgical 'cure' impossible.

Treatment Surgical removal of the tumour is the only effective management. The type and extent of surgery will depend on the site of the tumour. It may be possible for resection and end-to-end anastomosis to be performed (see Fig. 4.10), but often stoma formation is necessary on a temporary or permanent basis.

See also Young et al (1996) and Garden et al (2002) for further details.



4.15 Turn to Chapter 26 and read Case History 26.2 (p. 903). Mrs B represents a common clinical reality. She had felt unwilling to talk about her symptoms, hoping they were just haemorrhoids. Ultimately she required emergency intervention and a stoma formation for which she was totally unprepared. Can you think (or discuss as a group) how such a situation might have been prevented?

NURSING PRIORITIES AND MANAGEMENT: Colorectal cancer

Major considerations

Psychological support

The realisation that seemingly minor ailments are actually symptoms of cancer is most stressful for any individual. From the moment a patient is referred, as an outpatient or inpatient, a sensitive and tactful approach is of paramount importance. This is not easy. Many registered nurses working in general hospital wards are worried about their lack of skills in communicating with cancer patients and, in particular, in giving psychological care (McCaughan & Parahoo 2000). Psychological care needs to include the family and significant others in order to develop a trusting relationship. The beneficial effect of spending time to allow

130 Fig. 4.10 Surgical resections for colorectal cancer in various locations. (Reproduced with kind permission from Garden et al 2002.)

fears to be expressed and explanations and support to be given cannot be overstated.

Perioperative care

The principles of perioperative nursing care are given in Chapter 26. If surgery is to include stoma formation, this will present a further source of stress. A cooperative team approach by the various health care professionals involved will greatly assist the patient's physical and psychological recovery and adjustment to what may prove to be major and perhaps only palliative surgery. For the specific input of the stoma nurse specialist, see Box 4.4.

Discharge planning

For those patients for whom cure is not a possibility, planning for discharge and home care should aim to maximise their independence and quality of life for as long as possible. This requires the coordination and integration of hospital and community services, and a respect for the wishes of both the patient and the family. The reader is referred to Case History 31.4 (p. 1060) for a more detailed examination of this issue.

Health promotion

Great efforts are being made to detect colorectal cancer early, when its prognosis is so much more favourable. The 5-year survival rate for localised lesions is 80–90%. This rate drops to 35–65% once the disease has spread to adjacent structures and lymph nodes (Porrett & Daniel 1999). Factors being addressed include fostering awareness of early warning signs and information for those especially at risk. Preventive measures also include providing advice concerning diet and health screening. See, for example, www.hebs.scot.nhs.uk.

ANORECTAL DISORDERS

Anorectal conditions such as haemorrhoids, abscesses, fissures, fistulae and sinuses are relatively common and always distressing, but are often tolerated for many months or even years before professional help and advice are sought.

Haemorrhoids

PATHOPHYSIOLOGY

Haemorrhoids, commonly called 'piles', are generally considered to be varices of the superior haemorrhoidal veins occurring as a result of congestion of the venous plexus. It would seem that a lack of dietary fibre is the most important predisposing factor (see Box 4.8). The resulting chronic constipation and straining during bowel movements raises intra-abdominal pressure, leading to venous plexus engorgement. The bulging mucosa is dragged down and, as the condition worsens, the haemorrhoids prolapse into the anal canal. Other conditions that can lead to or aggravate the congestion are pregnancy, where the development of haemorrhoids is often neglected, tumours and cardiac failure.

For further information, see Kamm & Lennard-Jones (1994).

Haemorrhoids may be internal or external. Internal haemorrhoids are classified according to the degree to which they prolapse into the anal canal. External haemorrhoids occur outside the anal canal and are less common.

Common presenting symptoms Commonly the patient complains of 'fresh' blood in bowel movements, which at first may be thought to be due simply to the passing of constipated motions. The experience of prolapse, at first transient, becomes increasingly frequent and is associated with pain, the discharge of mucus and pruritus. Often such symptoms have been managed by over-the-counter (OTC) remedies such as creams to reduce the itching and pain. Education of the patient in order to achieve the passing of soft bulky stools with minimal effort, often yields more relief in the long term than conventional treatments. The addition of supplementary dietary fibre and ensuring an adequate fluid intake are often seen as more acceptable (Porrett & Daniel 1999). However, many people find the adjustment of diet too much of a change in lifestyle. Should the haemorrhoidal vessels thrombose, pain is always severe and it may only be at this stage that the patient seeks help.

MEDICAL MANAGEMENT

Investigations

- History and examination to exclude other pathologies, particularly a carcinoma.
- Rectal examination, proctoscopy and/or sigmoidoscopy to confirm the diagnosis.

Treatment

If the haemorrhoids are identified in their early stages, management requires no more than attention to the patient's diet and perhaps a bulk laxative. If the constipation is corrected, the problem will usually resolve but the patient must understand this and feel confident in diet alteration. The practice nurse can play an important part in patient education and in arranging a follow-up appointment to monitor the patient's well-being.

Surgical intervention The following surgical treatments may be used to resolve haemorrhoids that do not respond to conservative management:

- *Injection.* For haemorrhoids in the early stages, injection of the haemorrhoidal veins with an irritant solution provokes fibrosis and atrophy with minimal discomfort.
- *Band ligation.* Bands are applied to the mucosa-covered haemorrhoidal pedicle, constricting the vessels, which then eventually shrink.
- *Infrared coagulation.* Infrared radiation is applied in pulses to the haemorrhoid by means of a fibreoptic probe, causing coagulation and shrinkage.
- *Haemorrhoidectomy.* The above interventions are the most commonly used and can be carried out on an outpatient basis. If, however, the haemorrhoids are not amenable to such therapies, haemorrhoidectomy to ligate and excise the haemorrhoids may be required. If thrombosis has occurred, this procedure will be required immediately.

Box 4.8

Constipation

Constipation may be defined as difficult and infrequent defaecation. The following factors can contribute to its development.

Diet
A diet that is low in fibre and bulk predisposes to small faecal bulk. A low fluid intake also contributes to small bulk. Small bulk predisposes the GI tract to reduced peristaltic action and slow passage of contents along the colon. Epidemiological studies indicate that low-fibre diets contribute to many of the GI diseases found in the Western world, such as diverticulosis, appendicitis and haemorrhoids.

Exercise
Lack of exercise contributes to reduced peristalsis, due to reduced muscle tone of the bowel and abdominal muscles. Individuals who take less exercise include the older person and those who are ill or have a physical disability. Hospital patients are, in general, restricted in their mobility, given their environment and their medical condition, and investigations and treatment often predispose patients to constipation.

Elimination habits
Neglecting to empty the rectum when the stimulation caused by faeces therein (the 'call to stool') is ignored results in constipation; if this occurs repeatedly, faecal impaction can result. Watery diarrhoea, caused by the breakdown of faecal material proximal to the hard impacted mass, can bypass the mass. Impacted faeces can press on the urethra and cause retention of urine (see also Ch. 24).

Socioeconomic factors
Nutritional and dietary intake is determined by eating patterns formed in childhood and influenced by familial and social norms and income levels. A low income can result in the exclusion from the diet of fresh fruit and vegetables, which can be relatively expensive. Low-income families and older people living alone may have to make difficult choices in spending their limited resources on food, heating and clothing. Lack of transport or reduced mobility can also limit shopping expeditions and therefore the choice of foods. The older person living alone may be less likely to cook nutritious meals for a number of reasons, e.g. lack of motivation, poor appetite and limited mobility.

Medication
Many medications have side-effects that cause constipation; these include ganglion-blocking drugs, psychotropic drugs, muscle relaxants, and morphine and its derivatives.

Dentition
Poor dentition makes chewing difficult, especially where there has been dental clearance and dentures do not fit well or comfortably. This can result in the avoidance of fresh fruit and vegetables, and an emphasis on soft, easily chewed foods that do not add fibre to the diet.

Motility of colon
Eating results in increased colonic motor activity that may be perceived by the individual as an urge to defaecate, but mobility or lack of regular exercise decreases gut motility and may contribute to constipation (Doughty 2000).

The bowel may become obstructed by a growth, a hernia or by adhesions following surgery. In addition, spasticity can occur in inflammatory conditions such as appendicitis or diverticulitis.

Rectal conditions
Local conditions such as haemorrhoids or anal fissure, which cause pain on defaecation, can result in avoidance of defaecation with eventual constipation.

Prevention and treatment
Dietary advice is important in the prevention of constipation. Wholemeal bread, fresh fruit and vegetables, and cereals such as porridge oats and All Bran are important. Unprocessed bran can also be added to soups or stews. The individual should be advised to drink plenty of fluid throughout the day. Older people who have urinary incontinence tend to take inadequate fluid in an attempt to avoid being incontinent of urine.

The importance of emptying the bowel regularly and of not ignoring the call to stool should be emphasised. The individual should be encouraged to take as much physical exercise as possible.

The initial treatment of constipation can include the use of laxatives. Bulk-forming preparations such as Fybogel and stimulant laxatives such as bisacodyl by mouth or by rectum may be used initially. Where there is a faecal mass, rectally administered faecal softeners such as arachis oil may be necessary.

Any condition, such as haemorrhoids, anal fissure or diverticulosis, which is predisposing the individual to constipation, should be treated.

NURSING PRIORITIES AND MANAGEMENT: Haemorrhoids

General considerations

Whether it is the cause or the effect, it is most important that difficulty with defaecation is effectively corrected. Measures to achieve this include:

- increasing dietary fibre
- maintaining a high fluid intake (2–3 L/day)
- prescribing a stool softener to facilitate water and fat absorption into the faeces
- ensuring sufficient exercise and activity.

In addition, nursing priorities must include measures to alleviate pain and itching, to ensure good personal hygiene, to provide appropriate privacy in a hospital setting and to prevent infection.

Preoperative preparation (see Box 4.9)

If surgery is required, the aim of nursing care in the preoperative period is to control the acute symptoms and to ensure that the patient feels comfortable and free from any distress when defaecating. One of the major postoperative fears in any form of anorectal surgery is the pain that might be experienced upon the first bowel movement. Time is

Box 4.9

Principles of nursing care for patients undergoing perianal surgery

Preoperative preparation

- Ensure the patient's privacy to reduce embarrassment
- Give analgesics for the acute pain that is often present
- Provide bowel preparation. This may include the administration of suppositories or an enema to clear the rectum. Some surgeons prefer not to give any bowel preparation prior to haemorrhoidectomy so that evacuation of the bowel after surgery can occur more quickly

Postoperative care

- Observe for haemorrhage during the first 24 h by monitoring vital signs and checking the anal area
- Give analgesics as this area can be very painful after surgery
- On the first postoperative day, encourage the patient to bathe
- Assess the patient for urinary retention
- Assess for return of bowel movement
- Administer a bulk-forming aperient to facilitate easier bowel evacuation. Analgesics may be required prior to the first bowel movement
- Give the patient a bath after the bowels have opened to keep the area clean and to relieve discomfort
- Advise the patient on avoiding constipation

well spent explaining postoperative care and how any pain and discomfort will be relieved or minimised. Patients are very often comforted merely by the fact that the nurse understands their fears and has the knowledge and skill to help them to manage the problem.

Postoperative care (see Box 4.9)

Care priorities in the postoperative period include:

- the relief of pain and promotion of comfort
- the prevention of postoperative haemorrhage
- the prevention of postoperative urinary retention
- the prevention of infection
- the promotion of optimal faecal elimination
- patient education prior to discharge regarding lifestyle and diet.

4.16 Anaesthesia and pain may inhibit urination in the early postoperative period. What support and interventions might be considered?

4.17 What would be the key points in any pre-discharge advice and support given to a patient following anorectal surgery?

Other common anorectal disorders

Fissure in ano

PATHOPHYSIOLOGY

This is a tear in the lining of the lower anal canal. Pain is experienced only on defaecation. The cause of a primary fissure is uncertain, but it often follows an episode of constipation and the forceful passage of a hard stool. It is a common complication of Crohn's disease.

Common presenting symptoms The main symptom is extreme pain on defaecation that persists for some hours. Rectal bleeding may be seen on defaecation.

MEDICAL MANAGEMENT

Anal fissures can heal spontaneously with the local application of creams or suppositories. Constipation is treated and then avoided by a high-fibre diet. Surgical treatment is a lateral internal sphincterotomy.

Fistula-in-ano

PATHOPHYSIOLOGY

A fistula is an abnormal communication between two epithelial lined surfaces. A fistula-in-ano is a granulating track between the anorectum and the perineum. The cause is uncertain, but it may be associated with an anal gland infection that produces an abscess that then tracks. Fistulae are associated with Crohn's disease, ulcerative colitis, HIV infections, radiation damage and hidradenitis, i.e. a chronic suppurative condition that may affect the apocrine glands of the axillae, groin and perineum.

Common presenting symptoms Commonly an abscess is present, as well as pain, pruritus ani, rectal discharge and excoriation of skin.

SURGICAL MANAGEMENT

The fistula is laid open by fistulotomy and heals gradually by granulation over some weeks.

Pilonidal sinus

PATHOPHYSIOLOGY

This is a sinus that contains hair and occurs in the natal cleft. The hair curls and penetrates the skin, causing irritation. Secondary infection is common, which can lead to a pilonidal abscess.

Common presenting symptoms The individual will experience localised, throbbing pain. The site will be tender to the touch if an abscess is present. A discharge is often the first sign that a sinus is present.

MEDICAL MANAGEMENT

Antibiotic therapy is given prior to surgery if an infection is present, followed by excision of the sinus when the infection has cleared. The importance of good perianal hygiene and keeping the area free from future hair growth cannot be overemphasised (Porrett & Daniel 1999).

Anovaginal and rectovaginal fistulae

PATHOPHYSIOLOGY

Obstetric trauma is the most common cause for the development of these fistulae. Other causes include trauma, radiation damage, and inflammatory bowel disease, especially Crohn's disease.

Common presenting symptoms The patient complains of passing flatus and faeces per vagina. There may be vaginitis and recurrent urinary tract infections may also occur.

Diagnosis is readily made during examination under anaesthetic at which time multiple biopsies are taken.

SURGICAL MANAGEMENT

Direct repair of the defect or advancement of a mucosal–submucosal flap of rectum or vagina to cover the defect is often successful. Occasionally a bowel resection with or without a temporary defunctioning stoma is required.

NURSING PRIORITIES AND MANAGEMENT: Faecal incontinence

Faecal incontinence is a common and distressing symptom with many causes including:

- congenital malformation
- trauma
- obstetric injury
- rectovaginal fistula
- inflammatory bowel disease
- functional disorder
- postirradiation damage
- postoperative complications, e.g. following colorectal/perianal surgery
- neurological disease
- degenerative disorders.

Both a medical and a nursing history should be completed; in the latter the use of a checklist such as Norton (2001) may prove helpful. Investigations that may be indicated to confirm the diagnosis and determine treatment vary from digital examination to in-depth assessment of anorectal physiology and endo-anal ultrasound.

Treatment depends on the underlying cause but psychological support and education about methods of self-management must be given. Conservative treatment should be undertaken initially, including medication, biofeedback and sphincter exercises, control of bowel habit and advice about ensuring regular bowel motions. Surgical intervention may ultimately be necessary.

For a detailed description, see Keighley & Williams (1999).

DISORDERS OF THE HEPATOBILIARY SYSTEM

DISORDERS OF THE LIVER

The liver can be affected by a large number of diseases, some of which are more common than others. Because of the large number of functions that the liver performs, there are infinite combinations of manifestations, both specific and non-specific. The onset illness may be acute, as in an acute attack of viral hepatitis, or chronic, where disease processes have been progressing for many years before symptoms become evident. A patient with advanced chronic liver disease but who has little or no symptoms is said to be 'compensated'; when the liver begins to fail and symptoms appear, the patient is then said to be 'decompensating'.

Manifestations of liver disease

Non-specific symptoms such as anorexia, nausea, lethargy, malaise and vomiting are common. Weight loss also occurs in chronic liver disease, notably in malignant disease.

Specific features include enlargement of the liver, i.e. hepatomegaly, portal hypertension with associated ascites and splenomegaly, jaundice, oesophageal varices and hepatic encephalopathy.

ACUTE LIVER DISEASE

Acute hepatitis

PATHOPHYSIOLOGY

Hepatitis denotes inflammation of the liver that may be acute or chronic. Globally, viruses are the most common cause of acute hepatitis, but the disease may also be a response to certain medication (see Box 4.10) and alcohol. All types of hepatitis will cause similar symptoms, which can range from slight to severe and possibly life threatening, as in fulminant hepatic failure. This, fortunately, is very rare. Many patients with acute hepatitis will not require hospitalisation and some will not even contact a doctor. For patients who do have symptoms, these are considered in three phases as follows:

- *Prodromal or pre-icteric phase*. Flu-like symptoms which last from 2 to 7 days in hepatitis A virus (HAV), and slightly longer in hepatitis B virus (HBV). Symptoms include headache, low-grade fever (37.5–38.5°C), nasal congestion, sore throat, anorexia, lethargy, mild upper abdominal pain or discomfort in the right hypochondrium, arthralgia and arthritis. As the liver has no sensory innervation, pain is caused by stretching of the liver capsule. In inflammatory conditions such as hepatitis, pain is usually perceived as a dull ache in the right upper quadrant.
- *The icteric phase*. Prodromal symptoms usually disappear. Jaundice, of varying intensity, occurs but rarely causes plasma bilirubin to rise above 200 mmol/L. Jaundice is a yellowing of the skin and mucous membranes and occurs when the bilirubin level in the blood exceeds 50 mmol/L. There are three distinct types:
  — hepatocellular jaundice: hepatocyte destruction renders the liver unable to transport bilirubin; this is the type of jaundice seen in viral hepatitis

Box 4.10

Medication-induced hepatitis

Hepatitis may be caused by any drug, but the more common culprits include analgesics such as paracetamol taken in excess, psychotropic drugs such as the phenothiazines, antibiotics such as erythromycin, and anaesthetics such as halothane. Any patient with hepatitis should be questioned regarding medication taken recently, including those taken without medical advice, and including herbal remedies.

In most incidences of any medication-induced hepatitis, the biopsy shows changes as for viral hepatitis. However, some medications will also cause fatty changes in the liver cells.

  - haemolytic jaundice: caused by excessive red cell destruction (see Ch. 11)
  - cholestatic jaundice: caused by obstruction to the flow of bile through the liver ducts due to cirrhosis or malignancy. Obstruction of the larger extrahepatic ducts may be caused by gallstones or cancer of the head of pancreas (Fawcett & Smith 2004).
- *The convalescent phase*. Occurs approximately 2 weeks after the onset of jaundice. Jaundice lessens and eventually disappears. Other symptoms resolve.

Postviral syndrome It is recognised that hepatitis is a common cause of a postviral syndrome in which, despite liver function tests returning to normal, lethargy persists for some months. Patients need reassurance regarding recovery as many feel that they have developed chronic liver disease.

MEDICAL AND NURSING MANAGEMENT

There is no specific treatment for acute hepatitis, but advice can be given to help the patient cope with the illness. Any medication thought to have caused the hepatitis should be stopped, and no other medication should be taken without medical advice. Whilst strict bed rest is not necessary, it is advisable for the patient to rest as much as possible and to avoid strenuous exercise. The patient may have intolerance of fatty foods. A well-balanced, high-calorie diet should be encouraged. Alcohol should be totally avoided, as it can slow recovery and exacerbate symptoms. If required, referral can be made to an alcohol counsellor who can provide counselling and support for patients with alcohol dependency problems. The patient should be given education on the transmission routes of the hepatitis viruses in order that hygiene precautions may be taken (see p. 136).

Restrictions on certain professional activities may also be required if the hepatitis is viral in origin, e.g. to medical or dental personnel working in exposure-prone posts. Sexual intercourse during menstruation and sexual practices that may result in damage to the skin and mucous membranes should be avoided.

Fulminant hepatic failure

PATHOPHYSIOLOGY

This is a rare condition that results in sudden massive necrosis of liver cells and severe impairment of hepatic function. The most common causes are drug/medication-induced hepatitis and viral hepatitis; all other causes are extremely rare.

Clinical features The patient develops encephalopathy, in which confusion leads to stupor and progresses rapidly to coma. Jaundice and fetor hepaticus are present and ascites may develop later. Abnormal neurological signs, cerebral oedema, hypoglycaemia, circulatory and renal failure and coagulation defects develop.

MEDICAL MANAGEMENT

The medical management of fulminant hepatic failure is supportive care and management of complications such as infection. Liver transplant should be considered if early improvement does not occur, so that patients can be transferred to a transplant centre before severe coma occurs. Transplant for fulminant hepatic failure has a 71.7% 1-year survival rate and a 63.4% 5-year survival rate (UK Transplant Statistics Department 2004).

The prognosis without transplant is extremely poor, with the survival rate being approximately 10% once deep coma has occurred. However, there are patients who do survive and recover normal hepatic structure and function.

The nursing care of these patients is highly specialised and is of paramount importance to the patient's recovery. For this reason, patients with fulminant hepatic failure must be nursed in a specialist liver or intensive therapy unit.

Future management: the bioartificial liver As many patients die before a suitable liver transplant can be found, research is ongoing to find new treatment to support the patient until either a donor is found or the liver recovers sufficiently to support life.

For further information on research into the bioartificial liver, see Plevris et al (1988) and for information on an artificial recycling system such as the molecular adsorbent recirculating system (MARS), see Koivusalo et al (2003).

The bioartificial liver uses similar principles to renal dialysis. However, as there is no known artificial filter that can imitate the many functions of the hepatocyte, then human hepatocytes will be used. Originally it was thought that porcine hepatocytes would be used. However, in 1997 the United Kingdom Xenotransplantation Interim Authority was convened to advise on the ethical, safety and animal welfare issues that xenotransplantation raised, and to regulate its use. It is now very difficult to obtain permission to use animal cells and organs and most medical researchers prefer to use human cells.

The cells are loaded into a haemofiltration device known as a bioreactor and, using a delivery system similar to renal dialysis, blood is pumped through the bioreactor and back into the patient.

The MARS system is a novel dialysis system that removes albumin-bound substances from the blood.

These innovative treatment options remain in the early research stages, with many practical problems to be solved before they can be used routinely in the clinical setting.

VIRUSES THAT CAUSE HEPATITIS

All the hepatitic viruses can cause a similar initial illness. The differences between them would appear to be their modes of transmission and progression of disease:

- Common viruses
  - hepatitis A
  - hepatitis B
  - hepatitis C
  - hepatitis D (delta)
- Uncommon viruses
  - hepatitis E
  - hepatitis F (the status of hepatitis F as a true virus remains unconfirmed and its existence is now doubtful (Bowden 2001)
  - hepatitis G
  - Epstein–Barr (EB) virus
  - cytomegalovirus (CMV)
  - measles.

Hepatitis A

PATHOPHYSIOLOGY

Hepatitis A (HAV) is an acute condition. A chronic form does not occur. It is usually a mild illness, often occurring in epidemics in communities such as schools, prisons, army camps and psychiatric settings, or in areas where sanitation and hygiene are poor. It is transmitted by the faecal–oral route. The incubation period is 2–7 weeks, with faeces being the most important infective material. The person becomes infectious 2–3 weeks prior to the onset of the clinical illness and remains so for approximately 2 weeks thereafter. Blood and urine are rarely infectious. Male homosexuals are at risk of hepatitis A due to oral–anal contact. Patients with hepatitis A are usually only mildly unwell and are rarely admitted to hospital.

Improved standards of food and personal hygiene in the UK mean that most people have not been exposed to HAV and, as they will not have acquired natural antibodies, they are therefore susceptible to infection. Immunisation should be considered before travelling to regions where HAV is still prevalent (Crowcroft 2001).

HAV is not associated with a carrier state in that once the acute infective stage has ceased, transmission to another person is not possible.

MEDICAL MANAGEMENT

Investigations The diagnosis of HAV depends on the presence of antibodies to HAV in the patient's blood. The presence of anti-HAV IgM denotes recent or current infection. It is present from 1 week before onset of the clinical illness and disappears after approximately 3 months. The presence of anti-HAV IgG denotes previous infection and remains positive for life, conferring immunity.

Precautions If hospitalisation is required, the patient is usually independent and therefore the risk of infection is low. However, if a patient has diarrhoea and requires nursing assistance, the following precautions should be taken:

- plastic gloves and aprons must be used for all procedures
- linen and disposable wipes must be disposed of as per local policy
- thorough handwashing must be carried out after patient contact.

Immune serum globulin i.m. can prevent hepatitis A if given within a few days of exposure. A vaccine has now been developed which will give protection for 5–10 years and is recommended for food handlers, travellers in high-risk areas and homosexual men.

Hepatitis B

PATHOPHYSIOLOGY

Hepatitis B (HBV) can cause acute or chronic infection. Ten per cent of infected adults will become chronic carriers, of which there are an estimated 350 million worldwide and 1 in 1000 of the population of the UK. Of the 10% of chronic carriers, some will be asymptomatic and some will develop chronic hepatitis (Collier & Oxford 2000).

The virus is transmitted by the parenteral route. Patients receiving blood or blood products and i.v. drug abusers who share needles are greatly at risk. Tattooing can also spread the virus. The virus is present in body fluids such as saliva, urine and semen and therefore the disease can be spread by close personal contact, e.g. sexual intercourse, especially in male homosexuals, and particularly in areas of overcrowding, poverty and poor sanitation. The disease can also be transmitted from mother to baby either at birth or soon afterwards. Faeces will not transmit infection provided they are free of blood. The incubation period is approximately 2–6 months.

MEDICAL MANAGEMENT

Investigations The most important test in the diagnosis of HBV is for the hepatitis B surface antigen (HBsAg) in the blood. This appears from one to several weeks before the onset of the clinical illness and disappears 1–12 weeks later. However, this may not be present in patients who either clear the virus from the blood quickly or present late. It is therefore also necessary to look for antibodies to the hepatitis core antigen (anti-HBc). The presence of anti-HBc IgM denotes acute HBV; anti-HBc IgG denotes chronic HBV.

The presence of the hepatitis B 'E' antigen (HBeAg) in the carrier state reflects greater infectivity of blood and body fluids. It is also associated with a greater likelihood of progression to chronic liver disease.

Precautions There is great risk to medical and nursing staff when dealing with blood, blood products, body fluids and open wounds, e.g. venepuncture sites, skin lesions, and ulcers on injection sites of i.v. drug abusers. Care should also be taken in areas where the patient's identity is unknown, e.g. emergency departments. All precautions should be taken as per individual hospital policies, and hospital staff should be vaccinated against HBV infection.

Hepatitis B immune globulin i.m. can prevent hepatitis B if given within a few days of a high-risk exposure (e.g. a 'sharps' injury). Vaccination provides good long-term immunity but booster doses are needed every 3–5 years.

Treatment Current treatment for HBV is either interferon alpha, an immunomodulator, or lamivudine, a nucleoside analogue. Interferon has many side-effects and is poorly tolerated (see p. 677). Lamivudine is associated with increasing viral resistance the longer it is taken. Several new nucleoside analogues are currently being developed and it is hoped that these may increase the treatment options available for HBV (Younger et al 2004).

4.18 A staff member sustains a 'sharps' injury. What procedure should be followed and how can the individual be prevented from developing hepatitis?

Hepatitis C

The hepatitis C virus (HCV) was identified in 1989 and is now known to be responsible for 90% of what was known as non-A, non-B hepatitis (Blair & Hayes 1997).

PATHOPHYSIOLOGY

Like HBV, HCV is transmitted parenterally and the highest incidences are in i.v. drug abusers and people who received blood products before 1991, when screening became available. Other risk factors include body piercing, tattooing and needlestick injuries. Unlike HBV, sexual transmission appears to be low in HCV.

Acute infection occurs in about 10% of patients, but about 80% will go on to develop chronic infection. Of these, approximately 20% will develop cirrhosis after 20 years of infection. There is also an increased risk of hepatocellular cancer associated with chronic HCV infection (Nissen & Martin 2002).

MEDICAL MANAGEMENT

Investigations Diagnosis is made serologically by the presence of antibodies to HCV. An active viraemic state will then be confirmed by a technique, which amplifies nucleic acids, known as the polymerase chain reaction (PCR) test. Blood will also be tested for HCV genotype. There are six known genotypes worldwide (1–6), of which types 1, 2 and 3 are common in Europe, the UK and North America. In the UK approximately 50% of known HCV positive patients have genotype 1. This genotype is known to be more resistant to treatment (Lee 2003).

Liver biopsy can be useful for staging the extent of any liver damage.

Treatment The British Society of Gastroenterologists now recommends the combination of pegylated interferon, a naturally occurring protein with complex effects on immunity and cell function, and ribavirin, an antiviral agent, for the treatment of HCV. Pegylated interferon is administered as a s.c. injection once per week; ribavirin is taken as an oral preparation on a twice-daily basis and the dose is weight dependent. Patients with genotype 1 are treated for 48 weeks and the success rate is approximately 50%. Types 2 and 3 are treated for 24 weeks and have a success rate of over 80%.

Nursing support is vital for patients undergoing interferon therapy and most patients are now treated in nurse-led clinics. There are many associated side-effects and the patient will require regular haematological monitoring, as well as help and advice on coping with physical side-effects, which include:

- flu-like symptoms that can be ameliorated by regular paracetamol
- poor appetite and weight loss
- fatigue
- anaemia
- reduction of the white cell and platelet count
- mood lowering and depression
- thyroid dysfunction
- allergic type skin problems.

All side-effects are reversible on stopping treatment, with the possible exception of some cases of thyroid dysfunction.

Therapy is self-administered and the patient will require education on self-injection techniques and the safe storage and disposal of equipment and medications. Advice on diet and lifestyle may be necessary and the patient should be encouraged to avoid alcohol and drugs.

Hepatitis D (delta) virus

The delta virus occurs either simultaneously with an acute hepatitis B infection or as an added infection in a chronic hepatitis B carrier. It never occurs when the B virus is not present. It is diagnosed by the presence of anti-delta (anti-HD) in the blood.

For further information, see Pratt (2003). Further information on the less common hepatitis viruses can be found in Shearman et al (1997).

CHRONIC LIVER DISEASE

Chronic hepatitis

Hepatitis is referred to as chronic when the patient continues to have clinical symptoms or abnormal liver function tests 6 months after the onset of the illness. The main causes of chronic hepatitis are:

- the B, C and D viruses as already described
- autoimmune hepatitis
- drug-related hepatitis
- cryptogenic hepatitis.

Autoimmune hepatitis

PATHOPHYSIOLOGY

The cause of this disease is unknown but it is thought to be immune mediated. It is a chronic condition but may present as an 'acute' illness similar to acute viral hepatitis. This 'acute' onset is probably an exacerbation of long-standing but asymptomatic disease. It is identified by detecting non-organ-specific antibodies to nuclei, smooth muscle and occasionally liver–kidney microsomes. About 80% of those affected are women and about 20% have other autoimmune disorders, e.g. rheumatoid arthritis and ulcerative colitis.

Prognosis is dependent on the severity of the inflammatory activity. Patients with severe multilobular necrosis on biopsy generally develop cirrhosis within 5 years.

Clinical features Patients who present with an 'acute' illness will show signs and symptoms similar to those of acute hepatitis (p. 134); however, other features such as ascites and hypoalbuminaemia may be present, indicating the chronic nature of the disease.

MEDICAL MANAGEMENT

Steroids and immunosuppressive medications, prednisolone and azathioprine, are used to achieve remission. The doses are gradually reduced until a maintenance dose is achieved. If cirrhosis is present, treatment will include symptomatic relief of the manifestations of chronic liver disease.

SURGICAL MANAGEMENT

Transplantation has been described by Sir Magdi Yacoub as one of the miraculous achievements of modern medicine (UK Transplant Statistics Department 2004).

Liver transplant for chronic liver disease has been available in the NHS since 1983 and improved patient management techniques have led to increased success rates. Each year in the UK around 650 people undergo liver transplant in one of nine specialist centres. There are approximately 160 people waiting for a liver transplant in the UK at any given time. Around 85% of the livers transplanted for chronic liver disease are functioning well a year after surgery (Neuberger & Lucey 1994).

NURSING PRIORITIES AND MANAGEMENT: Autoimmune hepatitis

Nursing intervention is dependent on the severity of the illness. Initially the patient may require full nursing care and nutritional support. Occasionally a high-dependency setting may be appropriate.

As the patient improves, education regarding the condition is important to aid understanding of the symptoms and the need for long-term immunosuppressive therapy. Alcohol should be avoided, especially if there is cirrhosis.

Alcoholic hepatitis

PATHOPHYSIOLOGY

Clinical features This condition usually follows years of alcohol abuse and often a recent prolonged bout of heavy drinking. The patient will complain of anorexia, vomiting, lethargy, diarrhoea and upper abdominal pain. A fever will be present and the patient will appear generally unwell and malnourished. There may be signs of chronic liver disease, i.e. ascites and oedema, encephalopathy, jaundice and the dilated capillaries of spider telangiectasis. GI bleeding may occur from erosions or peptic ulceration, and also as a result of bleeding tendencies, due to the liver's inability to synthesise adequate clotting factors.

The diagnosis is made from an accurate picture of the patient's alcohol intake (often obtained from relatives and friends), liver function tests and liver biopsy provided the patient's clotting time allows this.

Cirrhosis of the liver

Cirrhosis or scarring of the liver is an irreversible condition caused by many hepatic diseases. There are many clinical manifestations, which vary with the severity and duration of the disease. Alcohol is the commonest cause, with the other major players being viral hepatitis, primary biliary cirrhosis, autoimmune hepatitis and haemochromatosis.

PATHOPHYSIOLOGY

Prolonged low-grade inflammation causes progressive scarring and destruction of the liver cells. The remaining liver cells proliferate to form nodules; this results in the liver becoming irregular and distorted in shape. The blood vessels are also destroyed. The resistance to the flow of blood increases, which in turn leads to portal hypertension (see p. 141). The major complications of cirrhosis, resulting from hepatocellular failure, portal hypertension and portal systemic shunting, are ascites, GI bleeding, hepatic encephalopathy, renal dysfunction and hepatocellular carcinoma.

Common presenting features As the disease progresses, the patient feels increasingly fatigued and lethargic. Anorexia, nausea and weight loss are common. Jaundice, bruising, spider telangiectasis and finger clubbing are also seen. Pruritus is a common symptom of cirrhosis (see Nursing Care Plan 4.1) and is probably caused by bile salt deposition in the skin. It is a feature of cholestasis but is not always accompanied by jaundice. It is especially troublesome in primary biliary cirrhosis. Endocrine abnormalities such as gynaecomastia and impotence in males and amenorrhoea and infertility in females can also develop.

MEDICAL MANAGEMENT

The aim of treatment is the removal of any identifiable cause such as alcohol abuse and the management of the major symptoms and complications. Liver transplantation is considered when earlier treatment fails. Considerable counselling and support may be required to eliminate an alcohol problem and improve nutrition. The medical and nursing management of the major complications of cirrhosis of the liver are considered in more detail below.

Ascites

Ascites is the abnormal accumulation of serous fluid within the peritoneal cavity and is a serious prognostic development (Jalan & Hayes 1997). It results from a combination of the following factors:

- raised portal pressure
- increased lymphatic pressure in the liver
- low plasma protein — albumin
- sodium retention.

Box 4.11 gives further details on pathophysiology.

MEDICAL MANAGEMENT

The main components of treatment are restriction of sodium and fluid intake, administration of diuretics and abdominal paracentesis in refractory ascites (see Box 4.12).

NURSING PRIORITIES AND MANAGEMENT: Ascites

Major considerations

The main aims of nursing care are as follows:

- To promote bed rest in the position most comfortable for the patient. The legs should be elevated to help reduce peripheral oedema. The semi-prone position improves kidney perfusion and also the venous return to the heart, which in turn promotes a diuresis.
- To provide pressure area care. This is vital because oedema may compromise skin quality and the patient is likely to experience reluctance and difficulty in moving.
- To obtain baseline observations before commencing treatment. This should include the patient's weight and a record of the extent of ascites and oedema.
- To encourage the patient to eat a diet very low in salt. Daily sodium intake must be restricted to 60 mmol, and to 40 mmol in severe ascites.
- To ensure that the patient manages the restriction in fluid intake and understands why it is necessary. It is

Nursing Care Plan 4.1 Care plan for an older man with liver failure due to alcoholic cirrhosis

Problem (actual/potential)	Reason	Nursing action
1. Anxiety, anger and fear	Due to: lack of knowledge; fear of the unknown and perhaps denial of the reality of his condition	• Encourage fears to be expressed and questions to be asked. Explain all procedures and maintain a non-judgemental approach. Confidence will be restored and he will feel better able to cope
2. Loss of self-concept: • **body image** • **role performance** • **self-identity** • **self-esteem**	Due to: – physical alteration resulting from jaundice, ascites and weight loss – loss of libido, impotence and gynaecomastia due to retention of oestrogens normally broken down in the liver	• Restore optimal liver function • Provide a trusting relationship • Refer to a specialist counsellor as appropriate
3. Pain and discomfort	Due to: – the enlarged liver that stretches the liver capsule (the liver itself has no sensory nerve innervation) – biliary obstruction secondary to the cirrhosis – gastritis due to alcohol abuse – oedema, ascites, bowel disturbance, dyspepsia and itching	• Relieve pain and discomfort via: – comfort measures such as positioning, gentle movement and distraction techniques – medication for pruritus: • sodium bicarbonate baths • calamine lotion • colestyramine which binds the bile salts in the intestines • antihistamine – analgesics, used with caution to avoid hepatotoxic effects
4. Insomnia	Due to: pain, anxiety, dyspnoea induced by ascites, itching and the strange environment	• Relieve pain, anxiety, dyspnoea and itching (see above) • Provide optimal peace and quiet when appropriate
5. Nutritional impairment: anorexia, anaemia and weight loss	Due to: – the inability of the liver to perform its metabolic functions and the reduction in production of bile – reduction in iron, vitamin B_{12} and red blood cells – fetor hepaticus (a bad taste in the mouth and bad breath) – previous dietary neglect due to alcohol excess	• A diet high in calories: – protein to restore plasma proteins – glucose, thought to aid liver cell recovery • Supplements, e.g. vitamins and iron • Low salt to reduce oedema • Controlled fat intake according to degree of jaundice • Small tempting meals • Oral hygiene • Monitoring of weight If anaemia becomes severe a blood transfusion and oxygen therapy may be required
6. Fluid and electrolyte imbalance and impaired tissue perfusion	Due to: – reduced arterial flow, portal hypertension, ascites – salt retention due to loss of detoxification of aldosterone and the triggering of the renin–angiotensin mechanism	• Reduce salt intake to no added salt (NAS) or less as necessary • Fluid restriction (1–1.5 L/day) if hyponatraemia develops • Gentle use of diuretics • Paracentesis if necessary

Nursing Care Plan 4.1 Care plan for an older man with liver failure due to alcoholic cirrhosis *(Continued)*

Problem (actual/potential)	Reason	Nursing action
7. Infection	Due to: loss of Kupffer cell function and lymphocyte production and exacerbated by nutritional, circulatory and respiratory impairment	• Hygiene maintained at a high standard. Strict asepsis with any invasive techniques. Regular monitoring of vital signs • Chest physiotherapy as appropriate • Infection screening as appropriate • Antibiotics if necessary but used with caution
8. Impaired skin integrity	Due to: oedema, loss of protein, jaundice, weight loss and bleeding tendency (see problem 11)	• Regular relief of pressure • Sensitive care of the skin, nails and when shaving • Use of emollients • Optimal positioning and repositioning
9. Immobility	Due to: malaise, weakness, ascites, dyspnoea and perhaps confusion	• Ensure optimal activity and rest. Provide companionship • Relieve symptoms as described
10. Impaired detoxification of natural and medicinal substances	Due to: liver cell damage	• Careful and tactful enforcement of abstinence from alcohol • Vigilance with all medications
11. Tendency to bleed that might be insidious or dramatic leading to hypovolaemic shock	Due to: – portal hypertension and development of oesophageal varices – gastritis – loss of clotting factors – inadequate absorption of vitamin K – reduced reserves of blood in the liver	• Regular monitoring of vital signs • Monitoring of any vomit for blood, fresh or digested • Skin and mucous membranes observed for bruises or bleeding • Give vitamin K as necessary • Manage hypovolaemic shock (see p. 725) should severe bleeding occur
12. Encephalopathy: • **lethargy** • **flapping tremor (asterixis)** • **irrational behaviour** • **aggression** • **loss of ability to perform daily duties**	Due to: inability of the liver to convert ammonia to urea. Ammonia levels rise to such a level that cerebral cell damage occurs due to nitrogenous neurotoxins Note: 1 A GI bleed constitutes a 'high protein meal' and will exacerbate encephalopathy 2 Infection will exacerbate encephalopathy by inducing a catabolic state 3 Hypoxia will exacerbate encephalopathy	• Careful monitoring of behaviour and ability to communicate effectively • Observe for precipitating factors, e.g. 1, 2 or 3 • Manage encephalopathy: – reduce protein intake – give rectal and colonic washouts, if necessary, to remove blood from bowel – give oral lactulose, an osmotic laxative, to reduce ammonia by acidification of bowel environment and to help evacuate bowel contents, *and/or* ... – give oral neomycin (poorly absorbed from the gut) to reduce intestinal flora – monitor level of consciousness (LOC) – ensure safety and comfort

important to help the patient to 'pace' the fluid intake throughout the day. It is also important that the patient's family and friends are made aware of diet and fluid restrictions.

- To administer diuretics as prescribed. Spironolactone is the medication of choice because of its potassium-sparing properties. Fluid loss is measured by weighing the patient at the same time each day in similar clothes, with an empty bladder.
- To control pain. Pain may be mild and responsive to non-opioid analgesics. However, in malignant disease it can be severe and difficult to control. Strong analgesics and small doses of prednisolone are used to control this severe pain.

Box 4.11

Ascites

The term ascites refers to a marked increase in the volume of fluid in the peritoneal cavity. This is usually due to an underlying disease in which the total body fluid is increased. Hepatic cirrhosis accounts for over 80% of cases but ascites can also be caused by cardiac failure, nephrotic syndrome, malignancy in the peritoneum or infection such as tuberculosis.

In health, serous fluid is continually produced in the peritoneal cavity and is sufficient to provide lubrication only, but ascites occurs when fluid enters the peritoneal cavity more quickly than it can be returned to the circulation by the capillaries and lymphatics. Fluid normally leaves a capillary at its arteriolar end and returns at its venous end but, in cirrhosis, portal hypertension causes more fluid to be produced in the hepatic sinusoids which are unable to drain via impaired hepatic lymphatics. The failing liver cannot synthesise enough of the plasma protein, albumin, and the resulting hypoalbuminaemia lowers the osmotic pressure of the blood, reducing the amount of peritoneal fluid reabsorbed at the venous end. This picture is further complicated by sodium and hence water retention. The presence of ascites in liver disease is a poor prognostic sign as it implies poor liver function. Severe ascites can cause great discomfort: dyspnoea, anorexia and the ability to eat only small meals; inhibited mobility and discomfort when lying in bed or sitting upright in a chair. If pain occurs, it is often felt in the back. Many of the symptoms correspond to the discomfort of full-term pregnancy! Increased intra-abdominal pressure also leads to hernias, especially at the umbilicus.

Ascitic fluid in cirrhosis is usually straw-coloured; bloodstained ascites indicates malignant disease; bile staining indicates a communication with the biliary system; and cloudy fluid denotes infection. Chylous ascites, which has a milky appearance, is caused by lymphatic obstruction.

Box 4.12

Abdominal paracentesis

In intractable ascites, i.e. when sodium restrictions and diuretic therapy have little effect, it is possible to drain the fluid from the peritoneal cavity by means of a catheter inserted through the abdominal wall. This procedure is known as abdominal paracentesis. Such patients are already hypoproteinaemic and the sudden loss of fluid and protein by paracentesis is likely to lead to a shift of both from the rest of the body into the abdominal cavity, sometimes with consequent hypovolaemia, shock and even death. The protein is therefore replaced at the time of paracentesis by an infusion of salt-poor albumin. The patient's blood pressure should be monitored closely and the fluid drained no more quickly than at a rate of approximately 2 L/h. Strict aseptic technique should be used when inserting the catheter to avoid introducing infection that can lead to bacterial peritonitis. This procedure requires cooperation from the patient to lie relatively still in bed while the catheter is in situ over several hours. Help will be required from the nursing staff to maintain comfort over this period. Any leakage on removal of the catheter can be collected in a drainable bag (e.g. a stoma bag) until the puncture site heals (usually within 48 h).

Gastrointestinal bleeding

GI bleeding is a direct result of portal hypertension. It may be slow and insidious, as in portal hypertensive gastropathy, or sudden and catastrophic, as in major oesophageal or gastric variceal rupture.

PATHOPHYSIOLOGY

Portal hypertension occurs when there is an obstruction in the intra- or extrahepatic circulation. Hepatic cirrhosis accounts for over 90% of cases of intrahepatic hypertension in this country. Extrahepatic portal hypertension is less common: in adults it is usually due to thrombosis, as occurs in polycythaemia rubra vera, local inflammation or sepsis, as in pancreatitis, or invasion by malignant tumours.

Common clinical features The cardinal signs of portal hypertension are splenomegaly, enlargement of the spleen, hypersplenism, splenomegaly and a deficiency in one or more types of blood cells, and a portosystemic collateral circulation. The collateral vessels open up to decompress the portal system and are present throughout the abdomen. They are, however, most problematic at the gastro-oesophageal junction where they can rupture and cause massive haemorrhage.

MEDICAL MANAGEMENT

Investigations Portal hypertension is diagnosed by medical history, palpation of the abdomen, and ultrasound when splenomegaly is demonstrated. Angiography of the portal venous system will determine the cause and site of the obstruction. Endoscopy will demonstrate gastro-oesophageal varices. Hypersplenism will cause thrombocytopenia and leucopenia. Anaemia may also be present.

Treatment The presenting symptoms are treated. Bleeding from oesophageal varices is treated by blood transfusion and by variceal eradication. This can be done endoscopically, either by injection sclerotherapy or band ligation. Balloon tamponade, compression of the varices using inflated balloons, and medication such as vasopressin are used only to stop active bleeding until variceal eradication treatment is commenced. Patients who do not respond to endoscopic management of their varices will be treated with a transjugular intrahepatic portosystemic stent (TIPSS).

Sclerotherapy is a treatment for oesophageal varices involving the injection of an irritant solution. This causes thrombosis and obliteration of the varicosed veins.

Banding is an alternative for the long-term treatment of varices as it has fewer complications than sclerotherapy.

Splenectomy is particularly valuable where there is portal hypertension due to obstruction in the splenic vein.

Transjugular intrahepatic portosystemic stent (TIPSS) is a radiological intervention whereby a metal stent is inserted in the liver to connect the portal and systemic veins. It is effective in lowering the portal pressure and thus controlling variceal bleeding and re-bleeding. It is associated

with a low complication and mortality rate (Redhead et al 1993).

For further information, see Miller (1996).

NURSING PRIORITIES AND MANAGEMENT: Oesophageal varices

If the patient is vomiting profusely from bleeding oesophageal varices, a high-flow suction catheter should be available for intermittent suction and maintenance of a clear airway.

Blood pressure and pulse should be observed quarter-hourly and the nurse should be alert for signs of hypovolaemic shock (see Ch. 18). Intravenous fluids and a blood transfusion should be maintained and an accurate record of all fluid intake and output kept. A urinary catheter is passed and urine output measured hourly during the acute phase, as underperfusion of the kidneys due to shock can result in renal impairment.

Intravenous infusion of a vasoconstricting agent such as vasopressin may be used to constrict the splanchnic arterioles and so reduce the blood loss at source.

The patient is fasted prior to transfer to theatre for endoscopic eradication of varices. Standard preparation is followed and on return to the ward, a clear airway and no oral fluids must be maintained until sensation and the ability to swallow have returned. The nurse will observe closely for recurrence of bleeding.

Because of the experience of either vomiting blood or passing melaena, the patient may be extremely anxious. A calm approach and clear explanations of treatment and care are essential in order to help relieve the natural fears that extensive bleeding causes.

Should the bleeding not be arrested endoscopically, a gastric or oesophageal tamponade is used to stop the bleeding by balloon tamponade, i.e. compression. A Sengstaken or Minnesota tube is passed well into the stomach and the gastric balloon inflated to approximately 300 mL of air. Gentle but firm traction is applied to maintain the balloon at the oesophagogastric junction. The oesophageal balloon is inflated only if bleeding persists, as it carries a risk of oesophageal perforation. Great care is required when inflating the oesophageal balloon (no more than 30 mL of air) and it must be deflated for 30 min every 4 h. The nurse will monitor the inflation pressures and times and move the tube from side to side in the mouth every hour to prevent pressure ulcers from forming there.

The tube should be in situ no more than 12 h and immediate therapy is required on removal, i.e. endoscopic eradication or TIPSS.

Anxiety and agitation can be relieved by small i.v. doses of a benzodiazepine sedative such as midazolam. As patients with liver disease are very sensitive to sedatives, the benzodiazepine antagonist flumazenil should be immediately available. Antiemetics such as metoclopramide should be given if the patient is nauseated and retching, as this increases the pressure in the varices and could cause further haemorrhage.

For further information, see Stanley & Hayes (1997) and Starr & Hand (2002).

Hepatic encephalopathy

PATHOPHYSIOLOGY

Hepatic encephalopathy (HE) is a neuropsychiatric syndrome that occurs only in significant liver disease. It may be overt or subclinical and is potentially fully reversible (Jalan & Hayes 1997). The subclinical form can be difficult to diagnose but the overt form can lead to bizarre and even violent behaviour. The exact cause is unclear, but one popular theory is that gut-derived neurotoxins which the failing liver has been unable to neutralise somehow cross the blood–brain barrier and cause changes in cerebral neurotransmission (Jalan & Hayes 1997). This gives rise to a range of behaviour patterns that are graded 1–4 in order of severity, as follows:

1. Lack of awareness, euphoria, short attention span and impaired ability for simple arithmetical calculations
2. Lethargy, apathy, disorientation in time and place, personality change and inappropriate behaviour
3. Semi-stupor, somnolence, confusion and gross disorientation
4. Coma.

MEDICAL MANAGEMENT

Medical treatment is aimed at reversing the commonly known precipitating factors of HE, which are:

- protein loading
- GI bleeding
- sepsis
- dehydration
- blood chemistry imbalances
- use of sedatives
- constipation.

For further information on the medical management of HE, see Riordan & Williams (1997).

NURSING PRIORITIES AND MANAGEMENT: Hepatic encephalopathy (HE)

Detection, avoidance and management of the above factors can be largely nurse-led. The better the nurse knows the patient, the easier it will be to detect subtle changes in the patient's personality and to reverse the encephalopathic process before coma develops. It is useful to involve family and friends in the monitoring process.

Good dietary advice is essential, not only to avoid protein excess but also to maintain a high calorie intake to avoid tissue catabolism. Dietary protein restriction is very rarely recommended nowadays as many patients with liver failure are malnourished due to ill health or alcohol excess. Constipation should be avoided and lactulose can be used to promote one to two bowel movements per day. Lactulose is especially beneficial following GI bleeding, as it alters bowel pH which then modifies colonic bacterial metabolism so that less ammonia is produced. A major GI bleed represents a large protein load in the bowel.

Close monitoring of fluid balance and daily weight is important to avoid dehydration, especially in patients on diuretic therapy or undergoing abdominal paracentesis.

Strict aseptic technique should be used for all invasive procedures and any focus of infection promptly reported and treated.

A safe environment must be maintained at all times for the patient who may be at risk of confusion and unsteadiness.

For further information on HE, see Shearman et al (1997).

Cancer of the liver

Tumours of the liver can be either primary or secondary growths. The liver is the most common site for metastatic spread and patients often present with symptoms from the secondary rather than the primary lesion.

Primary tumours

Hepatocellular carcinoma is the principal primary tumour. It is one of the major cancers of the world but the incidence varies greatly between countries. The highest risk populations are in sub-Saharan Africa and eastern Asia and males are more commonly affected than females (Chen et al 1997). Chronic hepatitis B and C virus infections are the main causes of the cancers in high-incidence areas. Hepatocellular carcinomas also occur in haemochromatosis and alcoholic cirrhosis of the liver.

PATHOPHYSIOLOGY

The tumour is highly vascular and occurs most frequently in the right lobe. It may invade the hepatic and portal veins, the obstruction to these vessels resulting in portal hypertension. There may be local spread to the peritoneum or metastatic spread to the lungs or lymphatic system.

MEDICAL MANAGEMENT

Investigations A very high serum alpha-fetoprotein (AFP >200 ku; normal: 2–6 ku) is diagnostic. Ultrasound with fine-needle aspiration or biopsy at laparoscopy is performed to obtain cells for histological examination. Ultrasound, CT scan and angiography are needed to define the extent of liver involvement and venous invasion prior to a decision being taken on treatment.

Treatment The first objective is to see whether the tumour is localised sufficiently in the liver to be resected surgically (see Box 4.13). Unfortunately, surgery is usually impossible, either because liver involvement is too extensive or because metastasis to other organs has occurred. Some patients may benefit from chemoembolisation of the vessels supplying the tumour, but as this treatment can have unpleasant side-effects, it is often reserved for patients with hepatic symptoms (see Box 4.14). Medical therapy also aims to relieve symptoms such as pain or ascites.

Secondary tumours

These are the most common malignant liver tumours and can originate from a primary growth in any part of the body.

PATHOPHYSIOLOGY

Multiple deposits are usually found and may be sited anywhere in the liver. The histology of the cells may indicate the primary site; however, the cancer cells may be anaplastic, giving no indication of their origin.

Clinical features are as for primary malignant tumours, with signs of associated cirrhosis. Pain is often the most common symptom for which the patient seeks medical help. The abdomen will become distended due to the enlarged liver, peritoneal invasion and ascites. The patient will have difficulty in bending and is usually anorexic. Jaundice may be present. Weight loss is usually marked.

MEDICAL MANAGEMENT

Diagnosis is by fine-needle aspiration under ultrasound imaging to obtain cells for histology. If the primary site is unknown and causing no symptoms, but there are metastatic deposits in the liver, the patient is not subjected to investigations to locate the primary tumour, as outcome is determined by the spread to the liver.

Treatment must generally be restricted to symptom control, although occasionally a localised metastasis from the colon can be resected.

Box 4.13

Surgical resection of liver tumours

Resection of liver tumours constitutes major surgery. In some cases, complete removal of the tumour may be possible, depending on the site and size of the tumour and on liver function. Resection is contraindicated in patients with extensive liver cirrhosis.

Because the liver has a good capacity to regenerate, following small hepatic lobectomy the prognosis is relatively good if the entire tumour has been resected. More extensive resections carry a higher mortality rate.

The nursing management of a patient following major liver surgery is intensive and should be carried out in a specialist unit.

Box 4.14

Hepatic artery ligation and tumour embolisation

Hepatic artery ligation may give worthwhile palliation in patients with hepatocellular carcinoma. Following ligation, tumour necrosis occurs. This treatment is contraindicated in patients with portal vein obstruction and cirrhosis because of the ensuing massive hepatic necrosis.

Tumour embolisation may also provide worthwhile palliation. During hepatic angiography, a gelatin sponge is injected into the branches of the hepatic artery, causing tumour infarction.

Chemotherapy may also be used; if so, the drug is delivered directly into the tumour to avoid systemic side-effects.

NURSING PRIORITIES AND MANAGEMENT: Cancer of the liver

Major patient problems

Nursing management is aimed at symptom control as well as providing the emotional support patients require when facing a terminal illness (see Chs 31 and 33). Time should be spent with the patient so that there is the opportunity to express thoughts, fears and anger. As the prognosis of this form of cancer is so poor, this patient may be left with a very short time to put their affairs in order and to prepare for impending death. Family and friends will also need support from nursing and medical staff.

Initially, the patient may be able to attend personal needs, and may also be able to return home. However, repeated admission may be necessary for abdominal paracentesis (see Box 4.12). As the disease advances, there will be progressive dependence on nurses and/or relatives for care. Due to extreme weight loss, much attention is required in maintaining intact pressure areas, and oral hygiene should be given regularly in the hope of preventing moniliasis. At this point, the patient and family may appreciate the privacy of a single room, but this should not be undertaken without prior discussion with them.

DISORDERS OF THE BILIARY SYSTEM

4.19 With the help of your physiology textbook, review the structure and function of the biliary system.

Cholelithiasis

Cholelithiasis, the presence of gallstones, is the commonest disorder of the biliary tree. It is more prevalent among women than men and its incidence appears to be increasing. In developed countries, at least 20% of women over 40 will develop gallstones. Until about 20 years ago, the most likely person to develop gallstones was said to be an obese woman in her 40s with fair skin ('fair, fat, fertile, female and 40'). This categorisation is now considered outdated as, for unknown reasons, gallstones are affecting people at a much younger age. Other factors related to the development of gallstones include the use of oral contraceptives, diabetes mellitus and genetic history.

For further information, see Garden (2002).

PATHOPHYSIOLOGY

Gallstones are formed from the constituents of bile salts. Stones vary in size and shape, and may be solitary or multiple. Their colour can vary from yellow to dark brown. There are three main types:

- pure cholesterol stones (a 'solitaire' that fills the gall bladder): 10%
- pigmented stones ('jack stones', black and shiny): 2–3%
- mixed stones (mainly cholesterol often with some calcium): 80%.

Biliary colic

Gallstones can be asymptomatic. It is believed that only 10–30% of gallstones become symptomatic. At postmortem 12% of men and 24% of women will have gallstones present (Garden 2002). More often they cause biliary colic or an acute or chronic cholecystitis. Cholecystitis can also, less commonly, be caused by trauma and, even more rarely, by tumours.

PATHOPHYSIOLOGY

Biliary colic is caused by a transient obstruction of the gall bladder from an impacted stone.

Common presenting symptoms The patient complains of a sudden onset of severe gripping pain in the right hypochondrium that often radiates to the back. It can be associated with nausea and vomiting. The pain may vary in intensity and can last for several hours. The pain will ease when the stone either passes into the common bile duct or falls back into the gall bladder.

MEDICAL MANAGEMENT

The patient will recover quickly, but repeated bouts of colic are common. Following investigations a cholecystectomy may be performed.

Acute cholecystitis

PATHOPHYSIOLOGY

It is thought that, in this condition, gallstones irritate the mucous membrane lining of the gall bladder, which then becomes inflamed.

Common presenting symptoms The patient presents with an acute illness that is severe in nature, and may be in shock due to pain and vomiting.

A mass may be felt and Murphy's sign, a catching of the breath at the height of inspiration when the gall bladder is palpated, is usually positive. The pain will be severe in the right hypochondrium and may radiate to the right shoulder tip.

There may be tenderness and guarding of the whole abdomen and the patient may not tolerate examination. Sweating and pallor may be present.

There will be pyrexia and tachycardia due to infection. Jaundice may be present if there is obstruction of the common bile duct; in this case the patient will have a history of pale stools and dark urine. A history of fatty intolerance may also be described, and the pain often starts following a fatty meal.

MEDICAL MANAGEMENT

Investigations Tests that may be used to establish a diagnosis are as follows:

- blood tests — liver function tests, serum amylase and white blood count
- ultrasound
- CT scanning
- endoscopic retrograde cholangiopancreatography (ERCP)
- intravenous cholangiogram (used occasionally)
- oral cholecystogram (less common).

Ultrasound is now the main investigative procedure for patients with suspected gallstones. It is non-invasive and causes minimal discomfort to the patient. The scanning

machine can be brought to the patient in the admissions ward, thus avoiding an uncomfortable journey to the radiology department. Ultrasound can identify stones in the gall bladder, thickening of the gall bladder wall and both intra- and extrahepatic duct dilatation. It can be done quickly and is relatively inexpensive.

Treatment Cholecystectomy is indicated in patients with biliary colic or acute cholecystitis and may be undertaken early in the acute admission. It may also be undertaken as an elective procedure around 6 weeks after an acute episode and following a full recovery. Antibiotic cover is always given. Moreover, with an 'early' cholecystectomy, the patient is not at risk of further attacks of acute cholecystitis while waiting for elective surgery. Removal of gallstones can also be performed by ERCP and sphincterotomy. In more specialised centres, surgeons are now performing laparoscopic cholecystectomy.

Laparoscopic cholecystectomy The advantages to the patient of this procedure are:

- reduced stay in hospital
- early mobilisation with lower risk of complications
- minor nature of surgical wounds
- reduced need for opioid analgesics
- speedy return to normal life.

The procedure is performed under general anaesthetic. The surgeon passes a laparoscope into the abdomen at the umbilicus. The abdomen is then insufflated with CO_2 to allow clear visualisation of the gall bladder.

Three more incisions are made in the region of the right hypochondrium to allow instruments to be manipulated. The cystic artery is identified and ligated. The cystic duct is identified, at which stage an intraoperative cholangiogram can be done to check for stones in the common bile duct. If stones are present, these can be removed.

By careful dissection, the gall bladder is then removed from the liver bed. It is brought to the undersurface of the umbilicus, where the stones are extracted and the gall bladder removed.

All stab wounds are then closed with a subcutaneous suture. On return from theatre, immediate nursing care is as for any routine general anaesthetic (see Ch. 26).

Free fluids can be given when the patient has fully recovered from the general anaesthetic. Normal diet is generally started the following day. Most patients are discharged on the first or second postoperative day.

4.20 Complications, such as damage to the common bile duct, are rare and often insidious in their development.

(a) In the relatively short postoperative period in hospital, what observations or clinical signs might indicate a significant complication?

(b) What specific advice might be given to the patient and family members?

NURSING PRIORITIES AND MANAGEMENT: Acute cholecystitis

Immediate concerns

Patients experiencing an acute episode of cholecystitis will be severely ill and will be referred to hospital as quickly as possible after being seen by their GP or by contacting NHS Direct/24. The priorities of care while the attack is being managed prior to surgical intervention include the following:

- administration of an i.m. opiate analgesic at frequent intervals
- hourly recording of vital signs until the patient's condition stabilises
- fasting the patient and commencing i.v. fluids
- careful monitoring of fluid and electrolyte balance
- i.v. administration of a broad-spectrum antibiotic
- if vomiting is persistent, a nasogastric tube may be passed and an antiemetic given.

Major patient problems

The patient will be restless and uncomfortable due to the pain. The most comfortable position for the patient should be sought and analgesics given regularly. Fear of pain and of the unknown increases pain (see Ch. 19). It is therefore vital to explain what is happening and to assure the patient that the condition can be treated. When the condition is stable, the patient should be introduced to the surroundings and information about the ward can be provided.

Once the acute phase has passed, fluids can be given and foods gradually reintroduced. The i.v. infusion may be discontinued when the patient can tolerate an adequate oral intake. Intravenous antibiotics are usually given for 5 days and then discontinued.

Sweating can be a problem and frequent washes and changes of bedclothes may be necessary to keep the patient comfortable. Oral hygiene should be maintained as necessary.

While the patient is in bed, gentle exercises to prevent deep vein thrombosis should be taught and frequent changes of position should be encouraged to alleviate pressure. Taking deep breaths to avoid pulmonary complications should be encouraged and smoking should be discouraged.

Perioperative care

Cholecystectomy is carried out on patients with acute cholecystitis to relieve symptoms and prevent complications. Exploration of the common bile duct may be undertaken if there is evidence of stones. Open cholecystectomy used to be one of the most common surgical operations; however, since the advent of laparoscopic cholecystectomy in 1978, the use of this operation has fallen sharply (Garden et al 2002).

Nursing care following an open cholecystectomy

In this procedure, the surgeon approaches the gall bladder through a subcostal paramedian or midline incision. An intraoperative cholangiogram is performed to identify any stones in the common bile duct. If stones are present, the surgeon will explore the duct, remove the stones, and may occasionally insert a T-tube to maintain patency and prevent stricture of the duct. The long leg of the T-tube is brought out through a stab wound in the abdominal wall and then connected to a drainage bag. It is vital that this

Box 4.15

Management of a T-tube

A T-tube is inserted into the common bile duct following exploration. This tube is necessary as a 'safety valve' because following surgery the duct will become inflamed and oedematous, blocking the flow of bile into the duodenum. Approximately 300–500 mL of bile should drain in the first 24 h. This amount will gradually decrease over the next 8–10 days as the patency of the duct returns. An accurate recording of the amount of bile drainage must be made. The presence of insufficient or excessive bile must be reported. When there is a sudden cessation of bile drainage, a kinked or compressed tube must be suspected.

It is also important to support the bile drainage bag at all times to prevent traction on the tube and accidental removal. An aseptic technique must be used when emptying or changing the bag. Daily cleaning of the skin at the drain site is necessary and the nurse should check for bile leakage from around the tube, inflammation or excoriation of the skin. Any excess tubing should be coiled and taped to the abdomen. Prior to removal, a T-tube cholangiogram will be done to check the patency of the bile duct and the flow of bile into the duodenum. If the duct is patent, the tube is removed. If there are residual stones in the duct, the T-tube is left in situ. These residual stones may pass spontaneously into the duodenum; otherwise it will be necessary to remove them under X-ray vision.

Prior to performing a T-tube cholangiogram some surgeons ask for the T-tube to be clamped for 24 h. This procedure is, however, becoming less common. If there is any complaint of abdominal pain whilst the tube is clamped, it must be respected and the clamp removed immediately.

The patient will require an analgesic 30 min before the tube is removed. The skin suture is removed and a firm steady pressure applied to the tube. The nurse should observe the amount of bile leakage following removal and apply a sterile dressing. Observation of the patient for any signs of biliary peritonitis should be made for 24 h.

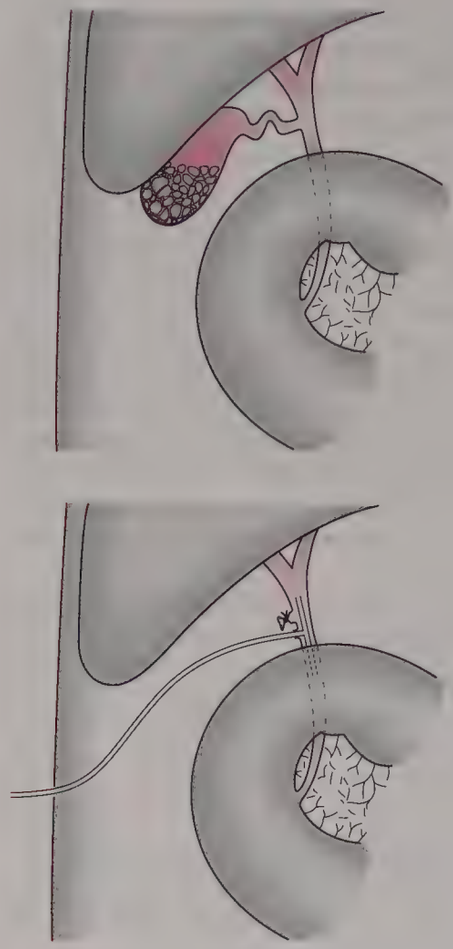

Fig. 4.11 The T-tube in the common bile duct (Forrest et al 1995).

tube is not removed accidentally (see Box 4.15). A T-tube cholangiogram is done 8–10 days postoperatively to ensure patency of the duct prior to its removal. If the ducts are stone-free, the tube will be removed following instructions from the surgeon (see Fig. 4.11).

There is usually a wound drain inserted into the gall bladder bed. Regular observation of the colour and amount of blood draining postoperatively is vital. Excessive drainage of bright red blood must be reported immediately to the surgeon. This drain is usually removed 24–48 h postoperatively.

Immediate postoperative care is as for any major abdominal surgery requiring general anaesthesia. Adequate analgesia is vital so that the patient can perform deep breathing and coughing exercises to prevent atelectasis and pneumonia. In most cases, the anaesthetist will perform an intercostal nerve block and top it up at regular intervals so that the patient is pain-free. This can be supplemented with i.m. or i.v. analgesics given regularly over the first 24–48 h. The nurse should check at regular intervals that the incision site and surrounding area are numb, to ensure the intercostal nerve block is working effectively. The patient should be raised to an upright position and encouraged to do breathing exercises to prevent pulmonary complications.

Other considerations

The patient may begin to take oral fluids gradually after the first 24 h (30–60 mL/h). If these are tolerated, free fluids may be given. Diet is gradually increased over the next 3 days. A nasogastric tube is not used unless the patient shows signs of paralytic ileus. In this case the patient should be fasted, a nasogastric tube passed and the stomach kept empty.

Sutures are removed 7–10 days postoperatively unless, as has become more common, an absorbable subcutaneous suture is used. If the wound is dry and clean, the dressing can be removed 24–48 h postoperatively and the wound left exposed.

Depending on the patient's fitness and age, discharge home normally occurs within 6–10 days. Discharge plans will need to be discussed with relatives or carers. The patient must be instructed to do no heavy lifting for 4–6 weeks to avoid wound herniation. Normal diet is allowed. In an uncomplicated recovery, the patient should be fit to return to work 4–6 weeks later. A detailed discharge summary will be sent to the GP, who will then certify when the patient is fit for work. A follow-up appointment will be given for 4 weeks after discharge so that the surgeon can make sure that the outcome is satisfactory (see Case History 4.3).

CASE HISTORY 4.3
Mrs G

Mrs G had suffered from episodes of cholecystitis and biliary colic for many months before she finally went to her GP. She was a busy mother of three and, as she recounted at a later date, 'There really was no time to be going to the doctor. Besides, the pain always went eventually, especially if my husband rubbed my back up between the shoulder blades'.

Eventually, when she felt so ill that she was forced to stay in bed, she 'gave in'.

The investigations and surgery passed uneventfully in surgical terms, as she had been quite well and free from symptoms at the time of admission. Unlike her sister in London, she had had an open cholecystectomy. It was the first time she had had an operation and, although she thought the nurses were wonderful and had explained everything, she later remarked: 'No one ever tells you just how awful the first day after the operation really is'.

Within 10 days, Mrs G was at home once more, delighted that at least her sutures were dissolvable ones. She knew that she must not do too much lifting and that although she should have a normal diet, she should avoid fatty foods as they might make her feel 'squeamish'. 'It's like only having weak washing-up liquid to deal with greasy dishes instead of good concentrated liquid,' she explained to a friend.

Three weeks after discharge, she visited the doctor. She was quite distressed and reported the following problems: 'I keep having episodes of diarrhoea and I'm so tired. No one said who was going to do the hoovering or put the shopping away in those high cupboards. The family thinks I'm back to normal because the wound is healed but I am so tired still. Everything is an effort'.

Chronic cholecystitis

PATHOPHYSIOLOGY

Chronic cholecystitis is caused by the presence of stones in the gall bladder. In this condition the gall bladder wall becomes thickened and fibrosed.

Common presenting symptoms The patient may present with biliary colic but more often complains of pain in the right upper quadrant of the abdomen, often following a big meal. There will be a history of fat intolerance, flatulence and heartburn. Abdominal distension may also be a problem following meals.

The pain is less severe than in acute cholecystitis and patients often put up with their symptoms for years before seeking medical advice. In chronic cholecystitis, the patient's general condition must be taken into account, particularly if elderly or suffering from other medical conditions that may increase the risks of surgery.

MEDICAL MANAGEMENT

Investigations are as for acute cholecystitis.

Treatment Usually the diseased gall bladder is removed, either by an open cholecystectomy or, more commonly now, by a laparoscopic cholecystectomy.

Choledocholithiasis

Stones in the bile duct occur in about 10–15% of patients with gallstones.

PATHOPHYSIOLOGY

Common presenting symptoms Colicky pain occurs if the stones impede the flow of bile through the sphincter of Oddi. Impaction of a stone at the sphincter will cause jaundice. The patient will have pale, fatty stools, dark urine and possibly complain of generalised itching. Some stones will clear spontaneously following passage into the small intestine.

If the stone becomes impacted, the bile duct will become dilated. Infection can cause cholangitis with rigors, severe pain and jaundice. Acute pancreatitis may develop due to obstruction of the sphincter of Oddi and reflux of bile salts into the pancreatic ducts (see p. 148).

MEDICAL MANAGEMENT

Investigations are as for acute and chronic cholecystitis.

Treatment Removal of the stones via ERCP and sphincterotomy to allow the stones to pass freely into the small intestine will be carried out either prior to surgery or in cases where surgery is contraindicated.

For further information, see Garden (2002).

Tumours of the biliary tract

Cancer of the gall bladder

PATHOPHYSIOLOGY

This is a rare cancer and is nearly always related to gallstones. It is more common in females than in males. Signs and symptoms are consistent with those for gallstones and a history of persistent obstructive jaundice may be present. A mass may be palpable. In most cases, surgery is not a chosen treatment and survival rates are poor. Eighty per cent of gall bladder tumours are adenocarcinomas. As with other tumours, the involvement of lymph nodes and the presence of metastases will determine the patient's prognosis.

Cancer of the bile duct (cholangiocarcinoma)

PATHOPHYSIOLOGY

The cause of bile duct cancer is unknown although there are strong associations with inflammatory bowel disease and primary sclerosing cholangitis (Garden 2002). It is more common in older people, and men are affected more than women. It is a rare cancer but its incidence appears to be increasing. Tumours can arise from the intra- or extrahepatic biliary tree. Direct spread and metastases are present in at least 50% of the patients who go for surgery.

MEDICAL MANAGEMENT

Treatment As cancer of the bile ducts carries a very poor prognosis, treatment is usually in the form of palliative therapy. Jaundice is a very distressing symptom and if this is not treated the patient may die from liver failure.

For some patients, palliation can be achieved by the insertion of a stent, either by ERCP or by percutaneous transhepatic techniques, e.g. percutaneous transhepatic cholangiography (PTC). In a few cases, where the tumour is at the lower end of the common bile duct, a radical resection

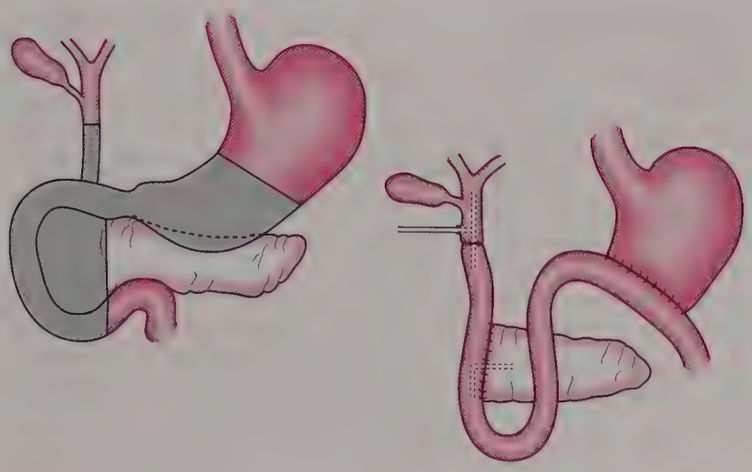

Fig. 4.12 Whipple's procedure. This extensive procedure involves resection of the head of the pancreas, the duodenum and the antrum of the stomach, as well as removal of the gall bladder. Reconstruction is carried out with choledochojejunostomy, pancreatojejunostomy and gastrojejunostomy. This is a major operation that carries a relatively high mortality rate. Leakage from the anastomosis, abscess formation and fistula are the main complications (Forrest et al 1995).

in the form of a Whipple resection may be possible (see Fig. 4.12). This is major surgery and should be considered only if the tumour is localised and if the patient is fit for surgery.

Tumours of the upper biliary tract are resectable in only 10% of cases. Following resection of the tumour, a Roux loop of jejunum is anastomosed to the biliary tract or, in some cases, the left hepatic duct. A hepaticojejunostomy then restores the continuity of the small intestine. A hepaticojejunostomy can also be performed to bypass the tumour and achieve palliation. Radiotherapy and chemotherapy have not been shown to improve survival.

NURSING PRIORITIES AND MANAGEMENT: Cholangiocarcinoma

The patient with a diagnosis of cholangiocarcinoma will require specialised nursing care. Only a few of these patients will be considered for major resection, following which they are cared for in a high-dependency ward for approximately 48 h. In some cases the patient is prepared for major resection but at the time of surgery it is discovered that only a bypass of the tumour may be carried out safely. These patients are usually devastated by this turn of events and require a great deal of support. Following palliation, jaundice will subside and the patient's appetite will improve. For a few months the patient may feel so well that they become unrealistic about the prognosis. Few patients survive more than a year following palliation. Following resection, the outlook is better. Good family support is necessary. It is important to take an honest approach and to give explanations to the patient and family as they request it. It will be necessary to spend time with the patient and the relatives to answer their questions and offer support. Close communication with the GP is also important so that community care can be provided when necessary.

DISORDERS OF THE PANCREAS

Pancreatitis

Inflammation of the pancreatic gland may be acute or chronic. Acute pancreatitis can range from mild oedema to severe necrosis and haemorrhage. Following an attack, the gland returns to normal. Chronic pancreatitis is associated with permanent anatomical and functional abnormality. The patient usually suffers from relapsing attacks with relative good health between episodes.

Acute pancreatitis

Acute pancreatitis can be life threatening, with approximately one in four patients presenting with severe disease; of these, one in four will die (Garden et al 2002). It can affect all adult groups. In the UK its two main causes are gallstones and excessive alcohol consumption. Other identified causes include smoking, infection, trauma, medication, e.g. corticosteroids, hypercalcaemia, hyperlipidaemia, pancreatic cancer and hereditary factors. In modern practice, intervention with ERCP can also cause pancreatitis.

PATHOPHYSIOLOGY

The pancreatic enzymes, trypsin and lipase, which are normally activated in the duodenum, are prematurely activated within the pancreas, causing autodigestion of the gland. This autodigestion leads to varying degrees of oedema, haemorrhage, necrosis, abscess and cyst formation in and around the pancreas. Spasm of the sphincter of Oddi with reflux of duodenal contents into the pancreatic duct is thought to be an important factor in this enzyme activation. Gallstones and alcohol are two contributing factors to spasm. Passage of stones down the common bile duct may also promote reflux of infected bile along the pancreatic duct when these ducts form a common channel to the ampulla of Vater.

Activated enzymes such as trypsinogen and chymotrypsinogen, phospholipase, elastase and catalase are responsible for increased capillary permeability. This permits large volumes of fluid to escape into the peritoneal and retroperitoneal cavity, causing damage to the surrounding tissue. This severe loss of circulating fluid leads to hypovolaemic shock and predisposes the individual to acute renal failure, which may result from local intravascular coagulation in the renal vascular bed. Development of pulmonary oedema with left-sided pleural effusion may result from release of toxins. The release of lipase causes fat necrosis in the omentum and areas adjacent to the pancreas. Calcium soaps become sequestered in areas of fatty necrosis, which may result in the development of hypocalcaemia.

MEDICAL MANAGEMENT

History and examination The patient usually presents with epigastric pain of acute onset radiating to the back, associated with nausea and vomiting. There may be a history of biliary tract disease or alcohol abuse.

Acute pancreatitis is often associated with severe shock. There may be signs of dehydration with rapid pulse and respiration, hypotension and pyrexia. Marked abdominal tenderness is usually present in the upper abdomen, which may appear distended. Bruising around the umbilicus

(Cullen's sign) and in the loin region (Grey Turner's sign) are rare late manifestations of acute pancreatitis due to petechial bleeding into the retroperitoneal space.

Investigations include blood analysis, urinalysis, X-ray ultrasound and CT scan, as follows:

- Serum lipase is one of the most reliable markers of acute pancreatitis.
- A serum amylase of above 1000 IU/L in the past 48 h is strongly suggestive of acute pancreatitis. Normal levels are 100–300 IU/L. Urinary amylase can remain elevated for 10–14 days.
- Plain X-ray films of the abdomen can reveal distended loops of small bowel with paralytic ileus; chest X-ray may reveal left-sided pleural effusion.
- Urea and electrolyte levels are important indicators of the state of hydration and are necessary for the correct management of the patient.
- A raised white blood cell count ($9–20 \times 10^9$) reveals an active inflammatory process.
- Hyperglycaemia and glycosuria are often present but are transient.
- Arterial blood gases may reveal severe hypoxia.
- Abdominal ultrasound and CT scan are used to detect the presence of peripancreatic collections and pancreatic necrosis.

Treatment

Conservative management Acute pancreatitis is usually managed conservatively; for mild attacks, treatment is generally symptomatic. The principles of management are as follows:

- *Pain relief.* This is usually provided in the form of opiate analgesics. Morphine can cause some spasm at the sphincter of Oddi, but is frequently prescribed as it is effective (Garden et al 2002).
- *Correction of shock.* If haemorrhagic pancreatitis is diagnosed, shock is treated by i.v. administration of large volumes of crystalloids, plasma, dextran or blood in order to maintain circulatory blood volume and adequate urine output. Oxygen therapy is essential to correct the associated hypoxia. PO_2 saturation levels should be monitored. Hypoxaemia may develop insidiously such that respiratory failure (ARDS) can develop. Arterial blood gases are closely monitored in case ventilatory support is required (see Chs 2, 18 and 29).
- *Suppression of pancreatic function.* The patient is fasted to decrease stimulation of pancreatic enzymes and a nasogastric tube is passed if the patient is vomiting persistently.
- *Controlling infection.* When there is evidence of infection, a broad-spectrum antibiotic is prescribed. For the majority of patients this supportive treatment will settle the acute attack and surgical treatment will not be necessary. If there is any doubt about the diagnosis, a laparotomy will exclude other causes of peritonitis, such as perforated peptic ulcer and mesenteric ischaemia.
- *Monitoring blood glucose levels.* This must be done as secondary diabetes mellitus can sometimes develop, requiring insulin therapy.
- *Monitoring cardiac status.* This will be required if electrolyte derangement is such as to cause potentially lethal dysrhythmias.

Surgical intervention At an early stage in management, gallstones as a cause of the acute attack are excluded by ultrasound scanning. Cholecystectomy during the course of the patient's admission is now advocated to avoid recurrent problems following discharge. Patients with gallstone pancreatitis can usually be identified by their slow clinical progress and by the use of various clinical and biochemical prognosis factors.

Early ERCP may demonstrate the presence of stones in the common bile duct, which can be extracted by a small balloon catheter or basket following sphincterotomy. The complication of peripancreatic necrosis or abscess can be detected by radiological imaging (see Appendix 1). Most patients will require necrosectomy, i.e. the removal of necrotic tissues, and drainage at laparotomy. It may be wise to put in place a gastrostomy and jejunostomy tube at this time, as recovery is slow and the patient may require prolonged nutritional support (see Ch. 21).

NURSING PRIORITIES AND MANAGEMENT: Acute pancreatitis

Major considerations (see Case History 4.4)

The care of patients with acute pancreatitis will vary according to the severity of the attack. Some individuals present with vague abdominal pain that resolves quickly. More often, patients present with severe epigastric pain, often radiating to the back, and with vomiting and shock. It should be borne in mind that the severity of the attack is not always easily judged by an initial assessment and that these patients therefore require close observation.

Priorities of nursing care are:

- to relieve pain and promote comfort (see Nursing Care Plan 4.2)
- to monitor vital functions
- to restore and maintain haemodynamic status, i.e. to restore volume deficit, correct electrolyte imbalance and correct impaired gaseous exchange
- to restore and maintain adequate nutrition
- to prevent or minimise potential complications (see Box 4.16)
- to prevent the development of pressure ulcers
- to maintain the nasogastric tube (if present) and provide frequent mouthwashes and oral hygiene

CASE HISTORY 4.4

Mr N (see also Nursing Care Plan 4.2)

Mr N, aged 36, is admitted with a history of sudden, central abdominal pain that is only partially relieved by sitting forward and hugging his knees. He describes the pain as 'boring through his back'. His skin is pale and clammy and his respirations rapid and shallow, his pulse is rapid and there is marked hypotension. Mr N is clearly in an advancing state of shock. In addition, he is nauseated and repeated vomiting has led to increasing dehydration, exacerbating his shocked state.

Nursing Care Plan 4.2 Care of a patient with acute pancreatitis: the management of pain (see Case History 4.4)

Nursing consideration	Action	Rationale	Desired outcome
1. *Pain* **Mr N has severe and potentially excruciating pain due to autodigestion of the pancreas, the 'chemical burn' of pancreatic exudate, inflammation, and distension caused by an adynamic bowel**	• Rapidly assess and then monitor verbal and non-verbal evidence of pain, noting factors that either aggravate or ease the pain	To assist in achieving effective pain relief	Mr N's pain is relieved, as evidenced by the verbal communication, body relaxation and corresponding changes in vital signs
	• Give the prescribed analgesic	All opiates may cause some spasm of the sphincter of Oddi, but they are very effective (Garden et al 2002). As analgesia is achieved, smaller and less frequent doses may be given	
	• Give other adjuvant medication, e.g. antibiotic therapy, sedative agents, H_2 antagonists, antiemetics	Such agents may be used to help control the acute attack and associated symptoms, particularly pain	
	• Pass an NG tube and aspirate stomach contents	This will relieve the pain associated with distension and minimise pancreatic stimulation	
	• Position Mr N as comfortably as possible, minimising any unnecessary activity	Pain will be minimised, as will Mr N's metabolic rate and pancreatic activity	

- to monitor blood sugar level in order to detect secondary diabetes
- to support the patient in maintaining personal hygiene
- to help the patient to be up and about as early as possible.

As the patient's general condition improves, clear oral fluids can be introduced, gradually progressing to a light diet.

An episode of pancreatitis can be a very traumatic time for both the patient and the family, who may have been unaware of the important functions that the pancreas performs. It is important to explain the rationale of all procedures and investigations carefully to alleviate anxiety. Showing the patient diagrams can be very helpful. The patient may be very worried about work, family and financial situation, and a visit from the social worker may be of value. Patients with alcohol-associated acute pancreatitis may, with their consent, be referred for counselling to address their dependency problem (see Ch. 36).

It is important to reduce the noise level on the hospital ward to a minimum to allow patients to have adequate sleep (see Ch. 25). It may be advisable to give some form of night sedation. Restricting visits from wider family and friends may reduce the strain on the patient during visiting hours. Communication with the family is of course vital. On the patient's admission to the ward, nurses should introduce themselves to the relatives and give a full explanation of what has occurred. Medical staff should be available to give regular updates on the patient's condition.

Further considerations

When the acute episode has resolved, and if gallstones are present, an early elective cholecystectomy with possible exploration of the common bile duct will be undertaken. If the attack has been due to alcohol, the patient must be advised prior to discharge to abstain totally or risk a life-threatening recurrence.

Advice regarding return to work is important. The patient often feels tired and it is often advisable not to return to work for perhaps 4–6 weeks. The patient will be reviewed in the outpatient clinic initially at 3–4 weeks. A detailed account of management will be sent to the GP so that continuity of care can be maintained.

For further information, see Garden (2002) and Fawcett & Smith (2005).

Box 4.16

Complications of acute pancreatitis

Pancreatic pseudocyst
This condition develops in about 10% of patients following acute pancreatitis or an exacerbation of chronic pancreatitis. A pseudocyst is a sac containing pancreatic juice, debris and blood within a lining of inflammatory tissue, directly connecting with a pancreatic duct. Small pseudocysts are often asymptomatic, but large cysts can compress surrounding structures, often causing pain, nausea, vomiting and, occasionally, obstructive jaundice. A raised serum amylase will be present. Ultrasound scan can be used in diagnosis and monitoring. Surgery is necessary if the cyst is symptomatic, since there is a danger that it may rupture or precipitate haemorrhage. Surgery consists of drainage of the pseudocyst into the stomach (cyst gastrostomy) or duodenum (cyst duodenostomy).

Pancreatic abscess
This is a more serious complication of acute pancreatitis. The patient is usually very ill, with pyrexia, a raised white blood cell count and tachycardia. Early diagnosis by CT scanning and the use of aggressive surgical intervention have improved mortality rates. Surgery consists of extensive drainage and debridement of infected tissues. Multiple large drains are used to drain the abscess cavity. Peritoneal lavage with normal saline 0.9% warmed to body temperature can be used to irrigate the cavity. Adequate nutrition following surgery is vital. Most surgeons establish a feeding jejunostomy and gastrostomy tube during surgery.

Pancreatic necrosis
This complication is a major cause of death in acute pancreatitis. Early diagnosis is essential. The patient often fails to improve with conservative management. A persistent pyrexia, raised white blood cell count, tachycardia, hypotension and poor respiratory function are ominous signs. At laparotomy, necrotic tissue is removed, peritoneal lavage is carried out and the pancreatic bed adequately drained. A feeding jejunostomy and gastrostomy tube are inserted.

In some cases, the surgeon may opt to leave the wound open to allow for packing of the wound and to minimise the need for repeated laparotomies to deal with recurrent intra-abdominal sepsis.

Duodenal ileus
Due to persistent pancreatic inflammation, duodenal ileus may persist. Nutritional status will need to be maintained either by parenteral means or by jejunostomy feeding. A gastroenterostomy may need to be performed.

Haemorrhage
Severe bleeding may occur from gastric or duodenal ulceration. Prophylactic i.v. cimetidine is given to patients with acute pancreatitis. On rare occasions, haemorrhage may occur into a pseudocyst or by erosion of a blood vessel by the inflammatory process.

Chronic pancreatitis

Chronic pancreatitis is a relatively rare condition in the UK but its incidence is increasing, due to the increase in alcohol consumption. However, the mechanism by which alcohol damages the pancreas is poorly understood.

PATHOPHYSIOLOGY

Chronic pancreatitis leads to permanent damage of the gland, with replacement by fibrotic tissue and calcification. The ducts become narrowed and the flow of pancreatic juice is obstructed. The cells slowly stop secreting pancreatic juice. The obstructed ducts can give rise to recurrent attacks of pancreatitis lasting a few days.

Common presenting symptoms The patient usually presents with a history of severe epigastric pain, often radiating to the back. The pain is often eased by bending forward. Nausea and vomiting may also be present. A history of recent alcohol abuse may be given.

Weight loss is common and may be due to the pain or to malnutrition associated with prolonged alcohol abuse. Malabsorption is also present as a result of pancreatic insufficiency. The stool may be pale, offensive and difficult to flush away. This type of bowel movement is known as steatorrhoea and is due to a high undigested fat content. It is often a distressing feature for the patient.

Diabetes mellitus develops in approximately one-third of these patients and may require treatment. Transient jaundice may be present due to inflammation of the head of the pancreas, which obstructs the common bile duct. The presence of jaundice may be upsetting for some people, who feel 'dirty' or 'old' due to the discoloration of the skin and the marked yellowness of the sclera.

MEDICAL MANAGEMENT

Investigations Clinical assessment is as follows:

- Plain abdominal X-ray may show speckled calcification of the pancreas
- Ultrasound scan and CT scan may show an enlarged, swollen gland
- ERCP is performed to outline the pancreatic duct if surgery is contemplated
- Faecal fat estimation, although used less often now, may reveal malabsorption

4.21 Why might bending forward ease the pain in chronic pancreatitis?

- Fasting blood sugars are assessed and a glucose tolerance test may be necessary.

Treatment Management of chronic pancreatitis is mainly symptomatic. The patient should be advised to stop drinking alcohol and may need professional counselling to this end. Replacement of pancreatic enzymes with a commercial preparation may help to alleviate the steatorrhoea and reduce pain. Good control of diabetes will be necessary.

Pain control can be difficult, since some of these patients become addicted to opiates (Haslett et al 2002). Management advice from a pain control specialist is invaluable. In a small number of patients in whom severe pain persists, surgery will be indicated. It may be necessary to resect the head of the gland (Whipple's procedure; see Fig. 4.12) or the body and tail (distal pancreatectomy). Adequate drainage of the duct (pancreatojejunostomy) may be undertaken where ERCP shows the pancreatic duct to be dilated. A total pancreatectomy is rarely undertaken due to the resulting permanent diabetes mellitus and exocrine insufficiency.

NURSING PRIORITIES AND MANAGEMENT: Chronic pancreatitis

Nursing management of an acute attack in relapsing pancreatitis is similar to that for acute pancreatitis.

Major patient problems

Pain

Pain is often constant in nature, radiating through to the back. It is often described as being like a sharp knife twisting in the gut and presents a major challenge to pain control. Assisting the patient into a comfortable position often helps. The patient may find that bending forward while leaning on a bed table helps. The use of a heat pad to the back may give some relief, and NSAIDs such as diclofenac sodium (Voltarol) in suppository form can be of value. It is often necessary to use opioid analgesics to alleviate pain or it may be necessary to seek advice from a pain specialist (see Ch. 19). Many hospitals now have pain teams that can advise on all aspects of pain management.

Alcohol dependency

Alcohol abuse is the most common cause of chronic pancreatitis. Total abstinence will help to resolve the pain. If the patient has had a recent 'binge', sudden withdrawal may precipitate delirium tremens. Mild sedation is frequently used to prevent this. Expert help may be necessary to assist the patient to overcome an alcohol problem.

Patient education is vital in view of the progressive destruction of the gland by this disease. Family life is usually already disrupted by the patient's alcohol abuse, and help from a social worker will be useful in assisting the patient and family to cope with the situation. Good liaison with the GP and primary health care team is important so that support can be continued in the community. Caring for these patients can present a professional and personal challenge to members of the multidisciplinary team, who may feel inclined to blame the patient for the illness (see Ch. 36).

The patient's nutritional intake must be assessed. The patient is weighed and a well-balanced diet low in fat is given once the acute attack has resolved. Pancreatic enzyme supplements can be prescribed and taken prior to meals to aid absorption of nutrients. This should also alleviate the steatorrhoea. Concurrent administration of an H_2-receptor antagonist may improve the efficacy of these supplements.

Cancer of the pancreas

Tumours of the pancreas can arise from exocrine or endocrine tissue. Benign tumours are very rare. Insulinoma arises from the islet of Langerhans cells and results in oversecretion of insulin, causing hypoglycaemia. Gastrinomas also arise from the non-beta islet cells, secreting gastrin and giving rise to the overproduction of acid of Zollinger–Ellison syndrome leading to peptic ulceration. Adenocarcinoma is by far the most common malignant tumour of the exocrine pancreas.

The cause of pancreatic cancer is unknown, but smoking and a high-fat, high-protein diet are thought to increase the risk. It is twice as common in men as in women and its incidence is increasing; over 6000 people die from pancreatic cancer in the UK each year (Garden 2002). It is the fourth most common cause of cancer deaths in men in the UK and the sixth most common in women. It mainly affects individuals aged 50–70 years.

PATHOPHYSIOLOGY

Adenocarcinoma of the pancreas arises from the ductal tissue and is more commonly located in the head of the gland. Lesions frequently obstruct the pancreatic duct, causing chronic pancreatitis. The carcinoma can also obstruct the bile duct, giving rise to obstructive jaundice. Cancer of the pancreas carries a very poor prognosis because the disease has often spread to nearby organs by the time a diagnosis is made. Surgical resection has not been shown to improve the rate of survival. However, cancer of the duodenum, lower bile duct and periampullary regions often presents earlier with obstructive jaundice, and surgical resection offers a much better prognosis.

Common presenting symptoms Jaundice is often the symptom with which the patient first presents to the GP. The urine is dark in colour, the stool pale and fatty, and the skin and sclera have a yellowish tinge. Severe itch can be a very distressing symptom.

Severe weight loss and anorexia are associated with vague epigastric pain, often radiating to the back. Initially pain is intermittent, but gradually it becomes constant and severe.

MEDICAL MANAGEMENT

Investigations are as follows:

- Blood is taken for liver function tests and to check for the presence of a coagulation defect
- An ultrasound scan will detect a dilated biliary tree and exclude the presence of gallstones

- A CT scan may demonstrate a pancreatic mass, local invasion by tumour, or metastases
- Pancreatic tissue may be obtained for cytology by using CT scan or ultrasound-guided fine-needle aspiration
- ERCP can be used to define the site of obstruction and obtain biopsies.

Treatment Relief of obstructive jaundice and pain control are all that can be offered to the majority of patients with pancreatic cancer. ERCP with stenting of the biliary tree can relieve obstructive jaundice and may reduce the necessity for surgical intervention. Chemotherapy has been used but appears to have little effect. Surgery is usually palliative but jaundice may be relieved by cholecystojejunostomy or choledochojejunostomy.

In a minority of cases, pancreatoduodenal resection (Whipple's procedure) may be worthwhile, if the tumour is less than 2 cm in diameter and confined to the head of the pancreas (see Fig. 4.12).

NURSING PRIORITIES AND MANAGEMENT: Cancer of the pancreas

Investigative procedures are extensive and surgery in the majority of cases only offers palliation. The nurse has a very important role in helping both the patient and the family to cope during this very difficult time.

Major patient problems

Anxiety

Patients with pancreatic cancer are usually very anxious. They may have no previous history of illness and often deny the diagnosis. They are often the breadwinner in the family and may even be approaching retirement. They may have difficulty coming to terms with the diagnosis and are often angry and withdrawn, especially with close family members. Relatives often feel shut out and helpless. The nurse can help by offering support and advice to the patient and family members, who should be given opportunities to discuss the illness and its implications.

Extensive discussion with the patient and relatives prior to surgery is necessary. Some patients are prepared for a Whipple's procedure but then at surgery it is found that the disease is more extensive than expected and a bypass is all that can be safely attempted. This is devastating for the patient and family, who will have built up hopes for recovery.

Pain

Pain is often persistent, particularly when the disease is at an advanced stage. Oral opioids may be given and titrated to the patient's specific needs. Progression to s.c. diamorphine may be necessary as the disease advances and an oral laxative will also be given to prevent the side-effect of constipation.

As the disease advances, pain may become more difficult to control. A coeliac plexus nerve block may also be of benefit.

Close monitoring of the effectiveness of pain control is essential to ensure that the best possible quality of life can be maintained for the patient (see Ch. 19). If the patient is discharged home, liaison with the primary health care team is essential to ensure that full continuity of care is achieved. As the condition deteriorates, discussion with the patient and family is essential to ensure the best option for care at home, in hospital or in a hospice (see Ch. 33).

Jaundice

Jaundice is usually persistent and accompanied by severe itching (pruritus). The itching is usually all over the body and the patient often scratches until the skin bleeds. Patients may be so distressed by itch that they feel they are being driven mad. Every effort should be made to relieve itching that is believed to be caused by a deposition of bile salts in the skin. Antihistamines are used but they can cause sedation. A twice-daily bath with added sodium bicarbonate is very effective. Calamine lotion or Eurax cream applied locally may help. Night sedation is important, as itching is often worse at night.

For further reading on pruritus, see Bosonnet (2003).

Following ERCP and stenting, the jaundice and itch will subside over 7–10 days. The patient will feel much better as soon as the itch disappears and as the jaundice fades. Patients should be actively encouraged to drink extra fluids at this time. This helps the jaundice to abate by flushing bilirubin and bile salts out of the blood and tissues.

Anorexia and weight loss

Poor appetite and subsequent weight loss are further distressing aspects of the disease. Meals should be small and attractively presented. Liaison with the dietitian is necessary. High-protein drinks between meals may be tolerated well. If weight loss is severe, special care should be taken to prevent the development of pressure ulcers. Malaise associated with anorexia and weight loss will increase the patient's dependency; nurses and other carers will need to offer more and more assistance with many aspects of daily life (see Box 4.17).

For further reading on cancer care, see Corner & Bailey (2001).

Box 4.17

Reversal of cancer cachexia in pancreatic cancer

Cancer cachexia is characterised by numerous metabolic abnormalities which would appear to be driven by cytokines such as interleukin-6 and also, perhaps, specific tumour-derived factors (McNamara et al 1992). The resulting alterations in energy balance and loss of lean tissue very much impair the individual's quality of life and shorten survival.

Conventional nutritional supplements for cachexia have failed to demonstrate any significant benefit in terms of nutritional status. While previous studies have shown that the administration of oral eicosapentaenoic acid (EPA) will stabilise weight in patients with advanced cancer, a recent pilot study undertaken by Barber et al (1999) combining EPA with a conventional nutritional supplement has demonstrated that this combination may indeed reverse cachexia in advanced pancreatic cancer.

DISORDERS OF THE SPLEEN

Trauma

The spleen is highly vascular and is one of the organs most frequently damaged by abdominal trauma. In 20% of patients who present with splenic injury, associated rib fractures are found on X-ray examination. The spleen is particularly susceptible to injury when pathologically enlarged.

PATHOPHYSIOLOGY

Injury to the spleen can result in rupture, evulsion from its pedicle or tearing beneath the capsule, with possible formation of a subcapsular haematoma. Delayed rupture of the spleen occurs in about 5% of patients and is thought to be caused by haematoma bursting through the capsule wall. This usually occurs within 2 weeks of injury, but in a few cases can be delayed for months or even years.

Common presenting symptoms Rupture and evulsion of the spleen cause immediate intraperitoneal bleeding. As blood spreads throughout the peritoneal cavity, signs of haemorrhage and hypovolaemic shock may develop. Patients generally present as an acute abdominal emergency.

The patient experiences abdominal pain with particular tenderness in the left upper quadrant. Referred pain is often felt in the left shoulder tip. Bruising to the abdomen may or may not be evident.

Non-acute presentation Not all patients present with splenic injury in such a dramatic way. If a diagnosis is difficult to establish and splenic injury is suspected, vigilant and careful observation of the patient is vital. The patient will be admitted to hospital for close observation, which includes frequent monitoring of blood pressure, pulse, respiration and PO_2 saturations. Any pain experienced by the patient should be monitored, noting its site, type and duration. Whether the pain is increasing or decreasing may be relevant. Analgesics may initially be withheld, as they may mask the true situation. The patient will be fasted during this period of observation and should be given frequent oral hygiene.

Any change in the patient's condition should be reported immediately as, following rupture, temporary improvement in the patient's condition may precede sudden deterioration.

MEDICAL MANAGEMENT

Treatment Injury to the spleen is an indication for splenectomy, provided the organ cannot be conserved. Preference is given to conserving splenic tissue if at all possible by suturing capsular tears or by performing a partial splenectomy because of the risk of systemic infection following splenectomy (Forrest et al 1995). Another method used following injury is to wrap the spleen in an absorbable haemostatic mesh.

NURSING PRIORITIES AND MANAGEMENT: Splenectomy

General considerations

The patient may be in a distressed and anxious state and the nurse should give reassurance whilst measures are being taken to establish and administer i.v. fluids along with blood and blood products as required. Oxygen therapy may be commenced to raise the circulating levels and a urinary catheter is inserted to assess renal function. Blood pressure, pulse, respirations and PO_2 saturations should be closely monitored and any changes reported quickly. A nasogastric tube may be passed to empty the stomach contents and prevent aspiration. Analgesics to relieve pain should be given and their effect monitored.

Relatives should be kept informed of what is happening and comfort and support given during this stressful and worrying time.

Perioperative care

In preparation for splenectomy, a full assessment of the patient's blood count and coagulation status must be made. In the presence of any bleeding tendency, a transfusion of blood or platelets may be administered. In patients with thrombocytopenia, platelets should be made available for use to cover the intra- and postoperative phase.

An antipneumococcal vaccine is given to prevent or minimise chest infection postoperatively; *Haemophilus influenzae* type B vaccine is also given prophylactically.

Preparation for surgery is as for abdominal surgery requiring general anaesthesia. A nasogastric tube is passed because handling of the stomach during surgery results in a temporary ileus.

In the postoperative period, the physiotherapist plays an important role in the care of these patients because of the increased risk of collapse of the left lower lobe of the lung. The nurse must encourage the patient to perform deep breathing exercises and aid expectoration between physiotherapy sessions. Some doctors advise the administration of low-dose heparin in all patients undergoing splenectomy as there will be a transient increase in platelet and leucocyte levels. The nurse must therefore be aware of the importance of passive exercises whilst the patient is on bed rest and encourage movement and early ambulation.

A complication that may follow splenectomy is pancreatitis caused by the handling and bruising of the tail of the pancreas during surgery. The nurse must therefore be alert to any change in the patient's condition, especially any increase or change in the nature of the pain experienced.

Due to the loss of lymphoid tissue, there is an increased risk of infection. As most infections occur within 3 years of splenectomy, some surgeons advise the use of prophylactic penicillin for this period, or even longer. This cover is mandatory when the patient is a child (Garden et al 2002).

Postoperative care is as for abdominal surgery requiring general anaesthesia and the patient will usually be nursed in a high-dependency area (see Nursing Care Plans 26.2, p. 922, and 26.4, p. 927).

Hypersplenism

Hypersplenism is a syndrome consisting of splenomegaly and pancytopenia and is common in patients with cirrhosis and associated portal hypertension. The bone marrow is normal and no autoimmune disease is present.

PATHOPHYSIOLOGY

Primary hypersplenism is due to hypertrophy of the spleen as a response to the need to destroy abnormal blood cells.

Secondary hypersplenism occurs when inappropriate cell destruction is secondary to splenic enlargement. It is unclear why some patients with cirrhosis develop hypersplenism but it is thought that, in portal hypertension, splenic congestion may lead to splenomegaly and hypersplenism. Other conditions causing splenic enlargement are haemolytic anaemia, idiopathic thrombocytopenic purpura, myelofibrosis and lymphoma. As ethanol has a direct toxic effect on the bone marrow and consequently blood cell production, a history of alcohol consumption may potentiate the manifestations of hypersplenism in cirrhotic patients (Peck-Radosavljevic 2001).

Clinical features The effects of hypersplenism include expansion of the blood volume to fill the increased vascular spaces. There is increased pooling of blood in the cells with excessive destruction, possibly induced by metabolic damage as the cells are packed tightly together in the enlarged spleen. Increased amounts of urobilinogen are present in the urine. Blood analysis will show anaemia, leucopenia and thrombocytopenia, and marrow turnover will be increased.

Evidence has also shown that severe hypersplenism is an independent predictor of variceal bleeding and spontaneous bacterial peritonitis (Liangpunsakal et al 2003).

MEDICAL MANAGEMENT

Management of hypersplenism in the cirrhotic patient is aimed at coping with effects such as variceal bleeding, infection and anaemia. Very rarely is splenectomy an option but it would be considered in cases of severe life-threatening anaemia as this may reduce the rate of red cell destruction.

NURSING PRIORITIES AND MANAGEMENT: Hypersplenism

In the context of gastrointestinal nursing, the nursing care of the patient with hypersplenism will be as for a patient with cirrhosis (see p. 138).

CONCLUSION

The many medical conditions included in this chapter highlight the wide variety of skills, and the depth of knowledge required, to nurse in the field of gastroenterology. Nurses specialising in gastrointestinal nursing, in addition to the essential and established skills of care, are now performing diagnostic and therapeutic endoscopy, measuring GI tract manometry and siting gastrostomy tubes. These advances are in line with evolving technology and the increased patient demand for rapid access to health care services and it is likely that the role will continue to evolve and grow to meet the needs of a modern health service. It is hoped that this chapter will provide the building blocks of knowledge required for gastrointestinal nursing now and in the future.

PART 2 DIABETES MELLITUS 190

INTRODUCTION

Endocrinology is the study of hormones — chemical messengers secreted by endocrine cells and neurones. Hormones, usually travelling in the bloodstream, maintain homeostasis by acting on and coordinating activity within target organs or tissues.

Endocrinology is a rapidly growing field (Wilson 2005). The word hormone was first used by Ernest Starling in 1905 and the study of endocrinology developed from that date. Considerable progress is being made, with important implications for other areas of medicine, e.g. neuroendocrinology, which in turn has important applications within psychiatry. Advances are constantly being made in this field and current research is adding to knowledge of genetic causes of many endocrine conditions. For example, the site of the mutation in the genes that causes both syndromes of multiple endocrine neoplasia (MEN I and MEN II) has been discovered (Thakker 1998, 2004). Identifying carriers of the mutation will allow biochemical screening of individuals before they are symptomatic, therefore providing an opportunity for earlier treatment (Bassett et al 1998). Genetic research is an area from which future treatments of endocrine disease will come. There are other areas of endocrinology that are not covered in this chapter, mostly rare conditions. A list of further reading at the end of the chapter will give the reader plenty of scope for further study.

Apart from diabetes mellitus and thyroid disorders, endocrine problems are not common. Many endocrine disorders are rarely seen and may be difficult to diagnose without complicated and exhaustive testing. As a result, patients may be referred by their general practitioner or local hospital to specialist centres for diagnosis. For the patient, this has the advantage of offering highly specialised care. It also means that relatively few nurses have the opportunity to treat and care for people with these disorders. However, given the wide-ranging effects of endocrine dysfunction, it is important that all nurses have a general understanding of endocrinology. Endocrine diseases can affect every system of the body, sometimes causing disfigurement and a change in body image or even posing a threat to life. These disorders can seriously affect the patient's psychological outlook, either as a direct result of the illness or by virtue of the individual's reaction to it.

It is well documented that individuals react differently to being ill. Some view their situation as a challenge, while others see it as a punishment, react with anger or try to apportion blame. Anger may be directed at family members or at nursing and medical staff (Sinclair & Fawcett 1991). This situation may be exacerbated by an unstable mental state, mood swings, depression or frank psychosis, which may, in fact, be sequelae of the disorder, e.g. Cushing's syndrome. The nurse must be aware of this possibility and react accordingly, offering support and understanding to the patient and their relatives. Identifying the patient's worries and concerns, providing factual information and educating the patient about their condition and its management will all help to minimise psychological distress. Explanations that the underlying illness may be influencing the patient's mood may help them and their relatives to cope (Ramirez & House 1997).

As the tests and investigations required to diagnose some of the rarer endocrine conditions are often long and exhausting, clear explanations are essential so that the patient understands the need for them and the procedures that will be followed. This will help to reduce anxiety and increase the patient's confidence in the health care team. The psychological support that the nurse can offer this group of patients cannot be overemphasised. Many benefit from referral to a patient support group (see 'Useful Websites', p. 189) and the contact this brings with other patients, who have the same condition. Often these patients are young and probably otherwise in good health, and therefore the impact of endocrine disease on their body image and/or self-esteem should not be underestimated. For example, patients experiencing sexual dysfunction may feel embarrassed to talk to and seek support from family members and friends — in such cases, support from the health care professional is crucial.

For further information on the psychological care of medical patients and recognition of need and service provision, see RCP/RCPsych (1995).

ANATOMY AND PHYSIOLOGY

The nature of the endocrine system, being one of control, means that it has far-reaching effects throughout the body on various target organs. In order to make this chapter as clear as possible, each endocrine gland will be considered separately. In cases where a disease is caused by the abnormal secretion of a trophic or control hormone, the disease will be discussed under the heading of the end organ. For example, in Cushing's disease, adrenocorticotrophic hormone (ACTH) is secreted in excess by the pituitary gland. This acts on the adrenal gland, causing it to produce excess amounts of cortisol. Therefore, as the adrenal gland is the end organ, and it is the secretion from this gland that causes unwanted effects on the body, Cushing's disease is discussed under the heading of the adrenal gland.

Hormones

The endocrine system is one of the two major control systems of the body, the other being the nervous system. The nervous system mediates its activity by means of nerves directly supplying the organs and structures to which it relates. The endocrine system operates by a system of hormones, which are secreted into the bloodstream for transport to their respective target organs.

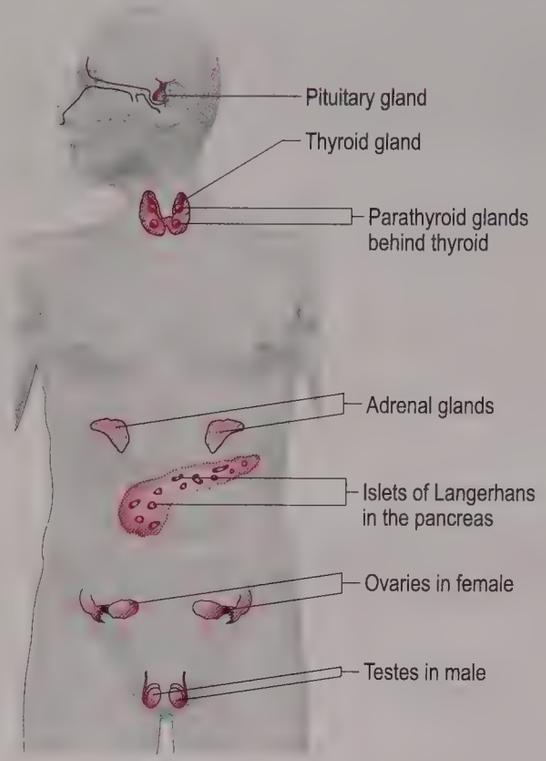

Fig. 5.1 The endocrine glands and their location in the body.

The endocrine glands and their anatomical position are shown in Figure 5.1.

Action

Although the hormones are carried to every cell in the body, they affect only those cells or organs upon which they have an excitatory or inhibitory action. This system allows individuals to respond to changes in their environment and is important in controlling growth and development, sexual maturation and homeostasis.

Many hormones are bound to proteins within the circulation. It is now known that only unbound or free hormones are biologically active, and that binding serves as a buffer against very rapid changes in plasma levels of a hormone. This principle is important in the interpretation of many tests of endocrine function.

Control

Most hormone systems are controlled by a feedback system which ensures that hormone levels, whilst fluctuating, remain within a preset range (see Table 5.1). Figure 5.2 illustrates how negative feedback operates in the hypothalamic–pituitary–thyroid axis.

Pattern of secretion

Hormone secretion is either continuous or intermittent. An example of the former is the secretion of thyroxine by the thyroid gland, in which hormone levels over a day, month or year show very little variation. Intermittent secretion is seen in three forms: circadian, menstrual and pulsatile.

Table 5.1 List of normal ranges (these may vary for different laboratories)

Hormone			SI units
Aldosterone (normal diet)	Pose	Upright (4 h)	330–830 pmol/L
		Supine (30 min)	135–400 pmol/L
Cortisol	Time	09.00 h	200–700 nmol/L
		18.00 h	100–300 nmol/L
		00.00 h (asleep)	<50 nmol/L
11-deoxycortisol	Time	09.00 h	7–18 nmol/L
Dehydroepiandosterone (DHEA) sulphate	Time	09.00 h	7–31 nmol/L
DHEA sulphate	Population	Women	3–12 μmol/L*
		Men	2–10 μmol/L*
		Prepubertal	<0.5 μmol/L*
Androstenedione	Population	Adults	3–8 nmol/L
		Prepubertal	<1 nmol/L
Oestradiol	Population	Prepubertal	<20 pmol/L
		Women	
		Postmenopausal	<100 pmol/L
		Follicular	200–400 pmol/L
		Mid-cycle	400–1200 pmol/L
		Luteal	400–1000 pmol/L
		Men	<180 pmol/L
Progesterone	Population	Women	
		Follicular	<10 nmol/L
		Luteal	>30 nmol/L
		Men	<6 nmol/L
Testosterone	Population	Prepubertal	<0.8 nmol/L
		Men	9–35 nmol/L
		Women	0.5–3.0 nmol/L
ACTH	Time	09.00 h	7–51 ng/L
FSH	Population	Prepubertal	<5 U/L
		Women	
		Postmenopausal	>30 U/L
		Follicular	3.0–15 U/L
		Mid-cycle	up to 20 U/L
		Luteal	3.0–15 U/L
		Men	1–7 U/L
GH	Fasting between pulses		<1 mU/L
LH	Population	Prepubertal	<5 U/L
		Women	
		Postmenopausal	>30 U/L
		Follicular	2.5–10 U/L
		Mid-cycle	25–70 U/L
		Luteal	<1–13 U/L
		Men	1–10 U/L
Prolactin			<360 mU/L
TSH			0.4–5 mU/L
Thyroxine (free)			10–20 pmol/L
Tri-iodothyronine (free)			5–10 pmol/L
Catecholamines	Taken with patient cannulated and lying for 30 min prior	Adrenaline	0.03–1.31 nmol/L
		Noradrenaline	0.47–4.14 nmol/L

Adapted from Besser & Trainer (1995).

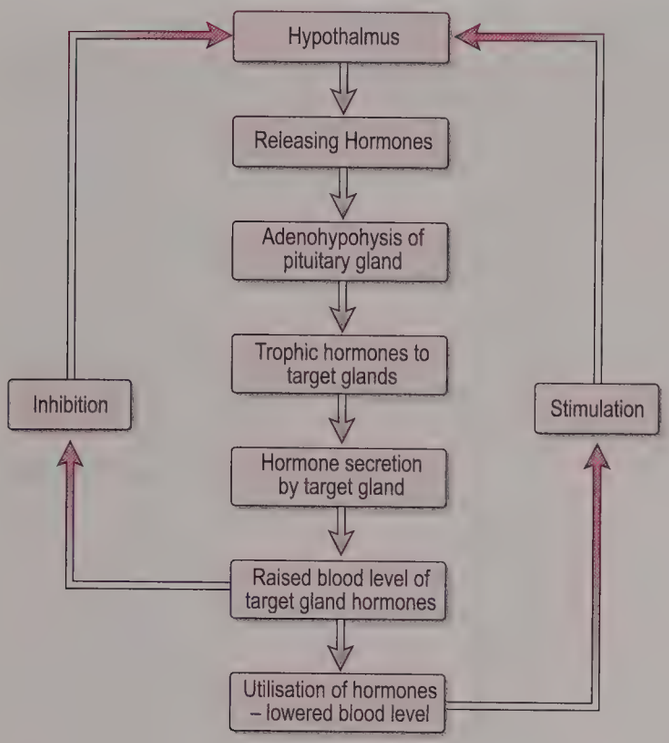

Fig. 5.2 Negative feedback regulation of the secretion of anterior pituitary hormones.

Other factors which affect hormone secretion include stress, disease, trauma, surgery or emotional upset. As in any complex regulatory system, it is likely that disequilibrium in endocrine function will have important consequences. Disorders of the endocrine system may be categorised most simply as those involving overproduction (hypersecretion) and those involving underproduction (hyposecretion).

For further information, see Montague et al (2005).

DISORDERS OF THE PITUITARY GLAND AND HYPOTHALAMUS

As stated above, disorders of the endocrine system result in either an oversecretion or an undersecretion of a hormone. Therefore, in principle, treatment should be straightforward, either replacing the missing hormone or removing, or suppressing the source of, the oversecretion. Advances have made the treatment of the wide range of endocrine disorders more successful, and the outlook for those suffering from them is becoming ever more hopeful.

Hypersecretion of a hormone usually arises from a so-called 'functioning' pituitary adenoma. As this adenoma grows, it is likely to 'crowd out' the normal function of other areas of the pituitary, and as a result progressive hypopituitarism occurs. This failure of the pituitary hormones occurs in a characteristic sequence (Besser & Thorner 2002). Secretion of growth hormone (GH) is lost first, followed by the gonadotrophins luteinising hormone (LH) and follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH) and then adrenocorticotrophic hormone (ACTH). Prolactin (PRL) deficiency is rare except as seen postpartum in Sheehan's syndrome.

ANATOMY AND PHYSIOLOGY

The existence of the pituitary gland has been known for at least 2000 years. It lies immediately below the hypothalamus in the pituitary fossa. It is connected to the hypothalamus by the pituitary stalk and consists of two lobes — anterior and posterior — which function independently of each other (see Fig. 5.3). In the developing fetus the anterior lobe is formed from Rathke's pouch, which grows upwards and becomes separated from the oropharynx to become the adenohypophysis. The posterior lobe is a down-growth from the forebrain, which becomes the neurohypophysis. The posterior pituitary contains nerve fibres which grow into it from the hypothalamus via the pituitary stalk. The hormones secreted by the pituitary gland, together with their action, are listed in Table 5.2.

The hypothalamus is part of the floor of the third ventricle of the brain. It is an area of specialised cells or nuclei which produce hormones. These hormones regulate pituitary function and act as releasing factors for the anterior pituitary hormones (see Fig. 5.4). The hypothalamus also controls many centres for functions such as appetite, thirst, temperature regulation, sexual activity, sleeping and waking.

The pituitary stalk carries blood to both lobes of the pituitary in a portal system by which the hypothalamic releasing or inhibitory hormones are carried to the anterior pituitary. The trophic hormones produced in the anterior pituitary stimulate the peripheral endocrine glands. The posterior pituitary acts as a reservoir for antidiuretic hormone (ADH)/vasopressin and oxytocin.

The optic chiasm sits just above the pituitary fossa. Therefore, an expanding lesion from the pituitary or the hypothalamus may result in a defect in the visual fields because of pressure on the optic nerve or optic chiasm.

Hyper- or hyposecretion of hormones or local effects of a tumour will all disturb the balance of the system.

HYPERSECRETION OF THE ANTERIOR PITUITARY HORMONES

Hypersecretion of adrenocorticotrophic hormone: Cushing's disease

Cushing's disease is found when an excess of glucocorticoid secretions is stimulated by an ACTH-producing adenoma of the pituitary. As noted above, this disease will be discussed under 'Disorders of the adrenal cortex' (p. 178).

Hypersecretion of growth hormone: acromegaly and gigantism

Aetiology

Acromegaly is a rare condition caused by prolonged, excessive secretion of growth hormone (GH) from a benign tumour of the pituitary gland occurring after fusion of the epiphyses of the long bones. The word acromegaly comes from the Greek 'akron' meaning extremities and 'megas' meaning great. It has a prevalence of 40–60 cases/million in the UK and an incidence of four new cases a year

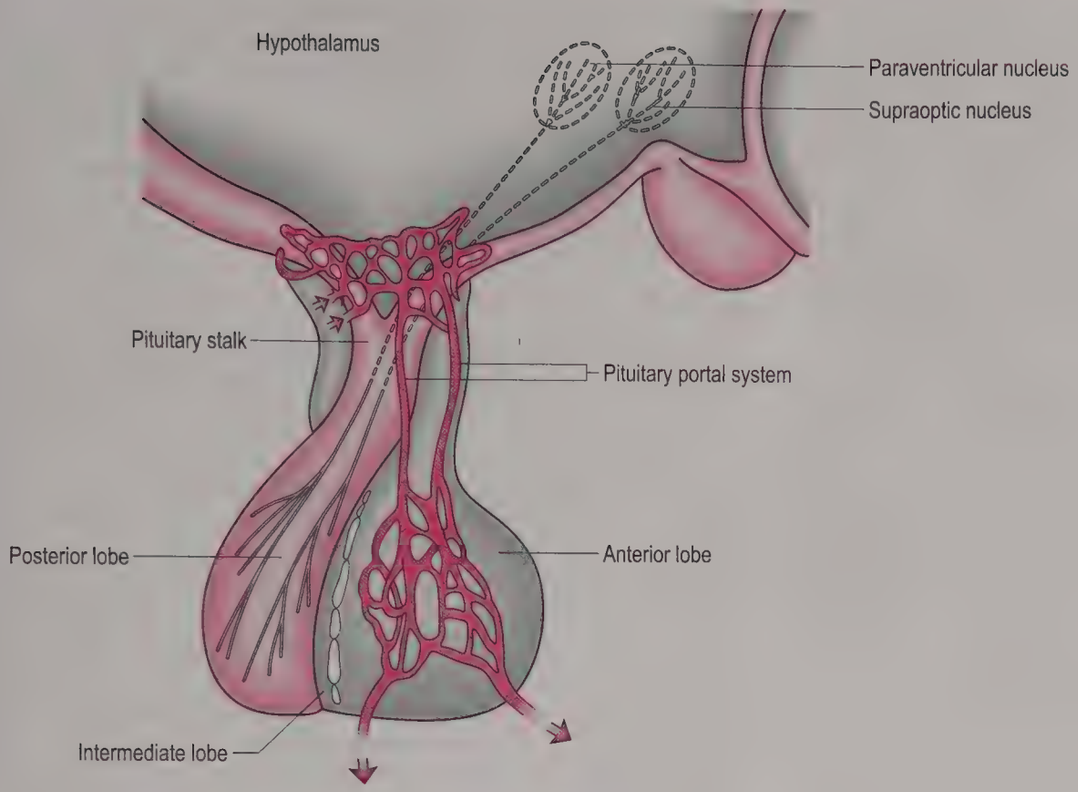

Fig. 5.3 Position of the pituitary and its associated structures.

Table 5.2 Hormones of the pituitary gland and their action

Hormone	Action
Anterior lobe	
Growth hormone (GH)	Pulsatile release. Does not have a single target gland but acts on a variety of tissues, e.g. bone, viscera and soft tissues. It is particularly important in children to stimulate growth. Action in adults recently thought to involve maintenance of cardiovascular activity, fat deposition and muscle development
Prolactin (PRL)	Main action is to stimulate lactation in females; also stimulates corpus luteum to secrete progesterone
Adrenocorticotrophic hormone (ACTH)	Secreted under circadian rhythm. Stimulates the adrenal cortex to secrete corticosteroids
Luteinising hormone (LH)	Promotes ovulation; stimulates formation of the corpus luteum
Follicle-stimulating hormone (FSH)	Stimulates the production of sex hormones and contributes to regulation of the menstrual cycle in women. In women, stimulates the production of ovarian follicles and secretion of oestrogen; in men, promotes the production of spermatozoa
Thyroid-stimulating hormone (TSH)	Stimulates the thyroid to release thyroxine
Posterior lobe	
Vasopressin — also called antidiuretic hormone (ADH)	Controls water homeostasis in the body by regulating water reabsorption from the renal tissues
Oxytocin	Induces uterine contraction during labour and ejection of milk from breasts postpartum

(Wass 2001). The incidence in men and women is equal. The mean age at diagnosis is between 40 and 50 years, although excessive secretion of growth hormone can occur at any age and, in children in whom fusion of the epiphyses has not yet occurred, leads to gigantism. Acromegaly leads to a reduction in life expectancy with a two- to four-fold increase in mortality rate (Colao et al 2004).

PATHOPHYSIOLOGY

Clinical features The onset of the disease is insidious, leading on average to a delay in diagnosis of around 8 years from the onset of symptoms, which include:

- excessive sweating, seen in >80% of patients
- headaches

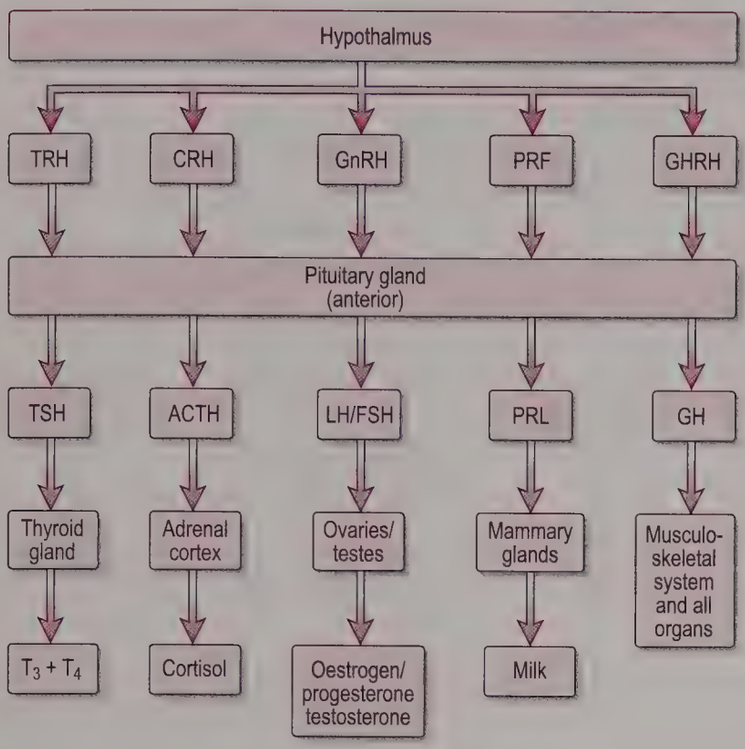

Fig. 5.4 Schematic diagram showing the relationship between the hypothalamus, the pituitary gland and their target organs. TRH, thyrotrophin-releasing hormone; CRH, corticotrophin-releasing hormone; GnRH, gonadotrophin-releasing hormone; PRF, prolactin-releasing factor; GHRH, growth hormone releasing hormone; TSH, thyroid-stimulating hormone; ACTH, adrenocorticotrophic hormone; LH/FSH, luteinising hormone/ follicle-stimulating hormone; PRL, prolactin; GH, growth hormone.

- enlargement of the hands and feet, often resulting in the need for ring size and shoe size to be increased
- tiredness and lethargy
- joint pain and osteoarthritis
- coarse facial features, frontal bossing, enlarged nose, protruding jaw and increased interdental separation
- oily skin
- deep voice
- tongue enlargement
- soft tissue swelling
- goitre and other organomegaly
- features of hyperprolactinaemia
- visual field defects.

Complications include:

- hypertension in approximately 40% of patients
- insulin resistance, impaired glucose tolerance and diabetes mellitus in approximately 20% of patients
- obstructive sleep apnoea
- increased risk of colonic polyps and colonic carcinoma
- ischaemic heart disease
- cerebrovascular disease
- congestive cardiac failure (Colao et al 2004).

Common presenting symptoms The patient may notice an increase in their shoe size or the fact that they have had to have their wedding ring enlarged. Along with their family and friends they may notice a change in their facial appearance. Women often feel very self-conscious about this, and also about their deepening voice, as they may be mistaken for men on the telephone. The major symptoms, which prompt a consultation with their GP, are usually headache and sweating. Visual symptoms may be identified by their ophthalmologist, or their dentist may notice their enlarging jaw and/or increasing spacing between their teeth. Patients can therefore find themselves referred to an endocrinologist by a number of routes.

MEDICAL MANAGEMENT

Investigations Diagnosis can be confirmed following clinical examination and pituitary function testing. On clinical examination, some or all of the symptoms listed above may be present. Magnetic resonance imaging (MRI) usually shows the pituitary tumour and whether there is enlargement of the pituitary fossa. If acromegaly is suspected, a blood sample should be obtained and an insulin-like growth factor 1 (IGF-1) and random GH level measured. If the IGF-1 level is 'normal', when compared to the age-adjusted range, and GH <0.5 mU/L, the diagnosis of acromegaly can be excluded (Trainer 2002). Otherwise, the patient should proceed to have an oral glucose tolerance test (OGTT). The OGTT has been the gold standard for the diagnosis of acromegaly for many years. False positives may occur if the patient has diabetes mellitus, renal or liver disease, or anorexia nervosa. In acromegaly, measurement of GH levels during the OGTT are consistently elevated and fail to suppress to <2 mU/L in response to a 75 g oral glucose load. Normally, the level of GH would be undetectable. Acromegaly is therefore diagnosed on the basis of an elevated IGF-1 and failure to suppress GH during the OGTT (Giustina et al 2000). Further pituitary function tests may be performed to assess whether the remainder of the pituitary gland has been compromised. Prolactin is co-secreted in 30% of tumours.

For further information, see Bouloux & Rees (1994).

Treatment In untreated acromegaly, the mortality is nearly twice that of the normal population; early treatment is therefore essential. The aim of treatment is to relieve and, if possible, resolve symptoms associated with elevated GH and IGF-1 levels and the local effects caused by the tumour mass itself, and to prevent co-morbidity by lowering mean GH and IGF-1 levels to accepted 'safe' levels with minimal disruption to the patient's lifestyle. Treatment may take the form of surgery, radiotherapy or medication (Wass 2001).

Surgery This is currently regarded as the first-line therapy for acromegaly and, when performed by a pituitary surgeon, remains the treatment of choice. Hypophysectomy via the trans-sphenoidal route, which has a low morbidity and mortality, is the surgical procedure most commonly used. It results in a rapid fall in GH levels, often with no loss of any other pituitary hormones. As a mode of treatment it is both rapid and inexpensive when compared to medical therapies. In patients with microadenomas (tumours <1 cm diameter) it is curative in ~80% of cases. In macroadenomas (tumours >1 cm diameter) this figure is nearer 40% (Kaltsas et al 2001).

Radiotherapy Conventional external beam radiotherapy (4500 cGy over 25 fractions) results in a delayed fall in

GH and IGF-1 levels over the following decade which is paralleled by the development of hypopituitarism (Wass 1997). Sixty per cent of patients have a normal IGF-1 after 5 years, rising to 84% of patients after 15 years (Biermasz et al 2000). Although used less often nowadays, it is safe and radiation-induced visual damage is extremely rare. Patients must be advised that they may feel tired during the period of treatment and may experience some temporary alopecia at the site of entry of the beams. Anecdotally, many patients later complain that their short-term memory has been affected, but evidence to support this is scanty. It is a useful treatment for patients in whom surgery is contra-indicated or if GH/IGF-1 levels are not too high and/or there is a large tumour or residual tumour postoperatively, or where medical therapy fails to control GH/IGF-1 levels. Other forms of radiotherapy include stereotactic or gamma knife radiotherapy (radiosurgery) which takes the form of a single dose (upper limit 8–9 cGy) administered as many beams. This is more expensive than conventional radio-therapy but is a 'one-off' cost. Long-term data are required, but early results suggest that GH and IGF-1 levels fall more rapidly for radiosurgery than with conventional radio-therapy and there is less damage to surrounding tissues which may reduce the incidence of radiotherapy-induced hypopituitarism (Swords et al 2003). These two forms of radiotherapy can be given following conventional radiotherapy but cannot be used if the tumour is in close proximity to the optic chiasm.

Medication This has changed radically in recent years. It is now possible to control GH and IGF-1 levels in more than half of patients with a somatostatin analogue, a synthetic compound which acts on the somatostatin receptors of the tumour and suppresses the secretion of GH, e.g. lanreotide (Somatuline Autogel) or octreotide (Sandostatin Lar). These are given by deep intramuscular or subcutaneous injection by a nurse every 28 days and are the most widely used form of medical therapy. There is evidence of tumour shrinkage in a large minority of cases, probably due to cell shrinkage rather than cell death (Bevan et al 2002). If the patient is resistant to this class of medication, pegvisomant (Somavert), a GH receptor antagonist, i.e. it binds to GH receptors, blocking the impact of excessive circulating GH which in turn causes IGF-1 levels to fall, can be used. This medication is capable of achieving normal IGF-1 levels in >90% of patients (van der Lely et al 2001). It is given by a once daily subcutaneous injection; however, it is very expensive and is currently used only for patients with active disease who have failed to respond to other medical therapies. Previously, patients were treated using dopamine agonists, the first effective medical treatment for acromegaly, e.g. bromocriptine or cabergoline, both tablets, taken orally. However, 'safe' levels of GH were achieved in only approximately 10% of patients on bromocriptine and 39% of patients on cabergoline (Abs et al 1998).

Long-term treatment strategies for acromegaly have changed. Until recently, surgery and radiotherapy were used in conjunction, with medical therapy then used to control residual excess GH secretion, as radiotherapy only lowers GH levels gradually. Medical therapy may also be used preoperatively to control symptoms or to attempt to shrink a large tumour prior to surgery. In patients unfit for surgery, medical therapy alone may be used.

NURSING PRIORITIES AND MANAGEMENT: Acromegaly

Major considerations

Giving psychological support

Change in body image is an important feature of this disorder. The patient may have considerable difficulty in coming to terms with their changed appearance and may be anxious about the investigations they must undergo and the treatment that may be required.

It is important to create as relaxed an environment as possible and to reduce anxiety by spending time with the patient and their family, explaining the reasons for their changed appearance, the effect of therapy and the expected treatment outcome. They will be reassured to hear that biochemical cure may result in a return to a more normal appearance, although the degree will depend on the stage of the disease at the beginning of treatment. Some symptoms, such as sweating, may be cured almost immediately, while others, e.g. soft tissue swelling, may take longer to resolve. Bony changes are usually not reversible.

Some patients benefit from meeting other patients who have been treated successfully and, if the patient wishes, nursing staff should try to arrange this either directly or through a local patient support group.

Perioperative care

The reader is referred to Chapter 26 for principles of pre-operative preparation and postoperative care, and to Chapter 23 for information on wound healing. Specific post-operative observations include neurological monitoring, with special care being taken to observe for leakage of cerebrospinal fluid from the nose which is a recognised complication (Baxter 1994). The patient is nursed well supported on pillows to ensure that an upright position is maintained. Recovery is usually rapid and the patient discharged home on the fourth or fifth postoperative day.

5.1 Miss W, aged 45 years, has been diagnosed as having acromegaly. She has undergone trans-sphenoidal hypophysectomy for the removal of a GH-producing adenoma. Identify the specific or potential problems and devise a plan to meet her care needs. What long-term treatment and care will she require?

Prolactin hypersecretion

Aetiology

It is now known that prolactin is the most common hormone to be secreted by pituitary tumours and that small micro-adenomas (<1 cm in diameter) occur frequently (Haslett et al 2002). However, a wide variety of medications and diseases can cause high prolactin levels. Before carrying out extensive investigations for pituitary disease, it is important to exclude other pathological causes such as hypothyroidism and to take a detailed medication history. Medications that block the dopamine receptor and so elevate prolactin levels include tranquillisers, e.g. chlor-promazine (Largactil); antiemetics, e.g. metoclopramide (Maxolon); and some antidepressants, e.g. amitriptyline and fluoxetine (Prozac). The other key differential diagnosis is a hypothalamic or suprasellar space-occupying lesion

which interferes with dopamine production. Dopamine is the natural prolactin inhibitory factor and therefore, in its absence, hyperprolactinaemia ensues; due to the mechanism this is known as disconnection hyperprolactinaemia.

PATHOPHYSIOLOGY

Hyperprolactinaemia causes galactorrhoea and amenorrhoea in women; the raised prolactin level suppresses gonadotrophin-releasing hormone (GnRH) secretion within the hypothalamus, leading to gonadotrophin deficiency (LH and FSH) and then oestrogen deficiency, resulting in infertility (Haslett et al 2002). In men, the galactorrhoea is much less frequent, but the elevated prolactin lowers LH and FSH levels which in turn lower testosterone levels, resulting in a reduced libido, impotence and infertility.

Common presenting symptoms in premenopausal women include menstrual disturbances, e.g. amenorrhoea, oligomenorrhoea (infrequent menstrual flow) and infertility. Galactorrhoea occurs in about 80% of these women (Schlechte 2003). The majority of prolactinomas in women are small (<1 cm diameter and referred to as a microprolactinoma) at the time of diagnosis, so headaches and neurological deficits are rare. Men, on the other hand, may present with headache, visual loss, cranial nerve defects and/or hypopituitarism due to the mass effect of the tumour which tends to be larger at the time of diagnosis (>1 cm in diameter and referred to as a macroprolactinoma). In both men and women elevated levels of prolactin over a long period can lead to low bone density which increases when prolactin levels are normalised but does not return to normal (Di Somma et al 1998).

MEDICAL MANAGEMENT

Investigations When other causes of the presenting symptoms have been excluded, prolactin levels should be measured in the unstressed patient. Because venepuncture is stressful, an intravenous cannula is placed in the patient's arm and the patient allowed to rest for 30 min prior to the blood sample being taken. The patient should not smoke or drink tea or coffee in this period. If the prolactin levels are raised, an MRI should be performed. If this shows a large pituitary tumour, tests of other pituitary functions should be carried out to see if there are any other pituitary hormone deficits. Visual field tests may also be carried out to assess if the tumour mass is causing pressure on the optic chiasm. Pituitary MRI will usually show even a small tumour of only a few millimetres in size. Prolactinomas are almost always benign.

Treatment The aim in the treatment of microprolactinomas is to lower the excessive levels of prolactin, thereby restoring gonadal function. In macroprolactinomas, the aim is to reduce tumour size, prevent tumour expansion and to restore gonadal function. Reduction of tumour size and lowering of hormone levels may be achieved by medication alone. Consequently, this is the treatment of choice (Molitch 2002). Prolactinomas respond well to dopamine agonists, e.g. bromocriptine (Parlodel), cabergoline or quinagolide. These result in a lowering of prolactin levels, restoration of gonadal function and termination of galactorrhoea, usually within a few weeks of starting treatment (de Rosa at el 1998). In most patients menstrual cycles resume and fertility is restored. Patients must therefore be given appropriate contraceptive advice. Trans-sphenoidal surgery is usually performed only in patients who are resistant to or cannot tolerate dopamine agonists. Irradiation of the pituitary gland results in a reduction in prolactin secretion, but this takes many years to achieve. Dopamine agonists are therefore continued while waiting for the effects of radiotherapy to occur, but the need for this treatment should be reassessed regularly.

NURSING PRIORITIES AND MANAGEMENT: Prolactin hypersecretion

Specific nursing care is aimed at ensuring that the medication regimen is followed correctly in order to avoid side-effects. Dopamine agonists, especially bromocriptine, often cause nausea, vomiting, constipation and postural hypotension mediated by dopamine release. Consequently, there should be a slow increase in dosage, the first doses being given whilst eating and on retiring to prevent the common symptoms of postural hypotension and gastric irritation. The dosage can then be built up gradually to 2.5 mg three times a day. Cabergoline, a longer acting dopamine agonist, need only be taken once or twice a week. It is more potent than bromocriptine and has a lower profile of side-effects (Webster 2000).

For further information, see Besser & Thorner (2002) and Liu & Couldwell (2004).

HYPOSECRETION OF THE ANTERIOR PITUITARY HORMONES

Hypopituitarism

The term hypopituitarism refers to partial or total deficiency of anterior pituitary hormone secretion. It may be associated with pathological processes that destroy the pituitary itself or with disturbance of the hypothalamic control of the pituitary. Total failure of all hormone production is termed panhypopituitarism.

Aetiology

As already stated, hypopituitarism is most commonly caused by the presence of a pituitary tumour. These are frequently benign. Pituitary carcinoma is very rare. Benign microadenomas having no clinical effects are surprisingly common and are found in up to 23% of people at postmortem (Bouloux & Rees 1994).

PATHOPHYSIOLOGY

Pituitary tumours can vary greatly in size and may extend outside the pituitary fossa to compress surrounding structures. They are generally classified as functioning or non-functioning, depending on whether they produce a hormone, e.g. GH or prolactin.

Common presenting symptoms Symptoms caused by local compression may arise (see Ch. 9, p. 408), but the individual usually presents with signs associated with pituitary

hormone deficiency. The precise symptoms will vary in accordance with the particular hormone that is deficient (see Table 5.3).

MEDICAL MANAGEMENT

Investigations Diagnostic investigations include visual field testing and biochemical investigation to determine the severity and degree of pituitary failure and to distinguish between isolated hormone failure and complete anterior pituitary failure. MRI is also performed.

Treatment The choice of treatment will depend on the diagnosis of the cause of the pituitary failure and will aim to relieve the clinical effects and symptoms experienced by the patient. Treatment may involve surgery, radiotherapy to reduce the tumour and medication to replace the deficient hormones (see Table 5.4).

NURSING PRIORITIES AND MANAGEMENT: Hypopituitarism

Major considerations

Giving information

Effective nursing intervention depends upon the establishment of a good nurse–patient relationship in a friendly environment. As the effects of hypopituitarism can be widespread, causing diverse physical and psychological changes which can be difficult to comprehend, it is important to ensure that all of the patient's questions are answered in a way that is understood. Open and frank discussion about changes in body image and sexuality is essential to the individual concerned. Clear, ongoing explanations of the extensive and possibly uncomfortable investigations will help to relieve the patient's anxiety. The presence of a nurse known to the patient during these investigations can be reassuring.

Table 5.3 Symptoms associated with anterior pituitary hormone hyposecretion

Deficiency	Symptoms
LH/FSH	*Men* Poor libido and impotence Infertility Small soft testicles Loss of secondary sexual hair *Women* Amenorrhoea Infertility Dyspareunia Breast atrophy Loss of secondary sexual hair
TSH	*Children* Growth retardation *Adults* Decreased energy Constipation Sensitivity to cold Dry skin Weight gain
ACTH	*All* Weakness Tiredness Dizziness on standing Pallor Hypoglycaemia
GH	*Children* Growth retardation Short stature *Adults* Cardiovascular activity Muscle development Fat distribution General sense of well-being

Table 5.4 Hormone replacement therapy

Deficient hormone	Replacement	Check
Anterior pituitary		
Women		
LH FSH	Ethinylestradiol Medroxyprogesterone	*Libido and symptoms of deficiency
Men		
LH FSH	Testosterone	*Libido and potency
Children	GH	Growth chart
ACTH	Hydrocortisone	Cortisol levels throughout the day
TSH	Thyroxine	T_3 and T_4 levels
Posterior pituitary		
ADH	Desmopressin	Plasma and urine osmolality

Reproduced with permission from Besser & Thorner (2002).

*For men and women, the only treatment of associated infertility entails regular injections of the deficient pituitary hormones (mainly FSH in the form of Pergonal or Metrodin) or, if the defect is hypothalamic, hourly parenteral injection of a gonadotrophin-releasing hormone via an implanted pump.

Neurosurgery or radiotherapy is a frightening prospect for most people. Preoperative preparation must include an explanation of procedures, the nature of immediate post-operative care and the expected long-term outcome. Reminding the patient that many of their symptoms will be relieved by surgery, radiotherapy and/or hormone replacement therapy will be of considerable psychological benefit.

Supporting the patient taking ongoing replacement therapy

Anterior pituitary hormone replacement

Cortisol Hydrocortisone, or sometimes prednisolone, is given to those who have ACTH deficiency. It is rapidly absorbed with a short half-life. The usual dose is 10 mg on waking, 5 mg at midday and 5 mg in the early evening. It can also be given as a twice-daily regimen with a total daily dose of 15–30 mg. It is important to monitor cortisol levels regularly, as over-replacement can be associated with hypertension, hyperglycaemia and hyperinsulinaemia, as well as reduced bone mineral density. The omission of even one dose may have serious consequences. Such patients should be advised to carry a steroid card and to wear a MedicAlert bracelet at all times, indicating they are cortisol deficient. Patients should also be given an emergency hydrocortisone pack to keep at home containing a vial of hydrocortisone for i.m. injection which they have been shown how to use. The nurse should demonstrate how to use this and ensure that the patient has practised and mastered the technique.

Thyroxine Thyroid replacement is given as an oral medication. The usual dose is 100–150 mcg/day, taken as one dose in the morning. As it has a very long half-life, the occasional missed dose is not critical. Thyroxine levels can be monitored by the patient's GP.

Growth hormone Until 1988 it was claimed that low levels of GH had little or no effect in adults, but studies have shown that replacement GH therapy in patients with adult onset GH deficiency has profound effects on patients' quality of life, vascular morbidity and cardiovascular mortality (Brooke & Monson 2003). It is now apparent that GH deficiency is associated with changes in body composition, bone density, lipid metabolism, physical performance and cardiovascular function (Mukherjee & Shalet 2004). GH replacement has been shown to improve symptoms and to reverse a number of the surrogate markers of metabolic and cardiovascular dysfunction. In 2003, the National Institute of Clinical Excellence (NICE) produced guidance for the prescription of GH in England and Wales which was subsequently ratified by the Health Technology Board for Scotland (HTBS). In order to be eligible to commence GH replacement, patients must fulfil several criteria, which include biochemical evidence of GH deficiency, and must demonstrate a reduced quality of life, as evidenced by their responses to a disease-specific questionnaire, the Adult Growth Hormone Deficiency Assessment – Quality of Life, or AGHDA-QoL (see www.nice.org.uk/pdf/AGHDA_questionnaire.pdf). Continuation of therapy is dependent on demonstrating that symptomatic benefit, based on improvement in questionnaire score, has been achieved (NICE 2003). GH is replaced by a daily subcutaneous injection which patients are taught to self-administer using a special pen device. Some of these pen devices offer needle-free delivery. GH is available in vials which contain either liquid GH or a powder and diluent which need to be mixed. The normal starting dose is 0.3–0.5 mg daily titrated over a 3-month period. During this time IGF-1 levels are checked every 6 weeks with the aim of keeping the levels within the age-matched reference range. The dosing schedule is adjusted to maximise benefits and minimise side-effects which can include transient oedema, arthralgia and headaches (Drake et al 1998). Older patients, women and those with a large body mass index (BMI) can be more prone to side-effects (Holmes & Shalet 1995). The usual maintenance dose is 0.2–0.6 mg/day. Women often require higher doses than men of the same age (Gaillard & Giusti 2004). Patients on GH replacement should be reassessed annually for evaluation of biochemical parameters (lipids and glucose), body composition (waist circumference, lean body mass and bone mineral density), exercise endurance and well-being using the AGHDA questionnaire.

For further information, see Piersanti (2004).

Gonadotrophins Testosterone replacement therapy has been available for over 50 years. Subcutaneous implants were developed in the 1940s, i.m. injections in the 1950s, oral tablets in the 1970s and transdermal patches and gels in the 1990s (Schubert et al 2004). Replacement can result in an improvement in sexual function, an increase in bone mineral density and improvements in body composition, e.g. increased lean body mass/decreased fat mass in hypogonadal men (Wang & Swerdloff 1997). In addition, positive changes are seen in erythropoiesis, prostate size and lipid profiles (Wang & Swerdloff 1999). Testosterone replacement is usually commenced when the diagnosis of hypogonadism is established and serum testosterone levels fall below a normal age-matched reference range.

There are now many testosterone preparations with differing routes of administration. Replacement depends on the formulation and there are advantages and disadvantages to each (Gooren & Bunck 2004). Most preparations have unfavourable pharmacokinetics which result either in sub- or supra-physiological and/or fluctuating levels of testosterone. Testosterone replacement can be by i.m. injection (250 mg every 3–4 weeks or 1000 mg every 3 months), implants (200–600 mg every 3–6 months), transdermal patches (2.5–7.5 mg/day or 4–EMG/day if scrotal patches are used), transdermal gel (1–2 sachets/day), oral tablets (25–40 mg t.d.s.) or buccal tablets (30 mg b.d.). Testosterone levels are monitored either immediately prior to an injection/implant or 8 h after the application of a patch.

Intramuscular injections have, for many years, been the most widely used and accepted form of testosterone replacement in the UK but these can be uncomfortable, are disruptive as the patient must make an appointment to see their GP or practice nurse every 3–4 weeks and can cause mood swings due to the fluctuating levels of testosterone, which are high immediately post-injection but then fall off over the next 2–3 weeks (Nieschlag 1998). Transdermal patches mimic the normal physiological and diurnal

variations of testosterone but frequently cause skin irritation and are often discontinued for this reason. Transdermal gels result in more stable levels of testosterone (Swerdloff et al 2000). Both the patch and the gel are self-applied, making them a popular choice. Ultimately, the choice of testosterone replacement therapy should be made by the patient once they have been provided with the information they require to make an informed decision. Younger patients are more likely to choose a long-acting preparation whereas men over the age of 50 should be advised to opt for a short-acting one. This is to ensure that if the preparation has to be stopped due to a contraindication to testosterone replacement therapy, e.g. the development of prostate cancer, levels of serum testosterone will immediately fall (Nieschlag 1998).

For further information, see Nieschlag & Behre (2004).

Posterior pituitary hormone replacement Replacement of deficient hormones should alleviate many symptoms, allowing the patient to lead a near normal life. It is essential that the individual feels free to contact the appropriate doctor or specialist nurse at any time to discuss their condition or any related anxieties. As pituitary disease is a lifelong condition that will require ongoing monitoring, hospital attendance will continue on at least an annual basis for many years, giving the doctor or nurse the opportunity to build therapeutic relationships with their patients.

DISORDERS OF THE POSTERIOR PITUITARY: ANTIDIURETIC HORMONE (ADH)/VASOPRESSIN SECRETION

Diabetes insipidus

Diabetes insipidus (DI) is defined as the passing of large amounts (>3 L/24 h) of dilute urine (osmolality <300 mOsmol/kg) and exists in two main forms:

- cranial DI, due to a deficiency of hypothalamic secretion of ADH
- nephrogenic DI, a condition in which the renal tubules are resistant to the action of ADH.

Causes of both cranial and nephrogenic DI may be familial or acquired and include pituitary tumours, infection (meningitis, encephalitis), inflammatory conditions (tuberculosis, sarcoidosis), trauma (head injury, neurosurgery), vascular (Sheehan's syndrome, sickle cell disease), chronic renal disease, metabolic (hyper/hypocalcaemia, hyperglycaemia) and some medications (lithium). Primary polydipsia may be psychological (Lindholm 2004).

PATHOPHYSIOLOGY

Clinical features Deficiency of antidiuretic hormone (ADH)/vasopressin leads to polyuria, nocturia and a compensatory polydipsia. Urine output may reach 10–15 L or more per day, leading to severe dehydration if the individual's fluid intake is restricted in any way.

MEDICAL MANAGEMENT

Investigations Diagnosis is often made by single paired urine and plasma osmolality, obviating the need for the more stressful and prolonged water deprivation test. Plasma osmolality will show high concentration and urine will be dilute. However, sometimes the results are equivocal and a water deprivation test is required to make the diagnosis.

Treatment is by the administration of synthetic vasopressin (desmopressin or DDAVP). This may be given orally, intranasally or by i.m. injection.

Syndrome of inappropriate antidiuretic hormone (SIADH)

The causes of SIADH are many, but include oat cell carcinoma of the lung, pneumonia, tuberculosis (TB), meningitis, head injury, acute intermittent porphyria and medication, e.g. tricyclic antidepressants, some anticoagulants and some chemotherapeutic agents such as vincristine.

PATHOPHYSIOLOGY

Clinical features SIADH may present with vagueness, confusion, nausea and irritability which, if not corrected, may lead to epileptiform attacks and coma. It is caused by an excess of ADH, leading to a dilutional hyponatraemia. Biochemical investigation will reveal low plasma sodium, low plasma osmolality and an inappropriately high urine osmolality. Blood pressure, thyroid function, kidney function and adrenal function will be normal.

MEDICAL MANAGEMENT

Medical intervention may include:

- fluid restriction to 500–1000 mL/day
- treatment of the underlying cause
- administration of demeclocycline to inhibit the action of ADH on the renal tubules
- administration of hypertonic saline infusions (in severe cases in ITU).

NURSING PRIORITIES AND MANAGEMENT: Diabetes insipidus

Major considerations

The nurse's interventions will include accurate recording of fluid balance with the full cooperation and participation of the patient. It is essential for the patient to have easy access to toilet facilities. Samples of urine will be required for osmolality assessment.

The nurse will also be involved in medication administration and education of the patient with regard to self-administration of medicines, continued measurement of fluid balance and regular weight recording. Most patients rapidly become aware if the therapy is no longer effective and will contact their GP or the specialist physician or nurse supervising their care.

DISORDERS OF THE THYROID GLAND

ANATOMY AND PHYSIOLOGY

The thyroid is a small gland in the neck that sits anteriorly to the larynx and is attached to the thyroid cartilages and

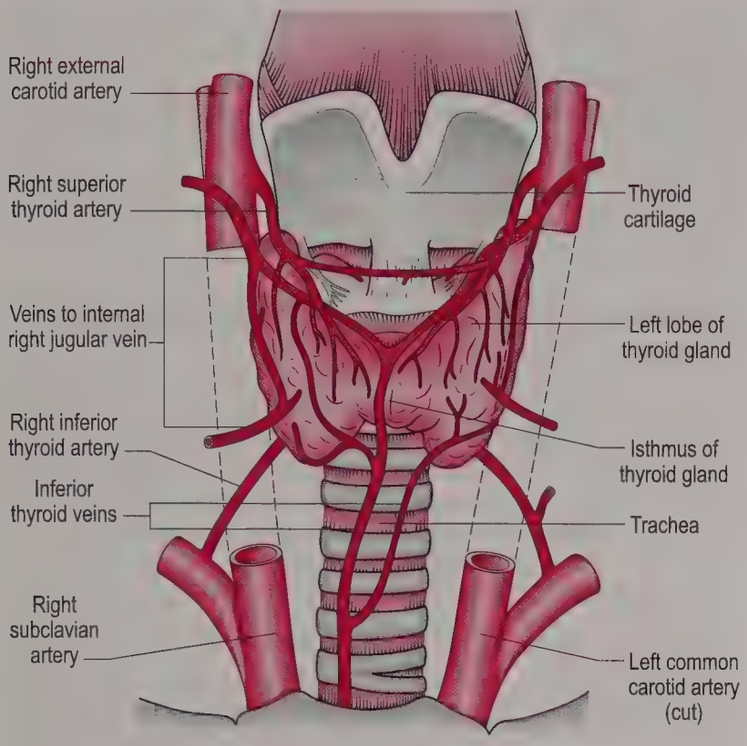

Fig. 5.5 The thyroid gland and associated structures.

the trachea. It consists of two lobes connected by an isthmus (see Fig. 5.5). Structures that lie in close proximity include the oesophagus, the parathyroid glands, the recurrent laryngeal nerves and the carotid arteries. These may all be affected by enlargement of the gland.

The thyroid receives a rich blood supply from the superior thyroid arteries, which branch from the external carotid arteries, and from the inferior thyroid arteries, which branch from the subclavian arteries. Each lobe is filled with hollow vesicles called follicles, which produce and store the thyroid hormones. Between the follicles are parafollicular cells ('C' cells), which secrete the hormone calcitonin; this, together with parathormone from the parathyroid glands, is involved in the metabolism of calcium.

The hormones, thyroxine (T_4) and 25% of circulating tri-iodothyroxine (T_3) are synthesised and secreted by the thyroid gland. This synthesis of thyroid hormones is dependent on the availability of iodine in the diet, e.g. from table salt, fish and milk. Dietary iodine is absorbed from the small intestine, changed to iodide and transported in the blood to the thyroid gland, where it is taken up by the thyroid cells. More T_4 than T_3 is produced, but T_4 is converted in some tissues to the more biologically active T_3. Over 99% of all thyroid hormone is bound to plasma thyroid-binding proteins. Only the free hormone is available for use by the tissues. If the levels of T_4 and T_3 in the blood fall, the hypothalamus releases thyroid-releasing hormone (TRH). As the levels of TRH rise, the pituitary gland secretes thyroid-stimulating hormone (TSH) which stimulates the thyroid gland to produce more T_4 and T_3. The principal effect of thyroid hormones is to influence the metabolism of cells and, therefore, the metabolic rate. Low levels of hormone are associated with a low temperature, i.e. patients will complain of feeling cold, slow heart rate and weight gain, whereas patients with high concentrations of thyroid hormones experience a rapid heart rate, heat intolerance and weight loss despite an increased appetite and high calorie intake.

5.2 Describe how the thyroid hormones T_3 and T_4 are controlled.

Simple goitre

A goitre is an enlargement of the thyroid gland. It can occur without over- or underactivity of the gland. The term 'simple goitre' is a paradox as its cause is poorly understood. In young adults the gland is soft and diffuse, enlarged two to three times its normal size. Thyroid hormone and TSH levels are normal and there is no evidence of autoimmunity. If the stimulus to goitre formation remains, whatever it is, the gland becomes further enlarged and nodular over the ensuing 20 years or so (euthyroid multinodular goitre) and when patients are 60 years of age or beyond they may develop hyperthyroidism (toxic multinodular goitre).

HYPERSECRETION OF THE THYROID HORMONES

Hyperthyroidism, thyrotoxicosis, is a condition in which there are high levels of circulating thyroid hormones. Hyperthyroidism and diabetes mellitus are amongst the most prevalent of the endocrine diseases. (Diabetes mellitus is discussed in detail in Part 2 of this chapter.) The most common cause of hyperthyroidism is intrinsic thyroid disease; pituitary-driven hyperthyroidism is extremely rare. Hyperthyroidism mainly affects women aged between 30 and 50 years, but can occur at any age in either gender.

Graves' disease

Graves' disease is the most common form of hyperthyroidism. It is an autoimmune disorder in which antibodies (anti-TSH receptor) behave like TSH, stimulating thyroid hormone production and in some cases thyroid enlargement or goitre. Graves' disease tends to run in families and may be associated with ophthalmic features. The ophthalmopathy of Graves' disease, which affects the majority of patients to some extent, is also autoimmune in aetiology. The result of the immune process is fibroblast proliferation in the retro-orbital space, with water accumulation and enlargement of the extraocular muscles and increased fat. The increased pressure behind the eye pushes the eye forward (exophthalmos) and the swollen muscles work inefficiently, causing double vision (diplopia). Vision may be threatened. The swelling of the eyelids is due to prolapse of retrobulbar fat and poor lymphatic and venous drainage.

Toxic multinodular goitre

As mentioned above, this is often the outcome of the simple diffuse goitre in the young adult. It is the second most common cause of hyperthyroidism after Graves' disease. As it presents in older people, the clinical aspects of hyperthyroidism may be different, with cardiovascular features, e.g. atrial fibrillation, predominating.

Toxic adenoma (solitary nodule)

This type of tumour constitutes about 5% of hyperthyroidism. In these patients, the thyroid nodule acts autonomously and produces excess levels of thyroid hormone, leading to suppression of the normal thyroid.

PATHOPHYSIOLOGY

In hyperthyroidism, high levels of circulating thyroid hormones stimulate cell metabolism, resulting in a high metabolic rate. TSH secretion is suppressed. The cardiovascular system is affected with tachycardia and, in older patients, atrial fibrillation and cardiac failure. Patients complain of general fatigue, although for short spells they may become more active, and find that they are restless.

Common presenting symptoms There is increased irritability, inability to relax and sleep, heat intolerance with excessive sweating, palpitations, perhaps a feeling of shakiness and a fine tremor of the hands. By far the most common symptom, however, is weight loss, despite an increased appetite. Patients often complain of excessive watering and grittiness of the eyes. An enlargement of the gland (goitre) may have been noticed.

MEDICAL MANAGEMENT

Investigations Clinical examination will confirm the tachycardia and atrial fibrillation, goitre and ophthalmopathy. The skin will be hot and moist and a fine tremor of the outstretched hands may be discernible. Diagnosis is usually confirmed by elevated serum T_4 and a suppressed TSH.

Treatment The three approaches to treatment in hyperthyroidism (thyrotoxicosis) are:

- antithyroid medication
- surgery
- radioactive iodine therapy.

Medication Antithyroid medication (carbimazole 30–40 mg/day or propylthiouracil 300–400 mg/day) is prescribed to inhibit the synthesis of thyroid hormones. The patient will continue to take the medication until a euthyroid state (i.e. normal thyroid function) is achieved, after which serum T_4, TSH and the medication dose are monitored to ensure that the patient remains euthyroid and to avoid over- or undermedication. Treatment usually continues for some 18 months, with regular outpatient visits. The patient is asked to report unexplained fever or sore throat, as the major side-effect of antithyroid medication is agranulocytosis, which occurs in approximately 1 in 300–500 patients (see Ch. 11, p. 480). The most common adverse reaction is an urticarial rash which occurs in about 2% of patients. Other side-effects include fever and arthralgia which can occur in 1–5% of patients, usually within the first few months of starting therapy, and are more common in patients treated with higher doses (Cooper 1999). Symptomatic control of tachycardia is obtained by administration of beta-blockers such as propranolol until thyroid hormone levels are normal.

Surgical intervention Partial thyroidectomy is performed only after medication has produced a euthyroid state. In some centres, the patient is given potassium iodide for 1–2 weeks before surgery, which will inhibit thyroid hormone release, reduce the size and vascularity of the gland and reduce the risk of peri- and postoperative haemorrhage. Approximately 80% of patients are cured by surgery (Parwardhan et al 1993). Partial thyroidectomy is also a useful treatment for patients with large or unsightly goitres — complications of this procedure include postoperative haemorrhage, recurrent laryngeal nerve palsy, hypocalcaemia and hypothyroidism. Features of postoperative nursing care specific to patients who have undergone partial thyroidectomy are described in Nursing Care Plan 5.1.

For further information, see Braverman & Utiger (2004).

Radioactive iodine therapy Iodine-131 (^{131}I) acts by destroying functioning cells or by inhibiting their ability to replicate. It is usually administered as a single capsule on an outpatient basis. Patients are advised to avoid eating for 3–4 h after administration to allow adequate absorption of the iodine; they are also advised to drink at least 2 L of fluid over the next 24 h and to pass urine frequently in order to excrete free circulating radioactive iodine as rapidly as possible.

Patients present a radiation hazard for approximately 1 week following this treatment. This type of therapy is used when surgery is not appropriate, but is not usually offered to women of child-bearing age.

CARCINOMA OF THE THYROID GLAND

Carcinoma of the thyroid gland is rare, comprising around 1% of all cancers (Haslett et al 2002). It is three times more common in women than men and can occur at any age (Schneider & Ron 2005).

The five main types of thyroid carcinoma are:

- papillary (this is the most common type and accounts for ~80% of all thyroid carcinomas)
- follicular (less common, usually found in older people)
- anaplastic (rare, more common in older people)
- lymphoma (usually of the type known as non-Hodgkin's lymphoma; see p. 515)
- medullary cell (rare, may run in families).

Papillary and follicular thyroid cancers are sometimes also called differentiated thyroid cancer because they still retain histological features typical of the thyroid gland.

PATHOPHYSIOLOGY

Papillary or follicular carcinomas usually present with a lump which can cause hoarseness or difficulty in swallowing. Metastases from follicular carcinoma commonly involve the brain, liver, lungs and bones.

Common presenting symptoms Often the patient will have noticed a painless small nodule or swelling in the neck. They may be euthyroid or may have symptoms associated with either hyper- or hypothyroidism.

MEDICAL MANAGEMENT

Investigations Tests of thyroid function (T_3, T_4 and TSH levels) are carried out and are followed by radiological

Nursing Care Plan 5.1 Postoperative care for a patient who has undergone partial thyroidectomy

Nursing considerations	Action	Rationale	Outcome/further action
1. **Compromise of airway as a result of anaesthesia and surgery to the neck area**	• Sit the patient in an upright position with plenty of support for the neck. Oxygen may be ordered for 1–2 h after surgery	Support of the head will reduce strain on the suture line and improve the comfort of the patient, who may be very anxious about moving the neck	The airway will remain clear and strain on the suture line will be minimal
2. **Risk of haemorrhage following surgery**	• Record blood pressure and pulse half-hourly, watching for signs of irregular or laboured breathing or stridor. Clip removers should be kept by the bed for up to 24 h after surgery	A rise in pulse and a fall in blood pressure can indicate haemorrhage, which should be reported. If respiratory embarrassment occurs due to haemorrhage, the clips must be removed to allow the blood compressing the trachea to escape. The wound should be covered with saline-soaked gauze and the patient returned to theatre immediately	Early detection of possible haemorrhage should prevent a crisis from developing and allow bleeding to be stopped sooner rather than later
3. **Risk of tetany due to accidental removal of the parathyroid glands**	• Observe closely for tetany, including tingling of fingers and toes, a positive Chvostek's sign (facial asymmetry on tapping of the cheek) or Trousseau's sign (inflation of blood pressure cuff causes spasm of hand) (see Box 5.3)	Sudden drop in calcium levels can lead to tetany, resulting in airway obstruction and, if left untreated, fitting and death	Early indications of lowered calcium levels should be reported, allowing treatment in the form of i.v. calcium gluconate to be given
4. **Risk of thyroid crisis** (This is now rare due to improved postoperative preparation of the patient about to undergo thyroid surgery. It is a life-threatening situation)	• Measure pulse, blood pressure, temperature and respiratory rate half-hourly, reducing as recovery allows	As a result of trauma to the thyroid, enormous amounts of thyroid hormones are released into the bloodstream, causing tachycardia, a rise in blood pressure and hyperpyrexia (up to 41°C). The patient appears very restless and irritable. Death may result from heart failure	Once thyroid crisis has been diagnosed, treatment must be commenced immediately with i.v. beta-blockers (propranolol in high doses), carbimazole, steroid therapy (i.m. hydrocortisone 100 mg)
5. **Risk of damage to laryngeal nerve**	• Observe for breathing difficulties, noisy breathing, stridor, swallowing difficulties and hoarseness, and report problems	Damage to the recurrent laryngeal nerve can result in vocal cord spasm and paralysis of larynx leading to respiratory obstruction	If damage occurs, tracheostomy is usually necessary initially. The damaged nerve should recover in a few weeks. Inhalation of nitrous oxide may help in the acute period to relieve the spasm

examination (ultrasound) of the neck. Fine needle biopsy or aspiration is necessary to distinguish cancer from benign pathologies, to give a firm diagnosis and to differentiate between the types of thyroid cancer. Radioactive isotope scanning, using technetium or iodine, is a painless procedure which involves injecting the radioactive isotopes into a vein in the patient's arm and then, after 20 min rest, scanning the thyroid gland with a gamma camera. As cancer cells do not absorb the radioactive liquid as well as normal thyroid cells, any cancer cells will generally appear as 'cold

areas' or 'cold nodules' on scanning. However, only 10% of such cold nodules are malignant. Many turn out to be cysts, and operative exploration may be avoided if aspiration cytology is normal.

Staging The stage of a cancer is a term used to describe the size of the tumour and whether or not it has metastasised. This information helps the clinician decide on the most appropriate treatment (see also Ch. 31, pp. 1041–1043).

Stages of thyroid cancers

- Stage 1. The tumour is <1 cm, is contained within the thyroid gland and has not metastasised.
- Stage 2. The tumour is between 1 and 4 cm, and is contained within the thyroid gland, i.e. has not metastasised.
- Stage 3. The tumour is >4 cm but is still contained within the thyroid gland *or* the tumour is of any size and has spread just outside the gland or to the lymph nodes in the neck.
- Stage 4. The tumour has spread into other structures in the neck *or* the tumour has spread to involve more lymph nodes in the neck or upper chest *or* the tumour has metastasised to other parts of the body. All patients with anaplastic thyroid cancer are considered to have Stage 4 disease.

When patients under the age of 45 are diagnosed with papillary or follicular thyroid cancer, different staging categories are used and there is no Stage 3 or 4 for these patients:

- Stage 1. The tumour can be of any size and the lymph nodes may also be affected but there is no spread to other sites.
- Stage 2. Any tumour that has metastasised, e.g. to the lungs or bones.

Treatment Surgery, radioactive iodine (^{131}I) or radiotherapy may be given alone or in combination. The treatment chosen will depend on several factors including the patient's age, general health, and the type and stage of the tumour. The treatment of choice is near-total thyroidectomy. This is usually followed by a large dose of ^{131}I to ablate any thyroid remnant. Any tissue showing radioiodine uptake subsequently must be assumed to be recurrent disease, and further ^{131}I may be taken up therapeutically by the tumour tissue. Follow-up is important and will usually be carried out at 6-monthly intervals initially. At follow-up, the tumour marker, serum thyroglobulin (Tg) is measured. It should not be detectable in a patient who has had a total thyroidectomy, ^{131}I ablation of remnant and is taking thyroxine in a dose sufficient to suppress serum TSH. If detectable, further surgery or ^{131}I therapy may be required.

NURSING PRIORITIES AND MANAGEMENT: Carcinoma of the thyroid gland

Major considerations

Caring for the patient receiving ^{131}I therapy

Before ^{131}I ablative therapy the patient will have discontinued thyroid hormones for 4–6 weeks to allow TSH to rise, which ensures better uptake of ^{131}I. In those in whom a period of hypothyroidism is best avoided, e.g. an older patient with ischaemic heart disease, high TSH levels in the blood can be achieved by giving Thyrogen (human recombinant TSH). Thyrogen is given as two i.m. injections 24 h apart, prior to commencement of ^{131}I, and negates the need to discontinue thyroid hormone replacement (Haugen et al 1999).

The patient and family should be given clear explanations regarding the effect of ^{131}I, the reasons for the patient being nursed alone with restricted access for staff and visitors, and procedures to be followed in the handling of body fluids. It should be explained to the patient that they cannot be discharged until their radiation level is safe.

Measures should be taken to prevent constipation, as this inhibits the subsequent excretion of radioactive material. A high fluid intake should be encouraged to promote a good urinary output. Commodes and bedpans should be designated for the patient's exclusive use. All body fluids will be highly radioactive following ^{131}I administration and the patient should be encouraged to bathe or shower regularly to remove contaminated perspiration.

The patient should be nursed in a single room containing a minimum of equipment. Film badges should be worn at all times by staff members to indicate radiation exposure. Duties should be coordinated so that each staff member spends a minimum amount of time with the patient.

As with all endocrine disease, prompt treatment should result in complete alleviation of all signs and symptoms; the patient should be reassured of this whilst undergoing treatment. Follow-up after treatment is essential. Nursing staff should encourage the patient to attend outpatient or GP clinics as advised. The patient should be reassured that, particularly with localised disease from a papillary carcinoma, the probability of 'cure' is extremely high (Dougherty & Lister 2004).

For further information, see Schafer (2005).

HYPOSECRETION OF THE THYROID HORMONES

Underactivity of the thyroid gland may be primary, resulting from disease of the thyroid, or secondary, due to pituitary failure.

Aetiology

Primary hypothyroidism as a result of autoimmune disease is the commonest cause of thyroid underactivity. It may be associated with other autoimmune disease. It is six times more common in women than in men.

Hypothyroidism (myxoedema) may also be iatrogenic, i.e. caused by previous treatment for thyrotoxicosis by means of surgery or radioactive iodine.

Iodine deficiency is another cause of hypothyroidism and is due to insufficient dietary intake of iodine. This leads to reduced thyroid hormone production. Goitre is a common feature of this condition. Endemic hypothyroidism is occasionally seen in areas where iodine levels in the water supply are low, usually inland areas far from the sea or mountainous regions. This was once a problem in Derbyshire in the UK. It is still seen in some areas of the world, such as parts of central Africa, central Asia and central and eastern

Europe as well as in the Andes and the Himalayas (Delange & Dunn 2005).

Congenital hypothyroidism occurs in approximately 1 in 4000 live births and usually results from congenital absence of the thyroid gland; it can also be caused by certain genetic enzyme defects. Some medications may also induce hypothyroidism; for example, lithium carbonate (used in bipolar disorders) can result in goitrous hypothyroidism (Haslett et al 2002).

PATHOPHYSIOLOGY

If congenital hypothyroidism is not detected and treated early, the child will not develop fully, either mentally or physically. Neonatal screening for congenital hypothyroidism is performed in most developed countries at 5–7 days. In primary hypothyroidism (myxoedema), serum T_4 is low and levels of TSH are high. The onset of myxoedema is slow and insidious. Because the affected individual is often an older person, it may be accepted as a normal part of ageing and it may be some time before a medical opinion is sought. The patient may report sensitivity to cold, weight gain, a general slowing down of body functions, lethargy, depression and an inability to 'think quickly'. The face will be puffy in appearance and hair sparse, coarse and brittle. In severe hypothyroidism, the patient may be admitted in a coma and perhaps be thought to be suffering from hypothermia. This represents a medical emergency in which intensive treatment and care are essential. Diagnosis of hypothyroidism is confirmed by low plasma levels of T_4 and raised TSH levels.

MEDICAL MANAGEMENT

Treatment Hypothyroidism is treated with replacement doses of thyroid hormone (thyroxine) commencing with a low dose of 25–50 mcg and increasing by increments of 25–50 mcg every 3–4 weeks until serum TSH is normal.

NURSING PRIORITIES AND MANAGEMENT: Hypothyroidism

It is usual to treat patients on an ongoing basis in the community. The community nursing team should follow up medical treatment and explanations and ensure that patients understand the reasons for the thyroxine replacement therapy and the importance of attending for regular checks to ensure that a euthyroid state is achieved and maintained. Patients are often seen in hospital for annual review at nurse-led clinics which are becoming more common.

DISORDERS OF THE PARATHYROID GLANDS

ANATOMY AND PHYSIOLOGY

The parathyroid glands are situated on the posterior lobes of the thyroid gland. They are usually four in number; however, more than four glands occur in up to 6% of individuals. This has been attributed to division of the glands during development. The blood supply is from the inferior and superior thyroid arteries.

The glands secrete parathormone (PTH), which is the most important hormone involved in calcium metabolism. Parathormone maintains plasma calcium levels within normal limits. It acts predominantly on the kidney tubules to increase reabsorption of calcium but also increases gut absorption of calcium and mobilises it from bone. Plasma calcium will therefore rise, and in turn suppress PTH secretion; conversely, a fall in plasma calcium will stimulate the secretion of PTH. In most instances, raised levels of calcium in the plasma are due either to hyperparathyroidism or malignancy.

Vitamin D and calcitonin are also involved in calcium metabolism (see Box 5.1).

Box 5.1

Vitamin D and calcitonin in calcium metabolism

Vitamin D is found in two forms: cholecalciferol (vitamin D_3), which is formed predominantly in the skin by the action of sunlight, and ergocalciferol (vitamin D_2), which is synthetic and added to food. It is the skin-synthesised form which is of greater importance and is perhaps best considered as a hormone.

Vitamin D is biologically inactive; only when it is metabolised by the liver (to form mildly active 25-hydroxycholecalciferol) and the kidney (to form very active 1,25-dihydroxycholecalciferol) does it have any action on calcium metabolism. The active metabolite increases calcium absorption from the gut and is essential for bone formation.

If 1,25-dihydroxycholecalciferol is present in excess, it causes increased resorption of calcium from bone, leading to hypercalcaemia. The kidney is able to detect rising levels and ceases production of the active form, producing an inactive form until the levels drop.

Bone is constantly being re-formed by deposition and reabsorption of calcium. Calcitonin reduces the reabsorption of calcium from bone. Local stress, such as weight bearing, is important in this process. Prolonged inactivity or immobility can result in calcium being lost from bone, while exercise increases bone formation and remodelling.

HYPERSECRETION OF THE PARATHYROID GLANDS

Hypercalcaemia

PATHOPHYSIOLOGY

In most instances, raised plasma levels are caused by hyperparathyroidism or are secondary to malignancy (see Box 5.2). Mild hypercalcaemia, which is often asymptomatic, occurs in about 1 in 1000 of the population (Kumar & Clark 2002).

Even mild symptoms can lead to an early diagnosis, due to advanced chemical analysis techniques; this means that it is now extremely rare to see the severe renal and bone problems associated with hypercalcaemia that occurred in the past.

Box 5.2

Causes of hypercalcaemia

Common
- Malignancy
- Myeloma
- Primary hyperparathyroidism

Rare
- Addison's disease
- Milk alkali syndrome
- Sarcoidosis
- Thyrotoxicosis
- Vitamin D poisoning
- Immobility
- Phaeochromocytoma
- Thiazide diuretics
- Tuberculosis

Common presenting symptoms Patients may present with symptoms of malignancy or of hypercalcaemia, including:

- constipation
- depression
- drowsiness, coma
- malaise
- nausea, vomiting
- nocturia
- polydipsia, polyuria
- psychosis
- weakness.

MEDICAL MANAGEMENT

Investigations Diagnosis is based on medical history, clinical examination and tests to ascertain the cause.

Treatment Hypercalcaemia caused by malignancy is usually seen only in patients with advanced carcinoma when bony metastases have occurred and signifies a poor prognosis (Ralston et al 1997). If possible, it should be treated, as this may improve the quality of the patient's life. Adequate hydration is of great importance and, in itself, is often enough to relieve the symptoms of the hypercalcaemia. However, it is now established that bisphosphonate medications (e.g. disodium pamidronate) are highly effective in lowering malignant hypercalcaemia (Fleisch 1998). These are administered by an intravenous infusion, but oral preparations, e.g. sodium clodronate or ibandronic acid, can be used in the long term to prevent a recurrence of hypercalcaemia (Ralston et al 1997). Other treatments include oral phosphate and steroid therapy.

Primary hyperparathyroidism

This condition is caused by the overproduction of PTH by the parathyroid glands. It affects three times more women than men and its incidence increases with age. It is usually idiopathic (Haslett et al 2002).

MEDICAL MANAGEMENT

Treatment Surgery is indicated for the management of hypercalcaemia due to excessive PTH secretion, as no long-term medication is available. However, asymptomatic hypercalcaemia requires no surgical intervention and can be treated conservatively with simple monitoring of calcium levels on an intermittent basis by the patient's GP or the hospital outpatient department.

Following parathyroidectomy, hypocalcaemia of either a transient or permanent nature may ensue. This should be treated promptly to prevent tetany. If severe hypocalcaemia occurs, i.v. calcium gluconate (10 mL of 10%) should be given immediately. Vitamin D and oral calcium supplements will be required. Calcium levels should be monitored closely until they have stabilised.

NURSING PRIORITIES AND MANAGEMENT: Primary hyperparathyroidism

Major considerations

The investigations for diagnosis of hypercalcaemia may require hospital admission, particularly if the hypercalcaemia is severe and/or is thought to be secondary to malignancy. The patient will probably have been unwell for some time and will be feeling very tired and weak on admission.

Careful explanations of the investigations and treatment are required. These will include a 24-h urine collection for calcium. As it is particularly important for the accuracy of this test that the urine collection is completed properly, it is essential that this is explained clearly, and is fully understood by the patient. If surgery is undertaken, the perioperative care is the same as for thyroidectomy (see p. 172). In addition, regular assessment for impending hypocalcaemia is undertaken (see Box 5.3).

Box 5.3

Detecting increased neuromuscular irritability (tetany) due to hypocalcaemia

Positive Chvostek's sign
The nurse can test for this sign by tapping the person's facial nerve about 2 cm anterior to the ear lobe. If hypocalcaemia (or hypomagnesaemia) is present, unilateral twitching of facial muscles, especially around the mouth, may be observed.

Positive Trousseau's sign
This may be observed when taking the blood pressure of a person with a low calcium level which, as yet, is not producing observable effects. The sphygmomanometer cuff is inflated around the person's arm and pressure is increased to above systolic pressure for 2–3 min. The constrictive effect of the inflated blood pressure cuff exacerbates the hypocalcaemia in the limb distal to the cuff. During blood pressure recording or shortly afterwards, muscular contraction or twitching will be noticed in the limb concerned.

Secondary and tertiary hyperparathyroidism

Secondary hyperparathyroidism occurs due to disease processes that cause hypocalcaemia, e.g. in vitamin D deficiency or in renal disease. The parathyroid glands strive to keep the calcium levels up, while calcium remains normal or is low. Rarely, this can lead to autonomous secretion of parathyroid hormone, leading to permanent hypercalcaemia, termed tertiary hyperparathyroidism. This is often seen in patients with renal failure.

HYPOSECRETION OF THE PARATHYROID GLANDS

Hypocalcaemia

The most common cause of hypocalcaemia is artifactual due to low albumin levels, i.e. the calcium is actually normal when the low albumin is corrected for by the biochemistry laboratory (Stewart 2005). Other relatively common causes include a low magnesium, renal failure and vitamin D deficiency (see Box 5.1). Autoimmune hypoparathyroidism is rare, but iatrogenic hypoparathyroidism following surgery to the neck is more common.

Rickets and osteomalacia

These are diseases of calcium and phosphorus metabolism resulting from a deficiency in vitamin D intake and synthesis. It may be questionable to discuss these under the heading of endocrinology, but as they are usually seen and treated by endocrinologists, as opposed to other physicians, they are considered in this chapter.

Vitamin D deficiency during growth produces abnormalities in the growing skeleton known as rickets. In childhood, rickets produces soft, painful bones in which the weight-bearing bones bend and may give rise to gross deformities. In the adult, where bone growth is completed, osteomalacia is the result; symptoms are generally diffuse bone pain and myopathy.

Rickets does not now occur commonly in the population of the UK, due to better nutrition and, possibly, to a reduction in industrial pollution which allows more sunlight through. It is, however, sometimes seen in the Asian community in the UK as they tend to cover up and avoid exposing themselves to sunlight, particularly those individuals with an increased vitamin D requirement, e.g. babies, children and pregnant women. The exact explanation for its prevalence is not clear, but it may be associated with an inability to synthesise vitamin D, as it occurs predominantly in people who eat a strict vegetarian or vegan diet.

Treatment is by vitamin D replacement, and prevention is the aim, particularly targeted to known vulnerable groups.

DISORDERS OF THE ADRENAL GLANDS

ANATOMY AND PHYSIOLOGY

The adrenal glands are situated on the upper part of the kidneys. They are highly vascular and derive their blood supply from the renal arteries, the inferior phrenic arteries and directly from the aorta; they are drained by the suprarenal veins (see Fig. 5.6). The adrenal glands have a composite origin. The cortex, the outer part, has the same embryonic site of origin as the gonads. The medulla, the inner part, is derived from neural crest cells which have migrated from the developing neural tube and have become enclosed within the cortex. The latter can arguably be considered part of the nervous system. The secretions, and therefore the actions of the two separate parts of the glands, are quite different and will be discussed separately.

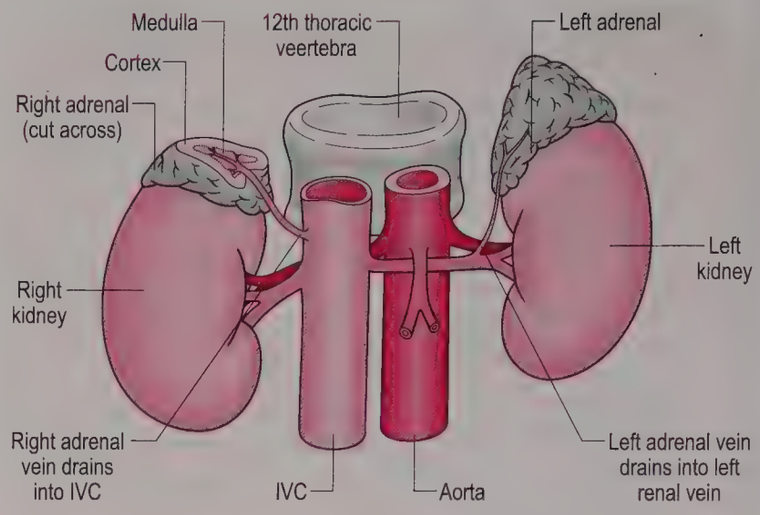

Fig. 5.6 The adrenal gland and associated structures. IVC, inferior vena cava. (Reproduced with permission from Jeffcoate 1993.)

The adrenal cortex

The adrenal cortex produces three types of hormone, collectively termed corticosteroids:

- mineralocorticoids
- glucocorticoids
- adrenal androgens.

Mineralocorticoids The most important of the mineralocorticoids is aldosterone, which is the most potent regulator of sodium and potassium and hence of the acid–base balance of the body. Aldosterone acts on the distal convoluted tubules of the kidney and stimulates the cells to reabsorb and thus conserve sodium.

Glucocorticoids such as cortisol, the principal glucocorticoid, have varied and wide-ranging actions, many of which are not fully understood (see Fig. 5.7). They are essential to life and, in their absence, blood sugar, blood pressure and blood volume fall, sodium excretion increases and muscle contractility decreases. Death ensues due to low blood volume, myocardial weakness and shock. If present in excessive amounts, an opposite set of changes occurs: blood volume expands, blood pressure rises, potassium falls, glycogen storage is increased, blood sugar levels rise, connective tissue is reduced in quality and strength, and immunity is impaired. Wound healing and the process of inflammation are also inhibited.

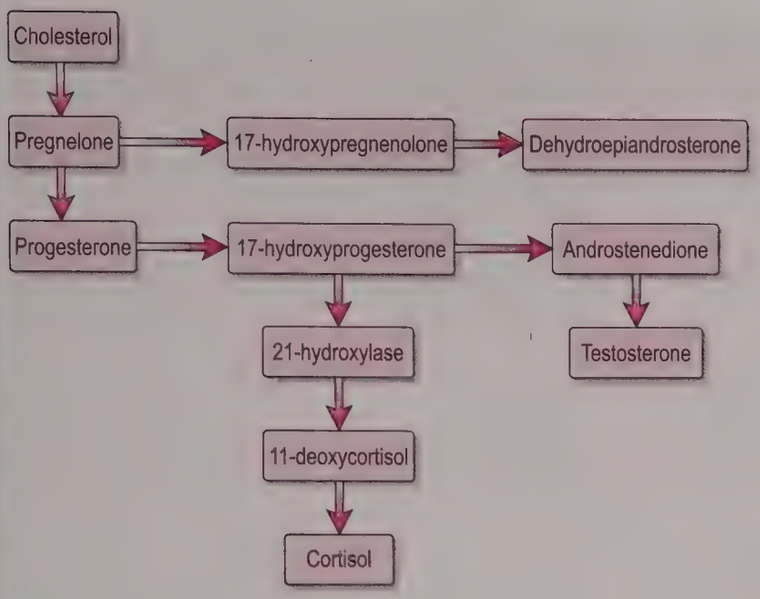

Fig. 5.7 Simplified schematisation of cortisol synthesis.

Adrenal androgens The adrenal cortex, in addition to the gonads, produces male sex hormones. The effects are appropriate in the male, but in the female excessive production may have a virilising effect.

The adrenal medulla

Adrenaline, noradrenaline and dopamine, i.e. the catecholamines, are secreted by the adrenal medulla. Eighty per cent of adrenomedullary secretion is adrenaline, most noradrenaline and dopamine being secreted by neurones and functioning as neurotransmitters.

In normal secretion, adrenaline probably has some effect on mean blood pressure; although it increases systolic pressure, it decreases diastolic pressure. When secreted under the control of the sympathetic nervous system (see Ch. 9, p. 407) it causes tachycardia, decreased gut motility and the closure of sphincters in the gut, pupil dilatation, bronchodilatation and piloerection.

Noradrenaline raises both systolic and diastolic blood pressure but has less effect on gut motility and does not produce bronchodilatation.

The difference between the effects of adrenaline and noradrenaline is partly explained by the presence of receptors on the surface of effector cells, i.e. those cells on which adrenaline and noradrenaline have their effect. These are termed α- and β-adrenoreceptors. Noradrenaline is most active at α-adrenergic receptors and adrenaline at β-adrenergic receptors. In addition, most cardiac receptors are termed B_1, to distinguish them from bronchodilator B_2 adrenoreceptors.

HYPERSECRETION OF THE ADRENAL GLANDS

The adrenal medulla

The main effect of the catecholamines (adrenaline, noradrenaline and dopamine) secreted by the adrenal medulla is on the cardiovascular system and the central nervous system, and on carbohydrate and lipid metabolism. Together, adrenaline and noradrenaline prepare the body for the 'fight or flight' response.

Phaeochromocytoma

Phaeochromocytoma is a very rare condition which causes about 1 in 1000 cases of hypertension (Kumar & Clark 2002). In this condition, a tumour of the adrenal medulla produces excessive adrenaline and noradrenaline. The tumour is small, with about 10% being multiple tumours and 10% being malignant.

PATHOPHYSIOLOGY

Clinical features The tumour produces the clinical effects of excessive catecholamine secretion which include hypertension and palpitations.

Common presenting symptoms Patients may present with anxiety, tachycardia, palpitations and panic attacks. Headaches, sweating and pallor may also occur. There may be a history of high blood pressure, which may be labile. Patients may present as an acute emergency with a hypertensive crisis (Spencer et al 1993) or may be asymptomatic (Bravo & Tagle 2003).

MEDICAL MANAGEMENT

Investigations A careful history and clinical examination may lead the physician to suspect a phaeochromocytoma. Investigations include 24-h urine collections for urinary free norepinephrine (NE) and epinephrine (E) and catecholamines or their two major metabolites, metanephrine and vanillylmandelic acid (VMA). Normal levels of NE/E and catecholamine secretion usually exclude a diagnosis of phaeochromocytoma. Abdominal X-rays and a CT scan may show a tumour of the medulla.

Treatment includes surgical removal of the tumour and administration of α- and β-adrenoreceptor blocking medications, e.g. phenoxybenzamine and propranolol.

NURSING PRIORITIES AND MANAGEMENT: Phaeochromocytoma

Major considerations

The first priority of care is to limit anxiety as much as possible and to nurse the patient in a quiet, non-stressful environment. Clear, concise explanations of the reasons for the symptoms will help to relieve the anxiety.

Blood pressure and pulse should be recorded 4-hourly, and any sweating or flushing noted. Antihypertensive medication must be maintained as the risk of postoperative hypotensive collapse is reduced by adequate preparation with adrenoreceptor blocking medication.

A care plan should be devised such that the patient can be as independent as possible in self-care tasks. Preoperative preparation is as for general abdominal surgery (see Ch. 26). Specific postoperative care includes $\frac{1}{2}$-hourly recording of blood pressure to observe for immediate postoperative hypotensive collapse brought on by the reduced blood volume characteristic of chronic vasoconstriction. Specialist medication such as sodium nitroprusside, a potent

Table 5.5 Unwanted effects of steroids on the systems of the body*

System	Pathological effect	Comments
Endocrine	Suppression of endogenous steroid production Diabetes Weight gain Amenorrhoea	Therapy should always be withdrawn gradually to enable the hypothalamic–pituitary–adrenal axis to recover
Cardiovascular	Elevation of blood pressure	Due to sodium retention
Gastrointestinal	Peptic ulceration/GI bleeding	
Renal	Polyuria Glycosuria	
Central nervous	Mood change Change in sleep pattern Appetite stimulation	May manifest itself as euphoria, depression and even so-called steroid psychosis
Musculoskeletal	Muscle wasting Osteoporosis Pathological fracture	Muscle wasting can be seen in proximal muscle; often severely affected patients cannot rise from a squatting position
Skin	Bruising Striae Thinning Poor wound healing 'Moonface' and acne	Skin becomes friable and may tear easily
Immune	Suppression	May mask signs of infection

*The use of steroids in medicine has proved to be beneficial in a wide variety of diseases, from asthma to bowel disease, and as an adjunct to other treatment in cancer therapy. They can provide effective pain relief in chronic musculoskeletal conditions. However, their use should be judicious and all patients having steroid therapy in the long term should be monitored and supervised. Short-term treatment, such as therapy used in the relief of an acute asthma attack, does not require such long-term follow-up. In the long term, use of steroid therapy, natural or synthetic, will mimic Cushing's syndrome, so-called iatrogenic disease.

All patients on steroid therapy should wear a 'MedicAlert' bracelet, and should inform doctors, dentists or nurses that they are on steroid therapy. Surgery or intercurrent illness will require dose increases to mimic the body's normal response to stress.

vasoconstrictor, should be available to control blood pressure in a hypotensive crisis.

The adrenal cortex

Cushing's syndrome

Cushing's syndrome is caused by the excessive and inappropriate circulation of glucocorticoids. It is most commonly seen in the therapeutic administration of synthetic steroids (see Table 5.5). Spontaneous causes of Cushing's syndrome are extremely rare. The major causes, excluding iatrogenic causes, are (Kumar & Clark 2002):

- pituitary-dependent disease (Cushing's disease)
- ectopic ACTH production
- adrenal adenoma
- adrenal carcinoma
- alcohol-induced.

PATHOPHYSIOLOGY

Clinical features Increased plasma cortisol levels have wide-ranging clinical effects on most systems of the body, i.e. altered fat and carbohydrate metabolism, diabetes mellitus and obesity, wasting of muscles, retention of sodium leading to hypertension, oedema, compromise of the immune system and osteoporosis. Other effects include thinning of the skin with bruising or purpura, hirsutism and oligomenorrhoea in women and impotence in men (see also Table 5.6).

Common presenting symptoms Because of the wide-ranging clinical effects of Cushing's syndrome, the patient can present with varying symptoms. Frequently, the patient will complain of infections which will not resolve, weight gain, bruising and discoloration of the skin.

MEDICAL MANAGEMENT

Investigations Diagnosis is confirmed by radiological and biochemical investigations (see Table 5.7). The differential diagnosis between pituitary disease, ectopic ACTH production and primary adrenal hypersecretion is important as the treatment and management of these three causes will vary considerably.

Treatment Surgery and medical therapy are the main forms of treatment. Metyrapone is commonly used to lower cortisol levels. An alternative approach is to remove completely endogenous cortisol by adrenalectomy and to supplement levels with an oral steroid.

Trans-sphenoidal surgery is the treatment of choice for removal of an ACTH-producing tumour of the pituitary. The antifungal medication ketoconazole may be used, due

Table 5.6 Signs and symptoms of Cushing's syndrome

Symptoms or sign	Aetiology
Muscle wasting which can be demonstrated by the patient being unable to stand from a squatting position	Catabolic effect of the steroids
Osteoporosis which can be so severe as to result in spontaneous fracture of vertebrae or ribs	Protein loss from the skeletal matrix
Skin thinning and purple striae, plethora, easy bruising and purpura	Atrophy of the elastic lamina allows disruption of the dermis so capillaries can be seen below the surface. Weakening of the capillaries leads to easy bruising (often without trauma)
Oedema	Weakening of the capillaries
Poor wound healing, immunocompromisation	The lymphocytes are destroyed, lowering the ability to fight infection. Signs of infection, e.g. swelling and redness, are masked
Obesity and 'buffalo hump' (pad of fat across shoulders)	Altered metabolism of fat. Fat is laid down over the trunk. Lipid levels may be raised
Hypertension	Sodium-retaining properties of glucocorticoids
Diabetes mellitus	Alteration in the normal metabolism of carbohydrate and the increased conversion of protein to carbohydrate
Depression, euphoria and frank psychosis	Unknown
Change in libido, impotence, oligomenorrhoea and infertility	Due to the general hormone imbalance that is occurring
Excess hair growth, hair loss (particularly of the male pattern type in women)	This is seen in Cushing's disease/syndrome but is not solely due to cortisol overproduction

Table 5.7 Radiological and biochemical tests for differential diagnosis of Cushing's syndrome

Test	Findings indicative of Cushing's syndrome
Radiological	
Adrenal CT scan	Adrenal adenomas and carcinomas are usually large and detectable on a CT scan
Skull X-ray	It is difficult to detect these often small pituitary tumours; 90% of X-rays are normal
CT scan of head and pituitary fossa, MRI scan	High-resolution scanning and increasingly sophisticated techniques often allow an enlarged pituitary to be detected
Chest X-ray	May show a bronchial carcinoma which may be a source of ectopic ACTH production
Venous catheterisation	This technique may be of value in confirming by blood sampling a pituitary origin of ACTH production as well as locating an ectopic source
Biochemical	
Dexamethasone suppression test	Under the principle that, as a result of the feedback system, high levels of steroids will switch off ACTH production and therefore steroid production, failure of suppression indicates Cushing's syndrome and at a higher dose may indicate pituitary disease. Ectopic ACTH production is not suppressed with a low or a high dose
Circadian rhythms	Patients with Cushing's syndrome may lose the normal variation in levels of cortisol. These should be measured at 09.00 h and at 24.00 h when the patient is sleeping and not warned. The patient should have been in hospital for at least 48 h before commencement of this test
Insulin tolerance test	This test, in which a dose of i.v. insulin is given, demonstrates that the normal rise in cortisol levels to hypoglycaemia is absent and will differentiate between true Cushing's, depression and alcohol-induced pseudo-Cushing's. It is performed mainly in specialist centres as a high level of supervision is required, and certain baseline measurements of pituitary function and confirmation of a normal ECG are recommended to ensure the patient's safety
Glucose tolerance test	This test will indicate that glucose metabolism is impaired; indeed, most people with Cushing's syndrome show a diabetic tendency
Urine collection	24-h urinary collections are performed and should show an elevation in excreted steroids. Accuracy in this test is difficult to achieve as it relies on the patient managing a complete, uncontaminated 24-h collection

to its activity in inhibiting steroidogenesis in the steroid synthesis pathway (see Fig. 5.7). Surgery for removal of a benign adrenal adenoma offers a good chance of cure, but adrenal carcinoma carries a poor prognosis. The medication mitotane (o,p'-DDD) is adrenolytic and may be used in the treatment of adrenal carcinoma (Allolio et al 2004).

Following adrenalectomy, patients will require lifelong hydrocortisone and mineralocorticoid replacement therapy. They must always wear a MedicAlert bracelet and carry a steroid card, and be informed of the dangers of hypocortisolaemia, a life-threatening condition.

Management of ectopic ACTH syndrome This condition most often occurs in patients with an oat cell carcinoma of the lung (see Ch. 3). The neoplastic cells themselves produce ACTH and give rise to Cushing's syndrome. Care is as for malignant disease (see Ch. 31), taking into account the additional complications of Cushing's syndrome.

There is another subgroup of patients with ectopic ACTH production from less malignant tumours, the so-called carcinoid tumours, who present with a picture of more classical Cushing's syndrome and who may survive for many years with appropriate treatment.

NURSING PRIORITIES AND MANAGEMENT: Cushing's syndrome

Major considerations

The main aim of nursing care is to relieve the symptoms of the disease. On admission, a full nursing history is taken and the patient's needs thoroughly assessed to provide a basis for a care plan.

A major consideration will be the psychological impact of the illness, e.g. related to a change in body image. Providing clear ongoing explanations of the hormonal changes that the patient is experiencing, the investigations and the subsequent treatment that they will undergo help provide optimal psychological support.

Ongoing follow-up after discharge from hospital is essential. Initially, 3-monthly tests will be carried out, gradually reducing to an annual check. If adrenalectomy or pituitary surgery has been performed, precautions will need to be taken regarding hydrocortisone replacement; this must be explained in detail. An information leaflet can be useful as a reference for the patient when at home. This should tell the patient when to increase the therapy, e.g. during illness, and when to seek medical advice.

5.3 Recall the physical symptoms that commonly occur in Cushing's syndrome. Identify the potential care needs that the patient will have and formulate a care plan responsive to those needs (see Case History 5.1 and Nursing Care Plan 5.2).

HYPOSECRETION OF THE ADRENAL HORMONES

Addison's disease

Addison's disease is a rare condition in which there is total destruction of the adrenal cortex resulting in failure of cortisol secretion. It may occur at any age and is more common in females. Autoimmune adrenalitis is the most common cause in the developed world and is responsible for 80–90% of cases. Adrenal destruction by adrenalytic medication such as mitotane (o,p'-DDD), TB, HIV or malignancy are rare causes.

PATHOPHYSIOLOGY

Clinical features High levels of ACTH result in pigmentation of the skin and mucous membranes. Glucocorticoid, sex steroid and mineralocorticoid production are reduced. Plasma levels of proteins are low and potassium are high, with serum urea being elevated due to volume depletion.

Common presenting symptoms The onset of the disease is usually insidious, often starting with a feeling of general malaise and weakness. Skin discoloration may have been noticed, especially in the palmar creases and on the inside of the lips and cheeks. Some patients present as medical emergencies with an Addisonian crisis (see below). Untreated, this can be fatal.

MEDICAL MANAGEMENT

Investigations Diagnosis is by clinical examination and blood tests to confirm high levels of ACTH and low levels of cortisol. In the short Synacthen test (SST), a dose of 250 mg tetracosactide (synthetic ACTH) is given i.v. or i.m. and blood samples for plasma cortisol taken at 0, 30 and 60 min after its administration will show a failure of the adrenal glands to respond to the stimulus of the parenteral ACTH. Once this has been demonstrated, the cause of the adrenal failure needs to be identified. The most common cause, i.e. autoimmune, can be tested for with an assay to detect the presence of 21-hydroxylase antibodies. If there are no antibodies present, infectious or genetic causes should be investigated. Tests will include an MRI of the adrenal glands and screening for TB, HIV and cancer.

Treatment is by long-term replacement doses of mineralocorticoid and glucocorticoid. This should lead to an improvement in the patient's well-being. Levels of hydrocortisone should be checked regularly to ensure the dose is correct. Mineralocorticoid replacement with fludrocortisone should be checked by regular blood pressure readings, which should show no postural hypotension, and by measurement of plasma renin.

Addisonian crisis Adrenal crisis is a life-threatening event. It occurs in such situations as injury, infections, anaesthesia and surgical procedures where, unlike in the healthy individual, the stress response does not occur. The absence of the cortisol surge to a major stressor results in a severely shocked patient. Addisonian crisis requires immediate intervention. Symptoms may include:

- sudden penetrating pain in the abdomen, legs or lower back
- fever
- severe vomiting and diarrhoea leading to dehydration
- hypotension
- hypoglycaemia
- loss of consciousness (O'Donnell 1997).

CASE HISTORY 5.1

J

J was a 20-year-old woman admitted to the unit following transfer from her local hospital with a history of weight gain, hirsutism, acne on her back and face, pain and increasing weakness in her limbs, amenorrhoea and depression.

She was transferred in a wheelchair, being unable to walk at this point. Her parents and her fiancé accompanied her.

Once J was settled into the unit, clinical examination showed her to have centrally located obesity, severe acne, marked facial hair and some loss of occipital hair. She had severe pitting oedema of her ankles and had been amenorrhoeal for 6 months. Purple striae were present on her abdomen and thighs, and bruising was noticeable on her shins. She was unable to stand from the squatting position, indicating marked proximal myopathy. She was tearful and anxious and complained of a poor sleep pattern and waking at about 04.00 h. Observations showed her to be hypertensive at 170/110 mmHg; pulse and temperature were normal. J had some photographs of herself taken at her engagement party some 4 months before, showing a pretty, very slim, smiling young woman.

She was helped to settle into the unit and her nurse sat with her and explained the investigations that were to be performed. As many of these involved multiple venepunctures, she was reassured that a local anaesthetic cream would be applied. (It is inadvisable to leave cannulae in situ as the risk of infection in someone who is immunocompromised is high.)

On the first day, blood tests showed that J's baseline cortisol levels were well above the normal range. Her haemoglobin, liver function, urea and electrolytes were measured, as well as her sex hormone levels and thyroid function. A measurement of ACTH was made and found to be extremely high. Skull and chest X-rays were performed.

An insulin tolerance test showed elevated cortisol levels throughout, with no response to hypoglycaemia. A glucose tolerance test showed elevated glucose levels throughout; glycosuria was present 1 h post-glucose load. This had not resolved at 2 h, indicating a diabetic tendency.

On the third and fourth days, blood was taken at 09.00, 18.00 and 24.00 h and repeated the next night, the midnight samples being taken when J was asleep. This was to establish her circadian rhythm; the results showed that the levels of ACTH and cortisol did not fall at night and remained high throughout the day.

The finding that both the ACTH levels and the cortisol levels were high indicated that the high cortisol levels were being driven by ACTH. The source of the ACTH had to be established.

During this time J was seen by a psychiatrist, who established that she was depressed but not suicidal. Medical staff kept her informed about the results of her tests and their implications; further explanations were given by her nurse. A CT scan the following day showed an enlarged pituitary gland.

Based on this it was decided that petrosal sinus sampling (www.cushings-help.com/petrosal.htm) would be performed and samples taken for ACTH and cortisol after a catheter had been inserted into the right groin. The procedure was explained to J and her consent obtained. Her right groin was shaved and she was fasted overnight. Samples were taken at various points, including the petrosal sinuses (the point nearest the pituitary gland on both the left and right sides). No sedation is permitted prior to this test as it interferes with the results, and so extremely detailed explanation of the procedure was required to gain J's confidence and understanding. She was accompanied by her nurse, who remained with her throughout the procedure. When assayed, the results showed a higher level of ACTH on the left side of the pituitary.

Once a source had been found for the excess ACTH, J could be started on medication to control her symptoms. She was started on metyrapone 500 mg t.d.s. and her cortisol levels were checked daily to ensure she did not become hypocortisolaemic.

After review of her results and X-rays, it was suggested that to try to remove the pituitary tumour would be the best treatment option. After discussion with J, her consent for the operation was obtained. It was explained to her and her fiancé that there was a possibility that she may become deficient in all pituitary hormones following the surgery, including those which would affect her fertility. In this eventuality, hormone replacement could be given.

A small adenoma was removed from the left side of her pituitary gland. On return from theatre J was nursed on the neurosurgical ward initially. Hydrocortisone injections were given (100 mg every 6 h for 48 h) to ensure that if the tumour had been removed, J's cortisol levels would not fall too rapidly and predispose her to an Addisonian crisis. J returned to the endocrine unit looking rather bruised around the eyes and wearing a nasal bolster but otherwise well. Nursing staff continued to monitor her lying and standing blood pressures. Temperature and pulse were checked 4-hourly and nasal discharge was observed and tested for signs of CSF leak.

Three days postoperatively J's hydrocortisone was withdrawn. A measurement of her 09.00 h cortisol and ACTH was taken the next day. Her cortisol level was very low and correspondingly J felt weak and light-headed. Her blood pressure showed a postural drop. The next morning the exercise was repeated and the results were the same. J was losing weight around her face and her ankle oedema was reduced. She said she felt very positive for the first time in many weeks and was sleeping well. On the afternoon of the fourth postoperative day, she became weak and dizzy and felt nauseated. Her blood pressure was measured and found to be low. She was helped to lie down and the doctor informed. It was felt that an Addisonian crisis was impending and so a blood sample was taken for cortisol measurement and J was commenced on oral prednisolone. Some days later all of J's hormone levels were checked and, as she felt well on her replacement therapy, she was discharged home to the care of her family. It was arranged for her to return to the ward in 12 weeks' time.

By the time J returned for this visit, she had lost a considerable amount of weight, was walking unaided, had lost most of her facial hair and had started menstruating. Her steroid therapy was stopped and close observation maintained to observe for impending adrenal crisis. A blood test 48 h later indicated that her cortisol levels were in the normal range. It was decided to repeat all the pituitary function tests done prior to the surgery. These showed all hormones to be in the normal range and responses to hypoglycaemia, as demonstrated by the insulin tolerance test, to be intact. This showed that the pituitary had recovered its normal function. J was discharged home with a regular follow-up inpatient appointment every 12 weeks to ensure that all was well.

Some months after, the nurses received an invitation to J's wedding and 1 year later J was the very proud mother of a baby daughter.

Nursing Care Plan 5.2 Care of a patient with Cushing's syndrome

Nursing considerations	Action	Rationale	Expected outcome
1. **Pain from fractured vertebrae or ribs as a result of osteoporosis**	• Provide immediate pain relief. Administer as prescribed, noting the efficacy • Handle and position the patient carefully	Pain will cause the patient discomfort and will increase anxiety. Pain relief will reduce this. Fractured ribs will cause shallow breathing and will increase chances of chest infection. Gentle handling will reduce distress and prevent further fractures	The patient should be pain-free and comfortable and anxiety reduced
2. **Infection as a result of immuno-compromisation**	• Make 4-hourly recordings of temperature, pulse and blood pressure. Report any variation from the normal range immediately	Death from overwhelming infection can occur. Signs of infection will be masked, so infection may be advanced before signs are seen	Any infection will be identified early and correct treatment commenced
3. **Damage to skin as a result of skin thinning and oedema or poor wound healing**	• If the patient is immobile, care of pressure areas will be required to prevent tissue damage. Legs will need to be elevated to relieve the oedema and any wounds will require scrupulous aseptic technique when dressed	Tissue will be rapidly broken down and slow to heal, so preventive measures are essential. Susceptibility to infection requires precautions to prevent introduction of infection	Further tissue damage will be prevented and any present source of infection healed as rapidly as possible
4. **Hypertension**	• Record blood pressure 4-hourly after 10 min lying flat and 1 min standing. Report levels beyond the normal range or postural deficit	Increasing blood pressure may lead to stroke or heart failure and if persistently high will need to be treated with drugs. Postural deficit will indicate a problem with sodium excretion or retention	Blood pressure levels will remain within acceptable limits
5. **Diabetes mellitus as a result of abnormal carbohydrate metabolism**	• Record pre- and postprandial blood sugar levels and perform daily urinalysis	Persistently high blood sugars will lead to the complications of diabetes mellitus and may need to be treated with insulin	Blood sugar levels will remain within the normal range
6. **Psychosis and mental disorder**	• Ascertain the patient's psychological status early on. A psychiatric opinion should be obtained. Mood swings and bizarre behaviour should be reported. The patient may be so disturbed as to require 24 h psychiatric nurse observation	The patient's psychological state may change rapidly and close observation for this is necessary. Some patients can become suicidal	The patient will not be a danger to themselves or others and patient safety is maintained at all times

Treatment aims to restore steroid, sodium and glucose levels to within normal range by i.v. administration of 100 mg hydrocortisone, and i.v. infusion of normal saline given quickly with dextrose if glucose levels are low. Hydrocortisone is then given i.v. or i.m. 6-hourly until the patient is stable, following which steroid replacement can be given orally and mineralocorticoids introduced.

NURSING PRIORITIES AND MANAGEMENT: Addison's disease

Major considerations

Careful observation of temperature, pulse, and standing and lying blood pressure should be made. A raised temperature will indicate signs of infection which the

patient may not be able to fight effectively. Any postural drop in blood pressure should be reported immediately.

The steroid replacement therapy should be administered with the patient's full involvement so that they have a full knowledge of dosage and timing and techniques for self-administration before discharge. The patient should be issued with a steroid card and advised to carry this and to wear a MedicAlert bracelet on their wrist or ankle at all times.

An ampoule of hydrocortisone 100 mg should be kept at home in case of serious illness or trauma, and the GP or community nurse called to administer it. It may be of value also to teach a member of the family how to do this.

It is vital that the patient and their relatives have a thorough understanding of their condition and the signs associated with complications. This will help to restore confidence and enable the patient to return to a full and active life.

5.4 With a colleague, undertake a role-play exercise by acting out the education of the patient regarding steroid therapy. Formulate an information sheet which could be given to patients prior to discharge.

5.5 Check within the local hospital context what advice is available for patients with Addison's disease. Where do patients obtain the MedicAlert bracelet? Are these patients exempt from prescription charges?

CONGENITAL ADRENAL HYPERPLASIA (CAH)

This is a group of inherited disorders caused by a deficiency of one of the five enzymes involved in cortisol synthesis (Charmandar et al 2004). It is one of the most common autosomal recessive disorders with a prevalence in the USA and Europe of approximately 1:15 000–16 000 (van der Kamp & Wit 2004).

PATHOPHYSIOLOGY

To understand CAH it is necessary to understand the biosynthesis of steroids. To take the most common deficiency, which accounts for 95% of cases of CAH (Labarata et al 2004) as an example, if the enzyme 21-hydroxylase (CYP21) is absent because of a gene defect located on the short arm of chromosome 6, cortisol will not be produced in sufficient quantity. By means of the negative feedback system, ACTH production will be increased to stimulate the production of cortisol. This in turn will lead to hypertrophy of the adrenal cortex and elevated levels of 17-hydroxyprogesterone, androstenedione and testosterone — the hormones occurring before the enzyme block (see Fig. 5.7). This will result ultimately in virilisation.

Definitions of CAH CAH disorders can be divided into three main groups:

- severe or classic – with or without salt wasting (SW)
- moderate/less severe – simple virilising (SV)
- mild – non-classic (NC).

Common presenting symptoms If severe or classic, CAH presents at birth or in early infancy with sexual ambiguity and salt-wasting due to mineralocorticoid deficiency. It has an incidence of 1 in 15 000 (Labarata et al 2004). Life-threatening vomiting and dehydration can occur in the first weeks of life. In the female, the high level of androgens present cause clitoral hypertrophy and fusion of the labial folds resulting in ambiguous genitalia. The syndrome may not be recognised in the male. Internal genitalia may develop normally. If a diagnosis is not made at birth, a genotypical female (XX) may be labelled male. Furthermore, if not treated with corticosteroids, the individual may go into adrenal crisis and die.

Moderate CAH is sometimes referred to as simple virilising CAH and is typically recognised by signs of virilisation in prepubertal children. Effects can include premature development of pubic hair (precocious puberty), advanced bone age, accelerated growth velocity and diminished final height in both men and women as a result of premature fusion of the bony epiphyses (New 2004).

Mild or non-classic CAH has an incidence of 1 in 1000 and because prenatal virilisation does not occur, presents in late childhood/early adulthood (Labarata et al 2004). Symptoms of androgen excess include hirsutism, severe acne, temporal baldness and infertility in adolescents and adult women. Menarche may be normal or delayed and secondary amenorrhoea is common (Otten et al 2005). Polycystic ovarian syndrome (PCOS) may also be present. In young men, early beard growth, acne and a growth spurt may prompt the diagnosis. Men may also present with oligozoospermia or diminished fertility despite appearing asymptomatic and are only diagnosed when efforts to conceive fail.

MEDICAL MANAGEMENT

Investigations include blood tests to confirm high levels of ACTH and 17-hydroxyprogesterone (Azziz & Zacur 1989). Replacement of the glucocorticoid is usually given in the form of prednisolone to suppress the ACTH production and thereby reduce the overstimulation of the adrenals. Other requirements frequently include mineralocorticoids such as fludrocortisone.

NURSING PRIORITIES AND MANAGEMENT: Congenital adrenal hyperplasia (CAH)

General considerations

Information should be given to the individual regarding steroid replacement therapy (see p. 178). Nursing care should concentrate on the psychological support which will be required, especially if the diagnosis is made in adulthood.

The psychosocial and psychosexual implications of CAH are considerable, and formal counselling and psychotherapy should be made available. In female patients, hirsutism and acne can be especially distressing. Antiandrogens, e.g. cyproterone acetate, are now the treatment of choice (Spritzer et al 1990). Other important issues for women, which need discussion, include menstruation, sexuality, fertility and the possible need for plastic surgery, as some effects of virilisation are not reversible by medication (Hagenfeldt 2004). This is particularly important as the patient approaches adulthood, as sexual intercourse may be rendered difficult, painful or impossible. Prevention of subfertility should be

implemented as a treatment goal from the start of puberty. The transition of care for the patient from the paediatric to adult endocrinologist is of utmost importance.

DISORDERS OF THE GONADS

ANATOMY AND PHYSIOLOGY

The gonads — ovaries in the female and testes in the male — are described in Chapters 7 and 8.

DISORDERS OF SEXUAL DIFFERENTIATION

In normal development, gonadal and phenotypic sex follow an orderly process of development determined by chromosomal sex at the moment of conception (see Ch. 6).

During the early stages of fetal life the gonad has the potential to develop female or male characteristics. In the presence of another X chromosome (i.e. 46, XX) or the absence of another chromosome (i.e. 45, XO), development will follow the female pattern. The presence of two X chromosomes is, however, necessary for normal ovarian function.

By the second month of fetal development the genital organs are undifferentiated duct systems, termed the Müllerian and Wolffian ducts. In the normal female, as development progresses, the Wolffian system regresses and the Müllerian system develops to form the fallopian tubes, the uterus and the upper vagina. The external genitalia undergo little change.

In the male, the Müllerian system regresses and the Wolffian system develops to form the testes, vas deferens, prostate and seminiferous tubules. The genital tubercle present in both systems forms the clitoris in the female and the penis in the male.

There is evidence to suggest that the normal development of a male child is hormone-dependent. It appears that testosterone inhibits the regression of the Wolffian duct and stimulates its development into the male sexual structures. In contrast to this, the ovary is not affected by hormones in utero.

Abnormalities of sexual differentiation may present with abnormal genitalia at birth, growth disturbance in childhood or abnormal secondary sexual development.

Abnormalities of gonadal development

True hermaphroditism, i.e. the presence of both male and female sexual characteristics in the same individual, is extremely rare (Karam & Baker 2004). It occurs when both the Müllerian and Wolffian systems continue to develop. Diagnosis requires a high index of suspicion for subtle abnormalities of the genitalia (Wiersma 2004). Ovotestes may exist or an ovary on one side and a testis on the other.

Chromosomal abnormalities

Chromosomal abnormalities affecting sexual differentiation may be described briefly as follows:

Klinefelter's syndrome is a condition in which phenotypical males have two X chromosomes and one Y chromosome. It is the most prevalent sex chromosome disorder in men with an incidence of 1 in 600 male newborns (Kamischke et al 2003). Men with Klinefelter's syndrome are typically tall, infertile and may exhibit a varying degree of Leydig cell failure resulting in testosterone deficiency. (Bojesen et al 2004).

Turner's syndrome is a condition in which the individual is phenotypically female, but has the genotype XO, i.e. complete or partial absence of one X chromosome. It is the most commonly occurring chromosomal abnormality in females, with an incidence of approximately 50 in 100 000 women and girls (Gravholt 2004). Affected individuals are of short stature with a 'web neck' and may have widely spaced nipples and peripheral oedema. The ovaries are atrophic and serum LH and FSH levels are elevated. They are prone to a variety of serious cardiac problems including coarctation of the aorta and aortic dissection. Women with Turner's syndrome are thought to have a reduced life expectancy, mainly due to these serious cardiac problems, but they may also have multiple co-morbidities, which can include hypothyroidism, deafness, osteoporosis, oestrogen deficiency and infertility (Ostberg & Conway 2003).

Kallman's syndrome In this condition there is a normal karyotype but a genetic defect in the pathway leading to gonadotrophin secretion; thus there is a deficiency of gonadotrophins and therefore sex steroid secretion is reduced. This condition is sometimes termed congenital hypogonadotrophic hypogonadism. Typically, the individual has a defect in their sense of smell (anosmia). Normal gonadal function can be restored with replacement of LH and FSH, meaning that fertility is possible. Otherwise, when fertility is not an issue, androgen replacement therapy is mandatory (John & Schmid 2000).

Testicular feminisation This is a syndrome of androgen resistance or complete androgen insensitivity (CAI syndrome) caused by mutations in the androgen receptor gene. While the karyotype is male (46, XY), the phenotype is female. Testes are present, but because of tissue resistance to circulating androgens but not oestrogen at puberty, breast tissue develops although pubic hair does not (Skordis et al 2005). Regression of the Müllerian system occurs due to tissue insensitivity but the Wolffian system does not develop and a blind-ended vagina results (Hannema et al 2004). The gonads may become malignant and are usually removed at the onset of adult life.

NURSING PRIORITIES AND MANAGEMENT: Disorders of sexual differentiation

Whilst disorders of the gonads are rarely life threatening or require admission to hospital, the psychological implications for the individual and their family cannot be overemphasised.

The role of the nurse in the investigation and treatment of these conditions is to offer psychological support to the individual, and, if they agree, their family, in an environment which is both relaxed and supportive.

Counselling on an informal and formal basis is essential during investigations, when complete privacy must be

ensured. Feelings of inadequacy regarding sexuality and low self-esteem are common. An approach which demonstrates empathy with the individual helps to create a positive image during the initial examinations and investigations and during subsequent treatment.

EATING DISORDERS

Eating disorders can be divided into two main diagnostic categories: anorexia nervosa and bulimia nervosa (Garfinkel 2002). Patients who do not fit either of these categories but who have a clinically significant problem are diagnosed as having an atypical eating disorder. The discussion of eating disorders in this chapter may seem controversial, as many would classify these as psychological illnesses and among the most common of all psychiatric disorders in women (Morgan et al 1999). However, as endocrine disorder is often a manifestation of an eating disorder, e.g. amenorrhoea in the patient with anorexia, such patients may be seen in endocrine clinics. For this reason eating disorders are considered here.

Studies into the role of the hypothalamus have highlighted the influence it has on appetite control and it is considered almost certain that the hypothalamus has a function in some eating disorders (Costin 1999). Hypotheses include the identification of a negative feedback system involving a specific protein produced by the fat cell, known as leptin, which may be malfunctioning in the obese patient (Farooqi et al 1998).

ANOREXIA NERVOSA

Anorexia nervosa is an eating disorder characterised by self-inflicted starvation and a relentless pursuit of thinness (Bruch 1999).

Epidemiology

Anorexia nervosa is seen in all social classes and in both sexes. However, only 5–10% of cases occur in males and there is a higher prevalence in social classes 1 and 2 (Hoek 2002). Bruch (1999) indicated that anorexic individuals tend to be young girls who come from highly successful families in which the parents have high expectations of their children.

Aetiology

Contributory factors in the development of anorexia nervosa include:

- Family background, parental pressure, sibling disability, parental overprotection and negative changes within family relationships (Horesh et al 1996)
- The onset of puberty and psychosexual development in which there is denial and avoidance of sexuality marked by the development of the breasts and change of shape of hips and thighs
- Sociocultural expectations — there is an enormous emphasis on thinness in society's image of female beauty.

Studies also suggest that there is a genetic risk factor for anorexia. Studies of twins in the USA suggest that approximately half the risk of developing this eating disorder is inherited (Grice et al 2002).

PATHOPHYSIOLOGY

There is a complex relationship between nutritional, endocrine and psychological factors in this condition. Disorders in nutritional status result from prolonged insufficient intake of carbohydrates, fats and other nutrients. Metabolic disturbances, e.g. hypokalaemia, can occur following self-induced vomiting or the continual use of laxatives.

Clinical features Endocrine dysfunction appears to relate to weight loss and affects the hypothalamic–pituitary–gonadal axis. Blood tests reveal low circulating levels of LH, FSH and oestradiol. Injections of GnRH stimulate a rise in these, indicating that hypothalamic function is affected and the pituitary response is intact. Amenorrhoea occurs in girls as a result of this disturbance, secondary to the loss of body fat. The individual's metabolic rate slows down, resulting in hypotension, bradycardia, reduced core body temperature and cold extremities.

Individuals with anorexia nervosa often have underlying depression. It would seem that their psychological symptoms are aggravated by the undernutrition, and some professionals argue that patients are more receptive to psychological help when they are better nourished. The characteristic psychological state involves a denial of the illness, a failure to recognise the need for treatment and a need to exercise control over eating behaviour. The individual will have a distorted body image and insist that their abnormally thin, wasted, cachectic body appears obese.

Common presenting symptoms Most frequently, the anorexia will have been present for some months before individuals can be persuaded to see their GP. A determination to lose weight, coupled with the desire to change the shape of the body is typical, as is the denial of any problem or illness. In women, amenorrhoea, typically beginning 3–6 months from the start of weight loss, is often found.

MEDICAL MANAGEMENT

History and investigation Diagnosis is reached after investigations have proved that there is no underlying cause for the weight loss. Objective criteria have been developed to aid diagnosis. These include:

- a determination to diet and lose weight and maintain the weight loss
- a change of body shape to one of extreme thinness
- distorted body image
- avoidance of sexuality
- amenorrhoea in female patients.

Treatment Depending on the severity of the weight loss and its effect on general health, most patients can be managed in an outpatient setting, with psychological treatment regimens for a minimum of 6 months. If the patient's condition deteriorates or there is no improvement during this time, more intensive forms of treatment may need to be considered. These may require day care or inpatient care in a specialist mental health unit.

It is commonly accepted that an eclectic approach to treatment is appropriate. Psychological treatment should focus on the patient's eating behaviour, their attitude to their weight and body shape and any wider psychosocial issues that may be affecting them. Psychological therapy may include cognitive–behavioural therapy (CBT) to improve attitudes towards body image and individual and/or family interventions focused explicitly on eating disorders. Restoring body weight and nutritional status will be at the centre of whatever approach is used. If the weight loss has led to physiologically life-threatening conditions such as hypokalaemia or renal failure, it may be necessary to correct fluid and electrolyte imbalance by i.v. fluids and to improve nutritional status by parenteral or nasogastric feeding for as short a time as possible. Given the invasive nature of these procedures, they can be psychologically damaging for the individual. Force feeding of the patient must be done in strict accordance with the Mental Health Act of 1983. Rigid inpatient behaviour modification programmes should not be used. Following any inpatient episode, patients should be offered ongoing outpatient treatment for at least 12 months. They should be regularly reviewed for any signs of physical and psychological risk, e.g. suicidal thoughts or self-harm (NICE 2004).

A multidisciplinary team approach in which dietitians, occupational therapists, medical staff, psychologists and nurses work together with the anorexic individual in an agreed and consistent framework is essential. Current therapy combines the use of psychotherapy and antidepressants (Bardin 1997). Other studies have looked at the maintenance of weight using drugs that act on serotonin uptake (O'Dwyer et al 1996). However, there is limited evidence for the benefits of medical therapy in the treatment of anorexia nervosa and this should never be regarded as the primary treatment (NICE 2004). Side-effects, especially cardiovascular, must be carefully monitored.

NURSING PRIORITIES AND MANAGEMENT: Anorexia nervosa

Major considerations

The main aims of nursing care for patients with anorexia nervosa are to facilitate physical and psychological recovery by seeking to:

- establish a good relationship with the patient
- restore body weight and nutritional status by aiming for 0.5–1 kg/week average weight gain as an inpatient and 0.5 kg/week as an outpatient, achieved by increasing calories by ~3500–7000/week
- establish a good eating pattern and the enjoyment of mealtimes
- eliminate self-induced vomiting and the use of laxatives
- help the individual to acquire a positive self-image.

Because of their condition, patients will often present strong arguments as to why they cannot eat and will resort to devious methods to avoid taking in calories. Visits to the toilet after eating, to vomit or to dispose of food not eaten, should be monitored and, where possible, prevented. Dental treatment and advice is important to minimise effects of vomiting, e.g. patients should be told not to brush their teeth after vomiting and to avoid the use of acidic mouthwashes. It is important that mealtimes are handled in a relaxed manner. Realistic goals should be set and agreed to by each patient, with regard to foods eaten and weight gain. A written contract can help to create a climate of trust and help to prevent manipulation of staff and parents.

As an inpatient, if goals are met and maintained, short stays with the family can be arranged. If these visits are successful, plans can be made for discharge home. Continued support and monitoring of nutritional and weight status is essential, as relapse is common among anorexic individuals.

BULIMIA NERVOSA

Bulimia nervosa is an eating disorder characterised by episodes of binge eating, followed by episodes of fasting, self-induced vomiting and the misuse of laxatives and sometimes diuretics to prevent weight gain, coupled with an exaggerated preoccupation with the individual's weight and body shape (Lilly 2003). It occurs in about 1% of young women in the developed world, with women being ten times more likely to be affected than men (Hay 2003). These women are usually of normal weight but some may be obese. As with anorexia nervosa, bulimia nervosa often begins during adolescence. It is a chronic condition which affects a patient's quality of life; however, very few actively seek help because of feelings of shame associated with the binge eating and purging, which have often gone on in secret for many years, becoming deeply ingrained patterns of behaviour which can be hard to change. Once identified, however, patients should be encouraged to follow an evidence-based self-help programme. Specially adapted forms of CBT are available and 16–20 sessions over a 4–5 month period are recommended (NICE 2004). If there is no response, or the patient is not willing to undergo CBT, other forms of psychological therapy should be considered, e.g. interpersonal psychotherapy. This should be continued for 8–12 months (NICE 2004). As an alternative to psychological therapy, or as an additional first step, a trial of antidepressants may be instigated. These can decrease the frequency of episodes of binge eating and purging. As a first choice, selective serotonin reuptake inhibitors (SSRIs) are prescribed. The SSRIs are well accepted and tolerated, and have fewer side-effects than the tricyclic antidepressants.

For further information on both anorexia nervosa and bulimia nervosa, see Murphy & Manning (2003) and Nicholls & Viner (2005).

INTRODUCTION

Diabetes mellitus is defined as a metabolic disorder of multiple aetiology. It is characterised by chronic hyperglycaemia with disturbances of carbohydrate, protein and fat metabolism which results from defects in insulin secretion, insulin action or both (World Health Organization 1999). In the UK, 1 in 20 people over the age of 65 has diabetes and in people over the age of 85 this rises to 1 in 5 (DH 2001). Diabetes UK (2003a) estimates that there are around 1.4 million adults with known diabetes and there could be as many as a further million who may have type 2 diabetes without yet knowing it.

Diabetes classification

In the past, diagnostic and treatment characteristics were the main classification criteria. Accordingly, diabetes was described as being insulin-dependent diabetes or non-insulin-dependent diabetes. This classification has been replaced by the World Health Organization (WHO) classification (WHO 1999) which recognises the main types of diabetes as follows:

- Type 1 diabetes (formerly insulin-dependent diabetes)
- Type 2 diabetes (formerly non-insulin-dependent diabetes)
- Gestational diabetes
- Impaired glucose regulation
- Other specific types.

For a detailed study of normal anatomy and physiology, see Tortora & Grabowski (2002); for information on gestational diabetes, see Diabetes UK (2004).

ANATOMY AND PHYSIOLOGY

The pancreas

The pancreas has both exocrine and endocrine functions. Exocrine tissue is responsible for the secretion of enzymes which are transported in ducts to the duodenum where they play a vital role in the digestion of food. The endocrine function of the pancreas is concerned with the secretion of hormones. Clusters of endocrine tissue, the islets of Langerhans, are found scattered throughout the pancreas. There are two principal types of cell contained within the islets: beta cells (β cells), which secrete insulin, and alpha cells (α cells), which secrete glucagon. Each has a role in the regulation of blood glucose.

Delta cells (δ cells), also within the islets, secrete somatostatin which contributes to the regulation of a variety of hormones throughout the body, including insulin and glucagon.

Blood glucose regulation

Within a 24-h period, the healthy human will alternate between the 'fed state' and the 'fasting state' several times. In the 2 h following a meal the blood glucose will tend to rise as absorption of nutrients takes place. This is termed

Table 5.8 The physiological effects of insulin

Process	Action	Tissue
Effects on carbohydrate metabolism		
Glucose transport	↑	Adipose, muscle
Glycolysis	↑	Adipose, muscle
Glycogen synthesis	↑	Adipose, muscle, liver
Glucose oxidation via pentose phosphate pathway	↑	Liver, adipose
Glycogen breakdown	↓	Muscle, liver
Glycogenolysis, gluconeogenesis	↓	Liver
Effects on lipid metabolism		
Lipolysis	↓	Adipose
Fatty acid synthesis	↑	Adipose, liver
Low-density lipoprotein synthesis	↑	Liver
Lipoprotein lipase	↑	Adipose

the postprandial or fed state. Once glucose has been taken up into the cells, blood glucose levels will tend to fall and will not rise again until the next meal is taken. This is termed the preprandial or fasting state. In health these fluctuations are very slight, as insulin is secreted at a low or basal level throughout the whole day, only rising to an increased stimulated level at mealtimes.

Insulin and glucagon are principally (but not exclusively) responsible for blood glucose regulation.

Insulin

Insulin, an anabolic hormone, is secreted in response to a rising blood glucose level. Its functions are (Table 5.8):

- to facilitate glucose uptake by the cells
- to promote glycogenesis, i.e. the conversion of glucose to glycogen for storage in the liver and skeletal muscle
- to promote protein synthesis
- to promote conversion of glucose to triglycerides for ultimate storage as body fat.

All of these functions have the effect of preventing an abnormal rise in blood glucose (hyperglycaemia) during the postprandial period (see Fig. 5.8). Insulin secretion is highest in the fed state and lowest in the fasting state.

Glucagon

Glucagon, a catabolic hormone, is secreted in response to a falling blood glucose level and has the following functions:

- to promote the conversion of stored glycogen to glucose (glycogenolysis) and its release from the liver
- to promote fat and protein breakdown in order to provide an alternative source of glucose via lipolysis and gluconeogenesis
- to influence the production of ketone bodies (ketogenesis). In total or near-total insulin lack, these weak acids are produced as a result of the chemical processes involved in fat breakdown.

The actions of glucagon and the other counter-regulatory hormones are all geared towards preventing an abnormal fall in blood glucose (hypoglycaemia). Glucagon secretion is highest in the 'fasting state' and lowest in the 'fed state'.

5.6 Imagine that 1 h ago you finished a three-course meal. What hormonal response would you expect from the islet cells in the pancreas right now?

Other influences on blood glucose regulation

The anterior pituitary secretes two hormones of significance to blood glucose regulation:

- *Somatotrophin (growth hormone)* — this hormone tends to raise blood glucose and is therefore described as diabetogenic in action and anti-insulin in effect. It influences blood glucose in two main ways:
  — by promoting glycogen-to-glucose conversion (glycogenolysis)
  — by inhibiting muscle glycogen storage.
- *Adrenocorticotrophic hormone (ACTH)* — this hormone stimulates the adrenal cortex to release cortisol (see below). A negative feedback mechanism operates in response to the circulating levels of cortisol in the blood.

The adrenal cortex secretes a group of hormones known as glucocorticoids, the most significant of which is cortisol. Cortisol is released in a diurnal rhythm such that secretion is higher in the mornings and lower in the evenings.

Like glucagon, cortisol is a catabolic hormone. Secretion is increased during periods of physical or psychological stress, when its effect is to raise the blood glucose level in an effort to meet the additional metabolic demands posed

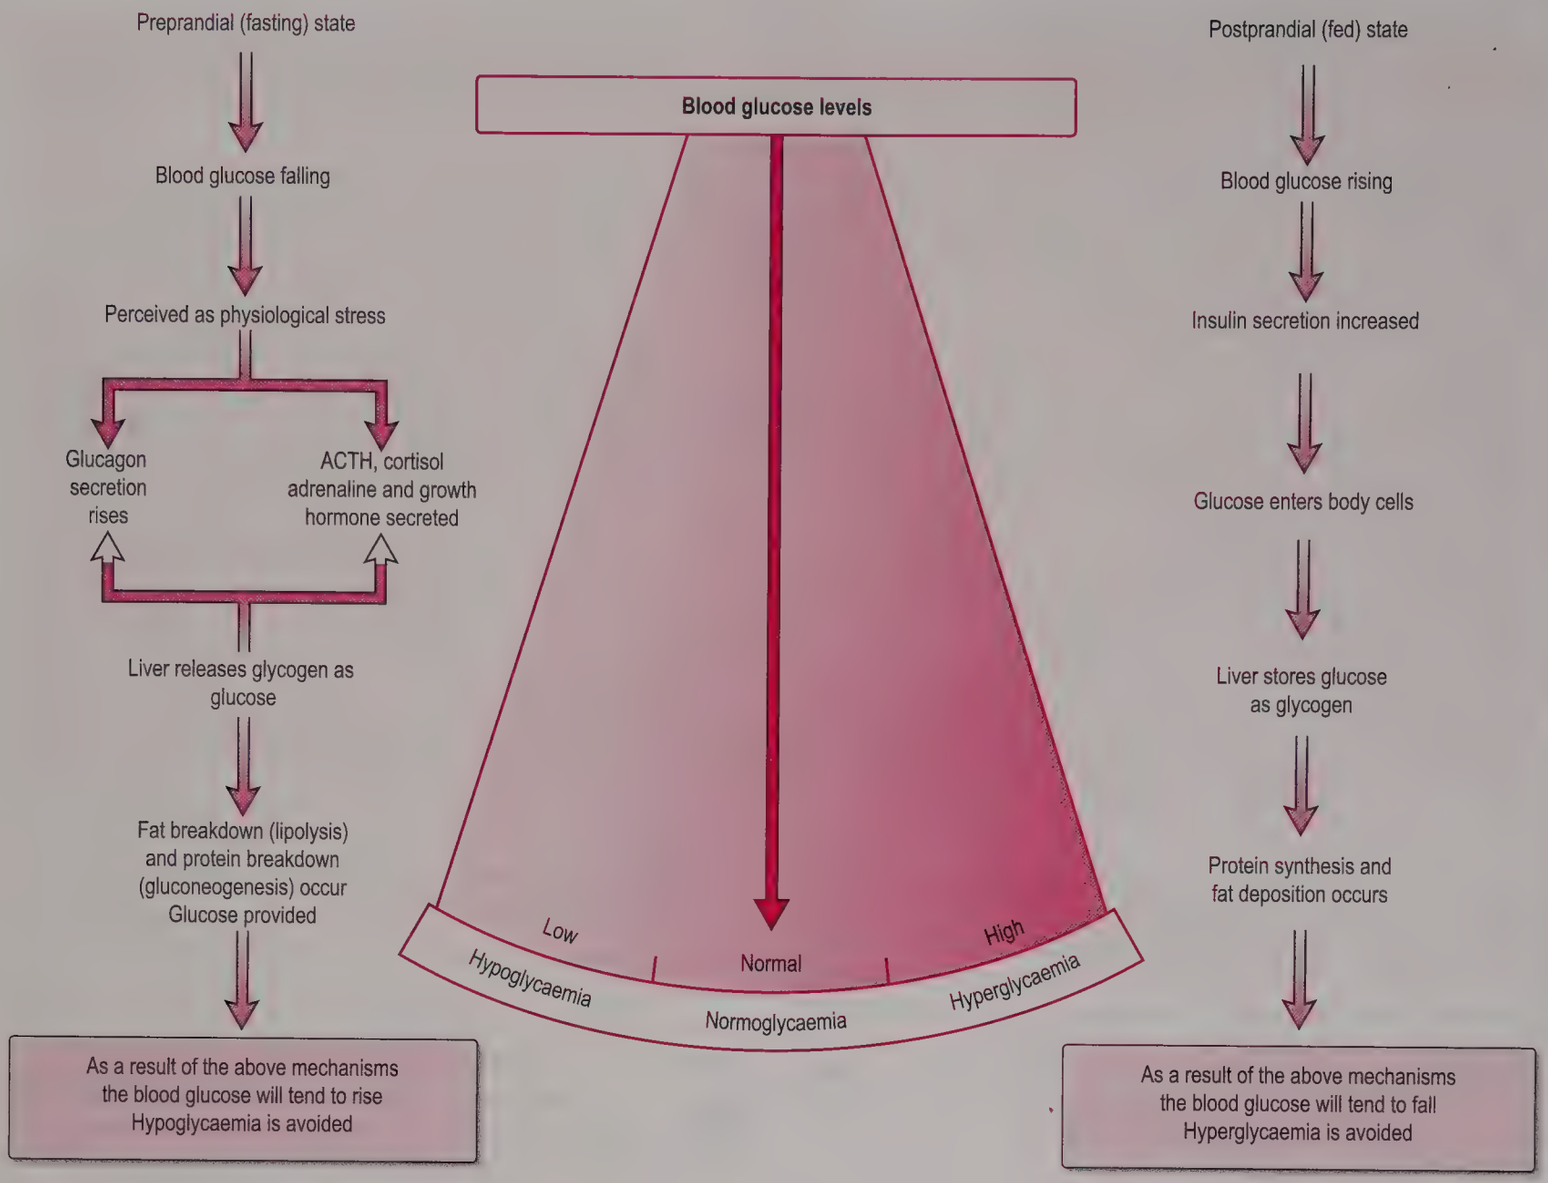

Fig. 5.8 The regulation of blood glucose in health.

by the stressed state. Cortisol causes stored glycogen to be converted to glucose and promotes the breakdown of fat (lipolysis) and protein (gluconeogenesis), thus providing an alternative source of glucose to meet the energy needs of the cells.

The adrenal medulla secretes adrenaline and noradrenaline, which together are known as catecholamines. These 'fight or flight' hormones are catabolic in their action. In response to stress, they place the body and brain in a state of 'high alert', causing blood glucose to rise as glycogen stores are released and fat/protein breakdown occurs. This increases the amount of available glucose and helps to prepare the body to meet increased energy demands.

The liver and skeletal muscle About 60% of absorbed nutrients are laid down as reserves in order to meet energy demands during fasting. Under the influence of insulin, the liver and, to a lesser extent, skeletal muscle can store glucose in the form of glycogen. The liver is also involved in protein and fat synthesis for subsequent storage.

During fasting, or in response to stress, glucagon (and other stress hormones) will promote the release of liver and muscle glycogen in the form of glucose. The liver also contributes to the chemical processes of gluconeogenesis by which body stores of fat and protein are converted to glucose (see Fig. 5.8).

TYPE 1 DIABETES

Aetiology

The pathogenesis of type 1 diabetes is complex and has been the subject of extensive research. It is currently thought that a genetic predisposition to the disease, possibly combined with environmental triggers, activates an autoimmune attack on the pancreatic β cells (see Box 5.4). In type 1 diabetes, insulin secretion is virtually totally absent, resulting in lifelong treatment with insulin.

PATHOPHYSIOLOGY

The process of islet destruction probably begins very early in life and is known to start several years before the clinical onset of diabetes (Watkins 2003). However, individuals often present with initial symptoms when the demand for insulin has been increased, e.g. in response to a physical or psychological stress such as illness, trauma, surgery, pregnancy

Box 5.4

Type 1 diabetes: the genetic link

A child with a mother with type 1 diabetes has a 1–2% increased risk of developing the same type of diabetes by 25 years; the risk is about three times greater if the father has this disease. If both parents have the disease the risk is further increased and genetic counselling should be sought in these rare circumstances (Watkins 2003).

Inherited susceptibility to type 1 diabetes depends on several genes. The strongest link has been traced to the DR3 and DR4 genes in the human leucocyte antigen (HLA) located on chromosome 6 (now called 'type 1 diabetes 1' locus) (Williams & Pickup 1999). Studies have revealed that in identical twins identified as HLA-DR3 'types', and in whom one suffers from type 1 diabetes, there is a high incidence of diabetes mellitus affecting the second twin. The HLA-DR3 group also shows persistent islet cell antibodies, indicating that genetic and immunological (possibly autoimmune) susceptibilities probably coexist. Within the general population it has been found that autoimmune disorders occur more frequently in people identified as HLA-DR3 types.

or bereavement. In such cases, the additional metabolic demands posed by the stressed state can no longer be met by the failing pancreas and symptoms of diabetes become evident for the first time.

Once insulin therapy has been started and good control achieved, the remaining β cell mass can temporarily provide sufficient insulin to meet the body's demands. In this case the external insulin can be reduced or stopped on occasions. Unfortunately, this 'honeymoon period' is short lived and, as the β cell mass reduces further, the symptoms will reappear, necessitating lifelong treatment with insulin.

The effects of lack of insulin The signs, symptoms and clinical features of type 1 diabetes can best be explained in terms of the effects of insulin lack, as follows:

- In the face of insulin lack, body cells are unable to obtain glucose for metabolism.
- Glucose which is unable to enter cells accumulates in the blood, causing an abnormally high blood glucose level — hyperglycaemia.
- Increased amounts of glucose are filtered at the glomeruli. The capacity of the kidneys to reabsorb glucose (the renal threshold for glucose) is exceeded and glucose appears in the urine — glycosuria.
- Glucose is highly osmotic, i.e. it attracts and holds water to itself. As glucose is lost in the urine, large volumes of water are lost with it — polyuria.
- As fluid loss continues, the patient will begin to experience symptoms of dehydration, the most common of which is copious drinking in response to severe thirst — polydipsia.
- The cells' requirements for glucose are not being met. The counter-regulatory response is an increased secretion of glucagon and other stress hormones in an attempt to increase cell glucose.
- Under the influence of these hormones specific mechanisms come into play:
  - — glycogen is converted to glucose and is released by the liver (glycogenolysis)
  - — glucose is produced from the breakdown of body fat and protein (gluconeogenesis)
  - — the patient's appetite may increase (polyphagia).
- These efforts to meet the demands of the cells for glucose have the combined effect of raising the blood glucose even higher.
- Weight loss occurs due to the depletion of body fat and protein stores. This, together with cell deprivation of glucose and fluid–electrolyte imbalance, causes muscle weakness and exhaustion.
- In the absence of insulin, fat breakdown results in the production and accumulation of ketone bodies (β-hydroxybutyric acid, acetoacetic acid and acetone). This leads to ketonaemia and ketonuria. Additionally, acetone excreted by the lungs gives a characteristic sweet, 'pear drop' odour to the breath.
- Ketone bodies are weak acids which release free hydrogen ions to cause the serious condition of metabolic acidosis to develop.
- Excess acidity of the blood leads to corrective respiratory buffering. The patient hyperventilates, i.e. respirations become faster and deeper (Kussmaul's respirations), which is a very useful way of removing H^+ from the blood, i.e. blow off carbon dioxide.
- Uncontrolled lipolysis in the absence of insulin, gluconeogenesis, ketogenesis and glycogenolysis combine to raise the blood glucose level still further, increase osmotic diuresis, and exacerbate dehydration and metabolic acidosis. This is a life-threatening situation known as diabetic ketoacidosis (DKA).
- As a result of these profound biochemical disturbances, the patient may experience nausea and vomiting and, although unexplained, colicky abdominal pain.
- Unless a diagnosis is reached and urgent medical treatment is established, the patient will progress to coma and ultimately to death.

Onset and progress of the disease Although the onset of type 1 diabetes may appear abrupt, the patient may have had undetected clinical signs, such as glycosuria, in the absence of actual symptoms over a period of months. Once symptoms do appear, the disease will usually have a rapid progression. However, there will be variations in severity, some patients being much more acutely ill than others at the time of diagnosis.

The patient with type 1 diabetes may visit their general practitioner (GP) complaining of thirst, an increase in the amount of urine passed and weight loss. They may also complain of feeling exhausted. The GP is likely to have the patient's urine tested for glucose and ketones. Blood glucose will also be measured. The presence of ketonuria and hyperglycaemia combined with symptoms of polyuria and thirst will usually be sufficient evidence upon which to refer the patient to a diabetes consultant. In hospital, following a full assessment, treatment can be commenced and the patient's response to therapy closely monitored. Although most patients are referred to hospital, admission is not automatic. The majority of newly diagnosed patients with

type 1 diabetes should be managed as outpatients under the care of a multidisciplinary diabetes care team giving a collaborative approach to care (Carson 2000).

Recently, care of people with type 1 diabetes has focused on diabetes centres and patients require admission to hospital less often, unless particularly unwell. The members of the diabetes care team in the hospital and community will have specialist knowledge about diabetes management. The central objective of care will be to help the patient acquire the knowledge and skills needed to resume an independent lifestyle. The patient will usually be asked to attend the diabetic outpatient clinic at specified intervals or, if unable to do so, may be visited at home by the diabetes specialist nurse. A shared care approach between community and diabetes specialist centre is essential for the ongoing care, treatment supervision and evaluation of progress of these patients.

TYPE 2 DIABETES

Aetiology

Type 2 diabetes seems likely to be multifactorial. Although these factors are not fully understood, they differ from those thought to cause type 1 diabetes.

Genetic factors leading to susceptibility Type 2 diabetes has a strong genetic component, manifest in the high concordance of diabetes in monozygotic twins, familial clustering and differences in prevalence between ethnic groups (Watkins 2003). One unusual form of type 2 diabetes has a clearly established autosomal dominant form of inheritance. It is non-insulin-dependent, commonly develops in those under 25, and is given the rather anomalous title of 'maturity onset diabetes of the young' (MODY; see British Diabetic Association 1997, Watkins et al 2003).

Age The prevalence of type 2 diabetes rises significantly with increasing age and can be as high as 1 in 10 in the over-70s (British Diabetic Association 1996). Glucose metabolism is known to become less efficient from the third or fourth decade of life onwards and this deterioration accelerates in people over 60 years of age. Whilst this alteration in glucose tolerance may not in itself be pathological, when compounded by other factors (see below) it can contribute to the onset of symptoms of diabetes.

Insulin resistance In type 2 diabetes, tissue sensitivity to insulin may decline. The result is that hyperglycaemia can occur even when the circulating levels of insulin are normal or raised. Several reasons have been suggested for the development of insulin resistance: these include resistance in peripheral tissues in obesity, the effects of ageing and the presence of anti-insulin antibodies in the blood. Whatever the cause, the result is the inefficient use of available insulin.

β cell deficiency There is a markedly reduced first phase insulin secretion in response to glucose and, in established diabetes, an attenuated second phase. Insulin pulsatility is also abnormal, thereby reducing tissue insulin sensitivity. In healthy individuals, insulin is secreted in a pulsatile manner during both the postprandial (after meal) and basal (between meals) periods. These pulses are separated from the insulin peaks induced by food (Williams & Pickup 1999).

Obesity Obesity is known to induce insulin resistance in body cells. However, only a minority of obese people develop type 2 diabetes and only around 60% of people with the disorder are obese. Glucose tolerance decreases as weight increases and can be reversed as weight loss occurs. Fat distribution would appear to be significant in that there is a relationship between central obesity and diabetes. Research data from Wei at al (1997) indicate that waist circumference is the best obesity-related predictor of type 2 diabetes, suggesting that distribution of body fat, especially abdominal localisation, is a more important determinant than the total amount of body fat.

Ethnic and environmental factors There are wide geographical variations in the incidence of type 2 diabetes. In western Europe, around 3% of the population develop type 2 diabetes, but in certain circumscribed societies incidences of up to 40% have been reported, e.g. among the Pima Indians of North America and the Nauru Islanders of the Pacific, where gross obesity is also very common. These remarkably high prevalences are probably due to the exposure of genetically isolated, diabetes-predisposed populations to influences such as a 'Westernised' diet and reduced physical activity. In many developing and newly industrialised nations, type 2 diabetes is thought to be epidemic (Griggs 1998). In the UK, the prevalence of type 2 diabetes is particularly high in Asian and Afro-Caribbean people, with 20% of Asians and 17% of Afro-Caribbeans over the age of 40 known to have type 2 diabetes (Watkins 2003). This presents a considerable health burden in some inner urban areas.

PATHOPHYSIOLOGY

Type 2 diabetes usually presents in those over the age of 40 and most commonly in people over 60. Typically the patient is overweight. The signs, symptoms and clinical features of type 2 diabetes, although still marked, are less severe than those of type 1 diabetes and are due to the more gradual onset and the effects of hyperglycaemia arising from a relative deficiency of insulin. In type 2 diabetes, there is still some insulin being secreted; as a result, ketogenesis is inhibited and, as the hyperglycaemia is less severe, dehydration is also much less common.

The effects of a relative lack of insulin are as follows:

1. *Hyperglycaemia-related symptoms* — nocturia, polyuria and thirst may develop gradually. The patient, who is often obese, may initially be gratified to note that weight loss is occurring.
2. *Genital or oral fungal infections* — candidal infections are common and result in the distressing symptoms of pruritus vulvae in the female and balanitis in the male. The sugar-rich urine around the genitalia appears to provide the yeast organism with favourable conditions in which to multiply.
3. *Staphylococcal skin infections* — these commonly result in boils and abscesses, and may provide the initial stimulus for the patient to visit their GP.

Table 5.9 Diagnostic glucose concentrations

Diagnosis	Venous whole blood (mmol/L)	Capillary whole blood (mmol/L)	Venous plasma blood (mmol/L)
Diabetes mellitus			
Fasting	≥6.1	≥6.1	≥7.0
2 h postprandial	≥10.0	≥11.1	≥11.1
Impaired glucose tolerance (IGT)			
Fasting and	<6.1 and	<6.1 and	<7.0 and
2 h postprandial	≥6.7	≥7.8	≥7.8
Impaired fasting glycaemia (IFG)			
Fasting and	≥5.6 and <6.1	≥5.6 and <6.1	≥6.1 and <7.0
2 h postprandial	<6.7	<7.8	<7.8

In the absence of diabetic symptoms, abnormality in both 2 h postprandial and fasting blood sugar is required to establish the diagnosis of diabetes mellitus. The 2 h postprandial test should be performed following the oral glucose tolerance test using 75 g glucose load (WHO 1999).

4. *Non-specific symptoms* — such as tiredness and lethargy — are also frequently reported. The cause is uncertain, but altered fluid and electrolyte balance may be responsible. Visual disturbance may occasionally be reported, as hyperglycaemia may cause opacity of the optic lens and accommodation may be affected by dehydration of the lens fluid.

Symptom-related complications At the time the patient first seeks medical attention, evidence of vascular and neurological complications such as proteinuria, sexual dysfunction, retinopathy and peripheral neuropathy may already have developed. Such patients have probably had asymptomatic diabetes with persistent hyperglycaemia for several years prior to diagnosis.

Onset and progress of the disease Type 2 diabetes may present in several ways. A diagnosis will usually be made on the evidence of glycosuria and a fasting or random venous plasma blood glucose concentration of more than 7.0 mmol/L and 11.1 mmol/L, respectively, in laboratory tests. The presence of symptoms and an elevated venous plasma blood glucose concentration of >11.1 mmol/L together are diagnostic of diabetes (WHO 1999) (see Table 5.9).

Ketonuria is not a feature of type 2 diabetes, as ketogenesis is inhibited by the presence of even small amounts of insulin.

Asymptomatic glycosuria may be discovered as an incidental finding, e.g. during a routine medical examination. Such a finding would normally prompt capillary and then venous blood glucose analysis. In the absence of symptoms, these results should be confirmed by repeat testing on a different day. If the fasting or random values are not diagnostic, a 2 h oral glucose tolerance test should be carried out (WHO 1999).

IMPAIRED GLUCOSE TOLERANCE (IGT) AND IMPAIRED FASTING GLYCAEMIA (IFG)

IGT and IFG are recognised as stages in the natural history of diabetes rather than as a class of diabetes (WHO 1999). It is not clear why some people may have blood glucose results at or just above the upper limit of 'normal'. Inconclusive results in the absence of symptoms may not necessarily be judged abnormal. For example, since glucose tolerance is known to decline with age and obesity, such factors would be considered in the overall assessment. To help determine to which category the patient should be assigned, an oral glucose tolerance test may be carried out.

It is known that some people with IGT or IFG will go on to develop diabetes mellitus and that they may have a greater risk of developing atherosclerosis.

Onset and progress of the disease Although it is clearly desirable that people should be spared the negative consequences of being inappropriately labelled as 'diabetic', they should nonetheless have access to regular medical screening and should be offered information about the prevention of atherosclerosis and its consequences (see Ch. 2). These health promotion functions will normally be carried out by the practice nurse or the GP and community nursing staff, although in some areas the patient may also be asked to attend a diabetic clinic for an annual review.

IGT has implications for women who are planning to conceive. Current evidence suggests that it is important to correct hyperglycaemia and ensure tight control of blood glucose prior to conception to reduce the risk of fetal abnormality (Williams 2003). Pre-conception advice should be made available and the patient's blood glucose brought within normal limits before conception and closely monitored throughout her pregnancy. Care of this kind may be provided at a combined 'diabetic–obstetric' clinic.

DIABETES MELLITUS SECONDARY TO OTHER DISEASES AND CONDITIONS

PATHOPHYSIOLOGY

In type 1 diabetes the fault is to be found in the islets of Langerhans where β cell output of insulin is either absent or insufficient to meet the needs of the cells. In type 2 diabetes, the islet cells may still produce insulin, but in insufficient amounts, or insulin function may be hindered

in some way. In contrast, hyperglycaemia in type 2 diabetes may be iatrogenic, i.e. occurring as a side-effect of certain medications, or be secondary to other disease.

Some medicines, notably steroids, have a diabetogenic effect. The thiazide group of diuretics have been known to worsen established diabetes and in some older patients may actually hasten the onset of the disease. Excess secretion or administration of glucocorticoids, aldosterone, catecholamines or growth hormone will have a diabetogenic effect and can result in hyperglycaemia. Diabetes may therefore be a feature of Cushing's syndrome, Cushing's disease, phaeochromocytoma, primary aldosteronism and acromegaly (see Ch. 5, Part 1).

Pancreatitis and carcinoma of the pancreas may greatly reduce the number of functioning β cells and result in impaired insulin secretion. Chronic hepatic disease will have considerable consequences for carbohydrate, protein and fat metabolism. Glycogenesis and glycogenolysis may both be impaired and consequently hyper- and hypoglycaemia frequently feature in chronic disorders of the liver. Chronic renal failure can cause impaired glucose tolerance and insulin resistance, although the underlying mechanism by which this occurs remains unclear.

There are other rare genetic disorders which give rise to secondary diabetes (Williams & Pickup 1999). Friedreich's ataxia, an inherited disorder of balance and movement, is one example. Another is a condition with an autosomal character which is referred to by the acronym DIDMOAD (Wolfram's syndrome) as it incorporates **d**iabetes **i**nsipidus, **d**iabetes **m**ellitus, **o**ptic **a**trophy and **d**eafness.

Onset and progress of diabetes mellitus are characterised by hyperglycaemia with glycosuria. Associated features such as thirst and polyuria may be experienced, and in hepatic disease the patient may also experience hypoglycaemic episodes, with symptoms such as trembling, sweating and clouding of consciousness. The underlying disease process will influence the nature and severity of the symptoms. Urinalysis and blood glucose will be monitored and dietary adjustment may be prescribed; this may be combined with oral hypoglycaemic medication or insulin therapy.

MANAGEMENT STRATEGIES IN DIABETES MELLITUS

Diabetes care in the UK and Europe has been strongly influenced by the St Vincent declaration (Krans et al 1992). Such was the concern over the duration and quality of life of people with diabetes, that the countries concerned pledged to deploy resources for its resolution and to intensify research into prevention and cure of diabetes and its complications.

Diabetes management requires a multidisciplinary approach. For those patients who are not acutely ill at the time of diagnosis, management may be provided entirely within the community setting. However, many patients are more acutely ill at the time of onset and require hospital care to allow close monitoring of the effects of early treatment.

The professionals in the diabetes care team will share common goals for care, each contributing expertise in accordance with the patient's individual needs. It is worth remembering, however, that the patient is the most important member of the diabetes care team, and full participation by the patient is necessary to achieve the following aims:

- Attainment and maintenance of normoglycaemia
- Monitoring of response to therapy
- Prevention and detection of diabetes-associated complications
- Facilitation of self-care through education
- Promotion of social and psychological adjustment.

ATTAINING AND MAINTAINING NORMOGLYCAEMIA

There are three main therapeutic approaches to this management:

- dietary therapy
- oral hypoglycaemic therapy
- insulin therapy.

NUTRITIONAL ADVICE FOR PEOPLE WITH DIABETES

Appropriate dietary advice is essential in the effective management of diabetes. The aim is to give people with diabetes information to enable them to make informed choices about the type and quantity of food they eat. The Clinical Standards Advisory Group recommend that all newly diagnosed patients should be offered a consultation with a registered dietitian within 4 weeks of diagnosis (Clinical Standards Advisory Group 1994). Dietitians are skilled in translating nutritional guidelines into practice. Dietary recommendations are the same as those given to the general population (see Ch. 22).

Current nutritional standards are summarised in Table 5.10.

Carbohydrate

All food that contains carbohydrate (CHO) will cause blood glucose levels to rise. The extent of the glycaemic response (the rise in blood glucose after eating) caused by food varies. This is affected by the amount of food consumed, the source of the carbohydrate such as glucose or starch, the cooking method and other components of the meal.

The glycaemic index was devised to help explain some of the differences caused by different carbohydrates on blood glucose levels. It allows the glycaemic effect of foods to be ranked against a standard such as glucose. Foods with a high glycaemic index cause a rapid rise in blood glucose levels and should be used sparingly. Lower glycaemic index foods cause a more gradual glycaemic response and if taken as part of a meal can lower the glycaemic effect of the whole meal (Dyson 2004).

Table 5.11 shows examples of the glycaemic index of certain foods.

Sucrose is no longer considered to be any more harmful to blood glucose levels than other CHO. However, it is still

Table 5.10 Current nutritional standards

Component	Comment
Protein	Not more than 1 g/kg body weight
Total fat	Less than 35% of energy intake
Saturated and transaturated fat	Less than 10% of energy intake
n-6 polyunsaturated fat	Less than 10% of energy intake
n-3 polyunsaturated fat	Eat fish, especially oily, once or twice weekly. Fish oil supplements not recommended
Monounsaturated fat	10–20% of energy intake
Total carbohydrate	45–60% of energy intake
Sucrose	Up to 10% of daily energy
Fibre	No quantitative recommendation
Vitamins and antioxidants	Encourage food rich in these
Salt	6 g or less of sodium chloride per day

Data from Diabetes UK (2003b).

an empty calorie source and harmful for teeth and should be taken sparingly as part of a meal.

Fructose Fruit consumption should be encouraged as fructose has a low glycaemic effect. People with diabetes should be encouraged to eat five servings of fruit and vegetables per day. These foods are a good source of soluble fibre, which is also found in oats, pulses, nuts and grains. Excessive fruit intake can significantly increase blood glucose levels and therefore a sensible intake level should be encouraged.

Carbohydrate restriction is not recommended but some measure of control may be discussed, particularly in those with type 1 diabetes. Carbohydrate can be measured in 10 or 15 g portions or exchanges. Historically, dietitians advised people to measure their intake in 10 g exchanges to rigidly control their intake. This approach became less common in the 1980s when advice focused more on healthy eating guidelines. Quantifying CHO is now being used more frequently in view of the Dose Adjustment for Normal Eating (DAFNE) project findings (DAFNE Study Group 2002). The DAFNE education programme teaches people to adjust their insulin injections to fit their lifestyle, instead of adjusting their lifestyle to a particular insulin regimen, thus improving glycaemic control and quality of life in people with type 1 diabetes. However, the emphasis is markedly different, with the educated patient adjusting the amount of insulin given for the amount of carbohydrate consumed, irrespective of the source of CHO.

Table 5.11 Glycaemic index examples

Low GI	Intermediate GI	High GI
Porridge	Croissants	Cornflakes
Most fruit	Cheeries	White/wholemeal bread
Granary bread	Potatoes	Chips
Pasta	Pineapple	Jelly babies
Beans	Couscous	Cornchips
Pulses	Sucrose	Honey
Yoghurt	Full fat ice cream	Glucose

Fat

Fat should not be overlooked when providing dietary advice to people with diabetes. It is the major energy source of the diet. A reduction in intake is generally necessary for weight control. All sources of fat contain the same number of calories per gram. It is a common misconception that fat from vegetable sources contains fewer calories than that from animal sources but this is not the case. It does, however, have less atherogenic potential than animal fats and a high intake of saturated fat, which is mainly found in animal products, is linked to elevated cholesterol levels (Segal-Isaacson et al 2001). People with diabetes should generally be encouraged to eat less fat and, where possible, to choose fat from monounsaturated sources (see Table 5.12).

Weight control

Weight control is particularly important in people with type 2 diabetes, where obesity is a well-recognised problem. Losing weight is notoriously difficult. A loss of 1–2 kg/month by means of a 500–600 kcal reduction in intake per day is considered to be successful progress (Scottish Intercollegiate Guidelines Network (SIGN) 1996). Advice on increasing physical activity should also be included.

Table 5.12 Sources of fat

Type of fat	Food source
Saturated fat	Fatty meat Butter Cheese Cream Pastry Baked products, e.g. cakes and biscuits
Polyunsaturated fat	Sunflower seeds and oils Corn oil Oily fish Some soft margarine
Monounsaturated fat	Olive oil Most nuts Avocado Grapeseed oil Peanut oil (ground nut) Some soft margarine

Alcohol

It is not necessary for people with diabetes to avoid alcohol completely. As with the adult population in general, a maximum of 14 units of alcohol per week for women and 21 units for men should not be exceeded. Care should be taken by those treated with insulin to avoid hypoglycaemia when drinking by ensuring adequate CHO intake. Those who are overweight should be advised as to the high calorie content of alcohol.

For a more in-depth review of nutritional advice for people with diabetes, see Diabetes UK (2003b).

ORAL HYPOGLYCAEMIC THERAPY

Oral hypoglycaemic medication can be effective only if β cells are capable of secreting some insulin. This form of therapy is therefore used exclusively for patients with type 2 diabetes.

In the absence of persistent symptoms, dietary treatment should continue for at least 3 months before drug therapy is commenced. Oral hypoglycaemic therapy would then be reserved for patients with type 2 diabetes who have persistent hyperglycaemia despite a period of dietary adjustment (United Kingdom Prospective Diabetes Study Group (UKPDS) 1998a, DH 2001, SIGN 2001). Five main groups of oral agents are available for use in the UK (see Table 5.13).

The sulphonylureas

Mode of action These drugs stimulate the β cells of the pancreas to secrete more insulin in response to blood glucose levels, increase insulin sensitivity and reduce the hepatic metabolism of insulin.

Side-effects The most common side-effect is hypoglycaemia. This can be minimised by starting the patient on the lowest dose possible and gradually increasing the amount over a period of weeks. As sulphonylureas lower blood glucose, it is important that both the patient and carers are aware of the risks of hypoglycaemia. The medication should be taken 20–30 min before food. The relationship between exercise, medication and diet will form an important part of the patient education programme.

Other side-effects include weight gain, gastrointestinal disturbance and skin rash. Facial flushing following alcohol ingestion can occur with chlorpropamide. It should be noted that the effect of sulphonylureas is potentiated by other protein-bound medication, e.g. warfarin. This interaction increases the amount of available sulphonylurea and may therefore cause hypoglycaemia.

The biguanides

Metformin

Mode of action Metformin reduces glucose absorption in the gut, reduces peripheral insulin resistance and inhibits liver glucogenesis. Guidelines recommend first-line use of metformin following UKPDS findings of a survival benefit in this group (UKPDS 1998a, SIGN 2001).

Side-effects Gastrointestinal upset is the most common. Medication-induced hypoglycaemia is very uncommon

Table 5.13 Oral hypoglycaemic agents

Drug	Dose range (mg/day)	Points to note
Sulphonylureas		
Gliclazide	40–320	Stimulation of β cells to secrete insulin and increases insulin sensitivity
Glipizide	2.5–20	
Glimepiride	1–6	
Gliquidone	15–180	
Tolbutamide	500–2000	
Chlorpropamide	100–500	Avoid use in older people: risk of hypoglycaemia
Glibenclamide	2.5–15	
Biguanides		
Metformin	500–3000	Inhibition of liver glucogenesis. Increases peripheral uptake of insulin. Treatment of choice for overweight patients with type 2 diabetes. Contraindicated in renal, liver and cardiac disease
Prandial glucose regulators		
Repaglinide	0.5–16	Beta cell stimulation. Shorter acting than sulphonylureas — fewer hypos. Take only at meals
Nateglinide	60–540	
Thiazolidinediones		
Rosiglitazone	4–8	Combats insulin resistance. Increases insulin sensitivity. Increases peripheral uptake of glucose. Reduces hepatic liver production. Contraindicated in heart failure and poor liver function. Used in conjunction with other agents
Pioglitazone	15–30	
Alpha glucosidase inhibitor		
Acarbose	50–600	Delays carbohydrate absorption. Poorly tolerated due to gastrointestinal side-effects

with biguanide therapy as is vitamin B_{12} malabsorption. Lactic acidosis is a rare occurrence but should be noted and metformin is contraindicated in patients with renal, liver and severe cardiovascular disease or serious systemic illness.

Prandial glucose regulators

Mode of action These drugs are designed to stimulate extra insulin release to coincide with meal digestion. They should be taken up to 15 min before each meal and are rapidly absorbed. As they are also quickly eliminated from the body, the insulin effect is short lived, thus reducing the risk of hypoglycaemia.

Side-effects Side-effects are uncommon, but can include gastrointestinal upset, nausea and skin rash.

Thiazolidinediones

Mode of action The thiazolidinediones (glitazones) tackle insulin resistance and act by increasing insulin sensitivity within the peripheral tissue, increasing peripheral glucose uptake and reducing hepatic glucose production. They are used in conjunction with other oral agents.

Side-effects can include weight gain, headache and fluid retention. Use of thiazolidinediones is therefore not advised in patients with cardiac failure or poor liver function.

Alpha-glucosidase inhibitor

Acarbose is poorly tolerated due to prominent side-effects and is now less commonly used. However, it can be used alone or in combination with other oral agents.

Mode of action Acarbose acts by delaying the breakdown of starch and sucrose into monosaccharides which can be absorbed in the small intestine. In the patient with diabetes, the effect is to reduce the postprandial peak in blood glucose.

Side-effects The most common side-effects are flatulence and diarrhoea.

INSULIN THERAPY

For all patients with type 1 diabetes, insulin therapy is essential to maintain life, and will be required throughout life. Insulin cannot be given orally as its protein structure would be inactivated by digestive enzymes. Parenteral administration is therefore necessary and normally takes the form of subcutaneous (s.c.) injection.

In patients with type 2 diabetes, glycaemic control deteriorates as the condition progresses and 30% of patients will eventually require insulin therapy (UKPDS 1998a). Others may require insulin therapy during periods of stress or illness but this does not change the classification of their disorder.

The objectives of insulin therapy are:

- to maintain blood glucose within normal limits
- to relieve hyperglycaemia-associated symptoms
- to correct metabolic/biochemical disturbances
- to prevent diabetes-associated complications.

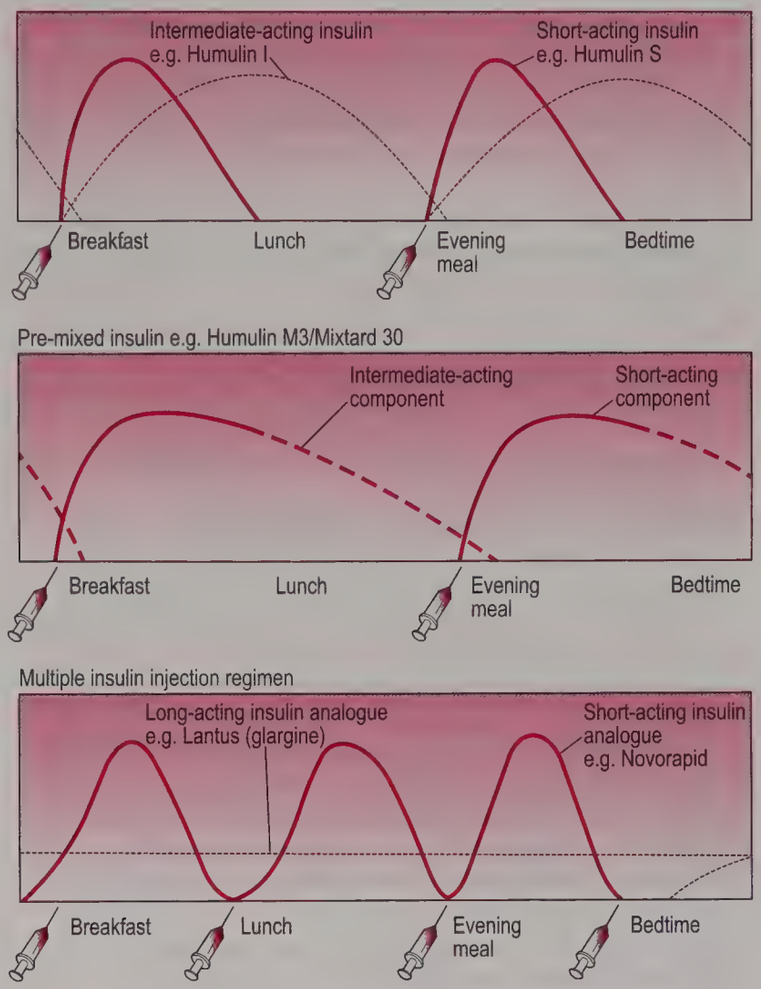

Fig. 5.9 Duration of action for short-, intermediate- and long-acting insulins and rapid- and long-acting analogue insulins.

Types of insulin

In the past, all insulin preparations were derived from animal sources, mainly beef and pork. Genetic engineering and other advanced techniques have resulted in the production of biosynthetic human insulin and purified or highly purified pork and beef insulin.

Throughout western Europe, biosynthetic human insulin is now the main source. Insulins are manufactured in various forms: soluble, isophane, insulin zinc suspension, analogue and ready-mixed in combination.

Duration of action

There are many insulin preparations on the market. These may be categorised as rapid-acting analogue, short-acting, intermediate-acting, long-acting (including long-acting analogue) and biphasic (see Fig. 5.9).

Rapid-acting analogue insulin (Humalog, NovoRapid) These are clear solutions. They have a rapid onset of action and therefore should be injected 0–15 min before meals. They are also licensed to be given up to 15 min after a meal. This may be a useful point if the patient is unsure of how much they will eat, perhaps as a result of illness or if the patient is a young child. The length of action is 4–5 h, and therefore this type of insulin is most commonly used within a basal bolus, multiple injection regimen. Its use

is associated with lower postprandial hyperglycaemia, reductions in HbA1c (see monitoring methods for explanation of glycosylated haemoglobin — HbA1c, p. 202) and, when compared to soluble, short-acting insulin, fewer hypoglycaemic episodes (Owens et al 2001).

Short-acting insulins (Actrapid, Humulin S) These are also clear solutions. The onset of action is delayed for 30 min when injected subcutaneously; their maximal effect occurs in 3–4 h but can last up to 8–10 h.

Rapid-acting analogue insulin and short-acting insulin may be prescribed in the following ways:

- *twice daily* — given in the morning and evening in combination with an intermediate-acting insulin (Insulatard, Humulin I)
- *by multiple injection regimen* — preprandial or postprandial injections with the dose adjusted to correspond with carbohydrate intake. This is usually combined with either intermediate-acting insulin or long-acting analogue insulin (glargine), which would be given once daily, usually being administered at breakfast or bedtime
- *by continuous s.c. infusion using an insulin pump* — this allows for a basal or background, continuous release of insulin and the ability to administer bolus doses when appropriate; patients undertaking pump therapy will receive intensive instruction on adjustment of basal rates, bolus doses and carbohydrate counting
- *intravenously* — during acute metabolic emergencies when immediate insulin effect is required, e.g. in diabetic ketoacidosis (DKA).

Intermediate- and long-acting insulins are cloudy in appearance. Their onset of effect is delayed for 1–2 h. The intermediate-acting insulins achieve maximum effect in 4–6 h and have a duration of action of 12–20 h. Long-acting insulins have their maximum effect in 8–12 h and a duration of action of up to 36 h.

Intermediate-acting insulins come in two main forms:

- Isophane insulin comes as a suspension of insulin with protamine (Insulatard, Humulin I). This type of insulin may be used in combination with short-acting insulin. It provides a stable solution in which each insulin retains its own pharmacological properties even when mixed and stored in the same syringe.
- Lente insulins are combined with zinc in two forms: amorphous 30% and crystalline 70%. The zinc binds the insulin, and as a result onset of action is delayed and the duration extended. Lente insulins are now rarely used due to the introduction of new insulins with more suitable action profiles.

Intermediate-acting insulins can also be used in conjunction with oral hypoglycaemic agents, and given at bedtime to control fasting hyperglycaemia in patients with type 2 diabetes. This regimen can help to prevent weight gain but may require large doses to achieve effective control, especially at the post evening meal glucose test (Yki-Jarvinen et al 2000).

Long-acting insulin suspensions, e.g. Ultratard, have a greatly extended period of action of up to 36 h. They have been used in the past in multiple injection regimens and also as once daily injections. With advances in insulin production, the use of these insulins is rare as more people are prescribed long-acting analogue insulin.

Long-acting analogue insulin (glargine) is more slowly absorbed, providing a continuous level of insulin over a 24-h period. It is a true basal insulin with a peakless action profile, which therefore reduces the risk of hypoglycaemia. It is a once-daily insulin which is used in conjunction with a rapid-acting analogue insulin in a multiple injection regimen. It may also be used in conjunction with oral hypoglycaemic agents in the treatment of people with type 2 diabetes.

Biphasic insulin These ready-mixed insulins include a combination of short-acting, e.g. Humulin M3 or Mixtard 30, or rapid-acting analogue, e.g. Humalog Mix 25 or Novomix 30, and intermediate-acting insulin in set ratios. Most are now available in pen form, making the administration of insulin more user friendly.

5.7 Using the *British National Formulary* or a current pharmacology text, e.g. Greenstein & Gould (2004), draw up a table which illustrates examples from rapid, short-, intermediate- and long-acting and biphasic insulins and indicate the species (source), onset and duration of action.

Administering insulin

The overall aim in administering insulin therapy is to achieve the best possible control of blood glucose throughout the 24-h period. The treatment should mimic the physiological response to normal variations in blood glucose. During the fasting state, there is a continual but low secretion of insulin. Following meals, a surge in blood glucose results in increased insulin secretion.

Frequency

To mimic normal blood glucose fluctuations, a single injection of insulin with a 24-h period of action, such as glargine, could be given once daily in combination with rapid-acting insulin with a short (4–5 h) duration of action, such as NovoRapid, before each meal. This multiple injection system has considerable advantages, not least of which are patient autonomy and flexibility of mealtimes and meal size. Patients using this system will carry an insulin injecting device in the form of a pen. This allows administration of insulin to be quick and discreet, enabling adaptability for the day-to-day changes in the patient's activity levels, eating pattern and lifestyle. This system is most effective if blood glucose levels are regularly monitored and patients are taught to adjust diet and insulin accordingly: the system does not, therefore, suit everyone. For many patients, twice-daily injections remain the preferred regimen, whereas some, especially older patients, who have perhaps been required to progress to insulin from diet and/or oral therapy, will be more willing to accept once-daily injections.

Mixing insulin

It is not advisable to mix zinc-based insulins and soluble insulins in a syringe for later use, as free zinc in the suspension can bind to the soluble insulin, extending the onset and duration of action. The injection should be given just

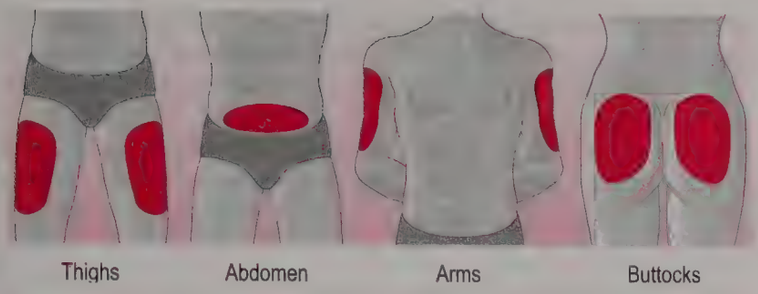

Fig. 5.10 Suitable injection sites for insulin. Repeated injections in the same area may cause pitting or lumpiness of the skin.

after preparation. This problem does not arise with isophane insulins as they do not contain zinc. Free mixing of two insulin types in this way is rare now with the availability of such a wide range of premixed biphasic insulins.

The insulin dose will vary from patient to patient according to carbohydrate intake and insulin sensitivity or resistance, and will take account of the patient's blood glucose levels, lifestyle, and growth and development needs. The patient and carers should receive information regarding the timing of injections in relation to food intake, as this differs depending on insulin type and is important in relation to avoiding hypoglycaemia. Information should also be provided about how to achieve a balance of food, exercise and insulin to avoid detrimental swings in blood glucose.

Injection sites

Insulin is given by s.c. injection. The most common sites for injection are the upper thighs and the abdominal wall. Patients can also use the outer aspect of the upper arms and buttocks but this may prove difficult when attempting to pinch up the skin. Overuse of one site can lead to lipohypertrophy, loss of sensitivity and impaired or erratic absorption of insulin. For this reason 'site rotation' is advised (see Fig. 5.10). Insulin is more rapidly absorbed from the abdomen and therefore the thighs are more useful for evening injections.

Injection technique

In the home environment there is no need to cleanse the skin with alcohol prior to injection. However, the site should be visibly clean. A mound of skin should be gently pinched up before injection to avoid intramuscular injection. The skin should not be pinched if 5 mm or 6 mm needle is used. The syringe or pen device should be held as illustrated in the appropriate device leaflets and the needle inserted straight into the subcutaneous tissue at a 90° angle. Insulin syringes and pen needles currently in use in the UK have a variety of needle lengths and gauges, and it is important to select the appropriate needle for the body weight of the patient to ensure a subcutaneous injection.

For further information on injection technique and pen use, see MacKinnon (2002).

The insulin should be injected steadily and the needle held in position for a further count of at least 6 s before withdrawing smoothly.

For a guide to insulin pens and needles, see Diabetes UK (2003b).

The care setting

The patient with type 1 diabetes may be managed in the primary care setting provided adequate supervision and support can be given to both patient and family during the early stages of treatment. It is still common for initial stabilisation on insulin to take place within the hospital diabetes unit and for outpatient attendance to be advised to allow for regular screening for diabetes-related complications. If ketoacidosis or dehydration is present, management in hospital will be essential.

MONITORING RESPONSE TO THERAPY

METHODS

The methods used for monitoring glycaemic control include:

- urinalysis
- blood glucose monitoring
- glycosylated haemoglobin
- body weight monitoring.

Urinalysis

Urine tests are performed to detect the presence of glucose and ketones. In order to screen for possible renal complications of diabetes mellitus, urine may also be tested for protein. Testing the urine for glucose is not completely accurate as it does not reflect the current blood glucose level. The urine may have remained in the bladder for some time before micturition and may therefore test high for glucose while the blood glucose may well be normal or low. In addition, the absence of glycosuria merely indicates a blood glucose level below the renal threshold for glucose, which in most people is around 10 mmol/L. Urinalysis cannot therefore detect hypoglycaemia. If there is any reason to suspect that the patient is suffering from, or is at risk of, episodes of hypoglycaemia, then instruction in blood glucose monitoring should be considered. Fewer people with diabetes are now being taught urine testing in the hospital setting.

Equipment

Chemically impregnated dipsticks (Multistix) are the usual means of urine testing on admission to hospital. Ketostix should also be used for the measurement of ketones. The manufacturer's instructions for use and storage of urine testing materials must be followed precisely.

Recording

Urinalysis results should be accurately recorded on the appropriate chart.

Blood glucose monitoring

Blood glucose monitoring is the most widely used method of testing glucose levels. Routine glucose measurement should be by near-patient blood testing, i.e. a blood glucose test performed at the patient's bedside on a suitable meter.

Advantages

Blood glucose monitoring offers increased patient involvement in diabetes management and helps to improve day-to-

day glycaemic control. It is used by patients to adjust their insulin levels, assess if blood sugar levels are low for driving or exercise and monitor the effect of certain amounts and types of food eaten (DAFNE 2002). It can also give warning of impending metabolic crisis and guide subsequent intervention.

Blood glucose monitors are inexpensive and often provided free from diabetic clinics. Each model has different functions to suit the individual patient's capabilities. Some have integrated test strips with capillary-fill dosing, most have a large memory store for downloading results and all come with quality control solution to check the accuracy of the test.

Disadvantages

Blood glucose monitoring requires a fair degree of manual dexterity, visual acuity, cognitive ability and motivation. For severely visually impaired individuals, there are talking meters which can be purchased; patients require intensive training from a diabetes specialist nurse in the use of these devices. Although expensive, this is justified because of the independence gained by the patient. Near-patient testing in a hospital setting requires a standardised system throughout, with a quality assurance programme in place involving internal and external quality control. This is often more successful if there is a diabetes link nurse system in place within the hospital (DH 1996).

Blood glucose measurement

Equipment

This includes:

- a spring-loaded finger-pricking device
- a blood glucose meter and test strips — for some patients, a blood ketone meter combined with a blood glucose meter and test strips.

Some patients with erratic blood glucose levels may require continuous monitoring, measuring interstitial glucose levels every 10 s, using a sensor inserted under the skin of the abdomen. One example of these devices is the MiniMed Continuous Glucose Monitoring System which can be used to detect hypoglycaemia and provide a profile of glucose levels over a 24-h period. It is used to help improve glycaemic control.

Frequency

For patients with type 1 diabetes, preprandial and pre-bed tests, with the occasional postprandial test, can provide important feedback and aid learning for all seriously motivated people with diabetes and can be an essential tool in achieving tight diabetic control (Watkins 2003).

Method

The hands should be washed to avoid any contamination of the test strip. Blood of sufficient quantity should be obtained and the procedure detailed in the manufacturer's directions should be followed precisely (Craddock 1996). If the test is conducted by a health care professional, gloves should be worn.

Blood glucose measurement provides a simple and, if performed correctly, reliable method of monitoring glycaemic control. Recording the results may be by using the meter memory system or may be written into the patient's monitoring diary. In the hospital ward setting, results recorded on a chart should be regularly monitored. The nurse or patient carrying out the test should know the target levels for which to aim, usually 4.5–7.7 mmol/L before meals, 6.0–9.0 mmol/L after meals and 7.0–9.0 mmol/L at bedtime (Watkins 2003).

For further information on blood glucose measuring systems, see Batki et al (1998).

Glycosylated haemoglobin estimation (HbA1c)

Glucose in solution binds to haemoglobin by a process of glycosylation. The rate at which proteins bind to glucose is directly related to the current glucose concentration in the blood. The blood proteins in which glycosylation is most readily measured are haemoglobin, albumin and fructosamine. The normal ranges vary according to the laboratory technique and reference ranges should therefore be provided by the laboratory undertaking the test.

Advantages

Measurement of glycosylated haemoglobin provides an independent check of other measures of glycaemic control. It gives an indication of control over a period of time, normally 2–3 months, and not merely a one-off recording as in plasma glucose estimation. Additionally, it provides a tool with which to assess the effects of interventions such as diet, medication or education.

Disadvantages

Anything which interferes with normal haemoglobin levels, such as haemorrhage or anaemia, could potentially distort glycosylated haemoglobin results. Similarly, conditions which influence serum albumin levels, such as renal or hepatic disease, may result in problems in interpreting glycosylated albumin results.

Body weight monitoring

Weight is not a sensitive indicator of glycaemic control. However, the negative significance of rapid weight loss accompanied by thirst, glycosuria and ketonuria should be recognised. Similarly, it can be a positive sign if the patient's weight is stable and within an acceptable range. Body weight therefore forms part of the overall monitoring picture. However, body mass index calculation can provide a more accurate picture of the patient's weight in relation to their height and thereby an indication of whether they are overweight or obese. A patient is considered to be overweight if BMI is >25 (see Ch. 21 for calculation of BMI).

In type 2 diabetes, it is often seen as a priority to help the patient lose weight. Obesity increases insulin resistance and therefore correction of obesity can increase the sensitivity of cells to insulin. Weight reduction alone may bring the blood glucose down within normal limits.

Associated problems

Social attitudes can lead to overweight people feeling stigmatised. As a result, guilt or low self-esteem may affect

the patient's response to dietary advice. It is important that nurses involved in monitoring the patient's weight in the home, clinic or hospital adopt a sensitive approach.

Equipment and procedure

Scales should be checked regularly for accuracy. If possible, the patient should be weighed at the same time of day, ideally having just emptied their bladder. As far as possible, the patient should wear clothing of comparable weight each time.

Frequency

For hospital inpatients, weekly weighing should be adequate. Routine weighing at each outpatient clinic appointment is advisable. Frequency of self-weighing by a patient at home will be at the patient's discretion and in relation to the advice offered and the goals which have been set. On the whole, weighing more frequently than once a week is neither psychologically desirable nor valuable as a monitoring tool.

PREVENTING AND DETECTING DIABETES-ASSOCIATED COMPLICATIONS

ACUTE METABOLIC COMPLICATIONS OF DIABETES

The acute complications arising from diabetes are:

- diabetic ketoacidosis (DKA)
- hyperglycaemic hyperosmolar non-ketotic coma (HHNK)
- hypoglycaemia.

Diabetic ketoacidosis (DKA)

This condition can be defined as uncontrolled hyperglycaemia caused by an insulin insufficiency, accompanied by dehydration and acidosis.

Epidemiology

In the UK, DKA is the most common cause of death for people with diabetes below the age of 20 years. There is very little recent research showing incident rates of DKA, although it is thought that this has not declined significantly through the decades despite increasing knowledge and more sophisticated management in specialist units (Dave at al 2004).

Aetiology

Newly presenting diabetes may lead to DKA in patients where there has been a delay in diagnosis. In patients with established diabetes, DKA can be precipitated by infection, myocardial infarction, stroke or physical or emotional trauma, as these increase stress hormone secretion. Stress hormones raise the blood glucose and increase insulin requirements. DKA may therefore be caused by an inadequate dosage of insulin being taken during intercurrent illness or other major stress, or by insulin being omitted altogether. Persistently poor diabetic control related to poor concordance with treatment regimens can be a particular contributing factor, often associated with repeated hospital admissions.

Fluctuations in diabetes control are common during adolescence and this is reflected in the number of young people admitted to hospital with DKA. It is the major cause of diabetes-related deaths in young people with diabetes mellitus (Lebovitz 1995).

5.8 Consider why diabetes may be unstable during adolescence.

PATHOPHYSIOLOGY

The symptoms of DKA are a consequence of the combined effect of insulin lack and increased secretion of catabolic, counter-regulatory stress hormones. As a result, two major biochemical disturbances occur simultaneously:

- Accelerated gluconeogenesis and glycogenolysis cause hyperglycaemia, which in turn results in osmotic diuresis, dehydration and electrolyte disruption with a loss of sodium (hyponatraemia) and potassium (hypokalaemia)
- Increased fat breakdown (lipolysis) results in the formation of ketone bodies which are weak acids and cause metabolic acidosis (see Box 5.5).

MEDICAL MANAGEMENT

Reversing the hyperglycaemia Short-acting, soluble insulin (Humulin S or Actrapid) is administered to lower blood glucose. Initially, 50 mL of sodium chloride 0.9% (1 unit/mL) is administered via syringe driver infusion at 6 units/h. The insulin dose will later be varied in accordance with the blood glucose level and can be reduced to 3–4 units/h when the blood glucose level is <16 mmol/L and then to 2–4 units/h when it is 10–15 mmol/L. The aim should be a gradual reduction in blood glucose over a period of 12 h. If blood glucose does not fall within the first hour, the insulin dose may be increased to 12 units/h. However, before doing this, it is important to ensure that the insulin delivery mechanism is intact, i.e. the venflon is patent and the infusion pump is working. Capillary blood glucose should be checked hourly. Venous blood glucose and plasma potassium (K^+) are measured 2-hourly.

Rehydrating Rapid restoration of circulating volume is necessary, followed by gradual correction of the interstitial and intracellular deficit. Sodium chloride (NaCl) 0.9% is given by rapid i.v. infusion: 1–2 L may be given over the first hour, and then 500 mL hourly for 2–5 h. The rate is then adjusted according to the patient's state of hydration; caution should be taken with older patients who may be at risk of cardiac failure. When blood glucose falls below 15 mmol/L, the sodium chloride is replaced by i.v. dextrose 5% to allow maintenance of blood glucose levels in the range of 10–15 mmol/L.

Replacing potassium Derangements in plasma potassium can vary. Hyperkalaemia may be evident in the very early stages due to severe metabolic acidosis, but once rehydration is underway, hypokalaemia is usual and may be severe. Intravenous potassium chloride (KCl) is prescribed in accordance with the blood biochemistry. Initially 10–30 mmol/h may be administered within the i.v. fluids. This must be administered by a regulated infusion delivery system.

Box 5.5

The development of diabetic ketoacidosis (DKA)

The key precipitating factors for DKA are inadequate supply of insulin and increased demand for insulin, often in combination. These are often triggered by:

- newly presenting type 1 diabetes
- infection, especially respiratory, urinary or abscesses
- trauma or surgery
- severe illness, e.g. myocardial infarction or cerebrovascular accident
- failure to take sufficient insulin — this may be accidental or deliberate; many young women in particular discover that ketosis will cause rapid weight loss.

As a result of reduced insulin and increased stress hormone levels, cells will be unable to utilise glucose, glycogen will be converted to glucose, protein will be broken down to provide glucose (gluconeogenesis) and fat will be broken down (lipolysis), releasing ketone bodies. The combined effects of these events are:

- hyperglycaemia and hyperketonaemia
- osmotic diuresis
- fluid and electrolyte disruption
- catabolism/wasting
- acidosis.

As a result the patient will exhibit the following symptoms, signs and clinical features:

Symptoms
- Polyuria
- Intense thirst
- Polydipsia
- Lethargy/weakness
- Nausea/vomiting
- Abdominal colic
- Muscle cramps
- Blurred vision

Complications
- Cerebral oedema
- Adult respiratory distress syndrome
- Thromboembolism

Signs and clinical features
- Hyperglycaemia and glycosuria
- Polyuria progressing to oliguria
- Ketonuria
- Ketone breath (sweet fruity odour)
- Weight loss
- Hypokalaemia
- Hypotension and tachycardia
- Acidaemia
- Rapid, deep (Kussmaul's) respirations
- Evidence of intercurrent infection/illness
- Skin flushed and warm
- Hypothermia may develop
- Confusion and drowsiness progressing to coma

Monitoring The patient will be closely monitored for the following:

Potentially mortal dysrhythmias Continuous cardiac monitoring commenced and a 12-lead ECG is performed to detect cardiac arrhythmias associated with serum potassium lack or excess.

Hyperglycaemia Capillary blood glucose is measured hourly and venous blood glucose 2-hourly until <20 mmol/L, then 4-hourly.

Dehydration Blood urea, electrolytes and plasma osmolality are checked 2-hourly.

Response to fluid and K^+ replacement Blood pressure and pulse are measured hourly as a guide to blood volume. Central venous pressure (CVP) or pulmonary capillary wedge pressure (PCWP) may be initiated and measured in the older patient or those with renal or heart failure.

Oxygen therapy This will be administered in accordance with blood gas results.

Nasogastric aspiration will be performed to protect the airway if the patient is vomiting, drowsy or unconscious.

Acidosis Arterial blood gases are checked initially, but venous bicarbonate levels are adequate for monitoring of acidosis 1- to 2-hourly thereafter.

Underlying infection A chest X-ray is performed. Blood cultures, full blood count, urine and sputum specimens are sent to microbiology. Temperature, pulse, pulse oximetry and respiration are recorded hourly.

Ketosis and renal function Urine is tested for glucose, ketones, protein, urea and electrolytes.

Additional therapy which can be used in the treatment of DKA includes:

The use of an alkaline — sodium bicarbonate This is not routinely used as it may exacerbate tissue hypoxia and hypokalaemia. As overcorrection may result in alkalosis, sodium bicarbonate is usually reserved for the treatment of very severe acidosis where the pH is below 7.0 and hydrogen ion concentration exceeds 100 mmol/L, and then only if the patient does not respond to adequate treatment with fluids and insulin.

Broad-spectrum antibiotics These may be given only if infection is suspected.

Anticoagulants Low-dose heparin 5000 IU s.c. twice daily may be given as standard venous thromboembolism prophylaxis.

Urinary catheterisation Urine volume is measured hourly as severe dehydration carries a risk of acute renal failure.

Space blanket This may be used if the patient is hypothermic due to the vasodilatory response to metabolic acidosis.

Subsequent medical management of DKA will address the following concerns:

Insulin When blood glucose is below 15 mmol/L, the i.v. prescription may be changed to an infusion of 50 units of soluble insulin in 50 mL of sodium chloride 0.9% (1 unit/mL) and infused using a syringe driver. The rate should be adjusted to allow a gradual reduction in blood glucose over 12 h, initially starting at 6 units/h and reducing to 2–4 units/h when glucose is 16 mmol/L.

Fluid and electrolytes If the patient is still dehydrated, or severely hyponatraemic, following the osmotic consequences of glycosuria and dehydration, further i.v. sodium chloride 0.9% can be given. Plasma electrolytes, osmolality and glucose levels will be checked 2- to 4-hourly. Capillary blood glucose is monitored hourly. The infusion rate will be adjusted in accordance with blood glucose and other

biochemical results. When the patient is deemed to be clinically and biochemically stable, s.c. insulin and an oral diet are resumed. The i.v. insulin therapy is discontinued 1 h after the first s.c. injection of insulin and when the patient has eaten the subsequent meal.

Prevention Once the patient is stable, every effort should be made to establish the cause of DKA and, where appropriate, the patient should be referred to the diabetes specialist nurse to discuss any changes to their diabetic medication and issues of self-management in an effort to prevent recurrence. For many patients, however, the experience of DKA is what first makes them aware that they have diabetes mellitus.

NURSING PRIORITIES AND MANAGEMENT: DKA

Each patient admitted with DKA will have unique problems and needs. The biochemical disruption of DKA is profound and life threatening. Priorities for nursing care will be strongly influenced by the prescribed medical therapy and the need for complex monitoring. Whilst the nurse must draw upon technical skills in such a situation, it is vitally important to remember to care for the patient as a whole person.

Immediate priorities

The newly admitted patient with DKA is vulnerable in a variety of ways. The nurse should be sensitive to this vulnerability and try to accommodate individual needs when planning and implementing care.

Case History 5.2 and Nursing Care Plan 5.3 provide an example of how a patient may present with DKA and how nursing priorities may be met following admission and until consciousness is regained. It should be pointed out, however, that the vast majority of patients presenting with DKA will not be unconscious. Individuals with long-standing diabetes mellitus can usually recognise the signs and symptoms of impending ketoacidosis and will seek medical help at a much earlier stage in its development. Those newly diagnosed with type 1 diabetes are taught how to recognise and respond to indications of hyperglycaemia and ketoacidosis.

CASE HISTORY 5.2

R (see also Nursing Care Plan 5.3)

R is a lively 18-year-old and the eldest of three children. At present she lives with her family but is soon to leave home to undertake a secretarial course at a college some 30 miles away.

R and her two brothers have recently suffered a bad bout of flu. The boys are now fully fit but R is far from well. She has been passing an excessive amount of urine and is constantly thirsty. She has lost weight and has recently been complaining of feeling tired all the time.

This morning she is very drowsy. Her skin feels hot and dry and she looks flushed. She has vomited several times and has complained of abdominal pain and cramps in her limbs. Her breath has a peculiar sweet smell and her mouth is very dry. She has also been complaining of blurred vision.

Her parents are alarmed and have called the GP to request an urgent visit. Alerted by the 'acetone breath', her symptoms and the history of recent illness, the GP checks R's capillary blood glucose and finds it to be greater than the upper limit on his blood glucose meter (33.3 mmol/L). R is too drowsy to produce a urine specimen to check for ketones but the GP is in little doubt about the diagnosis. An ambulance is summoned and R and her parents are taken to hospital. The ward is alerted to expect an unconscious patient with diabetic ketoacidosis (DKA).

On admission, R is acutely ill and has complex care requirements. A nurse who has the appropriate levels of knowledge and skill is assigned to care for her. She has prepared for R's admission and will subsequently assess her nursing needs and plan and evaluate her care (see Nursing Care Plan 5.3).

Further considerations

When the patient is alert and able to respond, the focus of care will change. The nurse will work with the patient, the dietitian and the medical staff to stabilise blood glucose and to monitor the effects of therapy.

The subsequent care of the patient in hyperglycaemic crisis, whether due to DKA or hyperglycaemic hyperosmolar non-ketotic coma (HHNK), will be similar in many respects.

Hyperglycaemic hyperosmolar non-ketotic coma (HHNK)

This term refers to uncontrolled hyperglycaemia and dehydration in the absence of ketonaemia.

Epidemiology

HHNK is less common than DKA. It is most often seen in people with undiagnosed type 2 diabetes and tends to affect an older age group. Mortality rates can be as high as 30%.

Aetiology

As in DKA, severe physical or psychological stress such as cerebrovascular accident (CVA), myocardial infarction, trauma or bereavement can precipitate HHNK.

Dietary indiscretion such as a marked increase in refined carbohydrate intake, perhaps over Christmas or a holiday period, may account for the onset of HHNK. Some patients give a history of drinking large volumes of sugar-containing drinks in an effort to quench an ever-increasing thirst. In 50% of patients, however, the cause of this metabolic disturbance will remain unknown.

PATHOPHYSIOLOGY

HHNK may develop gradually over a period of days or weeks. This is different from DKA, in which the symptoms of uncontrolled diabetes appear rapidly over a period of hours or days. However, the course of HHNK can occasionally, and especially in the young, develop over a few hours (Watkins et al 2003).

Due to the absence of ketones, the patient does not initially appear acutely ill and therefore the onset of the condition is often very gradual. The signs and symptoms are similar to those found in DKA, with the following notable exceptions:

- ketonuria is absent or slight
- severe weight loss is unusual
- in the absence of the serious symptoms of ketosis, the blood glucose may be even higher than in DKA before the patient feels ill (usually >50 mmol/L) and seeks medical attention

- physiological response to dehydration can be more marked due to the degree of hyperglycaemia and to age-associated intolerance to fluid and electrolyte disruption
- symptoms associated with ketonaemia/acidosis will not be in evidence.

5.9 Given the above differences, draw up a list of signs, symptoms and clinical features of HHNK. Compare this with the list given for DKA and discuss the reasons for the differences.

The features of HHNK may be further described as follows:

Hyperglycaemia can be severe but develops gradually. Although some insulin is still being secreted, there is a relative insulin deficiency and the blood glucose continues to rise. The severe hyperglycaemia in HHNK is due to the combined effects of cellular resistance to insulin and the generation of glucose by stress hormone-driven glycogenolysis and gluconeogenesis.

Hyperosmolality Normal plasma osmolality is around 280–300 mmol/kg. This is calculated using a formula which takes account of the sodium, potassium, urea and glucose levels in the blood. Hyperglycaemia accounts for much of the hyperosmolar state in HHNK. The high blood glucose will exert an osmotic pull and as a result fluid is drawn out of the cells into the circulation. Initially this will cause an increase in the glomerular filtration rate and large volumes of fluid will be lost by osmotic diuresis. As a result, the patient will develop polyuria, thirst, dehydration and hypovolaemia.

Hypernatraemia The normal range for plasma sodium (Na^+) is 135–145 mmol/L. In HHNK, Na^+ may be raised above this level. Hypernatraemia can develop in response to a reduction in circulatory volume. In order to conserve a falling blood volume, aldosterone is secreted by the adrenal cortex, causing the kidney to retain sodium and excrete potassium.

By the time the patient presents, the period of osmotic diuresis has usually passed and dehydration has developed. As a result, the glomerular filtration rate falls, oliguria develops and blood urea rises. The combined effect of fluid loss, raised sodium levels, high blood glucose and raised plasma urea is that the blood becomes highly 'concentrated', i.e. hyperosmolar (hyperosmotic).

Non-ketosis The production of ketones (ketogenesis) will be inhibited by the presence of insulin. Insulin also enables the small amount of ketones which result from lipolysis to be metabolised, thus preventing their accumulation in the blood.

Impaired level of consciousness This occurs due to the effects of dehydration (hyperosmolality) on brain cells, impairing cerebral function and leading ultimately to coma.

MEDICAL MANAGEMENT OF HHNK

This follows a similar approach to that of DKA, with some important differences, and centres on the following concerns.

Rehydration The fluid deficit is considerable and can be as much as 8–12 L. Replacement rate should be slower than in DKA and must be approached with a degree of caution, given the risks associated with over-vigorous fluid replacement to which older patients are especially vulnerable:

- Sodium chloride 0.9% (normal saline) is given if plasma Na^+ levels are either not yet known or lower than 145 mmol/L.
- If plasma sodium is higher than 145 mmol/L, then half-strength normal saline (0.45% NaCl) may be given.

The infusion is changed to 5% dextrose once blood glucose measures 10–15 mmol/L to allow maintenance of blood glucose levels in the range of 10–15 mmol/L.

Replacement of potassium As potassium levels are so variable and unpredictable in HHNK, extreme care is required during replacement to monitor cardiac effects. Continuous cardiac monitoring is strongly recommended.

Insulin therapy An infusion of 50 units of soluble insulin in 50 mL sodium chloride 0.9% is commenced. In HHNK, the patient is less insulin resistant than in DKA, so the insulin infusion is commenced at a lower rate, usually 3 units/h. Insulin resistance is a syndrome associated with type 2 diabetes, whereby there is reduced tissue sensitivity to the action of insulin, leading to a compensatory increase in insulin secretion.

Anticoagulant therapy A major cause of death in HHNK is thrombosis, often pulmonary or cerebral, which is presumed to result from dehydration and hyperosmolality. Patients who are comatose or who have severe serum osmolality should receive intravenous heparin. Patients with lesser degrees of hyperosmolality may be given heparin 5000 IU s.c. 8-hourly. Other therapy and monitoring is as for ketoacidosis.

NURSING PRIORITIES AND MANAGEMENT: Hyperglycaemic hyperosmolar non-ketotic coma (HHNK)

Aspects of medical management which have implications for the planning of nursing care (McHoy 2003) include:

- i.v. infusion (fluid replacement)
- i.v. insulin (by syringe driver)
- heparin (s.c. or by i.v. infusion pump)
- central venous pressure (CVP) monitoring
- neurological observations
- cardiac monitoring
- urinary catheterisation
- oxygen therapy
- nasogastric aspiration (if patient is unconscious).

Immediate priorities

These interventions will need appropriate attention to ensure the safety and comfort of the patient. In addition, the patient is likely to be vulnerable due to an impaired level of consciousness, dehydration, electrolyte imbalance, the

hazards of immobility and diabetes-associated risk factors. Nursing interventions will therefore include the following.

Monitoring consciousness

In patients with HHNK the level of consciousness is of particular importance as there is a risk of cerebral thrombosis due to the combined effects of immobility, dehydration and diabetes-associated atherosclerosis.

Another reason for vigilance is that the patient may be prescribed an i.v. infusion of half-strength normal saline aimed at reducing hyperosmolality. If the fall in plasma osmolality is too rapid, cerebral oedema can develop, raising intracranial pressure. The nurse should therefore promptly report any evidence of deterioration in the patient's neurological function (see p. 412).

Monitoring dehydration and electrolyte balance

The nurse should observe for the following warning signs:

Evidence of persistent hypovolaemia Hourly monitoring is required. The nurse should report hypotension, a rapid thready pulse, a CVP reading lower than 5 cm H_2O and a urine volume of less than 30 mL/h. Measures to raise blood volume and blood pressure will probably be prescribed. This can include rapid infusion of i.v. fluids or plasma. Such treatment will require close monitoring in order to detect circulatory overload (see below).

Evidence of fluid overload The nurse should promptly report a rising CVP, especially if this is accompanied by breathlessness, moist breath sounds, distended neck veins and a full pulse. These may indicate that fluid replacement has been too vigorous, causing over-expansion of the circulatory volume and placing strain on the left ventricle.

Evidence of electrolyte disruption Changes in pulse rate and rhythm should be reported promptly, along with ECG changes associated with hypo- and hyperkalaemia (see Nursing Care Plan 5.3), in order to allow adjustment to therapy and to prevent development of life-threatening cardiac dysrhythmias.

Monitoring response to insulin

Capillary blood glucose should be measured hourly to assess the response to i.v. insulin and to prevent overcorrection leading to hypoglycaemia. Accurate measurement and recording of blood glucose will provide the basis for adjusting insulin dosage.

Preventing complications

Many patients with HHNK are older people (DH 2001) who are especially vulnerable to the effects of hospitalisation and the complications of immobility. Maintenance of comfort and hygiene, including oral care, is of great importance.

Diabetes can cause neurovascular and ischaemic skin changes leading to impairment in circulation and sensation. There may also be disordered sweating due to autonomic neuropathy and increased susceptibility to infections, which places the skin at particular risk. Avoidance of skin damage is therefore a priority. The patient's position should be frequently altered, suitable pressure-relieving devices should be used and the skin, clothing and bedding should be kept cool, clean and dry.

Care is required when lifting, moving or positioning the patient to avoid damage to skin, muscles or joints. Particular attention should be paid to avoiding damage to the heels. Due to vascular and neurological changes, the feet of people with diabetes require particular attention to avoid serious complications (DH 2001) (see also p. 212).

Atherosclerosis is common in patients with diabetes, thus placing them at particular risk of vascular complications. Passive limb exercises whilst the patient is unconscious, and active limb movements when they are able to cooperate, will help to prevent venous stasis, which may result in deep vein thrombosis and pulmonary embolism. The nurse and the physiotherapist should encourage limb exercises.

Breathing exercises are also important as older, bedfast patients are at considerable risk of developing chest infections. Moreover, older people, and in particular those with diabetes, are less able to resist infection and tend to recover less quickly than younger non-diabetic people.

Monitoring the patient for pyrexia or other evidence of infection will allow prompt intervention. It is also important to ensure that the care environment and the standards of nursing care provided are such that infection risks are minimised (see Ch. 16).

Providing psychological support

The experience of a hyperglycaemic crisis can cause great distress, not only to the patient but also to family and close friends. Adopting a warm, empathic approach and accepting the fears of the patient and family is important if trust and rapport are to be established. The nurse should provide essential information using brief, clear explanations and should check to ensure these are understood. Access to medical staff and information about the ward or hospital should be provided.

Further considerations in DKA and HHNK

When the patient is deemed to be clinically and biochemically stable, on the basis of observation, bedside monitoring and laboratory tests, ongoing care is planned to address changing needs. If urine volumes are satisfactory, the urinary catheter is removed. The nasogastric tube is removed and oral fluids are offered. Diet is introduced under the guidance of the dietitian. When oral intake is adequate and blood urea and electrolyte levels are within normal limits, the i.v. fluids will usually be discontinued.

Subcutaneous insulin

This will replace the i.v. insulin when the patient is well enough to eat. Prescribing insulin is the responsibility of the physician but the nurse will be closely involved in monitoring patient response by frequent estimation of blood glucose. The nurse may also be required to adjust the insulin dosage within guidelines laid down in the written prescription.

Oral hypoglycaemic therapy

If possible, the patient is re-established on oral hypoglycaemic therapy. However, some patients may need to continue insulin therapy for some time before changing back to oral medication. Others may need to make a

Nursing Care Plan 5.3 Nursing care for R, a patient with DKA, during the first 24 h after admission (see Case History 5.2)

Nursing considerations	Action	Rationale	Evaluation
Impaired consciousness	• Position and support R in semi-prone or lateral position • Keep artificial airway in position until voluntarily expelled	To prevent asphyxia and prevent aspiration of secretion/vomitus	Skin colour and respirations are normal
	• Perform oropharyngeal suction if secretions are audible		
	• Provide nasogastric (NG) aspiration	Due to unconscious state and recent vomiting	
	• Continuously monitor colour and breathing		Risk factors eliminated
	• Administer oxygen as prescribed, ensuring that fire safety rules are observed	To correct hypoxia and prevent O_2 combustion	Blood gases improving
	• Monitor neurological status hourly. Record/report findings	To detect improvement/deterioration in conscious level	R is progressively more responsive
Hyperglycaemia and ketonaemia	• Administer prescribed short-acting insulin i.v. by infusion pump	To correct hyperglycaemia and ketonaemia	Trends indicate blood glucose returning to within the normal range
	• Monitor capillary blood glucose hourly: record/report findings	To evaluate response to insulin therapy and prevent hypoglycaemia	
Fluid deficit/replacement	• Administer i.v. fluids as prescribed. Observe venepuncture site for redness, swelling or extravasation. Record all fluids in fluid balance chart	To correct hypovolaemia	No discomfort or swelling of venepuncture site
	• Monitor CVP, BP, breathing, temperature: observe neck veins, skin colour and urine volumes	To monitor effects of fluid replacement	Vital signs are returning to within their normal ranges
	• Catheterisation usually prescribed if unconsciousness persists and if patient is oliguric	To monitor renal function and detect renal insufficiency (urine <30 mL/h)	Urine volume >30 mL/h
	• Test urine hourly for ketones: record results		Ketonuria diminishing
Electrolyte imbalance/replacement	• Observe effects of potassium replacement; provide continuous cardiac monitoring	Overzealous K^+ replacement can cause ventricular fibrillation, leading to cardiac arrest	
	• Report tall peaked T wave (indicates hyperkalaemia)		K^+ should be 3.5–5 mmol/L

Continued ▶

Nursing Care Plan 5.3 Nursing care for R, a patient with DKA, during the first 24 h after admission (see Case History 5.2) *(Continued)*

Nursing considerations	Action	Rationale	Evaluation
Electrolyte imbalance/ replacement *(Continued)*	• Report flattened or inverted T wave (indicates hypokalaemia)		
	• REPORT ECG CHANGES PROMPTLY	Persistent hypokalaemia due to inadequate K^+ replacement can result in heart block, which may lead to cardiac arrest	Cardiac monitor should display normal tracing
Probable current infection/ potential risk of infection	• Collect throat swab, catheter specimen of urine and, when consciousness returns, a specimen of sputum. Monitor TPR. Take venous blood specimen for culture and full blood count	To detect/monitor current infection	Specimen analysis Blood culture results and TPR normal
	• Administer prescribed antibiotics and note/report side-effects	To safely administer therapy	
	• Reduce risks of infection by high standards of nursing care (e.g. personal and catheter hygiene)	To prevent hospital-acquired infection	Patient infection-free
Inability to meet or communicate comfort needs	• Ensure bed is smooth, cool and crease-free. Provide regular position change and use of pressure-relieving aids to protect skin. Ensure careful positioning of limbs	To promote general comfort	Skin unblemished and free from discomfort
	• Wash, rinse and dry skin: observe for signs of pressure	To protect skin from damage	
	• Clean oral cavity 2-hourly. Lubricate lips. Clean nostrils and apply lubricant	To prevent oral and nasal discomfort and drying due to O_2 and the effects of dehydration and nasogastric tube	Oral/nasal mucosa intact
	• Keep hair groomed in preferred style. Use R's own nightwear. Maintain privacy throughout	To maintain R's individuality/ dignity	Patient feels/looks comfortable
Fear and shock as consciousness returns and diagnosis becomes apparent	• Display calm, empathic manner. Provide brief, clear explanations of reason for hospital admission and current care and treatment		
	• Provide access to parents and family	To convey positive attitudes To provide relevant information	R appears less acutely distressed
	• Encourage patient to verbalise concerns and express emotions		

Continued ▶

Nursing Care Plan 5.3 Nursing care for R, a patient with DKA, during the first 24 h after admission (see Case History 5.2) *(Continued)*

Nursing considerations	Action	Rationale	Evaluation
Fear and shock as consciousness returns and diagnosis becomes apparent *(Continued)*	• Avoid bombarding R with information at this stage		
	• Show sensitivity to the emotional needs of this vulnerable young patient	To recognise R's rights as an individual	R is able to express her needs
R's parents are anxious and shocked due to their daughter's hospitalisation and diagnosis	• Provide a comfortable, private waiting area for parents		
	• Explain (briefly at this stage) what has happened to their daughter		
	• Encourage/accept verbalisation of fears and expression of emotions	To provide essential information to answer immediate concerns	Parents are reassured and able to meet with and support their daughter
	• Provide access to R and to medical staff		
	• Supply information about the ward/hospital (booklets etc.)		
	• When parents feel able to cooperate, complete admission documentation and patient profile		
	• Assure parents of access to nursing staff to answer their questions as they occur		
	• Arrange a visit from the diabetes specialist nurse and dietitian at a mutually suitable time	To establish a trusting relationship, facilitate early educational interventions and offer support to the family	Parents' immediate needs have been met; they appear to feel supported

permanent change to insulin therapy in order to achieve better control of blood glucose levels.

Restoration of self-care

The physician, diabetes specialist nurse, dietitian and ward nurses will initiate the process of preparing the patient to assume responsibility for self-care, but a contribution will also be made by the GP and the community nursing staff once the patient returns home.

Patient education

The newly diagnosed patient will require information about how a balance between activity, food and medication can be achieved with the help of frequent blood glucose monitoring. This is especially important for patients with type 1 diabetes.

Once the crisis has passed, perhaps the most important aspect of care is to prevent further episodes of DKA or HHNK. This involves identifying the events which led up to the crisis and discussing with the patient where action might have been taken to avert the crisis or obtain help at an earlier stage. Glycosylated haemoglobin estimation can provide useful information about glycaemic control over the preceding weeks, as can the patient's record book containing blood glucose and urinalysis results.

It is all too easy to be wise in retrospect. It is therefore not helpful to blame the patient for any episode of DKA or HHNK. The main aims should be to help the patient understand their diabetes and have confidence in its management; therefore time should be spent re-assessing their knowledge and addressing any issues which may help to prevent further episodes of illness.

Emotional support

If severe underlying emotional distress or disturbance has precipitated the metabolic crisis, then the patient's difficulties may need to be sensitively explored. In accordance with the patient's wishes, appropriate counselling facilities may be provided. The newly diagnosed patient will require emotional support in meeting the immediate practical demands imposed by the condition.

Hypoglycaemia (insulin reaction/coma)

In people with diabetes, hypoglycaemia is a common side-effect of treatment and occurs when blood glucose falls below 4 mmol/L.

Epidemiology

Hypoglycaemia is the most common complication of insulin therapy. It occurs less frequently with oral sulphonylurea therapy. It can also feature in diabetes which is secondary to other disorders, e.g. in patients with certain liver diseases. Of those people with insulin-treated diabetes, 25–30% suffer one or more severe hypoglycaemic episodes every year (Williams & Pickup 1999).

Aetiology

There are several causes of hypoglycaemia. The three main causes are:

- excess insulin
- insufficient food
- increased exercise/activity.

For other causes, see Box 5.6.

Box 5.6

Hypoglycaemia: classification, causes and risk factors

Classification

- *Asymptomatic* — biochemical hypoglycaemia without symptoms
- *Mild* — easily recognised and corrected by the patient
- *Moderate* — patient conscious but requiring help from others
- *Severe/unconscious* — cerebral function severely affected by glucose lack

Causes

- Too much insulin
- Wrong type of insulin
- Inappropriate combination of insulins
- Excess dosage of oral sulphonylureas
- Delayed or missed meal
- More than usual amount of exercise
- Alcohol ingestion, especially when hungry
- Stress, such as hypothermia

Risk factors

- Impaired awareness of hypoglycaemia
- Strict glycaemic control
- Excess alcohol consumption
- Drug abuse

PATHOPHYSIOLOGY

Symptoms are idiosyncratic, often developing over a very short period of time of 5–15 min.

Endocrine/autonomic response Glucagon and counter-regulatory hormones are secreted in response to falling blood glucose and act to restore blood glucose to normal. The activation of the autonomic nervous system in response to the stress of hypoglycaemia provokes autonomic symptoms of hypoglycaemia (MacAuley et al 2001). These hormones potentiate the effects of the sympathetic nervous system to cause the following symptoms:

- pounding heart
- palpitations
- sweating
- trembling
- sensation of hunger
- sensation of anxiety.

Central nervous system response As brain cells are unable to metabolise alternatives to glucose for energy, a fall below the normal blood glucose will cause neuroglycopenic symptoms, such as:

- lack of concentration
- dizziness
- unsteady gait
- slurred speech
- tingling around the lips.

Other non-specific symptoms, including headache and nausea, can occur.

In addition, observers may notice abnormalities such as:

- pallor
- irrational behaviour
- muscle twitching/seizures
- extreme drowsiness or coma.

Some of these symptoms and signs could, with disastrous consequences, be mistakenly attributed to excess intake of alcohol.

Loss of sensitivity to symptoms Recently diagnosed patients tend to rely on autonomic symptoms such as sweating, tremor and pounding heart to alert them to a fall in blood glucose. However, after some years, patients may become less sensitive to these responses and come to rely on neuroglycopenic features such as visual disturbances and dizziness to alert them to impending hypoglycaemia.

In long-standing insulin-treated diabetes, the perception of the onset of symptoms of hypoglycaemia may become blunted, due to autonomic neuropathy or the effect of intensified insulin treatment (Williams & Pickup 1999). The patient may remain asymptomatic even when the blood glucose falls below 2 mmol/L, although at this level some signs may be obvious to others. This is known as impaired awareness of hypoglycaemia. Symptoms can also be masked by the following:

- *Alcohol* — if the patient is known to have consumed alcohol or smells of alcohol, this can lead others to mistake hypoglycaemia for intoxication, particularly as many symptoms and clinical features are similar.

- *Ageing* — in older people hypoglycaemia may cause neurological disturbances and the presenting symptoms can be mistaken for failing mental function or transient ischaemic attacks (cerebrovascular disease).
- *Time of day* — hypoglycaemia during sleep is asymptomatic. It is often not detected although features such as night sweats, restlessness, nightmares, stertorous breathing and headaches on waking may give the patient an indication of its occurrence. This causes rebound hyperglycaemia and is attributed to an increase in the release of counter-regulatory hormones during the night to correct the hypoglycaemia. This is known as the Somogyi phenomenon (Frier & Fisher 1999).
- *Sulphonylurea-induced hypoglycaemia* — long-acting preparations such as chlorpropamide and glibenclamide, even at normal therapeutic doses, have been implicated in severe, prolonged hypoglycaemic coma. This risk is increased in older people, particularly when they may be unwell and not eating, and in those with poor renal function (Burge et al 1999). This can lead to prolonged hypoglycaemia and may be fatal.

MEDICAL MANAGEMENT

Treatment of hypoglycaemia is simple and the effects are usually dramatic and gratifying. Nevertheless, the risks posed by hypoglycaemic coma and the importance of early detection and intervention must be stressed.

Hypoglycaemia can be treated with oral carbohydrate, s.c. or i.m. glucagon, or i.v. glucose — depending on the stage and severity.

The conscious patient should be given rapidly absorbed glucose as a glucose drink or as sweets, followed by a more gradually absorbed form of carbohydrate, e.g. glucose tablets or a glass of fruit juice, followed by biscuits or a sandwich. Hypoglycaemia can recur if food is not consumed after the initial treatment with glucose.

The confused or drowsy patient If the patient is too drowsy to eat or drink safely, glucagon 1 mg by i.m injection can be given. This will have the effect of raising the blood glucose. Where possible, relatives should be taught how to administer glucagon.

The unconscious patient Medical help should always be sought for the unconscious patient, although if hypoglycaemia is known to be the problem, glucagon i.m should be given while the doctor is awaited and the patient should be placed in the recovery position until consciousness returns. Nothing should be given orally whilst the patient is unconscious (MacKinnon 2002).

If glucagon is unavailable, or fails to bring a response within 10–15 min, i.v. dextrose in a dose of 30–50 mL of glucose 50% is required, which will usually raise the blood glucose sufficiently for consciousness to be regained. When coma persists, hospital admission will be necessary. Unconscious hypoglycaemia in the hospitalised patient may be treated by i.v. dextrose as first-line treatment.

The hospitalised patient with hypoglycaemic coma A specimen of venous blood will be taken for laboratory estimation of blood glucose. Continuous i.v. infusion of dextrose 10–20% will be commenced and the patient's clinical response monitored by regular measurement of blood glucose. Approximately 1–2% of patients with hypoglycaemic coma fail to respond promptly to parenteral therapy. For these patients, other causes of coma such as alcohol or drug overdose, hypothermia or cerebral haemorrhage should be excluded. As cerebral oedema can accompany prolonged hypoglycaemia, an i.v. infusion of mannitol (a hyperosmotic fluid) may have to be given and oxygen administered (Richmond 1996).

NURSING PRIORITIES AND MANAGEMENT: Hypoglycaemia

In hypoglycaemic coma the period of extreme vulnerability tends to be short. Nevertheless, the nurse must take the patient's vulnerabilities into account in nursing interventions by:

- ensuring the patient's airway is clear
- monitoring the patient's conscious level
- administering prescribed therapy
- monitoring capillary blood glucose
- exploring the possible cause of the hypoglycaemic coma
- providing information and encouragement for the patient to help improve diabetes control.

Metabolic complications of diabetes vary in cause, severity and outcome. All indicate a lack of stability of diabetes control which requires further assessment and investigation and possibly subsequent modification of treatment or lifestyle.

For a detailed account of the causes, symptoms, treatment and management of hypoglycaemia, see Frier & Fisher (1999).

CHRONIC COMPLICATIONS OF DIABETES MELLITUS

This section will consider chronic complications of diabetes mellitus which result in pathological changes in large blood vessels (macroangiopathies), small blood vessels (microangiopathies) and nerves (neuropathies). The Diabetes Control and Complications Trial conducted in the early 1990s (Diabetes Control and Complications Research Group 1993) is considered to be one of the most important pieces of diabetes research in the last 20 years. It demonstrated that tight control of blood glucose prevented or delayed the onset of complications in type 1 diabetes, particularly retinopathy, neuropathy and nephropathy. However, the risk of severe hypoglycaemic attacks increased three-fold.

In 1998, the United Kingdom Prospective Diabetes Study Group (UKPDS) reported their findings in relation to the reduction of long-term complications in patients with type 2 diabetes. It was found that, through tight control of blood glucose and maintenance of blood pressure within normal limits, the risk of deaths related to diabetes could be reduced. Additionally, the long-term complications of diabetes such as heart disease and stroke and the loss of sight and kidney damage could also be reduced (UKPDS 1998a,b).

5.10 Consider the potential risks of poor diabetes control.

Detailed management of specific diabetes-related complications is provided in Chapters 2 and 11.

Atherosclerosis

Epidemiology

Although atherosclerosis is not peculiar to diabetes, it is known that myocardial infarction, cerebrovascular accident (CVA) and gangrene are relatively frequent complications and are major causes of death in people with diabetes. Atherosclerosis develops at a much younger age in people with diabetes than in non-diabetic individuals: this is most noticeable in females.

Both types of diabetes carry increased risk, but those with type 2 diabetes show the strongest tendency to develop atheroma. This is probably due to age-related factors and perhaps also to the effects of long-standing asymptomatic hyperglycaemia prior to diagnosis. In type 1 diabetes, microvascular disease such as retinopathy usually precedes evidence of atherosclerosis.

Aetiology

Up to 70% of adults with type 2 diabetes have raised blood pressure and more than 70% have abnormal cholesterol levels (DH 2001). There are several risk factors for coronary artery disease (Kirby 2003):

- Increased concentrations of low density lipoprotein (LDL) cholesterol
- Decreased concentrations of high density lipoprotein (HDL) cholesterol
- Raised blood pressure
- Hyperglycaemia
- Smoking.

It is therefore essential that management of people with diabetes should focus on managing these risk factors.

Onset and progress of the disease

The development and vascular distribution of atherosclerosis in diabetes are similar to that found in the non-diabetic population, the exception being the more severe peripheral arterial involvement which may affect the lower limbs of some people with diabetes.

Cardiovascular disease

When compared with the general population, diabetes in men is associated with a two- to three-fold risk of developing coronary heart disease. In premenopausal women this is increased to four to five times the risk if the woman has diabetes (British Diabetic Association 1995). In a study coordinated by the World Health Organization, it was found that, of a group of 497 people aged 35–54 years with diabetes at 8-year follow-up, the prevalence of cardiovascular disease was 45%: 43% had coronary heart disease, 4.5% cerebrovascular disease and 4.2% had peripheral vascular disease (British Diabetic Association 1995).

Atherosclerosis of the coronary vessels can impair oxygen delivery to the myocardium, resulting in angina pectoris or myocardial infarction (MI). Due to the effects of autonomic neuropathy the patient may develop a cardiac arrhythmia and may have a 'silent' (painless) MI. Indeed, MI is more often fatal in people with diabetes compared with MI in those without diabetes (Stevens et al 2004).

Myocardial infarction (MI)

Approximately 10% of all MIs occur in patients with diabetes mellitus and mortality rates are also approximately two-fold higher than in the non-diabetic population (Watkins 2003).

A study of post-MI diabetic patients started on insulin therapy showed a reduction in mortality rate (Malmberg 1997). Further confirmation of these results is required, but at present this study provides the best evidence available in support of insulin treatment for all such patients — for some indefinitely (Watkins 2003).

For further details of heart disease in diabetes, see Fisher (2003).

Cerebrovascular disease

The incidence of stroke in patients with diabetes is also high and mortality following stroke is increased compared to the non-diabetic population. The clinical presentation is similar to that in the non-diabetic subject (Bell & Ovalle 1999). Hypertension is probably the most important of those factors which contribute to the development of atherosclerosis. Lowering the diastolic blood pressure to <80 mmHg in those at risk is of benefit (Hanson et al 1998).

Retinopathy

Diabetes is the leading cause of blindness in people under the age of 60 in industrialised countries. It is also a major cause of blindness in older people (National Institute for Clinical Excellence (NICE) 2002). By 20 years after the onset of diabetes, almost all patients with type 1 diabetes and over 60% of patients with type 2 diabetes will have some degree of retinopathy. Even at diagnosis, it is estimated that approximately one-quarter of patients will already have established background retinopathy (Watkins 2003).

Retinopathy results from changes in the basement membrane of small blood vessels of the retina (retinal microangiopathy) and can be classified as:

- background (non-proliferative) retinopathy
- maculopathy
- proliferative retinopathy.

Background retinopathy

Background retinopathy rarely causes a major threat to vision unless the macula is affected. In the early stages of retinopathy, the capillaries of the retina become more permeable. This can cause fluid exudation (hard exudates) into the retina. Retinal veins may swell at localised spots, giving the appearance of 'beading'. Microaneurysms can develop; these can rupture, causing small bleeds. Arteriolar occlusions cause retinal infarcts or 'cotton wool spots' on the retina. More spots occur in rapidly developing retinopathy or where there is coexisting hypertension. Evidence of venous bleeding and 'cotton wool' spots suggests progression to pre-proliferative retinopathy.

Maculopathy

Maculopathy can cause severe loss of central vision and is most common in type 2 diabetes. In this condition, oedema, haemorrhages and exudates are concentrated on the macular area of the retina.

Proliferative retinopathy

Microvascular disease of the retina can result in areas of hypoxia. This will give rise to the compensatory development of new blood vessels (neovascularisation) which grow forward from the retina to invade the vitreous body. These new vessels are fragile and poorly supported; consequently, haemorrhages into the vitreous body are common. Progressive traction on the retina can result in retinal detachment. Proliferative retinopathy and retinal detachment will seriously threaten vision.

MEDICAL MANAGEMENT

The main priorities in the treatment of diabetic retinopathy are to reduce the risk of haemorrhage and to limit new vessel growth into the vitreous body. Photocoagulation by means of laser technology can be used to treat proliferative and pre-proliferative retinopathy. Treatment should be considered in all patients with visual potential (NICE 2002).

Screening Annual ophthalmoscopic examination for those with no identified retinopathy and 6-monthly for those with background retinopathy is strongly advised. This will enable swift and appropriate treatment to help prevent blindness. Where glycaemic control is poor, or where hypertension or renal involvement is more frequent, eye examinations may be recommended. Referral to an ophthalmologist should be made for maculopathy, proliferative and pre-proliferative retinopathy, a fall in visual acuity, retinal detachment or rubeosis iridis (NICE 2002).

Retinal photography should be carried out annually and it is now possible to do this using non-mydriatic retinal cameras which allow the retina to be photographed without prior dilatation of the pupil. Many health authorities are using mobile units to carry out retinal screening in the community.

Prevention The patient should be aware of the established link between poor blood glucose control and retinopathy and of the importance of promptly reporting changes in vision. As eye tests for patients with diabetes are free of charge, the optician should be made aware that the patient has diabetes. The risks of retinopathy increase if the patient is hypertensive.

Other eye disorders

Although retinopathy poses the main threat to vision in diabetes, there is also an increased risk of cataract and glaucoma. The reasons why this should be so are not entirely clear. It is possible that glycosylation of protein in the optic lens can cause the opacities of cataract (Hamilton & Ubig 1991). The management of cataract and glaucoma are described in full in Chapter 13.

Sadly, many patients with diabetes do ultimately suffer partial or total blindness. Maintaining independence in relation to diabetes management and general self-care will present quite a challenge but patients may be referred to local visual impairment services and the Royal National Institute for the Blind (RNIB). Allwinkle (2002) describes various devices which can enable the blind or partially sighted patient to administer insulin and monitor blood glucose. These include pre-filled disposable insulin pens with an audible dialling mechanism and information on how to obtain a talking meter which can be purchased from the USA. This meter uses capillary-fill test strips which make the task of blood sampling easy for the patient. The nurse and the visually impaired patient with diabetes should work together to seek out ways of reducing the patient's dependence on others. Diabetes UK (the national charity for diabetes) and the RNIB can provide invaluable up-to-date information about the help currently available for these patients (see 'Useful websites', p. 227).

Diabetic nephropathy

Approximately 20% of patients with type 1 diabetes develop proteinuria after a disease duration of 25 years (EURODIAB IDDM 1994) and up to 40% of patients with type 2 diabetes will eventually develop diabetic nephropathy, the incidence of which is related to the duration of their diabetes (Molitch 1997). Between 10 and 20% of patients with type 2 diabetes who have diabetic nephropathy will eventually progress to end-stage renal failure (Cooper 1998).

AETIOLOGY AND PATHOPHYSIOLOGY

The kidneys of people with diabetes are vulnerable with respect to the following:

- *Microvascular changes* — damage to the capillaries in the glomeruli can occur. The basement membrane initially thickens and, in the later stages, nodules of glycoprotein are deposited in the glomerular capsule. As a result, the filtering capacity of the glomeruli is reduced.
- *Macrovascular changes* — atheromatous changes in renal vessels can lead to poor renal perfusion which will ultimately impair renal function.
- *Hypertension* — a common feature in diabetes, hypertension can contribute to kidney damage and, conversely, can also result from kidney damage.
- *Urinary tract infection* — this can occur for several reasons:
  - — diabetes-associated predisposition to infection
  - — damaged renal tissue vulnerable to infection
  - — the need for catheterisation during metabolic crisis
  - — atonic bladder associated with autonomic neuropathy, causing urinary stasis and ascending urinary tract infection.

Screening

All patients with diabetes should have their urinary albumin concentration and serum creatinine measured at regular intervals, usually annually, and this should be measured using an early morning urine sample. Urinary albumin:creatinine ratio should be measured by a laboratory method or a 'near-patient' test specific for albumin at low concentration. Any abnormal result should be confirmed by a further sample (SIGN 2001).

Microalbuminuria is defined by a rise in urinary albumin loss of between 30 and 300 mg/day. This is the earliest

sign of diabetic nephropathy and predicts increased total mortality, cardiovascular mortality and morbidity, and end-stage renal failure (SIGN 2001).

Blood pressure All patients with proteinuria should have their blood pressure measured at every clinic or surgery visit. The UKPDS demonstrated that reducing blood pressure from 154/87 mmHg to 144/82 mmHg in type 2 diabetes led to a risk reduction of 8% in developing microalbuminuria over 6 years (UKPDS 1998b). In the HOPE study, angiotensin-converting enzyme (ACE) inhibitor therapy for 4.5 years in type 2 diabetes was associated with an absolute risk reduction of developing proteinuria of 2% (HOPE 2000). Therefore, tight blood pressure control (<140/80 mmHg) in patients with type 2 diabetes should be maintained (SIGN 2001).Good glycaemic control should be maintained in all patients with diabetes. Both the Diabetes Control and Complications Trial (DCCT) (Diabetes Control and Complications Research Group 1993) and UKPDS (1998b) have shown that a reduction in mean HbA1c (glycosylated haemoglobin) was associated with a reduction in the occurrence of microalbuminuria and proteinuria.

MEDICAL MANAGEMENT

Diabetic renal disease is treated in the same way as renal disease in the non-diabetic population. The reader is referred to Chapter 8 for detailed coverage of early, advanced and end-stage renal failure. Only diabetes-related points will be mentioned in the short sections which follow.

Treatment choices for the patient in end-stage renal failure include haemodialysis, continuous ambulatory peritoneal dialysis (CAPD) or renal transplant using live or cadaver donors.

Renal transplantation using a live donor offers the best treatment for suitable patients. Careful selection of patients is important, given that other major diabetes-related complications usually coexist with the renal disease. Virtually all diabetic patients with end-stage renal failure have retinopathy, and 20–30% are blind. Retinopathy alone would not militate against active treatment by dialysis or renal transplantation but the presence of carcinomatosis, advanced dementia or severe cerebrovascular disease may do so. The prognosis in, for example, severe cardiovascular disease is also poor (Watkins et al 2003).

Oral hypoglycaemics Due to the danger of lactic acidosis, metformin (a biguanide) should not be used for patients with renal impairment. Chlorpropamide (a sulphonylurea) should also be avoided as it is mainly excreted by the kidneys and in renal failure can accumulate in the blood, causing serious hypoglycaemia. It may be necessary for some patients in renal failure, whose diabetes was previously controlled by oral medication, to be changed to insulin therapy.

NURSING PRIORITIES AND MANAGEMENT: Diabetic nephropathy

When renal function is impaired, diabetes control should be closely monitored by regular blood glucose measurement. Measurement and recording of fluid intake and output and body weight may be required to monitor renal function. Dietary and fluid restrictions may be imposed due to renal impairment. Patients and their families should be made aware of the vital importance of these measures.

Prevention of renal failure

By identifying early renal impairment by screening for microalbuminuria, making efforts to improve diabetes control and detecting and treating hypertension, it is possible to prevent or delay the progression of renal disease (Diabetes Control and Complications Research Group 1993).

Medical and nursing staff should exercise extreme caution in the introduction and subsequent care of urinary catheters in order to prevent infection. Prompt treatment of any established urinary tract infection will normally be required to minimise damage.

5.11 Identify three treatment approaches which may be used in end-stage renal failure in a diabetic person and discuss the potential lifestyle implications of each form of treatment.

For further information on diabetic nephropathy, see Hasslacher (2001).

Diabetic neuropathy

Aetiology

Although the cause of diabetic neuropathy is uncertain, it is known that neural function in the diabetic patient deteriorates in response to pressure, metabolic changes and ischaemia (Watkins et al 2003). The incidence of diabetic neuropathy is known to rise in line with the duration of diabetes and with increasing age. A popular theory is that nerve damage occurs as a result of the accumulation of metabolites of glucose (such as sorbitol), causing osmotic swelling and subsequent damage to the nerve cell. Ischaemia as a cause of diabetic neuropathy, however, remains controversial but must be considered a contributory factor (Watkins et al 2003).

PATHOPHYSIOLOGY

Structural damage affecting the Schwann cells causes segmental areas of demyelination to appear, thus impairing conduction of the nerve impulses. There is no widely accepted classification of diabetic neuropathy, but a number of clinical syndromes are recognisable (see Table 5.14).

Peripheral neuropathy This is a distal symmetrical neuropathy, principally affecting the lower extremities and playing a major part in the aetiology of diabetic foot problems. It can affect either sensory or motor nerves and the patient's symptoms will reflect this.

Polyneuropathy This term refers to widespread neuropathic changes affecting many nerves. Again, the lower extremities are often affected (peripheral polyneuropathy).

Mononeuropathies Single nerves or their roots are affected. The condition is often of rapid onset and reversible, suggesting an acute vascular origin rather than chronic

Table 5.14 Diabetic neuropathy

Type of neuropathy	Body system/part affected	Symptoms/signs	Special points
Peripheral neuropathies			
Polyneuropathies:			
• Sensory	The lower extremities are the most frequently affected area	Reduced sensation: numbness, heaviness, insensitivity to heat, cold, and pressure Increased sensation: tingling, burning, pain (worse at night)	Serious risk of tissue damage as a result of heat, cold or pressure
• Motor			
— Amyotrophy	Muscles of the pelvic girdle	Severe muscle wasting and pain	Physiotherapy
— Muscle wasting	Muscles of the hands and feet	Loss of strength in hand grip Changes in walking pattern Pressure points altered Painless foot ulcers can develop	Aids to assist hand grip Chiropody Adapted footwear Care of the feet
Neuropathic arthropathy	Joints in the feet: 'Charcot's joints'	See 'The diabetic foot'	
Mononeuropathies:			
• Sensory	Femoral, sciatic, radial or ulnar nerve 3rd cranial nerve	Acute pain with sudden onset Weakness and paralysis Ptosis: drooping of the upper eyelid	Provide pain relief Improve diabetes control Refer to an ophthalmologist
• Motor	3rd, 4th and 6th cranial nerves	Squint: diplopia	
Autonomic neuropathies	*Cardiovascular system*		
	• Heart and blood vessels • Vasomotor centre	Postural hypotension Tachycardia at rest Painless myocardial infarction Reduced perspiration in lower extremities Increased perspiration in upper extremities	Symptoms such as syncope, dizziness and sweating; can be confused with hypoglycaemia
	Gastrointestinal system		
	• Stomach	Diabetic gastroparesis (delayed emptying) Nausea, anorexia Feeling of fullness	Altered absorption rate of nutrients can affect diabetes control
	• Bowel	Constipation Diarrhoea	Adjust diet
	Urinary system		
	• Bladder	Loss of sensation Incomplete emptying Retention of urine Atonic bladder Sphincter incompetence	Urinary stasis creates risk of infection which may lead to renal damage
	Reproductive system		
	• Male genitalia	Erectile dysfunction Retrograde ejaculation Infertility	Neuropathic, vascular and psychological factors usually coexist

metabolic disturbance (Williams & Pickup 1999). Examples of mononeuropathy include ptosis (drooping eyelid) and diplopia which can occur as a result of damage to cranial nerve III.

Autonomic neuropathies Damage can occur within the autonomic nervous system, causing numerous abnormalities in many areas of the body. Common manifestations are abnormal sweating, postural hypotension, diarrhoea and erectile dysfunction. Less common are gastroparesis and bladder dysfunction (Williams & Pickup 1999).

Prevention

Major benchmark studies such as the DCCT and UKPDS have shown that strict glycaemic control can decrease the risk of complications, including neuropathy. Other sensible

measures such as avoiding smoking and tight control of blood pressure, blood cholesterol and triglycerides are advised (see Ch. 2).

MEDICAL MANAGEMENT

Diabetic neuropathy affects many systems of the body. Management, which is essentially symptomatic, may involve the multidisciplinary efforts of the diabetes care team. A variety of treatment approaches may be adopted, including medication, surgery and physiotherapy.

NURSING PRIORITIES AND MANAGEMENT: Diabetic neuropathy

Devising ways to meet the particular comfort needs of the patient will be a central focus for nursing care. Reducing the risk of accidental tissue damage arising from severe sensory impairment will also be a priority.

Neuropathies can seriously interfere with lifestyle and emotional well-being. An example of this is erectile dysfunction which affects up to 35% of all men with diabetes (Williams & Pickup 1999). Erectile dysfunction can be devastating for both the patient and his partner. Many men with diabetes and erectile dysfunction would like help for this problem but are reluctant to seek advice. Once the diagnosis has been made, there are several treatment options available, including professional sexual counselling, vacuum devices, penile injections and oral agents such as sildenafil. The choice of treatment will depend on local circumstances, personal experience and, most importantly, the patient's own preference (Mills 2003).

For further reading on diabetic neuropathy, see Gries et al (2003); for more information on erectile dysfunction, see Alexander (2003).

The diabetic foot (see Table 5.15)

Successful management of the diabetic foot requires input from the multidisciplinary team including nurse, podiatrist, orthotist, physician and surgeon (Edmonds et al 1999).

Education of the patient is vital in the prevention of problems (see Box 5.7) and it is essential that the patient with diabetes is screened, at least annually, for foot disease (SIGN 2001).

Table 5.15 Clinical signs of the diabetic foot

Sign	Neuropathic foot	Ischaemic foot
Temperature	Warm	Cool
Pulses	Present	Absent
Pain	Loss of sensation	Intermittent claudication and rest pain
Skin	Dry cracking skin	Blanches on elevation
Deformity	Present	Absent
Position of ulcer	Plantar surface, toes or high pressure areas	Margins of foot and toes

Box 5.7

Measures to protect the feet in diabetes

General measures

- Do not smoke
- Take a healthy balanced diet
- Try to maintain body weight within normal limits
- Exercise — try to keep active; this will help improve the circulation
- Get blood pressure and blood fats checked regularly

Footwear

- Ensure correctly fitting shoes — ask for feet to be measured when buying shoes. Break in new shoes very gradually
- Ensure that socks or stockings fit comfortably — avoid constricting around ankles and avoid socks with thick seams
- Change footwear as soon as possible if wet
- Avoid walking barefoot — wear slippers and beach shoes to prevent injury
- Do not wear sandals if there is any loss of sensation in the feet

Foot care

- Bathe feet daily using lukewarm (not hot) water and soap
- Pat feet dry gently; pay special attention to the area between the toes
- Apply a moisturising cream daily to avoid dryness and keep the skin supple
- Avoid exposing feet to excess heat or cold
- Avoid sunburn to the feet and legs
- Cut nails according to the shape of the toes while they are still soft from bathing but do not dig down the side of the toenails
- Inspect feet daily for blisters, corns, calluses, cracks or redness (a mirror can help in seeing the underside of the foot)
- Do not burst blisters
- If a minor cut or abrasion does occur, wash thoroughly and cover with a clean dressing. See your doctor if the cut has not healed in 48 h
- Your chiropodist should be consulted for treatment of ingrown toenails, corns or calluses. Do not use home remedies or over-the-counter (OTC) products such as corn plasters
- Your general practitioner should be consulted for the treatment of verrucae
- A doctor or nurse should be consulted if foot problems such as tingling, numbness, swelling, pain or loss of feeling develop
- Ensure you have your feet inspected annually by a trained professional

Screening Foot examination by trained professionals should consist of:

- testing of foot sensation using a 10 g monofilament or vibration
- palpation of foot pulses and use of a Doppler if possible (see Box 5.8)
- inspection of foot appearance and footwear.

Box 5.8

Doppler ultrasound

A hand-held Doppler probe is a portable ultrasound designed to detect blood flow. It works by transmitting high frequency sound waves through the tissue and collecting the reflected signal (Grasty 1999). The movement of blood flow causes the reflected wave to undergo a frequency shift, the extent of this depending on the speed and direction of the flow. Systolic pressure can be measured by combining the use of the Doppler and a blood pressure cuff. The Doppler is now widely used by trained practitioners as a screening test to assess the peripheral arterial circulation (Vowden 1999).

Disorders of the foot in diabetes can occur as a result of two syndromes: the neuropathic foot and/or the ischaemic foot (Edmonds et al 1999).

Based on UK population surveys, diabetic foot problems are a common complication of diabetes, with prevalences of 23–42% for neuropathy, 9–23% for vascular disease and 5–7% for foot ulceration (SIGN 2001).

Painful peripheral neuropathy can be a major problem for many people, particularly at night. It can be treated with some success by tricyclic antidepressants such as amitriptyline. Gabapentin has also been shown to be effective, with fewer side-effects. Topical capsaicin should also be considered for localised neuropathic pain.

Deformity of the foot can lead to ulceration, particularly in the absence of protective pain sensation and with the contribution of unsuitable footwear. Early detection can initiate properly fitting shoes before ulceration occurs.

Charcot foot/Charcot joint is a neuroarthropathic syndrome with osteoporosis, fracture, acute inflammation and disorganisation of foot architecture (SIGN 2001). The patient may complain of a hot, red and swollen foot with or often without pain. Diagnosis should be made by clinical examination supported, where available, by the use of thermography (SIGN 2001). Immobilisation of the limb, usually by casting of the foot, and reduction of stress by decreasing the amount of weight-bearing on the affected limb through use of crutches are the current mainstays of treatment. However, other treatment options are being considered. One option is the use of i.v. pamidronate, a bisphosphonate which is a potent inhibitor of bone reabsorption with minimal effect on bone formation. This action stops the osteoclastic activity of bone breakdown, promotes healing and decreases local inflammation (Mrugeshkumar 2004).

For further information on pamidronate use, see Selby et al (1994).

Management of ulcers

Neuropathic ulcers are most frequently caused from callus build-up but can also be due to thermal injury, e.g. stepping into hot water, and to chemical injury, e.g. from use of corn plasters. Whatever the initial cause, the injury is usually not perceived by the patient, due to loss of pain sensation. In the neuropathic foot, the aim is to redistribute plantar pressures by some form of cast or cradled insole. However, in the neuroischaemic foot, the aim is to protect the vulnerable margins of the foot by using a wide fitting shoe (Armstrong & Lavery 1998).

The ulcer should be subjected to initial debridement and drainage of exudate. The larvae of the green bottle fly (maggots) can be a very effective method of debridement (Yates et al 2003). Stimulation of subsequent wound healing can be improved by a number of preparations such as becaplermin (Regranex) as well as the use of absorbent, non-adhesive dressings. Living human tissue replacement therapy can also be used for persistent wounds (SIGN 2001) (see Ch. 23).

Infection Initial prescription of broad-spectrum antibiotics is vital to help improve healing. A wound swab for culture should be taken before antibiotics are commenced. Progression to cellulitis and osteomyelitis will require hospital admission for administration of i.v. antibiotics, immobilisation and appropriate wound treatment. Stress hormones will be released in response to severe infection, which in turn cause hyperglycaemia. The resulting increase in insulin demand will present an increased challenge to the pancreas, and as a result metabolic crisis may ensue. Intravenous fluids and insulin may be required to stabilise the patient's condition.

Necrosis The ischaemic foot results from atherosclerotic changes in the distal vessels of the legs. It is important to explore the possibility of revascularisation in the infected neuroischaemic foot. Angioplasty is indicated in the treatment of single or multiple stenosis or short segment occlusions of blood vessels. If angioplasty is not possible because of long arterial occlusions, bypass should be considered (Edmonds et al 1999). In the neuropathic foot in which there is necrosis, surgical debridement will probably be required. However, severely affected patients may eventually require digital amputation or, in even more serious cases, a below knee amputation.

Nurses involved in the care of people with diabetes should undertake regular monitoring of the patient's feet and commence appropriate and timely treatment whenever necessary (Edmonds et al 1999).

Chronic complications of diabetes mellitus can have important implications for the planning of nursing care. Whether the patient is at home or in hospital, the nurse should carefully assess the individual's nursing needs, giving special consideration to risks associated with impaired circulation and sensation, increased risk of infection and delayed healing. Recognition of these risk factors will enable care to accommodate the patient's particular vulnerabilities and will help to ensure that suitable educational support is provided.

5.12 Explain the way in which infection can have an impact on diabetic control and consider the role of the nurse in minimising the effect of intercurrent infections.

FACILITATING SELF-CARE THROUGH EDUCATION

In most hospital and community settings the overall coordination of patient teaching is undertaken by the diabetes specialist nurse working closely with the specialist dietitian and the patient's physician. The National Institute of Clinical Excellence (NICE) has published guidance on patient education, recommending that 'structured patient education is made available to all people with diabetes at the time of initial diagnosis and then as required on an ongoing basis, based on a formal regular assessment of need' (NICE 2003). In many cases, however, the care of patients with diabetes will be undertaken by community and hospital nurses who are not specialists in diabetes care. All such nurses may be required to undertake a teaching role and must therefore ensure that their own knowledge base is adequate.

Assessment

Before embarking on a teaching programme, the nurse must determine the needs of the patient and family for information, and plan teaching strategies that will make the learning experience pleasant and effective (Ley 1997). By establishing a rapport with the patient and family, the nurse will be better able to assess the patient's needs in relation to:

- current level of knowledge about diabetes
- understanding about the reasons for prescribed treatment
- knowledge and skills required for self-care
- emotional response to the diagnosis
- social support from family and friends
- barriers to learning, e.g. sensory loss, mobility and manipulation problems, language difficulties, reading and writing difficulties and intellectual impairment.

Planning a teaching programme

Personnel

Any member of the diabetes care team may be involved in teaching the patient and family about diabetes. However, it is likely that the main responsibility for patient teaching will rest with the nursing staff, and in particular with the diabetes specialist nurse who will work in partnership with the patient and family (Brown 2003).

Materials and methods

An impressive array of informative and attractive booklets is available, many of which are sponsored by manufacturers and written by diabetes health care professionals. These provide visual back-up for teaching and discussion sessions. Video and computer programs can be provided for patients to view individually or in groups. Diabetes UK is an excellent source of educational materials (see 'Useful websites', p. 227).

Teaching sessions

The NICE guidance suggests principles of good practice rather than recommendations on the type, setting and frequency of education (Avery 2003).

NICE guidance (2003) suggests education interventions should:

- reflect the principles of adult learning
- be provided by an appropriately trained multidisciplinary team
- be delivered to groups of patients unless considered unsuitable or inappropriate
- be accessible to all local people, taking into account cultural needs and disabilities
- use a variety of techniques to promote active learning.

Sessions should be short and information presented in small, easily assimilated and integrated sections with teaching points categorised into lists. Ordering presentation so that the most important point is always raised first can help the patient to prioritise information. Being direct and specific will aid retention, as will using simple words and brief sentences. Before going on to a new topic, the instructor should use sensitive questioning to check the patient's recall and understanding of the material already covered (Ley 1997). Patients should be encouraged to ask questions and discuss the topics within the group.

Staff members should be consistent in the information they provide. Adopting a friendly manner and taking time to talk about non-medical matters can relax the patient and set the scene for a more productive teaching session. It is important to consider the age group for which teaching materials have been designed in order to avoid giving inappropriate information.

The programme

The teaching programme should be tailored to suit the patient's individual needs but is likely to include some of the following topics:

- What is diabetes mellitus? — type 1 and type 2
- Treatment of diabetes
  - — oral hypoglycaemics
  - — insulin therapy
    - why insulin and how does it work?
    - types of insulin
    - storage and administration of insulin
- the diet–insulin–exercise balance — insulin dose adjustment (see Box 5.9)
- monitoring blood glucose
- recognising and treating hypo- and hyperglycaemia
- what to do during illness
- testing for ketones
- avoiding complications
- health screening
- lifestyle factors — alcohol, smoking, recreational drugs, driving, travel, pregnancy and sexual health.

5.13 J is 15 years old and has insulin-dependent diabetes. He plays football for the school team, enjoys partying and goes swimming once a week. Consider how a short teaching session might be prepared to help J understand the significance of exercise to overall diabetes control, personal well-being and the prevention of chronic complications.

Box 5.9

Exercise in diabetes

Exercise and increased activity can provide many health benefits for the person with diabetes, such as improving insulin sensitivity, weight control and reduction, heart and circulatory protection, strengthening of joints and bones and many other benefits. Exercise will reduce blood glucose levels and a clear understanding of the role of exercise in blood glucose control is essential for every patient with diabetes. The nurse must find a way of explaining this role that is appropriate to the learning needs of individual patients. The analogy of 'fuel intake' (food) and 'energy output' (activity/exercise) is often useful for the purposes of illustration.

What happens during exercise?
When energy output is low, the demand for fuel in the form of glucose is also low. However, during bursts of activity the demand for glucose will rise and it is then drawn from reserves in the muscles and liver. The rate at which glucose is taken up by the cells is influenced by medication (insulin or tablets). If available supplies of glucose are depleted and are not replaced, the patient's blood glucose will fall and may continue to fall for several hours after prolonged or intense exercise, thus increasing the risk of hypoglycaemia.

Avoiding exercise-induced hypoglycaemia
Insulin-treated patients should be advised to monitor blood glucose before and after exercise and when to take extra carbohydrate to avoid hypoglycaemia. A quickly absorbable form of glucose such as glucose tablets or a glucose drink may be used to augment diet and help prevent an abrupt fall in blood glucose. Another strategy to avoid exercise-induced hypoglycaemia is for the insulin dose to be reduced prior to planned and prolonged strenuous activity. Insulin dose adjustment in relation to exercise is an important aspect of the patient's education programme when commencing insulin therapy. Blood glucose should then be monitored to gauge the effects of any reduction. Patients on oral antidiabetic therapy may, less frequently, also experience exercise-induced hypoglycaemia and consequently may need to adjust their carbohydrate intake to meet the additional energy demands imposed by the exercise.

Patients with type 1 diabetes should also be made aware that hyperglycaemia (blood glucose >14.0 mmol/L) with ketonuria is an absolute contraindication to exercise as this can indicate that there is a lack of circulating insulin and that the patient is metabolically unstable. Exercise in this situation could cause higher blood glucose levels and a risk of diabetic ketoacidosis (Burr & Dinesh 1999).

PROMOTING PSYCHOLOGICAL AND SOCIAL ADJUSTMENT

The emotional impact of diabetes mellitus

There is extensive literature that acknowledges the 'grief' that people experience in the face of any kind of loss of health or lifestyle and people diagnosed with diabetes may experience such grief and sense of loss. The diagnosis of diabetes has been likened to the experience of bereavement (Everett & Kerr 1998). In the context of diabetes, Jacobson (1996) describes that for some there is 'a clearly demarcated period of bereavement' and it has been suggested that the degree of early adjustment to their disorder can predict the subsequent development of anxiety and depression in youths with type 1 diabetes (Kovacs et al 1995).

The experience of loss in an individual, especially with type 1 diabetes, may be masked by the apparent acceptance of diabetes by virtue of the necessity to engage in specific self-care activities such as insulin injections and blood glucose monitoring. This can be described as at an intellectual level of acceptance. However, the degree of emotional acceptance may be hidden as the patient engages in an intensive programme of education designed to provide the knowledge and skills leading to self-management. Such intellectual acceptance and emotional acceptance are described as two stages in psychosocial adjustment to physical disability (Livneh & Antonak 1994). Examples of emotional non-acceptance include denial or part-denial, feeling stigmatised, alienated, angry, rebellious, self-blaming, guilt, isolated and unable to disclose their diagnosis (Brown 2001). The difference between intellectual and emotional acceptance can be understood from comments made by people with diabetes:

- *'You ask me anything about diabetes I could tell you … I'm right up to date with everything … I know everything about diabetes ... I'm one of those people who strives to know what I've got … to watch for the pitfalls …'*
- *'Probably the main reason I know I'm not in charge of my diabetes is because I've not accepted it yet … It's all to do with my brain … once I've accepted it, I know for a fact I will be more in control …'*

Psychosocial factors influencing self-management of diabetes

Diabetes self-management has been estimated to be seen as over 98% the patient's responsibility (Anderson & Funnell 2002). This is an enormous demand, not only on the person with diabetes, but also on the individual's family. One of the purposes of diabetes education is to impart knowledge and skills that enable the person with diabetes to make informed decisions about how they are going to lead their life with diabetes. However, there are other determinants of behaviour which can influence behavioural choices. These include health beliefs, locus of control, self-efficacy, behavioural intentions, quality of life and emotional adjustment.

Health beliefs

The health belief model (see Fig. 5.11) points to the significance to the person with diabetes of the perceived benefits, costs, severity and susceptibility within the diabetes experience that the person subjectively perceives in relation to themselves and their diabetes (Becker & Janz 1985):

- *A benefit might be perceived as: 'If I follow my regimen then I will avoid ill-health in the future'.*
- A cost might be perceived as: *'If I follow my prescribed regimen then my life will revolve around diabetes and there will be no time for anything else'.*

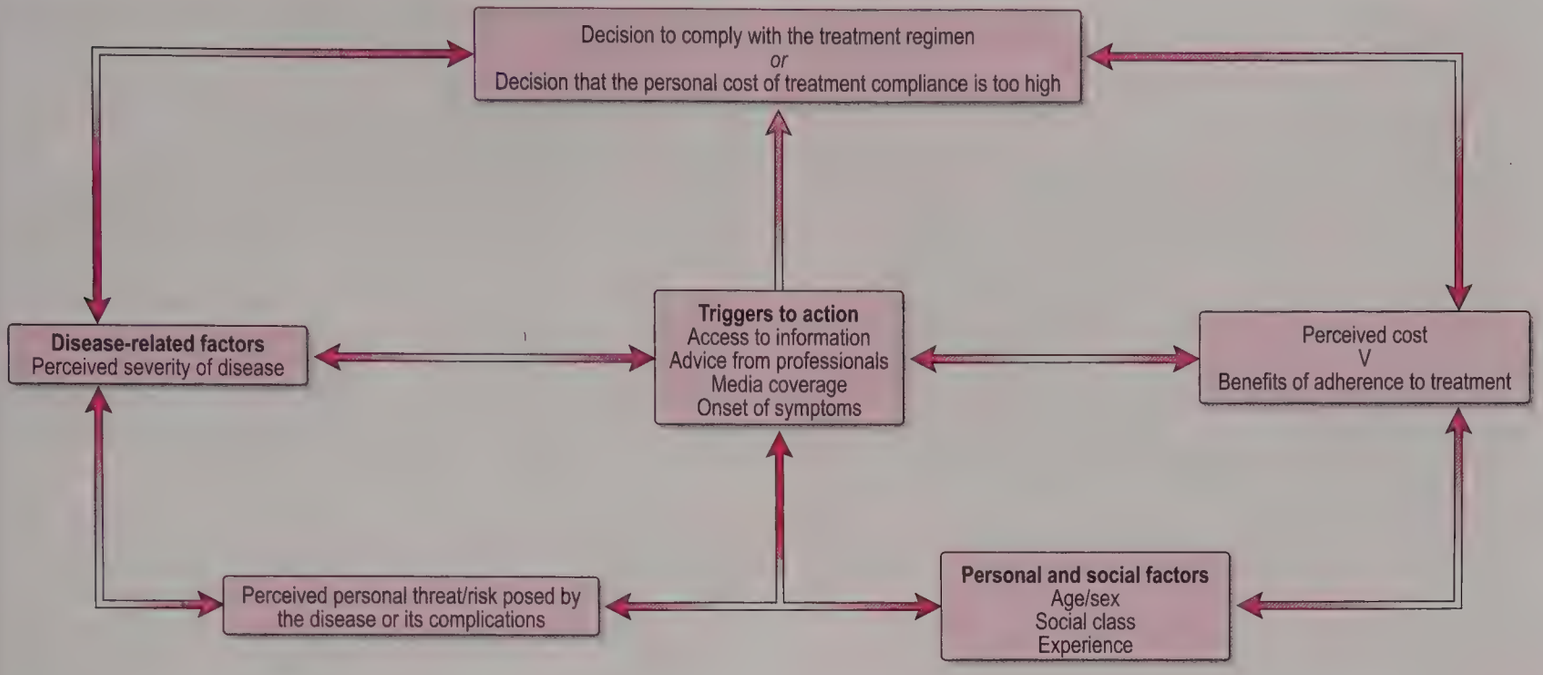

Fig. 5.11 The health belief model, summarised.

- Severity can be expressed as: *'Diabetes is serious and leads to complications'*.
- Susceptibility includes: *'If I have poor control then I will develop eye and kidney problems'*.

In order to live positively with their diabetes, people need to believe that benefits of self-care outweigh the costs.

People with type 2 diabetes may believe they are less susceptible to complications, particularly if they have been incorrectly told they have 'mild' diabetes.

Locus of control

Rotter's social learning theory of locus of control (1966) originally described the 'locus' as being either internal or external. It was suggested that a person operated somewhere along a continuum ranging from an internal locus, whereby the person felt personal responsibility for their health and subsequent outcomes, to an external locus, where the individual had no sense of influence over what happened to their health, perceiving it to be influenced by outside factors. The construct was further developed to recognise that some may see events as being in the hands of powerful others, such as health care professionals, or that events could be due to chance or fate (Wallston et al 1976). Bradley et al (1984), using a diabetes-specific multidimensional locus of control scale, found that when events were seen fatalistically, this was associated with poor glycaemic control.

Peyrot and Rubin (1994) designed a diabetes-specific locus of control instrument that helped them identify two components in internal locus of control that predict opposing outcomes in terms of self-management: the first component, autonomy, is linked with successful self-care; the second component, self-blame, may lead to negative outcomes because such self-blame results in an inability to access resources such as health care professional support. In addition, how the locus of control was perceived would influence how the individual would anticipate events happening in the future.

Self-efficacy

Self-efficacy theory describes the confidence, or otherwise, that an individual might have in expecting that a behaviour will result in a given outcome (Bandura 1977). Knowledge and understanding of the implications of health actions must be accompanied by a positive attitude and self-belief in individual capability to carry out those actions (Scriven & Orme 2001). Strengthening of self-efficacy is particularly important in older people to allow them to develop confidence and belief that they can reach desired outcomes (Heath & Schofield 1999).

Behavioural intentions

Peyrot and Rubin (1997) suggest that a person's intention to change their diabetes self-care practices leads to actual behaviour change but such change may not occur for several months. This is more likely to be the case for self-regulation behaviours such as blood glucose monitoring or taking medication on time, than for lifestyle change relating to diet or exercise.

Quality of life (see Box 5.10)

There are many definitions of quality of life (QoL) but, in general, QoL includes several domains such as psychological state, physical well-being, role functioning and social support (Everett & Kerr 2001). People with diabetes often have to make decisions about the balance between quantity of life versus quality of life; these issues are crucially important, because they may powerfully predict an individual's capacity to manage their diabetes and maintain long-term health and well-being (Rubin 2000). The most common decision may be about achieving a level of glycaemic control that prevents long-term complications against risking hypoglycaemia.

Box 5.10

Quality of life with diabetes mellitus: Mr P's experience

I have been an insulin-dependent diabetic for about 35 years, on two injections a day.

Over these years I have had a number of really bad 'hypos'. Some of them, my wife was able to bring me out of with the help of glucose drinks, chocolate or Dextrosol tablets. Other times, when I was saturated in sweat, and not able to respond in any way, and therefore appeared to be unconscious, only then would a doctor be called. This was usually in the night, and then 8 out of 10, an ambulance would be called, which was very alarming, for myself and also for my wife who felt unable to help me in those situations.

I had always regularly attended the hospital diabetic clinic, where the normal required checks would be carried out. However, a few months ago through the clinic I was offered the chance to go onto a different type of insulin given by using the pen system. I now give myself an injection of two different kinds before breakfast, then another before lunch, and another before tea.

The purpose of the changeover from pork insulin to synthetic human insulin, i.e. NovoRapid and glargine, was to try and eliminate high and low sugar readings in my numerous daily tests that I do, and to get them on a much more balanced level.

I have still had a number of episodes where my sugar level has become very low, when I have had to eat something sweet to push my blood sugar level up again. On the whole, the changeover is working out a lot better than before, and it just means minor adjustments to the amounts I give myself each day until I get it right. Since the changeover, I have been in contact with a specialist diabetic nurse and have spoken to her quite a number of times when I have had any queries. She also contacts me regularly just to see how things are, which I find very reassuring. I have always tried to lead a normal life, and to keep my diabetes under tight control, and to keep myself as fit as possible and my weight steady, as I know how important these factors are in keeping me as healthy as possible.

Some people will risk long-term complications in order to avoid hypoglycaemia. An example might be:

I'd rather not live so long, rather than live the way you have to live in order to keep the blood sugars low …

Emotional well-being and depression

Emotional well-being correlates positively with optimal self-care practices (Rose et al 2002). In particular, high self-esteem relates positively to self-care; depression and/or anxiety relate negatively to self-management. The incidence of depression and anxiety, affecting one in five people with diabetes, is much higher than in the general population. Although the aetiology is unclear, it is probably related to the daily demands of self-care practices, the physiological effects of blood glucose changes, including hyper- and hypoglycaemia, and to the disease process with its long-term complications (Lloyd & Brown 2002). Depression is considered to have such a significant impact on the person with diabetes and their self-management abilities that regular annual screening for depression is recommended for all people with diabetes (SIGN 2001).

Education and behaviour change

The compliance model of diabetes education

Traditionally, diabetes education was delivered using what is described as the 'compliance model'. In this approach, health care professionals (HCPs) teach patients knowledge and skills, and set targets for them to achieve, based on the evidence available, in order to prolong a physically healthy life. When glycaemic control is not achieved, the HCP uses their expertise to diagnose the problem and to instruct the patient on the best course of action. People with diabetes are expected to follow the HCP's advice.

The empowerment model

Since the early 1990s, an alternative model of educational care has been advocated. The empowerment model (Funnell et al 1991) acknowledges the patient's expertise, their personal responsibility in self-management and their right to informed choice in treatment. It acknowledges the importance of both quality and quantity of life, taking into account the many determinants of behaviour that exist.

The concept of empowerment in diabetes 'emerged out of the realisation that patients cannot be forced to follow a lifestyle dictated by health care professionals' (Feste 1992).

More recently, the idea of the empowered patient has been supported in the National Service Framework for England and Wales (DH 2001) and in health policy for Scotland (Scottish Executive Health Department 2002).

The key to facilitating self-empowerment is in the nature of communication between the nurse and the person with diabetes (Brown 1997).

- An open questioning style will help the person with diabetes to decide what they want to change (*'What do you find most difficult about your diabetes?'*).
- Exploring thoughts and feelings around the chosen issue (*'What is that like for you? … How do you feel about that? … What are your thoughts about the situation? … How would this have to change for you to feel better about it?'*).
- Inviting commitment to that behavioural change. Working together to develop a plan to implement the change, taking into account the costs and benefits and the obstacles and support that might be experienced (*'Are you willing to take action to improve the situation for yourself? ... What steps could you take to bring you closer to where you want to be?'*) (Anderson & Funnell 2002).

The planned behaviour change should be evaluated so that options can be considered if the initial plan is unsuccessful.

For further reading on psychology in diabetes care, see Snoek & Skinner (2000).

Relationships

Family relationships

If the family unit was previously stable, diabetes is unlikely to have an adverse effect on family relationships. Indeed, patients who enjoy good support from their families show enhanced stability and are more likely to adopt

recommended health maintenance behaviours (Maclean & Lo 1998).

However, the very nature of diabetes, with its attendant rules and restrictions, may allow the disorder to be used by family members or the patient as a means of manipulation or self-assertion. This is more likely to occur where family relationships were difficult prior to the diagnosis of diabetes (Laffel et al 2003).

Sexual relationships

Although embarking on a sexual relationship is anxiety-provoking for many people, it raises particular concerns for people with diabetes. Uncertainty may be felt about when, and if, to tell the other person about the diabetes. Practical issues such as what to do if a 'hypo' develops when out on a date or, even worse, during lovemaking, may cause real worry. Having to explain such things as set eating and injection times or dietary restrictions may cause embarrassment and may be seen as interfering with the spontaneity of a budding relationship. The mere presence of diabetes can affect the quality and quantity of a patient's relationships (Polonsky 2000).

Family planning

Information on pregnancy and contraception should be made available to all women with diabetes who are of child-bearing age. There are no contraceptive methods specifically contraindicated in women with diabetes. However, methods with a proven high degree of effectiveness are preferred, as unplanned pregnancy can lead to serious risks for the mother and baby. Low dose oestrogen preparations of the combined oral contraceptive group are safe for the majority of women. The presence of diabetes complications and other risk factors should be considered when deciding on the type of oral contraceptive pill, and progesterone only preparations may be more appropriate in women with these factors. It is important, with oral contraceptives, to monitor blood glucose levels regularly as some of these drugs can cause fluctuations in glycaemic control (Williams & Pickup 1999).

A healthy pregnancy and happy outcome is possible if excellent glycaemic control is achieved before and during pregnancy. Prospective parents may worry about passing on their diabetes to the baby and genetic counselling may be offered to enable the couple to make an informed decision (see Ch. 6). If the woman has severe complications of diabetes, the couple may be advised against pregnancy as it could lead to a worsening of her condition and put her at greater risk of illness during her pregnancy.

For a discussion of genetic and other pregnancy-associated risks, see Parker (1996).

Pre-conception Ideally the couple should attend for pre-conception counselling to help reduce the risks to mother and baby. Strict control of blood glucose before conception greatly helps towards improving the outcome of the pregnancy. Once pregnant, the woman's progress should be monitored on a regular basis by a specialist team, consisting of diabetes specialist nurses and midwives, diabetologists, obstetricians and dietitians.

For further information on diabetes and pregnancy, see Moshe (2003).

Gestational diabetes Gestational diabetes (GDM) is glucose intolerance, which presents or is first recognised during pregnancy and a diagnosis of GDM identifies the woman as at risk of developing type 2 diabetes in the future (SIGN 2001).

The Scottish Intercollegiate Network (SIGN 2001) details the management of both existing and gestational diabetes.

Social relationships

Patients with diabetes quite naturally resist being singled out and labelled. This can create real difficulties. On the one hand, coping with diabetes means that the individual may have to rely on others should a crisis occur. On the other hand, the person with diabetes may resent being treated differently from others. The patient's adjustment within their social milieu will involve a complex interplay of personal and social factors; the degree of success will vary considerably from person to person.

Access to counselling should be provided for those people who are experiencing relationship difficulties arising from their diabetes.

5.14 What do you understand by the term 'labelling'? Why do you think people with diabetes may be concerned about being labelled?

Lifestyle implications

Employment

In view of the risk of hypoglycaemia, people with diabetes who are treated with insulin are excluded from some areas of employment, e.g. those which involve certain categories of vocational driving (see below for driving regulations), airline piloting and air traffic control, deep sea diving, working on offshore oil rigs, working at the coal face, at heights or near dangerous moving machinery. Diabetes would also exclude an applicant from joining the UK armed forces or the police. However, in many cases, if diabetes develops while in the job, it is sometimes possible to continue employment.

For further information, contact Diabetes UK (see 'Useful websites', p. 227).

Driving

The UK Driver Vehicle Licensing Authority (DVLA) must, by law, be informed when a driver is diagnosed as having diabetes mellitus and is receiving treatment with insulin or oral antidiabetic medication. Those who are treated with insulin will be issued with a licence for a period of 1–3 years to allow periodic review by the DVLA. A medical practitioner may be required to advise on the stability of the driver's diabetes control prior to re-licensing. The DVLA must be informed if any problems or diabetic complications develop which may affect safety.

A person holding a Large Goods Vehicle (LGV) and/or a Passenger Carrying Vehicle (PCV) licence will have their licence removed when they commence insulin therapy. There are also restrictions on lighter goods and smaller passenger vehicle licences.

For further information, contact the DVLA at www.dvla.gov.uk.

Box 5.11

Diabetes UK

Diabetes UK (formerly the British Diabetic Association) is a charitable organisation which raises money for diabetes research and provides information and advice for people with diabetes and professionals involved in their care. As well as being a national organisation, it has local branches throughout the UK. Different sections cater for particular groups, e.g. teenagers. Diabetes UK offers help and advice on a wide variety of topics such as monitoring and treatment approaches, insurance, holidays and travelling abroad.

Full members of Diabetes UK receive the bi-monthly journal *Balance* free of charge. This is an excellent publication which provides a forum for people with diabetes and their families to exchange ideas and keep up to date with current progress in diabetes management. *Balance* is also produced on audiotape for visually impaired subscribers.

Hypoglycaemia is the main danger when driving. People with diabetes should receive education regarding how to avoid and effectively manage hypoglycaemia when driving.

Car insurance

Patients whose diabetes is treated with medication must inform their insurer. Failure to notify the insurer can invalidate any claim. Diabetes UK have their own insurance broker who can advise on any insurance-related matter (see Box 5.11).

Travel

Altered mealtimes, travelling across different time zones, and dietary and climatic changes may all have an effect on diabetes stability. It is therefore essential for the person with diabetes to monitor their diabetes closely whilst travelling. Travellers with diabetes should seek specific advice from their GP or the diabetes team regarding insulin adjustment. All medication and monitoring equipment should be carried in hand luggage to allow for ready access and to reduce risk of loss. Also, the extremely low temperature of the hold can adversely effect the action of insulin.

Most airlines now require the traveller to carry a letter from a medical practitioner detailing the need to carry syringes, pen needles and blood glucose monitoring equipment in their hand luggage.

For further information on travel, see www.diabetes-travel.uk or contact Diabetes UK (see 'Useful websites', p. 227).

Eating out

Flexible insulin regimens, insulin pen devices and home blood glucose monitoring (HBGM) have simplified eating out for people with diabetes. People on insulin therapy are advised as to appropriate insulin adjustment to allow more freedom of choice when dining out.

Smoking

People with diabetes are at greater risk than others of developing vascular and neuropathic disorders. Smoking compounds these risks. The health care team should encourage smoking cessation and should discuss the availability of resources to provide support whilst the patient is trying to give up smoking (Haire-Joshu et al 2003). However, it must be accepted that the patient has freedom of choice and may decide to continue to smoke against advice.

Identification

Patients should be strongly advised to carry a card or wear a MedicAlert pendant or bracelet to identify themselves and to give details of the type of diabetes they have and its management.

FUTURE DEVELOPMENTS

Research in diabetes care is at an exciting stage. Combined kidney and pancreas transplants are now undertaken in a number of centres in the UK for those in renal failure as a complication of type 1 diabetes. Successful transplantation allows the patient to be free of the restrictions of renal dialysis as well as daily injections of insulin. Five years after transplantation, 60% of patients remain well without needing insulin injections (Watkins 2003).

Islet cell transplantation offers people with type 1 diabetes hope for a cure. This process is the subject of intensive research trials (Swift & White 2003). Islet cells are isolated from the donor pancreas and injected into the liver of the recipient. In the liver, the cells develop a blood supply and begin to produce insulin, a process called the Edmonton protocol. At Diabetes UK's Spring 2003 National Conference, James Shapiro, the surgeon taking the procedure forward, reported that 50 patients in the UK had received islet cell transplants and, of these, 85% were insulin independent within a year. This figure fell to 70% in 2 years. New combinations of immunosuppressive agents prevent the body rejecting the transplanted islet cells, thus eliminating the need for steroid therapy which could damage the newly transplanted cells. The major drawback to the increasing availability of this advance is that the equivalent of two donated pancreas is required to provide sufficient islet cells for transplantation.

For further information, see Diabetes UK (see 'Useful websites', p. 227).

Over the years, feasibility studies into the effectiveness of non-enteral routes of delivering insulin have been attempted. These have included ocular, buccal, rectal, vaginal, oral, nasal and uterine delivery systems. However, a growing body of evidence suggests that inhaled insulin is an effective, well-tolerated, non-invasive alternative to s.c. soluble insulin for patients with type 2 diabetes (Cefalu 2003).

It is increasingly recognised that diabetes is not merely a disease of a single hormone (insulin) but that the absence of multiple pancreatic hormones is implicated. C-peptide, traditionally thought to be biologically inert, has been shown to have an effect on appetite and reducing hypoglycaemia. Various other pancreatic hormones including GLIP-1 and Exendin-4 have been synthesised and shown to be effective in treating type 2 diabetes soon after failure of oral therapy (Edwards et al 2001). These hormones have some benefit in type 1 diabetes and the value outweighs the cost of added injections (Idris & Donnelly 2003).

The ultimate hope is that diabetes will at some future date be preventable. Researchers continue to seek definitive answers to the questions surrounding aetiological factors, with a view to finding ways of manipulating these factors to prevent the disease developing.

Trends in health care provision

The political and economic climate in the UK over the past two decades has given rise to significant changes in the structure and function of the primary care team and has shifted the focus of health care toward the community setting. Emphasis has been on developing further the role of the diabetes specialist nurse who 'can transform the standard of diabetic care, achieving liaison between hospital, general practitioner and patients at home and offering a wide range of clinical and educational expertise' (Watkins et al 2003).

The growth in the number of practice nurses has made it possible for many GPs to run their own clinics for diabetic patients. In some areas, community dietitians and podiatrists are available for consultation in the health centres where clinics are run.

Community nurses and health visitors may find themselves, to an increasing extent, taking high-quality diabetes care directly into the patient's home. Effective hospital–community liaison will become especially important to ensure continuity for the patient in 'shared care'.

Whatever the care setting, it is important that the patient has access to facilities for estimation of glycated haemoglobin and microalbuminuria and for screening for retinopathy and foot-threatening neuropathic or vascular disease. It seems likely that integrated hospital and community care will offer the best use of resources for diabetes screening. However, dealing with a severe metabolic crisis such as DKA will remain the province of the hospital.

Continuing education for all members of the diabetes care team must be a priority. National standards and guidelines such as the National Service Framework (DH 2001) and Scottish Intercollegiate Guidelines Network (SIGN 2001) are necessary to create best practice through a firm research base and to support provision of the highest possible quality of care for people with diabetes. Diabetes specialist nurses and community diabetes facilitators can make a significant contribution in the education of their colleagues. Providing the education and support which will enable the patient to move away from the despondency and fear which frequently accompany diagnosis, towards independence and autonomy, is surely both the science and the art of nursing care in diabetes mellitus.

INTRODUCTION

Genetics is the study of genes and their relationship to hereditary characteristics. Genes are units of deoxyribonucleic acid (DNA) found in the chromosomes within the nuclei of living cells. They carry coded information that influences physical and psychological characteristics and susceptibility to many major life-threatening diseases.

This chapter provides a basic outline of the mechanics of genetic inheritance, raises awareness of the genetic aspects of common diseases and outlines nursing roles in genetic counselling. A small number of classic but rare genetic conditions are described and the principles of cancer genetics are introduced.

Our genes play a fundamental role in determining our health. Greater knowledge of genetics has had, and will continue to have, a major impact on the understanding of human illness, disease prevention, diagnosis and treatment. It is estimated that 6 out of 10 people by the age of 60 will develop a disease which is at least partially genetically determined (DH 2003). The wide range of genetic influences in health and disease will mean that nurses in most areas of practice will require an understanding of genetics and the ability to apply this to practice. As our understanding of the genetic predisposition to common diseases, such as cancer, heart disease, diabetes mellitus and asthma increases, genetics becomes an integral part of many nursing roles. The combination of environmental and genetic factors will determine whether a predisposition manifests in actual disease. Increasing public awareness of the environmental factors may help people avoid some of the consequences of their genetic makeup.

Within the specialised field of genetics, there is the more focused role of the specialist nurse, who is involved in non-directive counselling, diagnosis, testing and support of individuals and families with genetic conditions (Skirton et al 1997).

THE MECHANICS OF GENETIC INHERITANCE

Chromosomes

Each human cell contains 46 chromosomes within the nucleus, with the exception of the gametes (ova and spermatozoa), which contain 23 chromosomes. Of the 46 chromosomes, 23 come from one parent and 23 from the other. These chromosomes are paired, giving 22 pairs called autosomes 1–22 and one pair of sex chromosomes, either XX for females or XY for males.

By staining, photographing and arranging according to size, the chromosomes extracted from a cell can be organised into a karyotype. A normal female karyotype would be reported as 46, XX and a normal male karyotype as 46, XY (see Fig. 6.1). Chromosomal abnormalities can be identified by this method.

Cell division

To understand the mechanisms of genetic inheritance, it is necessary to be familiar with the basic processes of cell division, i.e. mitosis and meiosis.

Mitosis

is the normal process of cell division for growth and replacement of cells. The genetic information in one parent

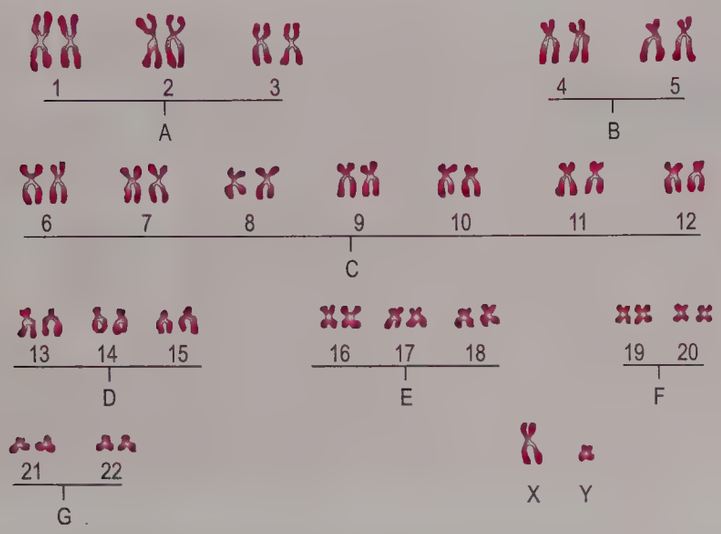

Fig. 6.1 Karyotype of a normal male.

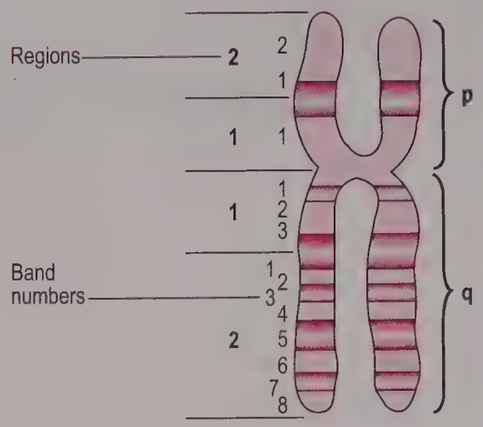

Fig. 6.2 The X chromosome: regions and bands. Each chromosome has a narrow waist called the centromere and a long and a short arm. The short arm is labelled p (from the French petit) and the long arm is labelled q. The tip of each arm is called a telomere. Chromosomes can be divided for reporting purposes into numbered chromosome regions, with region 1 closest to the centromere. Each region is further divided into bands.

cell replicates and divides to produce two daughter cells, each with 46 chromosomes carrying the identical genetic information.

Meiosis

is the process of cell division, which results in the production of gametes, ova or spermatozoa. Unlike mitosis, the four resulting cells have only one copy of each chromosome pair (23 chromosomes). New pairings are established when the ova and spermatozoa come together at fertilisation, re-establishing the full chromosome complement of 23 pairs (46 chromosomes). Within this process, rearrangement of chromosomal material results in the individual differences seen in offspring, whilst familial genetic patterns are still maintained. If meiosis is not successful, one gamete may end up with abnormal chromosomes or an incorrect number of chromosomes. The results of this are seen in the classic chromosome conditions. An example is Down's syndrome (trisomy 21) where the individual has 47 chromosomes, with three copies of chromosome 21. Chromosomal abnormalities often lead to miscarriage, usually early in pregnancy. However, some pregnancies may result in the birth of an affected child.

DNA and RNA

In 1944, chromosomal nucleic acid was shown to be the carrier of genetic information. Two types are recognised: DNA (deoxyribonucleic acid) and RNA (ribonucleic acid).

A molecule of DNA is composed of two nucleotide chains spiralled round one another to form a double helix. Genes are carried in this DNA.

Genes

Genes are units of DNA, consisting of coded hereditary information and are carried on the chromosomes. As chromosomes are paired, each pair carries two copies of each gene (with the exception of the genes on sex chromosomes in males). Each gene is located at a specific point on a chromosome known as its locus. Chromosomes can, for identification purposes, be divided into numbered chromosome regions and bands so that, if known, their position can be charted (see Fig. 6.2). Genes at the same locus on chromosomes are called alleles. If the two alleles at a locus are identical, the individual is said to be homozygous at that locus and if they are non-identical, the individual is said to be heterozygous.

With the exception of identical twins, each individual carries unique sequences or patterns of DNA. These genetic patterns can be recorded by a technique known as DNA fingerprinting and can identify individuals, as for example in forensic medicine or paternity testing (see Box 6.1).

There are at least two kinds of genes: structural genes, which specify protein synthesis, and genes that act as 'switches' to activate or deactivate structural genes and maintain homeostasis.

The coded information contained in the structural genes is translated with the help of RNA into specific proteins. The RNA becomes a mobile copy of the corresponding encoded blueprint in the DNA (messenger RNA, or mRNA).

Box 6.1

DNA fingerprinting

Paternity testing has been revolutionised by the technique known as DNA fingerprinting. Throughout the human genome, there are repeats of short sequences (tandem repeats) called minisatellite DNA. They have no known function but are valuable tools for genetic analysis. After DNA digestion with a restriction enzyme and electrophoresis, a DNA minisatellite probe will identify multiple DNA fragments from many chromosomal regions. The number and size of these fragments are unique to each individual, except for identical twins. In other words, one can generate a unique genetic fingerprint specific only to that individual. Each band is inherited from one parent and therefore a putative father can be either excluded or positively identified. DNA can be extracted from dried bloodstains or semen; for this reason this technique has had important implications for forensic medicine.

Some of these proteins are enzymes that catalyse specific chemical reactions. Others form part of the structure of body cells and tissues. Molecular biology has been able to describe the process of enzyme movement and matching of chemical bases along the coding strand of the DNA double helix, which is involved in translating genetic codes into mRNA for protein synthesis.

For information on genes and genetic inheritance, see Skirton & Patch (2002).

THE HUMAN GENOME PROJECT

The Human Genome Project (HGP) originally arose because of the need to develop new mutation detection methods and was a unique collaboration to determine the entire nucleotide sequence of the human genome.

The aims of this project were to:

- identify all of the genes in human DNA. There are approximately 30 000 genes in human DNA, fewer than were anticipated
- determine the sequences of the 3 million chemical base pairs that make up human DNA
- store the information on a database
- improve the tools for data analysis
- transfer related technologies to the private sector
- address the related ethical, legal and social issues.

Identification and understanding of the genes responsible for disease may help towards the future treatment of genetic conditions. Currently, however, there is very little available in the form of curative treatment.

For information on the Human Genome Project, see Venter et al (2001), Francis et al (2003) and www.genome.gov.

CATEGORIES OF GENETIC CONDITIONS

The three main categories of genetic conditions are:

- chromosomal anomalies
- single-gene or Mendelian conditions
- multifactorial or polygenic conditions.

Chromosomal anomalies

Autosomal variations

Numerical autosomal chromosome variations

Abnormalities can arise if, during meiosis, non-disjunction takes place and both of one pair of chromosomes passes to one gamete and the other gamete does not get a copy of that chromosome. If fertilisation takes place, the zygote will then have either three copies of the chromosome (trisomy) or only one copy (monosomy). One example of a trisomy is Down's syndrome (an extra copy of chromosome 21) with its characteristic appearance, a degree of learning disability, and sometimes cardiac and intestinal abnormalities.

Autosomal chromosomal deletions and translocations

Structural variations arise if a part of a chromosome breaks off and attaches itself to another chromosome. This will result in the gamete either having part of a chromosome missing (a deletion) or having a rearrangement (a translocation).

A balanced translocation does not cause any abnormality because chromosomal material is not gained or lost. However, there will be a higher risk of an unbalanced chromosome complement occurring when that individual has a child. This may result in a spontaneous abortion or an affected child with possibly physical and/or learning difficulties.

Chromosomal abnormalities are often found in spontaneously aborted fetuses. The risk of a couple having another affected child with a chromosomal abnormality is usually low. The risk to other family members is even lower. However, if one of the parents is found to carry a balanced translocation, the risk of another affected child is greatly increased. Balanced translocations account for approximately 5% of chromosomal abnormalities. In this situation, all relatives can have their chromosomes checked for the translocation (Bonthron et al 1997).

Sex chromosome variations

Although the psychological implications of the diagnosis of a sex chromosome anomaly may be profound, the problems caused by these abnormalities tend to be less severe than those resulting from autosomal abnormalities. Consequently, a significant number of people may have a sex chromosome variation without being aware of it. It is now known that numerical abnormalities of the sex chromosomes are not as rare as was once believed (Harper 2004).

Sex chromosome variations often result in infertility; therefore, the diagnosis may only be made for the first time following fertility investigations. Occasionally an affected fetus may be diagnosed during antenatal screening. Diagnosis in children may be made at a paediatric growth or endocrine clinic following investigation of abnormal growth patterns.

An example of a sex chromosome variation is Klinefelter's syndrome (an extra copy of the X chromosome in a male). The boys have a normal physical appearance and usually a normal level of intelligence. The personality may be more reticent. After puberty the testes are small, facial hair is scant and sometimes there can be a degree of breast enlargement. Most of those with Klinefelter's syndrome are infertile, but it is important to note that sexual performance is not impaired.

It is rare for sex chromosome abnormalities to recur in a family, even in the offspring of affected fertile individuals.

Single-gene or Mendelian conditions

These conditions are caused by a mutation in one of our genes. An individual who carries a genetic mutation is at risk of passing the mutation to the next generation. The risk of having an affected child can be calculated if the mode of inheritance and details of the family history are known.

The inheritance of single-gene conditions can be:

- autosomal dominant
- autosomal recessive
- X-linked.

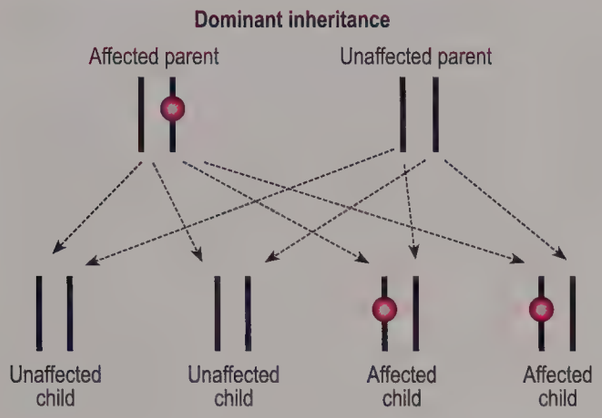

Fig. 6.3 Autosomal dominant inheritance.

Autosomal dominant inheritance

Autosomal dominant conditions are caused by a mutation in a dominant gene on one of the 44 autosomes. One gene on a pair of autosomes will be normal, while the corresponding gene on the other autosome will have a mutation. If the mutated gene is dominant, it will overrule the normal gene. As a result, the individual who carries the mutation will ultimately be affected by the condition. Those who carry a dominant gene mutation will have a 1 in 2 (50%) chance of passing it on to each of their children (see Fig. 6.3). This is because during meiosis only one of each pair of chromosomes will pass to each ovum or sperm. Whether the disease is or is not transmitted from the parent will depend on whether the ovum or sperm contains the chromosome with the normal gene or the chromosome with the gene mutation.

It is important to note that there is a 50% chance, in each pregnancy, of the fetus inheriting the gene mutation. Therefore, if there are two children, it is not inevitable that one will inherit the mutation and the other will not. It could be that both inherit the mutation, neither inherits it, or one will and one will not.

As the mutation is on an autosome rather than a sex chromosome, the sex of the individual is of no consequence to inheritance. If an individual tests negative for a known gene mutation in their family, they cannot pass on the mutation to their children.

Four distinct features can complicate genetic counselling in dominant conditions:

- non-penetrance or reduced penetrance
- variable expression
- anticipation
- new mutations.

Non-penetrance or reduced penetrance

In autosomal dominant disorders it is possible for an individual to have inherited a mutation from their affected parent, to show no detectable signs of the disease themselves and yet the disease manifests itself in their children. Although the disease may appear to have skipped a generation, the gene mutation must have been present in all three generations. This is known as 'reduced penetrance' or 'non-penetrance'. Hereditary breast cancer is a good example of this. Individuals who carry a BRCA1 mutation (one of the genes known to predispose to breast cancer) will not inevitably develop breast cancer. Their lifetime risk of breast cancer is high but approximately 15% will not develop the disease (Thompson et al 2002). This feature of autosomal dominant inheritance complicates the genetic counselling process as an extra element of uncertainty is introduced. However, it is possible, in a general way, to relate the degree of penetrance to the risk of developing the condition. Where penetrance of a condition is high, it is unlikely that an unaffected individual will carry the genetic mutation and where penetrance is low, even individuals who carry the gene mutation have only a small risk of developing the disorder.

Variable expression

is where a genetic disorder presents itself with varying severity or in different ways in individuals who carry the causative mutation. Individuals may be mildly or severely affected or may present with a variable clinical picture (phenotype). One example of this is tuberous sclerosis. Tuberous sclerosis is a multisystem genetic condition, the most commonly involved systems being the skin, central nervous system and the renal system. Apparently unaffected parents can have a child who is severely affected with uncontrollable epilepsy, severe learning difficulties and behavioural problems. During the process of genetic counselling, thorough investigation of the parents may reveal mild features of the condition (such as the skin features). Although in this case scenario the couple will have a 50% risk of having a second affected child, it is not possible to predict how severely affected the child may be. The child may be mildly affected like the parent, or severely affected like the sibling.

The age of onset of dominantly inherited conditions can also be variable. With some conditions, symptoms may not appear until young adulthood or middle age. Examples of these are myotonic dystrophy (see p. 243) and Huntington's disease (see p. 244).

Anticipation

In some conditions, the nature of the gene mutation allows it to increase in size as it passes down to the next generation. This is known as 'anticipation' and tends to result in a more severe form of the resulting disease. One example of this is myotonic dystrophy (see p. 243).

New mutations

A genetic disorder may be caused by a new mutation in that individual rather than the individual having inherited the mutation from the previous generation. This is a very important factor in the genetic counselling process as the risk of the couple having a second affected child will be very different. In tuberous sclerosis, two-thirds of newly diagnosed cases will be the result of a new mutation. If the disorder is the result of a new mutation, the risk of a second child being affected will be very low (1–2%), compared with the 50% risk if the mutation was inherited from either one of the parents.

The rate of identification of genes responsible for classic genetic conditions is small but is steadily increasing. Consequently, the availability of genetic testing for autosomal dominant conditions is also increasing. If the gene mutation responsible for causing a condition is identified in an

affected individual (proband), other family members can be offered a test to identify whether or not they have inherited the mutation. Knowing that they do not carry the mutation offers certainty that they will not develop the condition and cannot pass the condition on to their children. Knowing that they do carry the mutation means that they have a 50% risk of passing the mutation on to their children. However, in conditions where non-penetrance, variable expression or anticipation may be a factor, uncertainty remains regarding if, when and how the condition will manifest itself.

Autosomal recessive inheritance

Autosomal recessive conditions are caused by mutations in both copies of the same autosomal gene. An example of an autosomal recessive condition is cystic fibrosis (see p. 236). Parents have two copies of each gene and both pass on one copy to each child. If they have a gene mutation in one of their autosomes then there is a 50% (1 in 2) chance that they will pass that mutation on to each of their children. As the parents have one normal and one mutated copy of the gene, they are carriers and are not affected by the condition. The risk of having a son or daughter affected by the condition is 25% (1 in 4) (see Fig. 6.4). The risk that the child will inherit only one copy of the gene mutation from either parent is 50% (1 in 2), making them a carrier of the condition like their parents. There is a 25% (1 in 4) risk that the child does not inherit a mutation from either of the parents and this means that they will not be a carrier or be affected. Parents who are closely related (consanguineous) are more likely to have a child with a recessive condition, as they will share a greater percentage of the same genes and possibly the same genetic mutations. Population screening in subgroups of the population at high risk can detect carriers of certain conditions so that detection and early treatment can be offered if appropriate (Kingston 2002). In autosomal recessive conditions, the precise risk depends on the frequency of heterozygotes in the population. Screening can also be offered to relatives, usually following a diagnosis of a condition in the family. Many autosomal recessive conditions are severe and include complex malformation syndromes and recognised inborn errors of metabolism, e.g. phenylketonuria. It is not unusual to have an affected child born where there is no known family history of the condition (Harper 2004).

X-linked inheritance

X-linked conditions are caused by a mutation in a gene on the X chromosome. Males are affected by the condition as they only have one copy of the gene, whereas females are less likely to be affected as they have two copies. Females inherit one X chromosome from their father and one from their mother. If a female carries a mutation on one copy of her X chromosomes she will have a second normal copy. This results in her being a 'carrier' but she is unlikely to develop the condition. Occasionally a female can show signs of an X-linked condition; this is known as a 'manifesting carrier'.

A male inherits a Y chromosome from his father and an X chromosome from his mother. If he inherits a mutated X chromosome from his mother, he has no second copy and will therefore have the condition associated with the gene mutation.

If a carrier female passes on her mutated X chromosome to a daughter, the daughter will be a carrier like her mother. In the case of an affected male with an X-linked condition, all of his daughters will be carriers but none of his sons will either be affected by or carry the condition (see Figs 6.5 and 6.6).

Genetic testing can only be offered to family members if the causative mutation is identified in the affected child. Complicating features of X-linked conditions include new mutations (see autosomal dominant) and gonadal mosaicism. Gonadal mosaicism is when the mutation arises in the

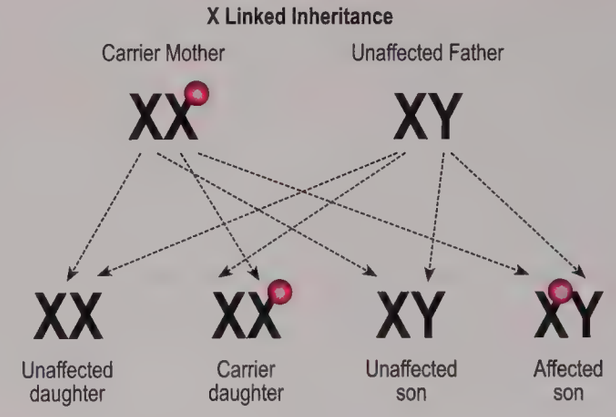

Fig. 6.5 X-linked inheritance — carrier mother.

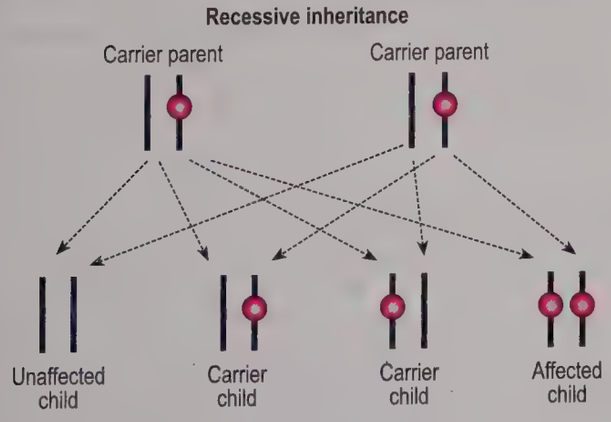

Fig. 6.4 Autosomal recessive inheritance.

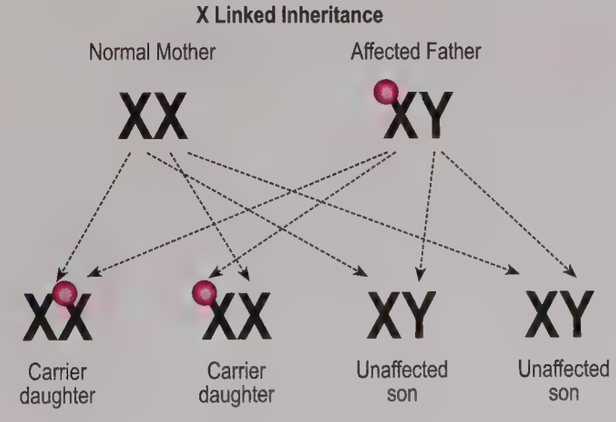

Fig. 6.6 X-linked inheritance — affected father.

cells of the mother's ovaries. This means that the risk of the mother having another affected son or carrier daughter can rarely be ruled out. However, in both new mutations and gonadal mosaicism there will be no risk to the wider family.

Multifactorial or polygenic conditions

In many conditions, genetic and environmental factors combine to give rise to disease. Risks of recurrence of these conditions within a family are generally regarded as low, the greatest risk being to first- and second-degree relatives (approximately 1%). When environmental factors are known, e.g. diet, smoking and exercise in coronary heart disease, these can be modified with beneficial effect. However, this approach is not possible for the majority of multifactorial conditions.

Factors that increase the risk of multifactorial conditions are (Harper 2004):

- the genetic component of the disease
- the closeness of the relationship to the affected person
- the presence of the condition in more than one family member
- the severity of the condition in the affected person
- the presence of the condition in a person not of the sex usually affected.

Common conditions which are considered to be multifactorial in origin include:

- asthma
- coronary artery disease
- congenital heart disease
- diabetes mellitus
- essential hypertension
- schizophrenia
- cleft lip and palate
- neural tube defects.

TESTING FOR GENETIC CONDITIONS

Testing for genetic conditions can be divided into four main categories:

- Antenatal
- Diagnostic
- Presymptomatic
- Carrier.

Antenatal testing, also referred to as prenatal testing, is used to predict whether a fetus is affected by a genetic condition or has inherited a gene mutation.

Techniques for antenatal diagnosis

Diagnostic ultrasound

Various abnormalities can be detected using high-resolution ultrasound imaging. Congenital abnormalities can, in some instances only, be detected by ultrasound scans from around 14 weeks' gestation.

Conditions detectable by ultrasound scanning include:

- skeletal abnormalities, e.g. severe short-limbed dwarfism, osteogenesis imperfecta
- neural tube defects, e.g. spina bifida
- major organ malformations, e.g. severe congenital heart disease, renal agenesis
- polyhydramnios, i.e. excess amniotic fluid
- oligohydramnios, i.e. decreased amniotic fluid
- hydrops, i.e. abnormal accumulation of serous fluid in a body cavity or tissues.

Amniocentesis

During pregnancy, fetal cells slough off into the amniotic fluid. It is possible to withdraw a sample of amniotic fluid between 16 and 20 weeks' gestation and to culture and test the fetal cells for chromosomal abnormalities. Alpha-fetoprotein (AFP) levels can be measured to detect neural tube defects such as spina bifida. Amniocentesis has the potential to diagnose around 200 genetic disorders. The risk of spontaneous abortion after the procedure is estimated to be less than 1%.

Conditions detectable by amniocentesis include:

- chromosomal disorders, using karyotyping
- inherited diseases, using biochemical and DNA studies
- open neural tube defects, indicated by amniotic fluid AFP.

Chorionic villus sampling (CVS)

This is carried out between 10 and 12 weeks of pregnancy and is thus termed first-trimester prenatal diagnosis. Essentially, this test provides the same diagnostic information as amniocentesis but gives a result more quickly as the cells grow faster; however, it is not suitable for diagnosing all genetic disorders.

Under ultrasound guidance, a catheter is inserted through the abdomen or the cervical os to the placental insertion site. Villi are aspirated and the cells are analysed. Conditions detectable by CVS are chromosomal disorders (using karyotyping) and inherited diseases (using DNA studies).

Transabdominal CVS can be done at any stage of pregnancy, providing the placenta is in an accessible position. Depending upon the type of analysis, results may be available within days. The risk of spontaneous abortion after CVS is estimated to be 2–4%.

Fetal blood sampling

This is occasionally used for diagnosis of disorders when DNA diagnosis is not possible. Under ultrasound guidance, a special sampling needle is passed transabdominally. A fetal vessel near the umbilical cord insertion is punctured and fetal blood withdrawn. This is carried out at 18 weeks' gestation (Proud 1995).

Diagnostic testing

Diagnostic testing, in the form of direct gene testing, is now available for a small number of conditions. However, the diagnosis of genetic conditions often relies on the presence or absence of signs and symptoms and the results of other investigations. Molecular confirmation of the underlying genetic mutation in the affected individual is required before presymptomatic testing can be offered to at-risk

relatives. The main techniques used in the diagnosis of genetic conditions are:

- chromosomal analysis or karyotyping (see Fig. 6.1)
- mutation analysis
- direct gene testing
- clinical examination
- biochemical tests
- radiography
- ultrasonography.

Presymptomatic testing

This is used to predict whether or not an individual 'at risk' of inheriting a genetic condition has inherited the gene mutation before there are any signs or symptoms. The benefits of presymptomatic testing are clear where treatment is available to prevent the occurrence of the disease. However, when no treatment is available to prevent, cure or alleviate the disease, the 'at risk' individual must examine the advantages and disadvantages of knowing their status. Presymptomatic protocols have been developed to enable individuals to make informed decisions (Bates et al 2002).

For further reading on presymptomatic testing, see Skirton & Patch (2002).

Carrier testing

Carrier testing is used to find out whether an individual carries a particular autosomal recessive or X-linked gene mutation. It has mainly been offered in families with a known genetic condition or to individuals in an at-risk group.

GENETIC COUNSELLING

> *Genetic counselling is the process by which patients or relatives at risk of a disorder that may be hereditary are advised of the consequences of the disorder, the probability of developing or transmitting it and the ways in which this may be prevented, avoided or ameliorated.*
>
> *(Harper 2004)*

A genetic team normally consists of consultant medical geneticists, genetic counsellors who may either be genetic nurses or non-medical health professionals, a data manager, scientists/laboratory staff and an administrative team. Referral to most genetic departments can be from any health professional involved in the care of the individual or family requiring referral. Indications for referral include:

- several family members with a classic genetic condition
- women, or couples, seeking advice on increased pregnancy risk of fetal abnormality
- individuals seeking advice on interfamily relationships
- the presence of dysmorphic features
- unexplained stillbirth
- unexplained developmental delay
- recurrent miscarriages
- family history of chromosomal abnormality
- family history of breast, ovarian or colorectal cancer.

Referral for genetic counselling should only be made with the consent of the individual or family.

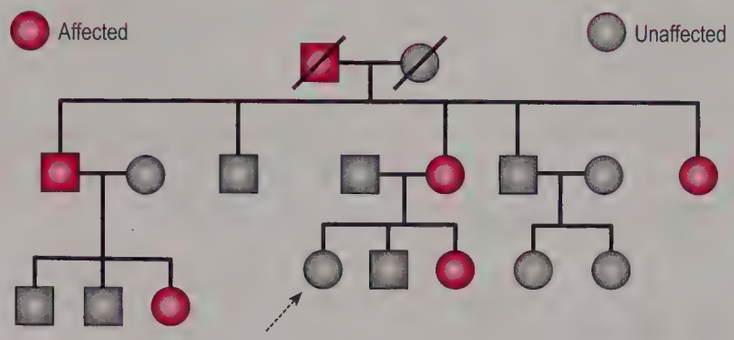

Fig. 6.7 Three-generation pedigree.

Family history is the first and very important part of genetic counselling. A three-generation family history is taken and a pedigree constructed (see Fig. 6.7). This pedigree gives a visual representation of the family and their relatives as to illnesses, miscarriages, deaths and consanguinity. The pedigree can demonstrate the inheritance pattern and may provide indicators for the diagnosis of a genetic condition. In some genetic conditions, the family history is also used to assess whether family members are at risk and/or are eligible for screening programmes.

Box 6.2 lists the information that should be included in a pedigree. The universal symbols used to construct a pedigree are illustrated in Figure 6.8.

The family pedigree is referred to throughout the genetic counselling process. There may be additions to the pedigree as more individuals from the extended family are seen. In many cases the original information is incomplete and requires confirmation by death certificate, medical notes or postmortem reports. However, it is not uncommon for the diagnosis to remain unclear and as a result families may be left with uncertainty. If a diagnosis can be made, the person receiving counselling will be encouraged to share the information with family members, enabling them to seek further advice. Genetic counselling aims to be non-directive (Harper 2004), i.e. it presents individuals with information in a way they understand and encourages them to explore in detail all the options available in order to make decisions without influence from the genetic counsellor.

Box 6.2

Drawing up a pedigree

Details are required from both sides of the family over three generations:

- Record dates of birth
- Record those who have died, plus cause and age of death
- Ask specifically about infant deaths, stillbirths and miscarriages
- Ask about consanguinity (marriage between relatives, e.g. cousins)
- Record maiden name of married women
- Record specific information related to the specific condition if known.

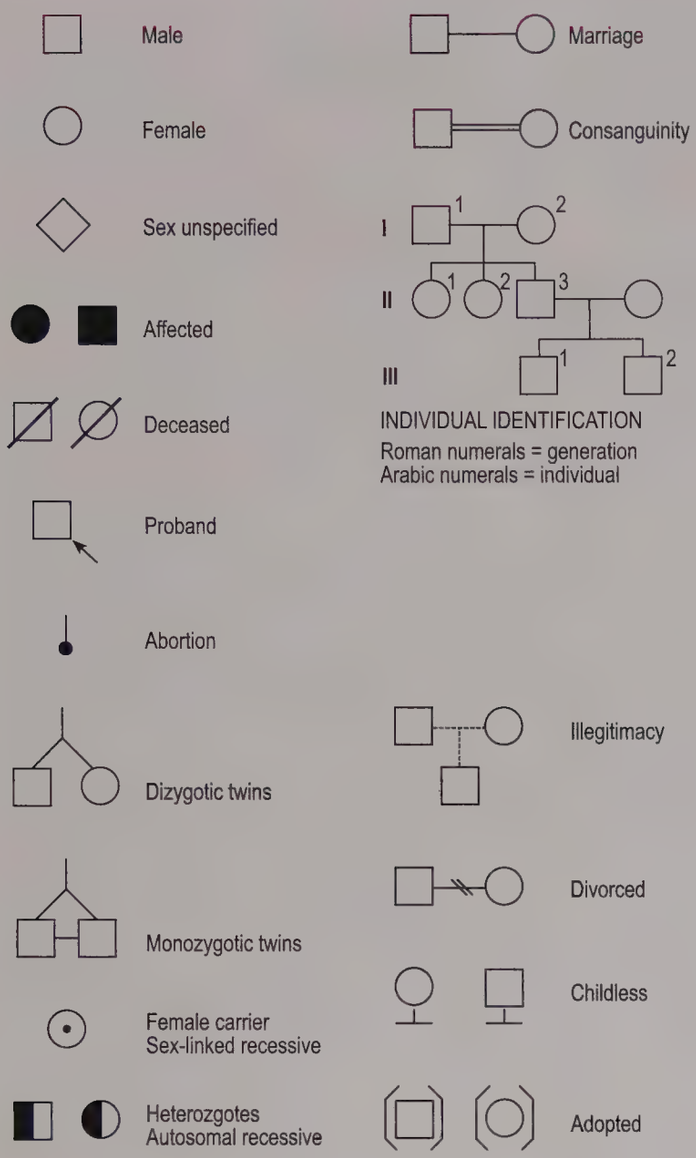

Fig. 6.8 Standard symbols used in constructing a pedigree.

Genetic counsellors

Genetic counsellors are an emerging professional group, related to, but separate from, existing health professions (Skirton & Patch 2002). There are two career pathways to becoming a genetic counsellor: the nursing pathway and the scientist pathway. The Association of Genetic Nurses and Counsellors (AGNC) developed and introduced a registration system ensuring that each professional practises at a competent level. This aims not only to ensure standards and safety but also to provide a framework for education in the clinical setting. It is envisaged that registration will be a statutory requirement for practice in genetic counselling.

CLASSIC GENETIC CONDITIONS AND THEIR MANAGEMENT

CYSTIC FIBROSIS

Cystic fibrosis (CF) is a single-gene, autosomal recessive disorder which disturbs the mucus-producing glands throughout the body, leading to respiratory problems, incomplete digestion and abnormal sweating. In the UK, it affects 1 in 2500 newborns and approximately 1 in 25 individuals carries a CF gene. There are 7500 affected individuals in the UK (Cystic Fibrosis Trust 2001).

There is no complete cure for CF. However, advances in treatment have resulted in a steady rise in survival rates over the past several decades and median life expectancy in the UK is currently 31 years (Hodson et al 2002). Despite this, affected individuals continue to have numerous medical problems requiring exhaustive and expensive therapy.

PATHOPHYSIOLOGY

In CF there is a defect in the passage of sodium and chloride ions in and out of the epithelial cells of a number of organs which affects fluid secretion in various glands.

Common presenting symptoms

Presentation usually occurs in early life with recurring respiratory problems, frequent bulky offensive-smelling stools and failure to gain weight satisfactorily. A proportion present neonatally with meconium ileus. A small number are not diagnosed until adulthood: 1 in 12 patients in the UK are diagnosed after 18 years of age (Cystic Fibrosis Trust 2001).

Clinical features

The air passages of people with CF secrete large amounts of thick, sticky mucus which plugs up the small airways and creates an ideal environment for bacterial infection in the respiratory tract. In the intestine, thick, abnormal mucus is also produced which clogs the ducts leading from the pancreas to the intestine. Food is incompletely digested; weight loss occurs despite a good appetite; and fatty, bulky, foul-smelling stools are passed. The pancreas regresses and may be completely destroyed; however, 10–20% of patients retain at least partial pancreatic function. The prevalence of CF-related diabetes mellitus (CFRDM) rises with life expectancy, with up to 30% of those surviving into their third decade displaying abnormal glucose tolerance (Liddle et al 1998). Five per cent of patients develop hepatic cirrhosis; some of these go on to develop portal hypertension and splenomegaly. Oesophageal varices may develop in these patients which, whilst treatable, can be fatal. The sweat glands also malfunction, secreting too much chloride and sodium in the sweat.

Most males with CF are infertile, as a result of an abnormality of the epididymis and vas deferens which end in blind channels instead of leading through to the urethra. In the female, fertility may be impaired because thick cervical mucus impedes the passage of spermatozoa. Delayed secondary sexual development is an almost universal finding in adolescents.

The gene responsible for cystic fibrosis is on chromosome 7 and has been labelled the 'cystic fibrosis transmembrane regulator' (CFTR) gene.

The clinical consequences of CF are outlined in Figure 6.9.

Prognosis

Elborn et al (1991) predicted that individuals with CF born in the 1990s would survive into their 30s and 40s. This is indeed the case, but some still die as young adults (Nir et al

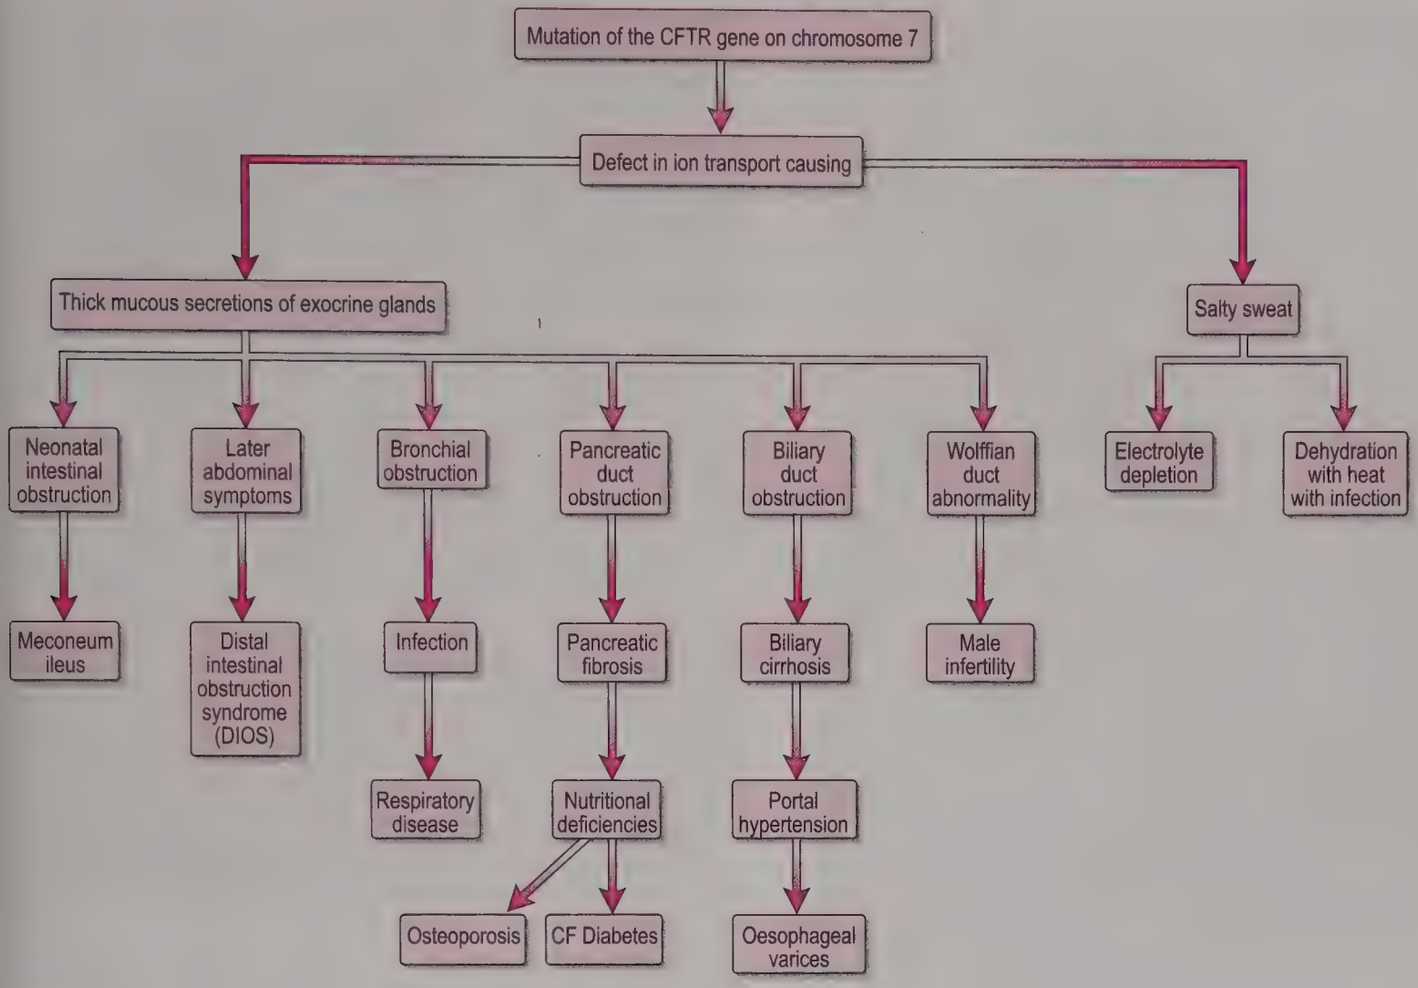

Fig. 6.9 Clinical consequences of cystic fibrosis.

1996, Cystic Fibrosis Trust 2001). Advances in treatment are largely due to improved nutrition and aggressive antibiotic therapy.

The psychological burden of living with a debilitating disease which needs constant drug therapy and physiotherapy is great for both those affected and their families, particularly during adolescence; however, this does not deter many sufferers from living full and productive lives (Walters et al 1993, Lowton & Gabe 2003).

MEDICAL MANAGEMENT

Investigations

Until the CFTR gene was identified, testing to determine high levels of sodium and chloride in the sweat was the single most important method for diagnosing CF.

In CF the potential difference between interstitial fluid and the respiratory surface epithelium is abnormally large. This can be measured in the nasal epithelium and may aid diagnosis.

Other supporting evidence is based on X-ray examination, CT scanning and sputum cultures. There may also be pancreatic insufficiency or a history of recurrent respiratory infection. In some cases there may be a family history of CF.

Genetic diagnosis

At least 900 different mutations within the CFTR gene have been found. One common mutation, called Delta F508, is found in 60–70% of the affected UK population. This mutation, along with a number of others, allows detection of most affected individuals by analysing their DNA. At present, most suspected CF cases are diagnosed by a combination of a sweat test and genetic testing.

Genetic screening

To have cystic fibrosis, an individual must inherit one copy of the mutated gene from each parent (see Fig. 6.10). It is a recessive disease, where both parents are carriers or heterozygotes and have a CF gene on one chromosome 7 and a normal gene on the other chromosome 7. Carriers have no symptoms of the disease, as the normal gene compensates fully for the CF gene (see p. 233). Using DNA from a mouthwash sample, it is possible to detect 85% of those who carry a CF gene by testing for the most common CF mutations. It is not practicable to test routinely for all 900 mutations. If both partners are found to be carriers, they are given the option of prenatal diagnosis.

Newborn screening, by a heel prick test, at around 6 days has been introduced in Scotland, Wales and Northern Ireland and will be made available throughout the UK (NHS Scotland 2003).

Aims of treatment

The overall aim of management is to help affected individuals reach adulthood, leading as normal a life as possible

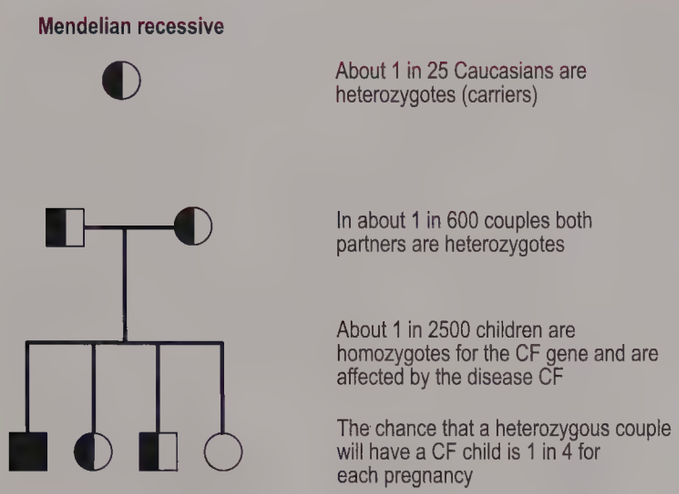

Fig. 6.10 Genetic inheritance of cystic fibrosis.

with minimal dependency. The ultimate aim is a self-determining life, and from the time of diagnosis this concept should be fostered in the parents and, in turn, in the affected individual. This aim is promoted by a multidisciplinary team whose skills, along with close cooperation between the parents, patient and family, are put into action from the time of diagnosis. Regional cystic fibrosis treatment centres lead the way in management.

The treatment programme

At a regular clinic visit 6–12 weekly, the patient is weighed, lung function tests are carried out and sputum is sent for culture and sensitivity. At regular intervals, exercise testing and chest X-rays are carried out and blood is taken for biochemistry and haematology. Aspects of dietary regimens and physiotherapy techniques are checked and specific problems requiring detailed involvement of particular team members identified. A standard form is used to record findings, including details of physical examination.

Improved survival is largely due to improved nutritional status and earlier antibiotic treatment against staphylococcal and pseudomonal infections. If *Pseudomonas* colonises the lungs, it is almost impossible to eradicate and causes deterioration of lung function. Many CF centres practise segregation of patients in hospital and at clinics to reduce the incidence of cross-infection. However, this segregation has potentially detrimental psychosocial implications for peer and family support.

Pancreatic enzyme supplements are taken at each meal or snack. The amount of capsules required varies greatly between individuals and is also dependent on the size and fat content of the meals or snacks. Small snacks between meals require a lower dose of capsules.

NURSING PRIORITIES AND MANAGEMENT: Cystic fibrosis

Cystic fibrosis is a long-term, life-threatening multisystem disorder and there are a number of essential areas of management.

Respiratory infection

Persistent recurrent lower respiratory tract infections result in lung damage and impaired function.

Physiotherapy

is accepted as an essential part of respiratory tract management and daily performance of airway clearance techniques (ACT) is generally recommended. There is a variety of ACTs and treatment should be tailored to individual needs and preferences of the patient (Fig. 6.11). These include postural drainage and percussion, the active cycle of breathing technique, autogenic drainage and oscillatory positive expiratory pressure devices, such as flutter, cornet and positive expiratory pressure mask (PEP) (Association of Chartered Physiotherapists in Cystic Fibrosis 2002). Much time is spent with adults, children and parents educating them in physiotherapy techniques, as this is a key element of the treatment programme.

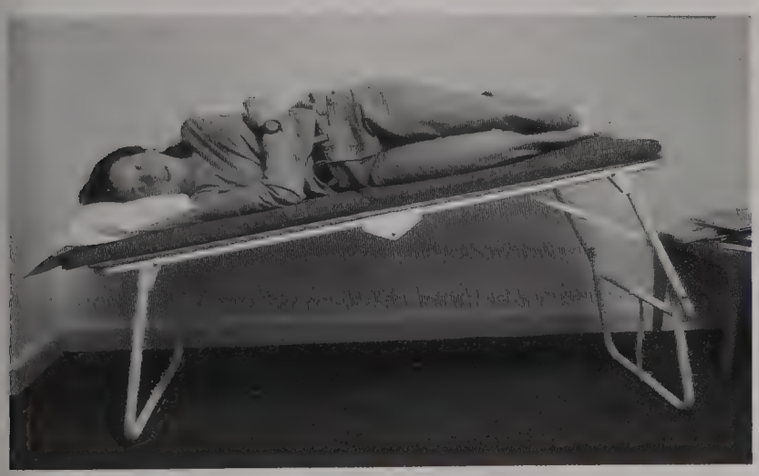
Exercise

It has been shown that regular exercise not only increases the efficiency of the lungs, heart and circulation but also improves the general physique and self-esteem (Webb & Dodd 2000). Activities must complement, not replace, physiotherapy and can be adapted to all stages of the illness trajectory.

To reduce the length of stay in hospital, parents and older children are taught to administer their own antibiotic drugs intravenously so that treatment initiated in hospital can be completed at home. This allows patients to feel more in control of the situation and less dependent on hospital staff. An implantable venous reservoir has greatly improved acceptance of home intravenous treatment.

The increased use of intravenous antibiotics has resulted in a rise in anaphylactic and anaphylactoid reactions in CF patients and must be taken into account when prescribing home intravenous treatment.

Nebulised antibiotics have been shown to be effective (Hodson et al 2002), and require a special compressor and nebuliser system. Other nebulised drugs such as bronchodilators and antimucolytic agents may be an integral part of the treatment regimen.



Nutrition

It has been shown that CF patients require 20–50% more than the normal daily food intake. Individuals with CF have a higher basal metabolic rate and resting energy requirement; extra energy is also needed to combat chest infections. Due to a loss of bile and pancreatic enzymes, a significant amount of nutritional intake is lost in frequent, bulky, greasy stools. However, pancreatic enzyme preparations are now so effective that fat absorption can reach 80–90% of normal. Three daily meals and supplemental snacks are usually required to bring the energy level up to that desired.

Distal intestinal obstructive syndrome (DIOS) can occur in adults with CF. Symptoms include colicky abdominal pain, bloating and constipation. Treatment includes oral aperients and occasionally the use of gastrografin enemas to detect potential for perforation. Following an attack of DIOS, enzyme dosage should be reviewed to ensure its appropriateness. Fat-soluble vitamin supplements are given to compensate for loss in the stools. Osteoporosis is

increasingly recognised as a complication of poor nutrition due to the loss of absorption of fat-soluble vitamins in CF (Haworth et al 1999) and the use of bisphosphonates and calcium supplements is increasingly recognised as beneficial.

Salt depletion can occur in hot weather or as a result of strenuous exercise, and salt supplements are recommended where appropriate.

Enteral feeding is encouraged in children who fail to gain weight over a 6-month period and in adults who are chronically underweight (body mass index <19, see Ch. 21, p. 797), either by the nasogastric route or via a gastrostomy tube. Good nutrition, by whatever means, correlates positively with increased survival (Corey et al 1988, Hallyar et al 1997).

Control of diabetes mellitus

An annual oral glucose tolerance test is recommended for patients over 10 years of age. If a modest glucose intolerance is demonstrated, no action is taken. If patients progress to develop diabetes mellitus, insulin is the treatment of choice and blood glucose is regulated by insulin dose adjustment. Diabetic complications are rare (Koch & Lang 1995).

Liver disease

Significant disease may already have occurred by the time the liver function tests (LFTs) become abnormal. Ursodeoxycholic acid may improve the LFTs but long-term effects are unclear (Nousia-Arvanitakis et al 2001). Banding can be performed to halt variceal bleeding that can

result from significant liver damage (see Ch. 4, p. 142). Transjugular intrahepatic portosystemic shunting may be considered for those with portal hypertension. Liver transplant is an option in end-stage disease and has been found to be associated with an improvement in lung function post-surgery (Westaby 1995, Genyk et al 2001).

Pregnancy and infertility

Development of secondary sexual characteristics occurs later in CF. However, women with CF can still reproduce, unlike their male counterparts. However, pregnancy in a woman with CF may cause deterioration in health. Outcomes are closely linked to pre-pregnancy lung function (Edenborough et al 2000) and it is a time of close cooperation between the CF multidisciplinary team and the obstetrician. Moreover, the woman with CF must also consider the impact of a potential shortened life expectancy upon her children. Progression of the disease may prevent her from carrying out day-to-day care of her child. Those who become pregnant require increased supervision, more physiotherapy and carefully managed antibiotic therapy. Adult males with CF are now in a position to seek help at assisted reproduction clinics, where techniques such as artificial insemination by donor (AID) and microscopic epididymal sperm aspiration (MESA) with intracytoplasmic sperm injection (ICSI) are allowing fatherhood to become a reality. These techniques are expensive, not always easily available and may also raise further ethical dilemmas.

Transplantation

Lung transplant has brought renewed hope for those with CF, but may also cause new problems as a direct result of the surgery, or from tissue rejection. Moreover, there are psychosocial problems which can be difficult to foresee. The idea of a lung transplant should be introduced very sensitively, as consenting to this procedure is a grave decision. Patients, relatives and professionals may have differing viewpoints and conflicting emotions (see Case History 6.1). The overwhelming shortage of cadaveric donor organs has resulted in the use of living donor transplants, which creates further ethical dilemmas. Survival from lung transplant is approximately 60% at 5 years (Egan et al 2002). However, approximately a third of those on a transplant list will die whilst awaiting transplant.

Psychosocial considerations

Patients, parents and siblings are profoundly affected by the psychosocial and emotional stresses of living with CF. The CF nurse is in an ideal position to recognise that problems exist, and to plan and implement measures to help deal with issues such as the transition from paediatric to adult care, education, careers, relationships, body image and coping with the terminal stages of illness (UK Cystic Fibrosis Nurse Specialist Group 2001). Case History 6.2 describes some of the difficulties that might be faced by a teenage boy with CF, and how the sensitive intervention of a specialist nurse might help. The advent of segregation policies in and out of hospitals has seen the demise of the social networks once so strong in the CF community. Other innovative ways to help support and bring together patients and their families without direct contact are being utilised, such as the use of advocates, CF magazines, websites and teleconferencing.

CASE HISTORY 6.1

Individuals with cystic fibrosis — J, A and S

J thought about a lung transplant for over a year but elected not to attend for assessment at the transplant centre. She eventually chose to discontinue active treatment because she wished to avoid coping with a protracted terminal illness. J died in relative peace and dignity in her local hospital within a short time.

A was keen to find out if he was a suitable candidate for transplant and was pleased to be accepted and placed on the waiting list. Everything in the family centred on the time when the bleeper would go off calling him for transplant. Alas, A ran out of time and died before a suitable donor was found.

S was one of the lucky few. He finally underwent lung transplant after three false alarms; on each previous occasion when he was called, the donor lungs were found to be unsuitable. S leads a full life and is back working full time. He has had two rejection episodes requiring hospitalisation and suffers from immunosuppressant-induced peripheral neuropathy. His wife worries about the future in terms of further rejection.

Outlook for the future

Since the discovery of the CF gene, advances in the understanding of the role of CFTR and ion transport have been made. Future therapies will involve correction of the faulty gene either by viral or non-viral gene therapy or correction of the defective CFTR protein by 'trafficking' medication such as the prodrug thapsigargin, a tumour promoter which increases intracellular calcium stores. Studies to optimise current therapies include the long-term use of the macrolide antibiotic azithromycin (Equi et al 2002); its mode of action may include anti-inflammatory as well as antimicrobial activity.

Whilst some of these therapies give hope for an eventual cure for CF, the focus continues to be on supportive treatment such as physiotherapy, antibiotics and intensive nutritional support. The prospect of CF sufferers surviving into their fourth, fifth and sixth decades reflects real progress but also creates further challenges for those individuals and for the health professionals involved in their care.

HAEMOPHILIA

Haemophilia is an inherited disorder in which there is a defect in the clotting mechanism of the blood. It is present from birth, is lifelong and is characterised by recurrent and persistent bleeding episodes involving mainly the deep tissues of muscles and joints (Rizza 1997).

PATHOPHYSIOLOGY

There are two types of haemophilia: haemophilia A, where bleeding is due to the deficiency of the clotting factor VIII (FVIII) and haemophilia B, also known as Christmas disease, where bleeding is due to the deficiency of clotting factor IX (FIX).

CASE HISTORY 6.2

G

G is a small, thin, red-haired 16-year-old in his fourth year at high school. He is judged to be academically average by his headmaster. G is a particularly keen cyclist and is a member of the school cycling team. He was diagnosed with cystic fibrosis (CF) at the age of 3. Since that time, his care has been shared by his GP, the local hospital and the regional CF centre. G attends the centre every 3 months. At these visits he has spirometry, a sputum sample is taken and he sees the physiotherapist, dietitian, CF nurse and the doctor to review all aspects of his care. Once a year he has a full review, which includes an X-ray, blood tests, a glucose tolerance test to screen for diabetes and a meeting with the psychologist to assess his psychological well-being.

G has been admitted twice in the last year for intensive intravenous therapy for Pseudomonas respiratory infections. He has recently had a Portacath device inserted for ease of administration.

Today G is going to talk to the specialist nurse, who will suggest that he sees a careers guidance officer. She knows G well and has already submitted a report to the careers office. G has had periods of absence from school when his condition necessitated admission to hospital. Some teaching was given while in hospital and he had extra tuition at home. His father helps with physiotherapy and they have a close relationship.

The specialist nurse knows from discussions with G that he is quite sensitive about his illness. He is smaller and thinner than his classmates; he weighs 50 kg and is currently 1.62 metres tall. His friends have entered puberty at the normal time but he is lagging behind and there is no sign of secondary sexual characteristics. He is self-conscious about this and gets embarrassed when using the shower and communal changing rooms at school. Reassurance from the CF consultant that he will catch up is little consolation.

For a time G had shown signs of depression and stopped adhering to his treatment regimen. He questioned what the point of it all was if he was going to die anyway.

His parents were concerned and asked the CF nurse to chat to him. Because of the problems of cross-infection between patients, the nurse was unable to arrange for G to meet with other patients to share experiences and thus support each other. However, she was able to give G some details of websites and chat rooms used by other sufferers and to get him subscribed to the CF magazine. Through these forums he learnt he was not alone and shared many of the same thoughts and feelings as his peers. He learnt that he was not the only one who had to cope with an average twice daily routine consisting of physiotherapy, nebulisers and enzymes before and after school. He found out that his peers wore jogging bottoms under their trousers to make them look more bulky and tried this out. Knowing that he was not alone and being able to express this made him feel better. In addition, he realised through the chat lines that there were people out there with CF who were in their thirties and forties with careers and wives and families, and this gave him hope for the future.

Within the UK, the incidence of haemophilia is approximately 1 in 10 000 live male births, haemophilia A being five times more common than haemophilia B (World Federation of Haemophilia 2004). Both share the same symptoms and inheritance patterns and no differentiation is made between them with regard to bleeding tendency.

The severity of the condition depends upon the level of circulating factor VIII or IX. The unit of activity of factor VIIIc/IXc is the amount of factor VIII/IX coagulant activity in 1 mL of fresh normal plasma (Colman et al 1994). Normal values are expressed in reference to average normal plasma, and range from 50 to 150 IU/dL. Levels less than 50 IU/dL are regarded as abnormal. A frequent classification of haemophilia is to define the severity of the condition as severe, with FVIII/FIX level of 0–2 IU/dL; moderate, with FVIII/FIX level 2–10 IU/dL; and mild, levels >10 IU/dL. Although the severity of the disease is variable, it is constant within a family.

Mode of inheritance

Haemophilia is sex linked and recessive in nature. The abnormal gene responsible for the disorder is carried on the X chromosome. As males only have one X chromosome, affected males will pass the faulty gene to each of their daughters. All daughters will be carriers and are termed obligate carriers. These daughters have a 1 in 4 chance of producing a son with haemophilia and a 1 in 4 risk of having a carrier daughter. All sons of a man with haemophilia will be unaffected, as they inherit his Y chromosome which does not carry an affected gene (see Fig. 6.12). Prenatal diagnosis is possible for carrier women by chorionic villus sampling at 10 weeks' gestation, or amniocentesis at approximately 14 weeks' gestation, to obtain material for genetic analysis by looking for a particular gene mutation in the DNA of the fetus. In families where the genetic mutation has not been identified, linked markers can be used in DNA-based family linkage analysis if there is a suitable family structure. Carrier testing is also available for other family relatives. These tests are offered by specialised genetic units (Bonthron et al 1997).

Two-thirds of children diagnosed with haemophilia have a family history of the disorder which can be traced through the maternal family tree. The remaining third has no family history, suggesting that the child or his mother may represent a spontaneous new genetic mutation, or it may have been transmitted undetected through generations with no affected boys being born.

Common presenting symptoms

In haemophilia, although the factor VIII/IX levels are reduced at birth, babies rarely present with bleeding from the umbilical cord. Children with severe haemophilia are usually diagnosed within the first year of life when they start to crawl. Often the first symptom is that they start to bruise easily. Unfortunately, if there is no known family

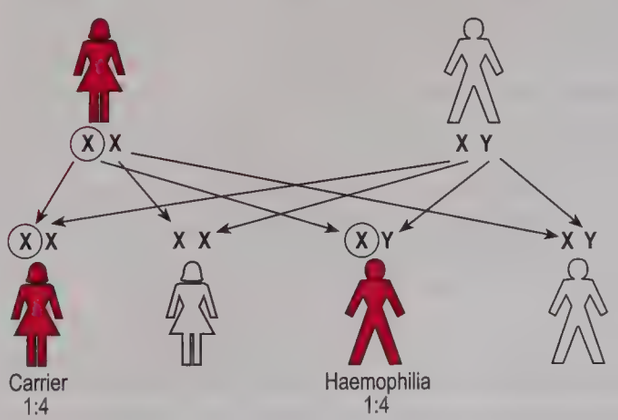

Fig. 6.12 Genetic inheritance of haemophilia.

history, the early signs of haemophilia can sometimes be wrongly interpreted as non-accidental injury (Haemophilia Society 1997a). The individual who has severe haemophilia can present with spontaneous internal bleeding, most commonly into joints and muscles. This type of bleeding may result from normal daily living but can present with life-threatening bleeds such as intracranial haemorrhage or gastric bleeding. Frequent and severe bleeding, particularly into the joints, can result in arthropathy and disability. The main joints affected are the hinge joints, namely the knee, elbow and ankle.

Mild and moderate haemophilia may not be diagnosed until later in childhood, or even adulthood. As some clotting factor activity is present in the blood, minor injuries heal normally. It may not be until surgery, dental extraction or if an injury occurs that the deficiency is revealed.

Individuals with haemophilia can experience a tingling sensation at the onset of a spontaneous bleed which then results in pain. As the bleeding progresses, the pain increases, the joint/muscle may feel warm to touch and may begin to swell, thus restricting movement.

Prognosis

The life expectancy of those with haemophilia should not differ from that of the average person and most individuals reach adult life with only a moderate degree of disability. This contrasts greatly with the past when it was a debilitating condition which resulted in a shortened lifespan (Harper 2004).

Great advances in treatment products and regimens have helped to change the outlook for young haemophilic children. Historically, patients with haemophilia have suffered from repeated bleeds into joints, causing damage and leading to disablement. New treatment regimens have dramatically lessened the likelihood of this.

MEDICAL MANAGEMENT

Diagnosis

Any individual with prolonged or unexplained bleeding should be tested for haemophilia. Diagnosis is made, within specialised haematology laboratories, via a blood sample which can differentiate which clotting factor is deficient.

Treatment of a bleeding episode

The goals of haemophilia treatment are to minimise permanent damage, minimise suffering and pain, permit tissue healing and restore function. By giving intravenous factor replacement therapy, raising the circulating factor level to within the normal range, joint damage and subsequent arthropathy can be prevented. There are two different modes of delivery of replacement therapy: on-demand therapy, where treatment is given on the first evidence of a bleed, and prophylaxis, where treatment is given in order to prevent bleeding from occurring.

Intravenous treatment with the appropriate factor concentrate is given for bleeding into a joint or muscle, or injury, for example, to the head, eye, mouth, tongue or neck. It is imperative that pain is controlled and activity reduced by resting the affected joint/limb, supporting it with pillows and applying cold packs to the affected area. The use of aspirin must be avoided due to its antiplatelet activity and intramuscular injections should never be given as they may cause a haematoma. Any weight or pressure on a joint must be avoided and, after the acute phase has passed, referral made to the physiotherapist.

Some patients develop inhibitors to FVIII and FIX. This is because, lacking factor VIII or IX, the body considers replacement coagulation factor concentrates to be a foreign protein, and produces antibodies which combine with the clotting factor and inhibit its action (Haemophilia Society 1997b).

Prophylaxis involves administering replacement factor concentrate, in advance, to prevent bleeding. It can be given as a single dose, for example, prior to an event that may result in bleeding, as a short-term procedure to counter a temporary increase in the frequency of bleeding or as a long-term procedure in order to prevent haemarthrosis and the development of arthropathy.

Within the UK, practice is guided by the United Kingdom Haemophilia Centre Doctors' Organisation (UKHCDO 1994). Guidelines recommend prophylactic treatment for all severe haemophilic boys to protect them from long-term joint damage and arthropathy. It is generally started in children when they are 1–2 years old. An infusion of the replacement factor concentrate is given three times a week in haemophilia A and twice a week in haemophilia B.

Complications

When a bleed occurs within a joint, the patient will stop using the joint because of severe pain and the muscles can become slack and wasted. The joint, no longer supported adequately, becomes susceptible to injuries which cause further bleeding. Blood enters the joint space causing damage to the articular cartilage, the synovium and the joint surface. The joint space becomes smaller, leading to permanently restricted movement and cysts can develop. Repetitive bleeding episodes result in arthritis, particularly if not adequately treated (Rodriguez-Merchan 2000).

Muscle bleeding, if untreated, can cause contractures and compression, leading to nerve damage, permanent palsy and loss of the use of the affected limb, e.g. 'foot drop' from a bleed into the calf muscle or 'claw hand' from a bleed into the forearm. Bleeding into muscles can weaken them, rendering them unable to support joints and causing risk of joint damage. If blood is lost into a large muscle it can cause a drop in the haemoglobin level; if blood loss is rapid, hypovolaemic shock can occur (see Ch. 18).

NURSING PRIORITIES AND MANAGEMENT: Haemophilia

The Haemophilia Centre

There is a network of haemophilia centres throughout the UK that aim to provide the best care and management for haemophilia patients. These may be comprehensive care centres or local haemophilia centres. At a comprehensive care centre, potential patients are tested for haemophilia by using the specific factor assays; new patients are registered and special medical cards issued. Some of the initial investigations include specialised laboratory testing which cannot be carried out in smaller centres. Twenty-four hour emergency cover is supplied by a multidisciplinary team

of consultant haematologists, specialist nurses, physiotherapists, social workers, orthopaedic surgeons, liver specialists and dentists. Patients are reviewed on a regular basis.

Home treatment

In the past two decades there has been a move to deliver care in the home and community setting rather than in hospital. Specialised nursing posts have been developed to help to deliver and facilitate care that can meet the needs of the patient and their family (Haemophilia Alliance 2001). This is particularly visible in haemophilia care.

Many patients, both adults and children, are selected for home treatment after being taught and carefully supervised to proficiency in all aspects of care. This includes the recognition of bleeds and the administration of factor concentrate either through direct venepuncture or using an intravascular access device such as a Portacath. This allows immediate treatment of bleeding episodes and consequently the need for less factor concentrate. Pain is minimised and hospitalisation often avoided, allowing the patient to maintain as normal a life as possible. Self-management of treatment allows a degree of control over the disorder, raises confidence and increases independence. Initially it is the parents who are involved with the home treatment of their child and when the child gets older they too become increasingly involved in their own treatment.

The haemophilia nurse plays the key part in the education and care of the patient and their family. 'It is the role of the haemophilia nurse to provide flexibility, experience and knowledge, to give support, regular home assessment and act as a bridge between the family and the multidisciplinary hospital-based team' (Vidler 1999). Lasting relationships are formed with the nursing staff as this service is likely to be continued throughout the patients' entire lives.

Outlook for the future

The development of effective therapy for haemophilia has been a story of success combined with tragedy. Haemophilia treatment has been hampered by the human immunodeficiency virus (HIV) and hepatitis C transmitted via the early factor concentrates. However, the development of factor VIII/IX concentrates during the last three decades has revolutionised haemophilia care.

The introduction of plasma donor screening, viral inactivation methods and DNA technology into concentrate manufacturing has minimised the problem of new viral transmissions by clotting factor concentrate (Lusher 1995). The range of products available today for the treatment of haemophilia reflects the advances made in biotechnology and includes products produced in animal cell culture by recombinant gene therapy (Watson & Ludlam 1997).

Advances are also being made in gene therapy and trials have already started in some centres in the USA. It is hoped that gene therapy will result in the release of FVIII/FIX which may effectively convert someone with severe haemophilia into someone more mildly affected, thus reducing the number of episodes of spontaneous bleeding. With safer products and the possibility of 'cures', the future outlook looks positive for patients with haemophilia.

MYOTONIC DYSTROPHY

Myotonic dystrophy is a multisystem autosomal dominant condition (see p. 232) that presents with myotonia, slow relaxation of voluntary muscle after contraction, and progressive weakness and wasting of the facial, sternomastoid and distal muscles. The disorder is due to an expansion of the myotonic dystrophy gene located on the long arm of chromosome 19. The size of the expansion correlates broadly with the severity of the disease in the individual. The age of onset is variable but the majority of those who have the expanded myotonic dystrophy gene show some symptoms by the time they reach adult life. There is great variation in severity: some people with the expanded myotonic dystrophy gene can be so mildly affected that they are unaware of it, while others can have major problems. As inheritance is autosomal dominant, an affected individual of either sex has a 50% risk of passing the gene on to a child of either sex (see p. 232). The genetic abnormality is unstable and tends to increase in size as it is passed from one generation to the next. This explains the progressively earlier age of onset and greater severity of the disease as it is passed from generation to generation. Affected females are at risk of having a child with the severe congenital form of the disorder, as the expanded gene is thought to be more unstable when maternally inherited. Babies affected by congenital myotonic dystrophy present with respiratory failure, feeding difficulties and ongoing developmental problems requiring specialist multidisciplinary support. New mutations are thought to be rare and it should be assumed that all cases have been inherited unless there is positive evidence to the contrary. Myotonic dystrophy is no longer thought to be a rare disorder and is regarded as the most frequently occurring muscular dystrophy of adult life, affecting approximately 1 in 8000 of the population (Harper et al 2004).

Common presenting symptoms

The main muscle groups involved are facial, sternomastoid and the distal limb muscles. Other systems and associated problems may include:

- eyes — cataracts, ptosis (see Ch. 13)
- endocrine — diabetes mellitus (see Ch. 5)
- cardiac — mainly conduction defects (see Ch. 2)
- gastrointestinal tract — swallowing difficulties, constipation, diarrhoea and abdominal cramps (see Ch. 4)
- central nervous — variable cognitive impairment, specific personality changes in adults, somnolence (see Ch. 9)
- respiratory — muscle weakness, hypoventilation, anaesthesia risks (see Ch. 3).

NURSING PRIORITIES AND MANAGEMENT: Myotonic dystrophy

Major considerations

The prevention and management of complications

It is important that medical problems are diagnosed early and treated appropriately to prevent exacerbation and avoid complications. This should be stressed, both to those at risk

and to those already affected. The severe degree of apathy characteristic of myotonic dystrophy can be a major obstacle to overcome and can be responsible for low attendance rates at clinics and lack of motivation in treatment regimens.

Myotonic dystrophy affects a number of body systems and thus requires careful management both in daily living and when particular medical problems arise. The multidisciplinary team should be aware of the following points:

- Problems with anaesthesia may arise because the surgeons and anaesthetists are unaware that the patient has such a neuromuscular disorder. Individuals should be encouraged to wear a MedicAlert bracelet or to carry an alert card in case of accidents requiring surgery.
- Breathing exercises may help to reduce the tendency to hypoventilate. If there are signs of nocturnal hypoventilation, such as recurrent chest infections, morning headaches and increased daytime sleepiness, referral to the respiratory team will be required.
- When there is evidence of oesophageal/pharyngeal muscle weakness causing swallowing difficulty, it may be necessary to adjust the diet and to refer to the speech and language therapist (SALT), who may also help with speech difficulties due to weak facial muscles.
- Regular electrocardiograms (ECGs) should be carried out with appropriate medication as required. If there is evidence of conduction defects, a cardiac pacemaker may be considered.
- Cataract surgery is often required.
- Special obstetric care is necessary during pregnancy and delivery due to uterine muscle involvement, the increased risk of miscarriage and the risk of a congenitally affected baby.
- A high-fibre diet will help to alleviate constipation. Laxatives may be necessary.
- Sternomastoid weakness makes the use of headrests in cars imperative.
- Below-knee calipers or plastic moulded splints may help to control foot drop should it occur.

Psychological support

The diagnosis of a hereditary, slowly progressive muscle disorder of varying severity with associated multisystem involvement can have a profound psychological effect upon the individual and the family.

Living with myotonic dystrophy is not easy either for those affected, who have little energy or motivation, or for their partners or offspring. To live with someone who has an expressionless face, a monotonous voice, a marked lack of enthusiasm and may keep falling asleep, can put a great strain on a relationship. Sympathy and understanding are necessary for all family members.

Other forms of progressive muscular dystrophy include:

- Duchenne muscular dystrophy — inherited in an X-linked recessive form which usually affects boys and is severe
- Becker muscular dystrophy — also inherited in an X-linked recessive form which also affects boys but is less severe
- Facioscapulohumeral dystrophy — inherited in an autosomal dominant form with variable expression.

The Muscular Dystrophy Campaign (see 'Useful websites') is a charitable organisation which funds advisors who offer support and information to individuals affected by muscular dystrophy and their families.

HUNTINGTON'S DISEASE

Huntington's disease (HD), previously known as Huntington's chorea, is a progressive inherent neurodegenerative disorder, mainly of adult onset. Symptoms become apparent at any age but the average age of onset is normally between 40 and 50 years (Kremer 2002). There are, however, rare exceptions, with reports of symptoms starting as early as 2 years of age or as late as 80 years (Huntington's Disease Collaborative Research Group 1993). Approximately 7% of individuals with HD show symptoms before age 20 and are classed as having juvenile HD (Wells & Warren 1998).

The disease has a particularly rich historical literature which can be traced back to well over a century. The remarkable description of HD by George Huntington, an American physician, in 1872 has subsequently borne his name. The disease is characterised by an insidious onset which progresses over 15–20 years to a prominent and complex movement disorder, with changes in behaviour, mood and cognition. The incidence in the UK tends to vary between 5 and 10 per 100 000 (Bates et al 2002).

NEUROPATHOLOGY

The manifestation of symptoms and progression in HD is related to its neuropathology, characterised by loss of specific neuronal populations in many areas of the brain. The most striking neuropathological feature at autopsy of advanced HD patients is the gross atrophy of the caudate nucleus and putamen (see Ch. 9).

Genetics and testing

Huntington's disease is an autosomal dominant condition and therefore affects both sexes equally. Any offspring has a 50% chance of inheriting the faulty gene which will almost always mean that they will develop HD in their lifetime.

The gene mutation is confined to a small section on the short arm of chromosome 4 and has been named IT15. The gene codes for a protein called huntingtin whose function is not clearly understood. The gene is composed of three chemical bases — cytosine, adenine and guanine (CAG) — and is often referred to as a trinucleotide repeat. In the mutated HD gene, the first section is longer than normal and is associated with a CAG repeat size of 36 or more (Quarrell 1999). Individuals with a repeat size greater than 36 will eventually develop HD in almost every case.

In 1993 the Huntington's disease gene was identified. Following this, direct genetic testing became available and testing is now available at genetic centres throughout the UK.

Three categories of testing are discussed: predictive testing, diagnostic testing and prenatal testing.

Predictive testing

This test is carried out by DNA analysis of a blood sample and is available to asymptomatic individuals who should normally be 18 years or older and who have a family history

CASE HISTORY 6.3
E

E is 33 years old. Her father suffers from Huntington's disease (HD) and is cared for in a hospital for the chronically ill. Her younger sister, P, has early signs of the disease and the diagnosis has been confirmed by direct gene testing which shows that she is carrying the HD gene.

E has asked her general practitioner if she can be referred for genetic counselling. E is seen at the genetic department and is given information on the HD presymptomatic test protocol. She decides to go ahead with the test programme and understands that it involves four counselling sessions with staff in the genetic unit, including one with a specialist psychiatrist who will assess her coping mechanisms. Three months later, at the end of the programme, she is still sure that she wants a test because, for her, the uncertainty of being at risk of HD is even worse than knowing for certain that she has inherited the altered gene.

of HD. Genetic centres follow a strict testing protocol developed from guidelines set up by the Committee of the International Huntington's Association (IHA) and the working group on HD of the World Federation of Neurology (WFN) in 1994. The guidelines recommend that individuals at risk and considering testing should be seen for genetic counselling on two to four occasions over at least a 3-month period to allow them to consider fully the implications of testing prior to a blood sample being taken (see Case History 6.3). Post-test counselling should also be available and most centres will offer ongoing support whilst the individual remains asymptomatic, as well as monitoring of the disease as symptoms develop.

Diagnostic testing

This would also be undertaken by means of a blood test, but unlike predictive testing, it is carried out in someone thought to be symptomatic of HD, thus helping to confirm the diagnosis.

While the development of direct genetic testing has made the diagnosis of HD easier, it is still very much a clinical diagnosis matched by the demonstration of an expanded CAG repeat in the HD gene. A firm diagnosis will only be given with certainty when someone presents with specific extrapyramidal motor abnormalities, as opposed to minor motor abnormalities, subtle cognitive changes or psychiatric problems (Kremer 2002).

Prenatal testing

The isolation of the HD gene has given reproductive choices to couples who have an increased risk of passing on the genetic mutation associated with HD, although it has not proven to be a widely chosen option (Simpson et al 2002).

A parent who has tested positive for the faulty HD gene can have direct genetic testing carried out on the fetus during early pregnancy by means of chorionic villus sampling or amniocentesis. The decision to have this test is a considerable one with many complex questions to discuss including the ethics of such a procedure.

For further information about genetic testing, contact your nearest genetics department.

It is also possible for prenatal exclusion testing to be carried out when a parent is at 50% risk of having the faulty HD gene and does not want to risk passing it on, but does not want to have direct genetic testing themselves. This test is also carried out in early pregnancy using chorionic villus sampling or amniocentesis. Blood samples are required, however, from both parents and if possible, both grandparents on the affected side of the family or from several other family members. Family linkage analysis is used in this technique. If the fetus has inherited the gene from the grandparent who is from the unaffected side of the family, then the child has virtually no risk. If the gene is inherited from the grandparent who is affected, the risk to the fetus is 50%, which is the same as that of the at-risk parent, as it is not identified whether it is the affected grandparent's 'normal' or faulty gene that is passed on.

Ethically, this also leaves difficult decisions to be made, as the parents may decide to terminate a pregnancy where there is only a 50% risk.

It is also important to consider that invasive tests in early pregnancy do carry an increased risk of miscarriage.

Preimplantation genetic diagnosis (PGD) is a relatively new technique combining in vitro fertilisation (IVF) with genetic testing. Using PGD in Huntington's disease offers an opportunity to couples where one partner has the faulty HD gene, to avoid passing the faulty gene on to their children. This specialist technique is only offered at a limited number of centres in the UK.

Common presenting symptoms

The early symptoms of adult onset Huntington's disease can be very subtle. Throughout the illness, individuals usually demonstrate a combination of complex motor, cognitive and emotional or psychiatric symptoms, but there is wide individual variation in how these symptoms present.

Motor symptoms There are two parts to the movement disorder of HD: the presence of involuntary movements and the impairment of voluntary movements. Some people with the illness initially have problems with motor control. This can lead to choreic movements, which may be noticed as jerks, twitches or exaggerated gestures. Changes in balance and coordination can also occur at this stage, leading to clumsiness and difficulty carrying out tasks that require fine motor control.

As the disease progresses, chorea tends to become more obvious and incapacitating. In many patients, however, chorea eventually peaks and then begins to decline, with rigidity and bradykinesia (slowness of movements) becoming more significant.

Over a number of years, motor symptoms worsen, such that walking difficulties become more pronounced. As a result, the individual is at high risk of falls with significant associated morbidity and, ultimately, confinement to a wheelchair (Kremer 2002). Speech is often affected early in the illness, often as a mild disturbance of clarity which deteriorates as the disease progresses, causing significant communication difficulties. Dysphagia generally occurs late in the illness, resulting in an increased risk of aspiration. In the advanced stages of the disease, there is a significant loss of independence and functioning with patients being highly dependent on others for most, if not all, aspects of their care.

Although the motor symptoms of Huntington's disease are often the most visible, it is often the non-motor symptoms that have the greatest impact on patients' and families' daily lives. For some people, changes in mood or personality may be the first symptoms of the disease, for example having sudden changes in mood, being irritable or making irrational judgements. Depression and anxiety can also occur at this stage, as well as difficulty concentrating and forgetfulness. As a result, it is often only in retrospect, once a diagnosis has been made, that families recall these changes as being the onset of the disease.

Cognitive symptoms The cognitive disorder in HD is characterised by impaired memory and executive function, and slowed thinking.

Executive functions which are affected include organising, prioritising and regulating information, as well as impulse control and flexible thinking. Impairments in executive functioning can lead to difficulties in judgement, problem solving, divided attention, irritability and disinhibition. Processing of information is also slower so that more time is required to answer questions and complete routine tasks. Cognitive changes vary in severity between individuals but in most cases become more severe as the disease progresses (Craufurd & Snowden 2002).

Psychiatric symptoms can occur at any stage of the disease and vary amongst individuals.

The most common psychiatric disorder in patients with Huntington's disease is depression, which is thought to occur in up to 40% of individuals at some stage of the disease (Quarrell 1999). Anxiety, changes in personality and apathy are also common symptoms (Caine & Shoulson 1983).

Other less common psychiatric disorders that can occur include bipolar disorder, obsessive–compulsive symptoms and psychosis.

Management

Huntington's disease is a very complex condition and the issues that confront patients and their families span the expertise of many professionals and are best met by a coordinated multidisciplinary approach. As there is currently no preventive or curative treatment for HD, the goals of management are to reduce symptoms, maintain independence and improve quality of life.

Most people with Huntington's disease will live at home with support until the more advanced stages of the disease, when some will need long-term care. Nursing staff may, however, come into contact with patients with HD at any stage of their illness in a variety of settings.

In the early stages of the disease, management is mainly concerned with ensuring that individuals have accurate information and access to support services. The main issues with which patients may need support at this stage include employment, driving and finance as well as emotional support for themselves and their families. Cognitive changes may be apparent and the patient will benefit from assistance in looking at strategies to aid daily living such as using reminders, calendars and lists and establishing routines.

Baseline assessments of cognitive functioning, nutritional state and dysphagia may also be carried out.

As the disease progresses, management of symptoms should be regularly reviewed.

MEDICAL MANAGEMENT

It is important that the clinical features of HD are assessed and disease progression monitored. Patients may be seen by a variety of medical specialists at different stages of their illness, depending on the most significant clinical problems, or be monitored solely by their GP. Pharmacological treatments of the psychiatric features of the disease are available and can be successful in treating these symptoms. Such treatments are also available to manage the involuntary movements present in HD.

Chorea, whilst being a highly visible symptom, may not be distressing to the patient, however, and it is important to remember that medications used to suppress chorea can have side-effects, including worsening of voluntary motor control. It is advisable, therefore, to consider non-pharmacological interventions in the management of chorea, which can include exercise, massage, stress reduction and relaxation.

As the symptoms of HD change over time, any medication used should be reviewed regularly.

NURSING PRIORITIES AND MANAGEMENT: Huntington's disease

Mobility

The movement disorder present in HD affects an individual's mobility, which will deteriorate over time, with falls becoming common. The main management of falls involves risk assessment of the patient and modification of the environment. It is important to involve occupational therapists and physiotherapists to assess functioning and mobility, advise on strategies and provide aids and adaptations to assist daily living. For example, furniture with sharp corners should be avoided and obstacles minimised. Specialist seating, padded bed sides and adapted wheelchairs can assist with the patient's comfort and minimise the risks or injury.

Swallowing

Dysphagia is common in HD and is, directly or indirectly, a common cause of death in people with advanced stage HD. This is often due to choking, aspiration or malnutrition. Dysphagia results from impaired voluntary control of the muscles involved in swallowing, impaired respiratory control and impaired judgement, which can result in eating too quickly or taking too large mouthfuls. A referral to a speech and language therapist will allow for an assessment of the patient's swallowing and provide advice on the most appropriate consistency of food and fluids.

Devices such as large-grip cutlery, non-slip mats, plate guards and spout-lid cups can help maintain independent eating. Patients should be encouraged to eat slowly and deliberately, to take small bites and to clear their mouth of food between bites. Sitting upright with the chin tucked down is the optimal position for swallowing as this reduces the risk of aspiration. Distractions should be kept to a minimum whilst eating, as patients may be distracted by noise such as from the television. Patients may need observation and supervision at mealtimes and will eventually require assistance with eating. Dysphagia may result in weight loss.

Diet

Weight loss is common in HD and patients will generally require a higher calorific intake to maintain their body weight. This is partly to do with increased energy requirements due to choreic movements and partly (though not yet fully understood) to increased resting basal expenditure. Referral to a dietitian will be made for nutritional assessment and nutritional supplements may be recommended. Patients should be weighed and reviewed regularly.

For patients who have severe dysphagia and/or significant weight loss, alternative feeding methods may be considered, the most common of these being percutaneous endoscopic gastrostomy (PEG) tube feeding. This is, however, a very individual decision and ideally an individual should be given an opportunity to discuss this early in their illness, as their capacity to make decisions may be affected as the disease progresses.

Communication

Communication is greatly compromised in HD and deteriorates over time due to impairment of the muscles involved in speech production as well as cognitive changes, such as lack of initiation and word retrieval. It is extremely important that communication is maintained for as long as possible and general strategies include allowing more time for conversation, minimising distractions, using prompts, simple closed questions and communication boards. Assessment by a speech and language therapist is recommended. For individuals whose ability to communicate is impaired it is often helpful to make up a life story book with photos and information about their life, friends and family and likes and dislikes. This allows for a means of communication as well as ensuring that any new staff are able to learn about the patient. It is important to remember that it is very likely that a high degree of awareness and comprehension will still be present even when the patient is unable to communicate verbally.

Behavioural changes

Due to the cognitive changes that occur in HD, a patient may be distracted, irritable, confused, uncooperative or withdrawn. They may demand that you respond immediately, become aggressive if their needs are not met, and may not be able to consider the consequences of their actions. This can be very challenging, but it is vital not to take the patient's behaviour personally and remember that the behaviour is a direct result of the changes taking place in the brain. Patients with HD can have little control over their impulses and emotions, become very inflexible and appear to make irrational judgements.

It is important to look carefully at any difficult situations to try to establish the exact cause and any precipitating factors that might be avoided in future. It is also important, when managing behavioural changes, to be willing to try several strategies and develop a team approach. Ensuring that the patient has a very structured routine and that distractions are minimised can also help manage behavioural changes. Any sudden changes in behaviour may have been caused by head injury following a fall, infection, side-effects of medication or other illnesses that may need further investigation.

Personal care

As the disease advances, patients will have more difficulty managing their personal care and will require assistance in areas such as bathing and dressing. Patients sometimes find it difficult to make judgements about their personal appearance and may resist taking a shower or brushing their teeth, or may have difficulties with initiation and simply require prompting. In order to help a patient maintain some independence as well as being more practical, it is often easier if clothing is loose and comfortable with limited buttons and zips. Many patients with HD have problems with temperature control and may complain of being too hot or too cold. It is necessary therefore to attempt to ensure that the environment is comfortable for the patient's individual needs.

Incontinence can be a problem for some patients in the later stages of the illness and should be investigated to rule out causes such as urine infection. Patients may benefit from protective underwear and regular toileting (see Ch. 24). Using the toilet can also cause difficulties for patients who are still mobile and, due to a decreasing ability to regulate movement and possible problems with visual and spatial impairment, patients often 'flop' down onto the toilet seat, potentially loosening fixtures or causing injury.

Many patients with HD smoke and it is important to ensure that this is done safely to reduce the risk of fire and burns.

It is important to ensure that patients who are losing their independence are treated as valued individuals and are cared for with dignity and respect. Seeing a loved one becoming more debilitated by HD can be devastating for families and their grief is compounded by the fact that other family members may also be affected or at risk of HD. It is therefore vital that a support network is put in place, not only for the patient with HD but also for their family. Caring for a patient with HD is undoubtedly challenging, but can also be greatly rewarding and optimal care can result in a major improvement in the patient's quality of life.

The Scottish Huntington's Association and the Huntington's Disease Association of England and Wales have professional advisors who can offer emotional support to individuals and families as well as offering specialist assessment, advice and information on HD and its management (see 'Useful Websites').

CANCER GENETICS

Cancer genetics is a relatively new subject and is becoming an increasingly demanding aspect of the work of all genetics departments. As knowledge advances and more is understood about cancer genetics, the possibilities for testing will increase.

At a cellular level, all cancers, both sporadic and inherited, are genetic (Kingston 2002). The latter may be due to inherited changes in the genes directly involved in normal cellular growth and proliferation or to genetic changes resulting in the increased possibility of a mutation in the genes related to cell growth. The formation of a human cancer is a multistep process and is the result of a series of mutations in a single cell. Genes with a positive effect on growth and proliferation of cells are known as oncogenes, and those with a negative effect as tumour

suppressor genes or anti-oncogenes (Hodgson & Maher 1999). Oncogenes and tumour suppressor genes are often referred to as the 'gatekeeper' genes (Kinzler & Vogelstein 1997). Activation of oncogenes and inactivation of tumour suppressor genes are both important in the formation of the malignant cell (Hodgson & Maher 1999).

A third class of genes has been identified which is also known to predispose to malignancy. These genes are involved in DNA mismatch repair. Their role is to maintain the integrity of the genome (Hodgson & Maher 1999) and they are referred to as the 'caretaker' genes (Kinzler & Vogelstein 1997).

The aims of cancer genetics include:

- the identification of a subgroup of the population who are at significantly increased risk of developing cancer
- reduction of mortality from 'common' cancers, e.g. breast, ovarian and colorectal, by offering appropriate screening or surgery for those at increased risk
- reassurance and discharge from screening for those not at increased risk compared with the general population risk.

Cancer is a common disease, said to affect 1 in 3 people in their lifetime (see Chs 31 and 35). Therefore, chance may account for the apparently high incidence of 'common' cancers in some families (Eeles et al 2004). However, factors which may imply a genetic predisposition to cancer are:

- a family history of cancer on one side of the family with an autosomal dominant pattern of inheritance. The cancers may be the same or with a known association, e.g. breast and ovarian
- onset of cancer at a young age (under 50 years)
- the presence of multiple primary tumours or bilateral tumours in an individual
- the presence of rare cancers.

The detection of an identifiable germline mutation in a relevant gene, in an affected family member, would be regarded as confirmation of an inherited predisposition to cancer within a family (Hodgson & Maher 1999).

Familial breast cancer

Two genes (BRCA1 and BRCA2) have been found to influence the occurrence of familial breast cancer and may be responsible for approximately 5–10% of breast cancers (Mitchell & Eeles 1999). The BRCA1 gene was cloned in 1994 (Futreal et al 1994) and over 100 different mutations have been identified so far. The overall lifetime risk of breast cancer for those with a BRCA1 mutation is up to 87% (Thompson et al 2002). The BRCA2 gene was cloned in 1995 (Wooster et al 1995). The overall lifetime risk of breast cancer for those with a BRCA2 mutation is up to 84% (Ford et al 1998). There is an increased risk of ovarian cancer in those with a BRCA1 or BRCA2 mutation. Mutations in BRCA2 are more likely to be implicated in families with cases of male breast cancer. It is apparent that BRCA1/BRCA2 do not account for all familial breast/ovarian cancer families. Research is ongoing for new gene mutations.

Unless the history is from the paternal side of the family, women at increased risk of breast cancer are recorded as those with a first-degree relative (mother, father, sister, brother, daughter or son) affected by cancer within a family that meets one of the following criteria:

- one first-degree relative who developed breast cancer under the age of 40 years or a male with breast cancer at any age
- two first- or first- and second-degree relatives on the same side of the family who developed breast cancer under the age of 60 years or with ovarian cancer
- three first- or first- and second-degree relatives on the same side of the family with breast or ovarian cancer at any age. One first-degree relative unless history is from the paternal side
- one first-degree relative with breast cancer in both breasts (separate primary cancers)
- one first-degree relative with breast and ovarian cancer.

Screening

The options available for women at an increased risk of developing breast cancer include screening by mammography and breast examination. Screening protocols vary nationally. The following approach is adopted in Scotland (Scottish Cancer Group 2001):

- From age 35 or 5 years younger than the earliest onset of breast cancer in the family (rarely under the age of 30) mammography is offered every 2 years and clinical breast examination every year.
- From age 40–50 years a mammography and clinical breast examination is offered every year.

The National Breast Screening Programme offers 3-yearly screening with mammography for women from age 50 to 70 years (see Ch. 7).

High-risk women over age 50, e.g. BRCA1 or BRCA2 gene carriers, may be offered 18-monthly breast examination and mammography; however, this depends on local amendments to guidelines.

The sensitivity of mammography improves with age as the glandular tissue is replaced by fat (involution) so the breast becomes less radiodense, softer and droopy. This process of involution begins after the age of 30.

The UK National Study of Magnetic Resonance Imaging (MRI), called the MARIBS research, has assessed the value of MRI as a method of screening for young women at an increased risk of developing breast cancer (Leach 2002).

Clinical trials assessing the value of tamoxifen in the prevention of breast cancer in women with a family history have reported mixed results. The overall risks with tamoxifen use and benefits in prevention remain unclear (IBIS 2002) (see Chs 7, Part 2, and 31).

Prophylactic surgery — risk-reducing mastectomies

Women who have, or are likely to have, a gene mutation may elect for prophylactic surgery. This may seem a drastic course of action (Hatcher et al 2001), but is acceptable to some women who have seen a number of their relatives suffer from breast cancer.

Aspects for discussion regarding this include (Eeles 1996):

- the surgical technique to be used — subcutaneous or total mastectomy

- surgery to remove enough breast tissue to prevent the development of invasive breast cancer, i.e. wide local incision (WLE)
- minimisation of psychological complications.

Women with a high risk of developing breast cancer due to a family history or to being a carrier of a BRCA1/BRCA2 mutation, also have the option of prophylactic salpingo-oophorectomy. This has been shown not only to reduce their risk of ovarian cancer, but also to significantly reduce their risk of breast cancer by up to 50% (see Ch. 7, Part 2).

Familial ovarian cancer

Two types of ovarian cancer susceptibility genes have been identified: the breast and ovarian cancer tumour suppressor genes (BRCA1 and BRCA2) and the mismatch repair genes associated with hereditary non-polyposis colon cancer (HNPCC) families (see p. 249). Mutations in the BRCA1 gene are estimated to confer an increased ovarian cancer risk of up to 66% (Thompson et al 2002) and mutations in the BRCA2 gene an increased risk of up to 27% (Ford et al 1998). The mismatch repair genes confer an increased lifetime risk of ovarian cancer of approximately 12% in addition to an increased risk of endometrial cancer (Aarnio et al 1999).

At present, relatively few patients are classed as high risk because a mutation in a cancer predisposing gene has been detected in their family. In most cases, risk estimates are based on family history. The following list defines women who are at greater than five times the population risk of ovarian cancer based upon family history (Thompson et al 2002). Screening protocols vary nationally.

Women at increased risk of ovarian cancer are those with a first-degree relative (mother, father, sister, brother, daughter or son) affected by cancer within a family that meets one of the following criteria:

- two or more individuals with ovarian cancer, who are first-degree relatives of each other
- one individual with ovarian cancer at any age, and one with breast cancer diagnosed under age 50 years, who are first-degree relatives of each other
- one relative with ovarian cancer at any age, and two with breast cancer diagnosed under 60 years, who are connected by first-degree relationships
- known BRCA1 or BRCA2 (or other relevant cancer gene mutation) carrier
- untested first-degree relative of a predisposing gene carrier
- three or more family members with colon cancer, or two with colon cancer and one with stomach, ovary, endometrial, urinary tract or small colorectal cancer in two generations, one with cancer under age 50 years
- an individual with both breast and ovarian cancer.

The options available to these women to manage their increased risk of ovarian cancer include screening or prophylactic salpingo-oophorectomy.

Screening

Survival in ovarian cancer is dependent on stage at presentation. The 5-year survival rate for Stage I disease is over 85%, whereas Stage IV is approximately 10%. Therefore, detecting ovarian cancer early through screening has the potential to have a major impact on prognosis. Unfortunately, the effectiveness of screening for ovarian cancer has yet to be demonstrated (Scottish Cancer Group 2001). Studies are investigating the use of the CA125 tumour marker and transvaginal ultrasound at variable frequencies.

Prophylactic surgery

The alternative to screening for women at an increased risk is prophylactic salpingo-oophorectomy. Recent studies have confirmed that the risk of both ovarian and primary peritoneal carcinoma (a cancer indistinguishable from ovarian cancer) is reduced by 90% following prophylactic surgery in BRCA1/BRCA2 mutation carriers (Kauff et al 2002, Rebbeck 2002). There is also a reduction in breast cancer risk, which is very significant given that most women at increased risk of ovarian cancer are also at increased risk of breast cancer.

Hereditary non-polyposis cancer of the colon (HNPCC)

Almost all cases of HNPCC are due to a germline mutation in one of the known DNA mismatch repair (MMR) genes (Vasen et al 1991). HNPCC is defined by the number of individuals in a family diagnosed with an HNPCC-related cancer (see below), their age at diagnosis and their relationship to each other.

There are internationally agreed diagnostic criteria, known as Amsterdam criteria, for identifying HNPCC families. Initially, only colorectal cancers were considered in these criteria. Further research has identified a spectrum of cancers in HNPCC families and the modified Amsterdam criteria have been established (Vasen et al 1999). Families meeting the criteria below are given a high genetic risk.

At least three relatives must have a cancer associated with hereditary non-polyposis colorectal cancer (colorectal, endometrial, stomach, ovary, ureter or renal pelvis, brain, small colorectal, hepato-biliary tract or skin (sebaceous) tumours):

- one must be a first-degree relative of the other two
- at least two successive generations must be affected
- at least one of the relatives with cancer associated with hereditary non-polyposis colorectal cancer should have received the diagnosis before the age of 50 years
- familial adenomatous polyposis must have been excluded in any relative with colorectal cancer
- tumours should be verified whenever possible.

Several HNPCC genes have been identified. The three genes most commonly associated with HNPCC are MLH1, MSH2 and MSH6. HNPCC gene carriers have an increased risk of developing the cancers shown in Table 6.1.

The options available to these individuals to manage their increased risk of cancer include screening and/or prophylactic surgery. Screening recommendations for those at high risk differ throughout the country but all include colonoscopy at varying intervals. Screening recommendations in Scotland (Scottish Cancer Group 2001) are:

- 2-yearly colonoscopy, from age 30 or 5 years younger than the youngest affected until age 70

Table 6.1 Gene carrier risk of developing cancer

Cancer type	Gene carrier risk (%)
Colorectal, male	74
Colorectal, female	30
Endometrial	42
Ovarian	12
Gastric	7
Biliary tract	9
Uroepithelial	8
Kidney	5
Brain	4.5

Adapted from Aarnio et al (1999).

- gynaecological screening for ovarian and endometrial cancer, from age 35 years
- 2-yearly upper gastrointestinal endoscopy, from age 50 or 5 years younger than youngest onset of stomach cancer.

In addition, consideration needs to be given to screening for other cancers which may occur in specific families that are part of the HNPCC spectrum.

Prophylactic colorectal surgery may be considered, particularly if numerous polyps are identified through screening. Women may wish to consider prophylactic gynaecological surgery.

Only a small proportion of families will meet the modified Amsterdam criteria. However, a greater proportion of families will be identified at a moderately increased risk above the population risk; for these moderate risk families, colonoscopy screening is offered less frequently.

Familial adenomatous polyposis coli (FAP)

FAP affects 1 in 8000 of the population (Burn & Chapman 1994). It is inherited in an autosomal dominant fashion with almost complete penetrance, although 25% of cases seem to arise from a new (sporadic) mutation (Dunlop 2002). FAP is characterised by hundreds to thousands of adenomatous polyps, which are present mainly in the large intestine and rectum but can occur in the upper digestive tract. The vast number of polyps makes it highly likely that a cancer will occur (Scott et al 2001, Dunlop 2002). As these polyps are usually present by the teenage years, at-risk individuals are screened by flexible sigmoidoscopy from the age of 13. Annual screening is recommended until the age of 30 years and thereafter screening can be offered on a 3- to 5-yearly basis until age 60 years (Dunlop 2002). If no polyps are identified by the age of 60 years, the individual is deemed not to be at risk and screening is usually discontinued. Cancer commonly occurs at the mean age of 40 years (Jarvinen 2003) and prophylactic colectomy is indicated in the early 20s in individuals with recurrent polyps at screening. The operation of choice is a proctocolectomy and ileoanal pouch (Dunlop 2002).

Extracolonic tumours can be found in FAP. These can be bone and soft tissue abnormalities such as papillary thyroid tumours, abdominal desmoid tumours, osteomas, epidermoid cysts and hepatoblastomas. Tumours can also occur in the upper gastrointestinal tract (Chung et al 2003). Screening of the upper gastrointestinal tract is offered at 3-yearly intervals from the age of 25 years.

FAP is caused by a single gene fault on chromosome 5 (APC gene) and mutations can be unique to individual families (Jarvinen 2003). The disease and severity within the family can be variable (Crabtree et al 2001). There are some families where the gene fault cannot be identified and direct gene testing will not be available to other family members at risk. There is a milder form of this condition called attenuated FAP, where the onset is in the later years and there is a reduced number of polyps present. The mutations in these cases are generally located in the extreme end of the APC gene. Early identification of cases and prophylactic surgery have improved the survival rate in FAP (Dunlop 2002).

Genetic testing for cancer predisposition

The availability of gene testing is currently limited to families with a strong history of breast, ovarian or colorectal cancers. However, as more cancer susceptibility genes are identified and more is understood about their role in the aetiology of cancer, an increasing number of tests may become available. Cancer genetics is a rapidly developing field and guidelines for risk assessment, screening and genetic testing are continuously being reviewed and developed.

Genetic modification and gene therapy

There are a number of ways in which human gene therapy could potentially be used (Resnick & Langer 2001): genes could be deleted from somatic cells, genetic mutations corrected or missing genes introduced. This would affect only the individual being treated and has been judged by controlling committees as acceptable practice in most cases. Currently gene therapy is not part of clinical practice but this may change with future advances. Debate continues over ethical issues related to the potential practice of gene modification or therapy.

CONCLUSION

In the field of human genetics the use of scientific knowledge raises ethical and moral problems, particularly where every advance has an enormous potential for good and evil. Recognition of the destructive potential of genetic engineering has prompted the imposition of strict controls on biotechnology and genetic research. This chapter has presented an outline of current developments in genetics and molecular biology. It has outlined nursing involvement in genetic counselling and care of patients with genetic disorders. The information gained from the Human Genome

Project and related genetic research will undoubtedly create significant changes in health care practice. As public awareness continues to grow, individuals and families are increasingly requesting genetic counselling. All health care providers, in particular nurses, will therefore require a fundamental understanding of basic genetic concepts and genetic influences on health and disease. Consequently, it is imperative for nurses to be well informed.

PART 2 THE BREAST 320

INTRODUCTION

Any threat to an individual's reproductive capacity affects that person's body image, self-esteem and gender identity. Since these are influenced by personal attitudes, social customs and cultural background, people respond differently to such a threat. Reproduction of the human species involves a complex series of events affected by physical and psychological capacities and the state of health. Attitudes towards sexual reproduction, underlying beliefs held and feelings experienced are influenced by cultural norms, current social values, religious background, lifestyle and parental and peer pressure.

Human reproduction and the ability to procreate are important issues, evidenced by the incidence of subfertility in the United Kingdom (UK) and the growing development of reproductive technologies. While the physiological aspects of reproduction are concerned with continuance of the species, the psychosocial aspects of reproduction are of significance to the feelings of health and well-being for both men and women.

Human beings are individuals with their particular aspirations and values. Thus, for some people, having their own children and raising a family are perceived as important parts of their role in life. For others, these are inconsequential. For yet others, they may be desirable but unobtainable, giving rise to sadness and regret. Whether or not individuals wish to use their reproductive capacity

to have children, sexuality is an important concept of self-expression and interaction with others.

The ethos of disease prevention is paramount in health care. Practice nurses, in particular, have an important role in advising and encouraging good health awareness and in facilitating and conducting screening and health monitoring. However, screening is not always possible and some diseases can be far advanced before diagnosis.

Although scientific advances and more sophisticated technology may become available, there are economic constraints on practical therapeutics, and choices must be made when resources are limited. In addition, the rapid progress of science and technology creates ethical issues that society has yet to debate and fully explore as a basis for action and future directions in health care. The Joint Report of the Council on Scientific Affairs and the Council on Medical Science (1992) recognised that the proliferation of health care technology requires thorough evaluation of new technologies in terms of safety and effectiveness.

Advanced minimal invasive techniques also have the advantage of a shorter anaesthetic, allowing patients a shorter stay in hospital. This has implications for nursing and patient care following hospital treatment to adapt to the dynamic nature of nursing in a changing society.

The anatomy and physiology of the male reproductive system appear in Chapter 8.

ANATOMY AND PHYSIOLOGY OF THE FEMALE REPRODUCTIVE SYSTEM

The primary function of the reproductive system is the propagation of the human species. Sexual drive and anticipated pleasure help to meet the reproductive need. The female reproductive system is structured to produce gametes (ova or eggs), to receive the male penis during sexual intercourse and to facilitate the passage of sperm. It accommodates and promotes the growth of the embryo before birth and feeds the newborn infant.

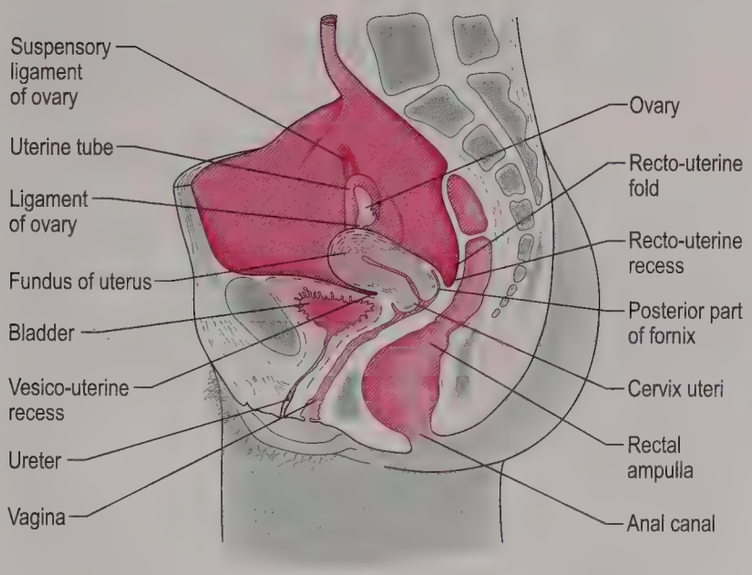

Fig. 7.1 The relationship of the female reproductive organs: sagittal section.

These complex functions are maintained by the following structures (see Figs 7.1 and 7.2):

- the internal organs
  - — the ovaries
  - — the uterus
  - — the uterine (fallopian) tubes (or oviducts)
  - — the vagina
- the external organs
  - — the vulva
  - — the mammary glands or breasts.

The ovaries

Women have two ovaries, the size and shape of large almonds, one on either side of the uterus. The surface of the ovary consists of a single layer of germinal epithelium surrounding connective tissue that forms the stroma of the ovarian cortex and medulla. The ovarian follicles develop in the cortex. A woman is born with approximately 100 000 follicles, although this may fall to approximately 30 000 by adolescence. Each follicle contains an immature ovum known as an oocyte. The medulla, in the centre of the ovary, consists of fibrous connective tissue, blood vessels and nerves.

The production of ova and hormones

The ovary has two functions:

- ovum production
- internal secretion of hormones.

Ovum production

The ovarian cycle begins at around 12–13 years of age. Follicles begin to mature under the influence of the follicle-stimulating hormone (FSH) and luteinising hormone (LH), released by the anterior pituitary gland. During the cycle, follicles can pass through five stages (see Fig. 7.3):

- *primary follicle* — each oocyte is surrounded by a thin layer of epithelial cells
- *developing follicle* — the follicular epithelium proliferates, the oocyte moves to a side position, and a fluid-filled cavity develops within the epithelium

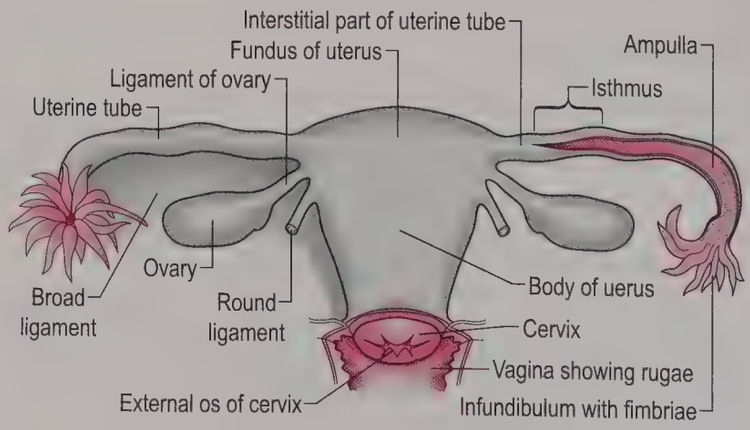

Fig. 7.2 The organs of the female reproductive system and attachments.

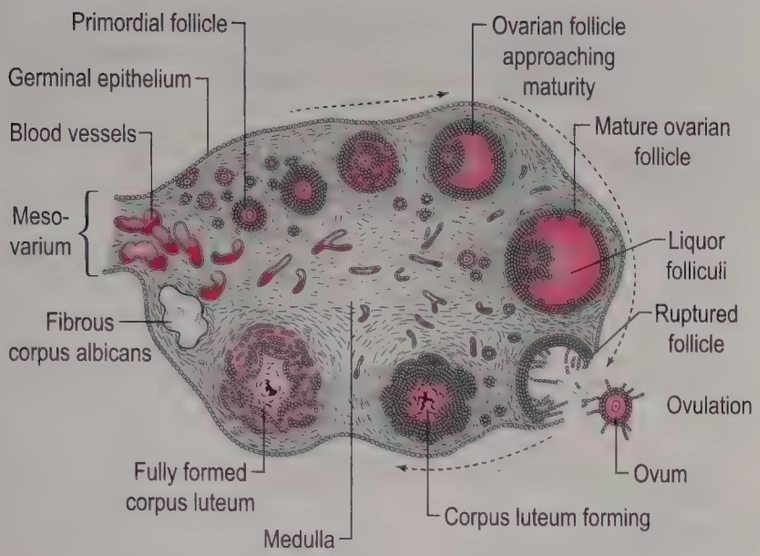

Fig. 7.3 Sequence of development of the ovarian cycle.

- *mature (Graafian) follicle* — the follicle reaches its maximum size
- *corpus luteum* — a yellow mass which forms in the ovarian follicle after ovulation
- *corpus albicans* — scar tissue on the surface of the ovary when the degenerated corpus luteum atrophies.

The maturing follicle is surrounded by a layer of ovarian tissue, known as the theca. Several follicles may develop together but only one will mature fully, as others regress. The mature (Graafian) follicle ruptures at the surface of the ovary and discharges the ovum and fluid into the peritoneal cavity, a process called 'ovulation'. Wafting movements of the finger-like ends of the uterine tubes assist the transfer of the ovum into the tube (oviduct). It is thought that fertilisation of the ovum usually occurs in the ampulla of the uterine tube.

The ruptured follicle contracts around leaked blood after discharging the ovum. The epithelial cells (granulosa) multiply and the corpus luteum is formed under the influence of LH, secreted by the anterior pituitary gland. The corpus luteum synthesises steroid sex hormones for at least 8–10 days. If the ovum is not fertilised, the corpus luteum degenerates, stops its hormone production and forms scar tissue called the 'corpus albicans' near the surface of the ovary. If the ovum is fertilised, the corpus luteum continues to develop, increasing its size and hormone production for about 2 months.

Secretion of hormones

The production of sex hormones is influenced by the hypothalamus of the brain. The hypothalamus produces gonadotrophin-releasing hormone, which stimulates the anterior pituitary gland to release FSH and LH: FSH stimulates the initial development of ovarian follicles and their secretion of oestrogen; LH stimulates further development of the ovarian follicles, initiates ovulation and incites production of ovarian hormones. FSH and LH control the secretion of two types of ovarian steroid hormones: oestrogens and progestogens.

The oestrogens Oestrogens have three main functions:

- development and maintenance of female reproductive structures
- control of fluid and electrolyte balance
- increase of protein anabolism.

The compound secreted by the theca interna cells of the developing follicle is oestradiol, and its metabolite (waste product) is oestriol. Many other oestrogens may be identified in the urine. Oestradiol is also produced by theca interna cells that invade the corpus luteum.

The progestogens The main compound of this group is progesterone, produced by the luteinised granulosa cells of the corpus luteum. The metabolite of progesterone is pregnanediol, which is also excreted in the urine.

The uterus (see Figs 7.1 and 7.2)

The uterus is a pear-shaped organ approximately 7.5 cm long. It has three main parts:

- the fundus
- the body
- the cervix.

The uterine tubes enter the uterus at its upper outer angles or cornua. The body of the uterus narrows towards the cervix, an area known as the isthmus. The cavity of the uterus connects with the cervical canal at the internal os. The cervical canal opens into the vagina via the external os. The cervix occupies the lower third of the uterus and half of the cervix projects into the vagina. The uterus normally lies in an anteverted position, almost at right angles to the vagina (see Figs 7.1 and 7.4).

Structure

The uterus has three coats:

- endometrium — mucous lining
- myometrium — smooth muscle
- parietal peritoneum — serous coat.

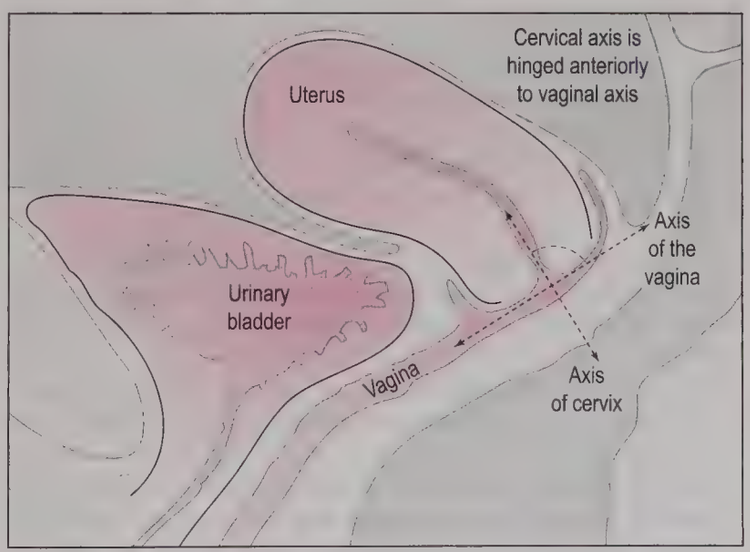

Fig. 7.4 The anteverted position of the uterus.

Endometrium

This is the tissue lining the uterus. This mucosa is continuous with the vagina and the uterine tubes. There are three layers of endometrial tissue:

- *the compact surface layer* — partially ciliated, simple columnar epithelium (stratum compactum)
- *the spongy middle layer* — composed of loose connective tissue and glands (stratum spongiosum)
- *the dense, inner layer* — responsible for the regeneration of the endometrium after menstruation (stratum basale).

During menstruation the compact and spongy layers slough away from the inner layer. The thickness of the endometrium varies from 0.5 mm just after menstrual flow to about 5 mm near the end of the endometrial cycle.

Myometrium

The myometrium is formed from three layers of muscle fibres that extend in all directions:

- the outer layer of longitudinal fibres
- the intermediate layer, in which fibres run irregularly, transversely and obliquely
- the inner layer of circular fibres.

Parietal peritoneum

Peritoneum forms the external coat of the uterus but does not cover the lower anterior quarter of the uterus and the cervix.

Blood supply

The blood supply to the uterus is from the uterine artery, a branch of the internal iliac artery. Veins accompany the arteries and drain into the internal iliac veins. Tortuous arterial vessels enter the layers of the uterine wall and divide into capillaries between endometrial glands.

Nerve supply

The nerves supplying the uterus and the uterine tubes are formed from parasympathetic fibres from the sacral outflow and sympathetic fibres from the lumbar outflow.

Supporting structures

The uterus is maintained in position in the pelvis by fascia and muscle structures (see Fig. 7.5). The uterine ligaments are:

- *the broad ligament* — a fold of peritoneum and fibromuscular tissue extending from the uterus to the pelvic side wall
- *the cardinal ligaments* — these are formed by dense fascia at the base of the broad ligaments, from the cervix to the pelvic side wall
- *the round ligaments* — these extend from the anterior cornua of the uterus forwards and down through the inguinal canal to the subcutaneous fat of the labia majora
- *the uterosacral ligament* — this passes from the cervix and cardinal ligaments backwards to the sacrum, dividing to pass around the rectum
- *the pubocervical ligament* — this passes from the anterior cervix forwards to the pubic bone, dividing to pass around the urethra.

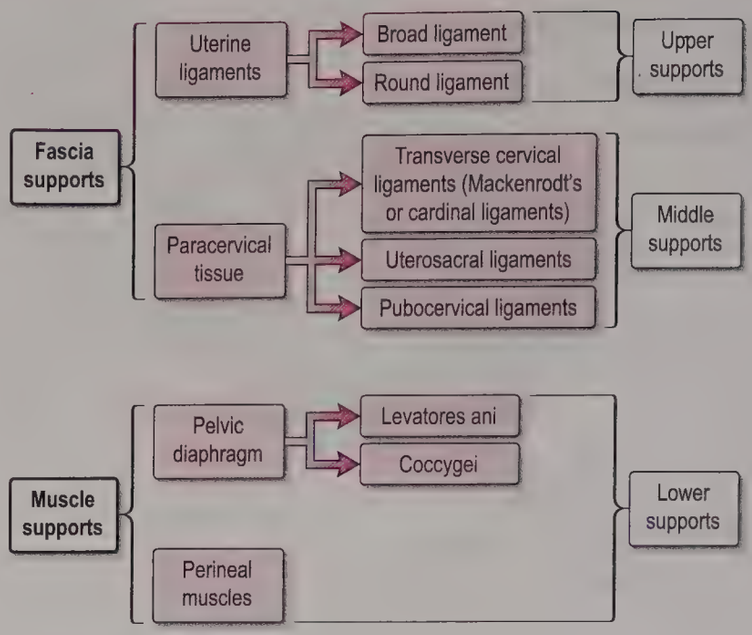

Fig. 7.5 The supports of the uterus.

These ligaments support the position of the uterus within the pelvis. Paracervical tissue, fatty and connective tissue form a supportive sling, allowing the uterus to pivot either backwards or forwards. This gives the uterus mobility anteriorly and posteriorly. Lateral and downward movements are limited by the muscles of the pelvic floor.

The axis of the vagina is considered to be a straight line that is related to the axis of the cervix. When the cervical axis is hinged anterior to the vaginal axis, the uterus is 'anteverted' (see Fig. 7.4), which is its normal position. When the cervical axis is hinged backwards to lie posterior to the vaginal axis, the uterus is 'retroverted'. This can be a normal position for the uterus to occupy provided that the retroversion is mobile and not fixed.

Functions

The functions of the uterus are:

- *menstruation* — sloughing off of compact and spongy layers of endometrium attended by bleeding from torn vessels
- *maintenance of pregnancy* — an embryo implants itself in the endometrium and takes all its nourishment throughout fetal life
- *initiation of labour* — it develops powerful, rhythmic contractions of the muscular wall for the birth of the infant.

The uterine tubes (fallopian tubes or oviducts) (see Fig. 7.2)

The uterine tubes (10–14 cm long) turn posteriorly as they extend laterally from the cornua (or horns) of the uterus towards the lateral pelvic wall. The ends open as funnel-shaped structures with finger-like projections (fimbriae). The broad ligament of peritoneum forms the outer serous layer of the tubes. The middle coat, of muscular tissue,

is arranged in two layers: an outer longitudinal layer and an inner circular layer. The lining of mucous membrane, comprised mainly of ciliated columnar epithelium and secretory cells, lies in folds. The lumen of the tube is narrow. The ends of the tubes are mobile and at ovulation the fimbriae enfold the adjacent ovary to take up the released ova.

Functions

The functions of the uterine tubes are to convey ova from the ovary to the uterus and to allow the sperm and ova to meet for fertilisation within the tube. Passage of the ova along the tube is facilitated by the action of cilia and peristalsis.

The vagina

The vagina is a fibromuscular channel extending downwards and forwards from the cervix to the labia, thereby connecting the internal and external reproductive organs. The cervix of the uterus is inserted into the upper end of the vagina, known as the vault. This creates anterior, posterior and lateral fornices (see Fig. 7.1). The anterior wall of the vagina is approximately 7.5 cm and the posterior wall about 9 cm in length. The vagina is composed mainly of smooth muscle with a lining of mucous membrane arranged in folds or rugae. In the virginal state, a fold of mucous membrane, the hymen, forms a border around the external opening of the vagina, partially closing the outlet. Normally the anterior and posterior walls lie in apposition but the vagina is capable of considerable distension during childbirth.

The vagina is kept moist during the reproductive years by mucus from the cervix and transudation of fluid through the vaginal wall. Glycogen produced in the vagina is fermented by the Doderlein bacilli (normally inhabiting the vagina) to produce lactic acid. This maintains a slightly acid environment in the vagina, inhibiting the growth of other microorganisms.

Functions

The vagina:

- receives semen from the male, deposited in the posterior fornix during sexual intercourse
- provides an outlet for the fetus and other products of conception
- provides an outlet for menstrual flow
- provides a barrier to infection.

The vulva

The vulva comprises the female external genital organs, consisting of:

- the mons pubis
- the labia majora
- the labia minora

- the vaginal orifice
- Bartholin's glands.

The pelvic floor

The pelvic floor is formed by tissues that fill the pelvic outlet and support the pelvic organs.

- The *levator ani muscles* form a broad muscular sheet extending from the pubic bone to the sacrum and coccyx and laterally to the pelvic walls. The urethra, vagina and rectum perforate this muscular sheet.
- The *superficial perineal muscles* lie under the levator ani muscles. They pass from the pelvic side walls, the pubis and the sacrum to unite centrally between the vagina and the rectum, where they form the superficial part of the perineal body.
- The *perineal body* consists of wedge-shaped muscle and fibrous tissue lying between the lower vagina and lower rectum.

The endometrial cycle

The ovarian cycle (see 'Ovarian functions', p. 254) and the endometrial cycle together constitute the menstrual cycle. The endometrial cycle is driven by the hormonal events of the ovarian cycle and can be divided into four phases:

- the menstrual phase
- the proliferative phase (follicular or pre-ovulatory)
- the secretory phase (luteal or post-ovulatory)
- the ischaemic phase.

The menstrual phase

Menstruation is believed to be caused by low levels of progesterone and oestrogens causing vasospasm of arteries to the endometrium. The menstrual phase lasts for 3–6 days and is characterised by bleeding from the uterus, with 50–60 ml of blood being lost at each menstrual period when necrotic parts of the compact and spongy layers of endometrium slough away, leaving a thin, bleeding area of tissue. By the third day of menstruation new epithelial cell growth has begun to cover the disorganised basal layer of endometrium; by the fifth day, epithelium covers the whole surface.

The proliferative phase

The proliferative phase begins while bleeding is still continuing. It is a time of regrowth of endometrium, under the control of oestradiol from the maturing follicle. The growth of epithelium, glands, blood vessels and connective tissue produces thickening of the endometrium. This phase extends to the 14th or 15th day of the cycle, when the peak of proliferation is reached.

The secretory phase

Soon after ovulation, glycoprotein secretory granules appear in the endometrium and can be seen with an electron microscope as large, clear vacuoles developing under the nuclei. Progesterone produced by the corpus luteum promotes the secretory phase. The endometrial glands become enlarged, the arteries coil, connective tissue hypertrophies and tissues rich in glycogen become oedematous. At 7–8 days following ovulation, the endometrium is 5–6 mm in depth and is in a state of readiness to implant a fertilised ovum.

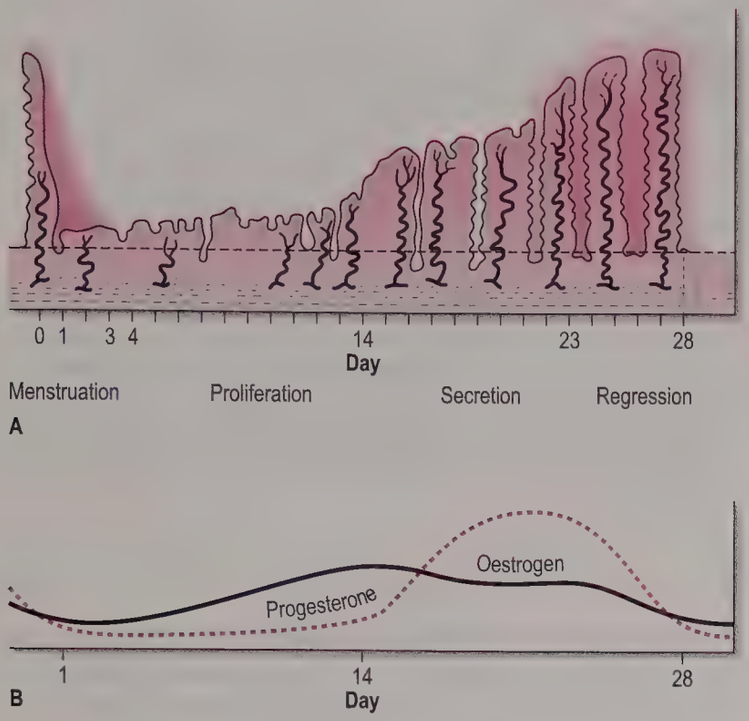

Fig. 7.6 The hormonal control of the menstrual cycle.

If implantation occurs, the corpus luteum continues to produce progesterone and maintains the pregnancy (see Fig. 7.6).

The ischaemic phase

In the absence of implantation, the corpus luteum degenerates and the production of oestrogen and progesterone declines. A leucocytic infiltration of the endometrium takes place, the stroma starts to disintegrate, oedema disappears and the endometrium shrinks. Vasoconstriction occurs. There is lack of nourishment to the endometrium and it begins to slough and separate; menstruation begins again 14 (±1) days after ovulation. This time relationship is constant.

Fluctuations in the length of the cycle occur in the preovulatory phase, as follicles may not mature at the same rate each month. Thus there may be variation in the time of onset of menstruation. Most women establish an average pattern that is normal for each, although many young women have irregular patterns.

The menarche

In Western cultures, girls first menstruate (reach the menarche) within the age range of 9–16 years. Nutrition and body weight influence menstruation and sexual development. This has cultural ramifications in that amenorrhoea and infrequent menstruation are more common in developing countries, especially in the rural areas (Helman 1997). The onset of menstruation may be delayed by intensive physical activity.

Some oestrogen synthesis stimulates early physical sexual changes to occur some time before the first menstruation. There may be follicular growth and some oestrogen withdrawal bleeding to give the early periods of the first few months. These periods are anovular, ovulation having not yet occurred. Such periods are painless. More discomfort may be experienced with the menstruation that follows ovulation. A rise in basal temperature may be a guide to whether ovulation has occurred.

Variation in menstrual cycle length occurs in response to significant life events. Excitement, stress, anxiety or change of environment can delay the maturing of a follicle, ovulation and menstruation. Excessive exercise, as in athletes, can result in irregular periods, anovulatory cycles and amenorrhoea.

The climacteric and menopause

The word climacteric comes from the Greek word klimacter, meaning a step or rung of a ladder. This signifies a step or phase in life from the child-bearing years to a period of infertility associated with age-related changes. The process of the climacteric is usually gradual and may extend over several years. Most women experience the climacteric or perimenopause over a period of 2–3 years, but it may extend over 10 years. During this time the body adjusts to lower levels of oestrogen.

The ageing process of the ovaries results in ripening of fewer follicles and a decreased stimulation by the pituitary hormones. The ovaries atrophy and less oestrogen is released into the circulation. Initially this reduced oestrogen level in the blood results in excessive production of FSH from the anterior pituitary gland, and this feedback mechanism can continue for several years. The withdrawal of oestrogen and the increase in pituitary hormone contribute to the changes associated with the climacteric.

The menopause is sometimes confused with the climacteric. However, the menopause is defined as the cessation of menstruation and is marked specifically by the date of the last menstrual period. It follows, then, that the time of the menopause (last menstrual period) can only be identified in retrospect some months after the event. The menopause is only one effect of the climacteric. 'Postmenopausal' is a term applied to events occurring after menstruation has stopped for at least a year.

The menopause signifies the end of a woman's reproductive capacity. This normally occurs between 45 and 55 years of age, with the mean age for cessation of periods being 51 years. This has remained constant for many years (Abernethy 1997).

A premature menopause is one which occurs before the age of 40 years. This can occur naturally or may be induced iatrogenically. The age of menarche, socioeconomic factors, race, use of oral contraceptives and number of pregnancies appear to have no effect on whether a woman has an early or a late menopause (Abernethy 1997).

Endocrine changes influencing the climacteric

Endocrine changes occur prior to changes in a woman's menstrual pattern when there is an alteration in the ratio of the pituitary gonadotrophins (FSH and LH). FSH levels begin to rise between the ages of 35 and 40 years, affecting the oestrogen feedback mechanisms and resulting in altered ovarian function. As a consequence, some anovular menstruation occurs and there is a reduction in progesterone produced by the theca-lutein cells. During this period

the amount of oestrogen produced shows considerable fluctuation.

Although ovarian cycles may become anovular many years before the menopause occurs, women between the ages of 40 and 45 can still become pregnant as regular ovulation may continue.

Eventually there is further deterioration in ovarian response to the pituitary gonadotrophins and disturbance to the feedback between the hypothalamus–pituitary and the ovaries. There is then a further alteration to the FSH:LH ratio, with an elevation in LH and a steep rise in FSH. However, fewer follicles are stimulated so oestrogen secretion is reduced. The fluctuations in oestrogen production, while following a gradual decline, alter the menstrual pattern in many women, showing considerable variation amongst women until the menopause.

After the menopause there is continued secretion of oestradiol and oestrone, although in varying and declining amounts. Oestrone becomes the predominant oestrogen. Small amounts of oestrogen can be found in the blood and urine of postmenopausal women. Some of this oestrogen may be derived from adrenal activity and the conversion of some androgens into oestrogen. Some oestrogen may be produced by residual ovarian stroma.

Uterine bleeding patterns

The climacteric is characterised by irregular menstruation. Periods may become scanty, or bleeding may be heavy. The menstrual cycle shortens, associated with a decrease in oestradiol secretion. As this continues, LH levels rise and then menstrual cycles lengthen. Anovulatory cycles result in oestrogen-withdrawal bleeding patterns, irregular cycles with intermittent and prolonged spotting (low oestrogen profile) or prolonged amenorrhoea followed by sudden, profuse bleeding (high oestrogen profile).

Somatic changes associated with the climacteric

The somatic changes associated with the climacteric occur as a consequence of a decrease in circulating oestrogen and an increase in gonadotrophins. Since the diurnal secretion of oestrogen varies from woman to woman, the changes experienced vary in severity but are progressive.

The ovaries atrophy and follicles disappear or fail to respond to gonadotrophins. Uterine atrophy is accompanied by a transformation of the muscle fibres to fibrous tissue. The endometrium becomes thinner. The cervix tends to remain dilated and the external os more lax. The fallopian tubes become smaller and the fimbriated ends retract from the ovaries. Atrophy of the vaginal epithelium results in thinning of the vaginal wall, a loss of folds, elasticity and lubrication, and an increase in pH. Vaginal dryness can result in pruritus and dyspareunia. Loss of acidity within the vagina allows organisms to multiply more easily. There is an increase in connective tissue beneath the mucosa, causing narrowing and shortening of the vagina. The vagina is more prone to ulceration and bleeds easily to touch. Senile vaginitis may occur in older women. The labia become thin and lose their sexual responsiveness. Skin over the vulva loses support due to a decrease in subcutaneous tissue and lack of tone of the underlying tissues. Hair growth in this area decreases with advancing years. The muscles and connective tissue of the pelvic floor lose tone and elasticity, and consequently become less effective in supporting the pelvic contents. The urethral mucosa may also show atrophic changes, resulting in symptoms of urethritis and cystitis, although no bacteria are isolated in the urine. In the breasts, subcutaneous fat is reabsorbed and glandular tissue atrophies.

Some of these physiological changes, resulting in lack of lubrication, loss of libido and dyspareunia, can contribute to sexual problems for the woman. Hormone replacement therapy (HRT) may be a possible treatment option or psychosexual counselling may be of benefit. Many factors contribute to a satisfying sex life — satisfaction in a relationship, psychological well-being and emotional security can all make a significant contribution, illustrating the need for a holistic approach.

Vasomotor disturbances

Vasomotor disturbances commonly accompany the climacteric changes (see Box 7.1). Hot flushes (or hot flashes) are the most common but perspiration, headache, fainting and palpitations may also be experienced. Hot flushes can start with a sensation of extreme warmth in the chest, quickly followed by flushing of the face and neck. The feeling of heat may become generalised. This is caused by dilatation of the blood vessels to the skin and an increased blood flow. The flush may be accompanied by sweating and palpitations. Dizziness and nausea may also be experienced. Shivering is often reported after the flush, probably due to compensatory constriction of the blood vessels. While vasomotor symptoms will eventually subside with no long-term effects, hot flushes and sweats are embarrassing,

Box 7.1

Hot flush

It has long been postulated that dysfunction of central thermoregulatory centres in the hypothalamus, caused by changes in oestrogen levels at the time of menopause, result in hot flushes. Oestrogen withdrawal, rather than low circulating oestrogen levels, seems to be the main factor that leads to hot flushes. Weir (2004) describes a model of the pathogenesis of hot flushes whereby oestrogen withdrawal leads to decreased levels of endorphin and catecholestrogen (a metabolic by-product of oestrogen). This results in increased hypothalamic release of norepinephrine and serotonin. Norepinephrine and serotonin lower the set point in the thermoregulatory nucleus, allowing mechanisms of heat loss to be triggered by subtle changes in core body temperature. Thus, it is suggested that endorphins play a key role in the regulation of norepinephrine release, and that agents that increase oestrogen and endorphin levels, or that decrease central norepinephrine release, would be expected to reduce hot flushes.

While oestrogen therapy effectively relieves hot flushes, for women who do not wish hormonal therapy, some antidepressants that affect the release and uptake of serotonin and norepinephrine provide a promising alternative. Venlafaxine, fluoxetine and paroxetine have been found to reduce hot flushes significantly (by 50–60%) when compared with placebo (Shanafelt et al 2002).

RESEARCH ABSTRACT 7.1

Efficacy and safety of estradiol transdermal system compared with placebo on vasomotor symptoms in menopausal women.

A double-blind, placebo-controlled, parallel-group, multicentre trial involving 196 menopausal women complaining of symptoms was conducted to evaluate the efficacy and safety of three doses of Esclim (0.025, 0.050 or 0.100 mg) 17beta-estradiol/24 h as a therapy for moderate to severe vasomotor symptoms. The women received continuous, unopposed treatment with one of three doses of Esclim or a matching placebo transdermal patch for 12 weeks. Findings indicated that the frequency of moderate to severe vasomotor symptoms was reduced significantly compared with the effect of the placebo ($P<0.05$). The severity of the symptoms was also reduced. The adverse effects of oestrogen, notably endometrial hyperplasia and metrorrhagia, were less frequent in the smallest dose.

Utian W H, Bury K A, Archer D F et al 1999 Efficacy and safety of low, standard and high dosages of an estradiol transdermal system (Esclim) compared with placebo on vasomotor symptoms in highly symptomatic menopausal patients. The Esclim Study Group. American Journal of Obstetrics and Gynecology 181(1): 71–79

uncontrollable and can be distressing for many women. Porter et al (1996) report on a Scottish survey of 6096 women aged 45–54 years and note that 84% experienced at least one of the classic symptoms associated with the menopause and 45% of the women reported one or more symptoms as a problem. Randomised controlled trials (RCTs) have indicated the value of oestrogen in reducing the severity of vasomotor symptoms when compared with placebo (see Box 7.1 and Research Abstract 7.1).

In addition to oestrogen therapy, other treatments, such as vitamin E and/or B_6, clonidine, plant oestrogens, propranolol and oil of evening primrose, have been used. Progestogens have been shown to alleviate hot flushes (Loprinzi et al 1994). Phytoestrogens, found in soya, can be taken as a supplement and have been suggested as a remedy for menopausal symptoms. While some women do find them valuable, there is controversy about advocating them as a therapy for menopausal symptoms (Davis 2001, Naftolin & Stanbury 2002).

Emotional changes

Some women complain of irritability, anxiety, difficulty in concentration, dizziness, a bloated feeling and depressive feelings after the menopause. In addition to hormonal changes occurring at the perimenopause, women may also be facing other psychological or social changes which can affect their emotional state. While HRT is commonly accepted as a method of treating a negative mood and is promoted by pharmacological companies, it is difficult to establish a causal relationship between oestrogen deficiency and the emotional behaviour of women (Stephens & Ross 2002).

CONDITIONS AFFECTING MENSTRUATION

Amenorrhoea

Amenorrhoea means the absence of menstruation and is a symptom, not a disease. It is described as primary or secondary.

Primary amenorrhoea is defined as non-appearance of menstruation in a female by the age of 16 years. A delay in the onset of menstruation may be a cause of concern. There may be an anatomical fault or some disturbance in hormonal secretions. Delayed puberty may be familial or constitutional. Secondary amenorrhoea is the absence of menstruation for a period of time which is twice the length of the normal menstrual cycle for a woman who has previously menstruated. Thus, if two or more menstrual periods are missed then secondary amenorrhoea may be said to exist. This often means that the woman may wait until menstruation has been absent for a year before seeking investigation.

Physiological amenorrhoea

Amenorrhoea is physiological before puberty, during pregnancy and lactation, and after the menopause. Inheritance, race, climate and general nutrition influence when menstruation begins. The potential for maturation of ovarian tissue is in place before birth. After puberty, full regulation of ovarian activities by the hypothalamus and pituitary gland is achieved and menstrual cycles are established, but the exact time for this is unpredictable.

Before puberty

A teenage girl may be seen by her GP because of delay in the onset of menstruation. The doctor may undertake a general physical examination to determine if other secondary sex characteristics are present; if so, menstruation will follow in due course. If secondary sex characteristics or menstruation fail to develop, the doctor will refer the patient to a consultant gynaecologist and endocrinologist for investigation.

During pregnancy

After ovulation has occurred, the lining cells of the ovarian follicle are stimulated by LH to develop the corpus luteum which produces progesterone. This hormone in turn stimulates the endometrium and its secretory glands into a state of readiness to receive the fertilised ovum from the uterine tube. When the fertilised ovum becomes embedded in the wall of the uterus, it produces the hormone human chorionic gonadotrophin (hCG). This hormone enables the corpus luteum to continue its production of progesterone for 3–4 months until the placenta grows and produces its own progesterone and oestrogen. The presence of the growing fetus and the continued production of progesterone prevent the loss of endometrium and the menstrual flow.

Amenorrhoea is frequently one of the first symptoms that lead a woman to suspect that she is pregnant. Levels of hCG in the urine provide a positive diagnosis when a test for pregnancy is completed in the clinic or laboratory. The doctor usually confirms the pregnancy by abdominal palpation and a vaginal examination, when the uterus is found to be increased in size.

During lactation

Mothers who totally breast feed their baby may not ovulate or menstruate during the first 6 months after the birth or until they start to wean the baby. Breast feeding therefore exerts a measure of birth control, but it cannot be recommended as 100% effective as a contraceptive. Sutherland (2001) claims that the contraceptive effectiveness of lactational amenorrhoea has been reported as 98% effective provided the woman is fully breast feeding, is within 6 months of the birth and menstruation has not returned. However, Hartmann (1991) states that fertility may return as early as 2 weeks after birth in some women who are fully breast feeding and Farrer (1990) indicates that most women will ovulate before their first menstruation following childbirth.

Total nipple stimulation is important for suppression of ovarian function. The suckling stimulus to the nipple leads to a neurohormonal reflex production of prolactin by the anterior pituitary gland and the consequent maintenance of high circulating levels of prolactin inhibits gonadotrophin hormone release, preventing ovulation and menstruation.

Suppression of the ovaries declines where supplements comprise more than 50% of the diet of the baby who is breast feeding. The incidence of ovulation and the risk of pregnancy then rise rapidly.

A poor state of nutrition in the mother is also known to inhibit ovulation, particularly in developing countries (Lunn 1992). To ensure contraception during the period of lactation, the mother may be advised to use a barrier method. The progestogen-only pill is considered safe during lactation since it does not affect the milk supply and only insignificant quantities enter the milk. The combined oral contraceptive pill, however, inhibits lactation and small quantities enter the milk (Everett 1997).

After the menopause

The menopause, or date of the final menstrual period, may not be fully acknowledged until a year without periods has passed. Many women pass this milestone without regrets and without unpleasant physical symptoms. Medical intervention may be sought if physical discomfort such as hot flushes, headaches or sweating is experienced.

Information and support from the nurse, outlined later in this chapter (p. 273), can be helpful.

Pathological amenorrhoea

Uterine lesions, congenital abnormalities

PATHOPHYSIOLOGY

- *Congenital absence of uterus and vagina* may occur, although ovaries and secondary sex characteristics have developed.
- In *primary deficiency of endometrium* a diagnostic test can be performed by giving ethinyl oestradiol 0.05 mg by mouth, twice a day for 21 days. If withdrawal bleeding occurs within 7–10 days then there is not a failure of endometrium but probably failure of stimulation by the ovaries. If there is no bleeding, an endometrial problem exists. The endometrium may be absent, deficient or unable to be stimulated by oestrogen. In this case, the amenorrhoea is entirely of uterine origin.

Ovarian lesions

Failure of normal development is a rare condition of the ovary. Chromosomal abnormalities such as Turner's syndrome may occur.

PATHOPHYSIOLOGY

Turner's syndrome is a condition that results from the absence of one female chromosome. The chromosome complement is written as 45XO. The woman is reported to be 'chromatin negative'. The condition shows infantile development of the genitalia, absence of breasts, short stature and a webbed neck. There may be associated congenital cardiac lesions (see Ch. 5).

MEDICAL MANAGEMENT

Chromosomal studies confirm the diagnosis. Early diagnosis is important and investigations can usually be initiated before puberty, suspicion being aroused by the short stature of the child.

Treatment, such as ethinyl oestradiol 0.01 mg twice daily, in 3-week cycles, given for several months, then norethisterone added for the last 10 days of each cycle, can be used to stimulate development of the breasts and uterus. Menstruation may occur with this treatment.

Pituitary disorders (see also Ch. 5)

- *Deficiency of gonadotrophin secretion* may occur without deficiencies of other trophic hormones. No cause may be found but it is often associated with emotional responses.
- *Infantilism* may result from congenital failure of the pituitary gland, causing dwarfism, lack of sexual development and amenorrhoea. FSH is absent or low. Oestrogens may be undetectable in the urine.
- *Fröhlich's syndrome* is a disturbance of the hypothalamus, resulting in underdevelopment of genital tissues, amenorrhoea, obesity, hirsutism and retardation of mental responses.
- *Ischaemic necrosis* of pituitary tissue may result from thrombosis of pituitary vessels following profound shock and anaemia, often due to severe postpartum haemorrhage. The production of trophic hormones ceases or is reduced. The condition is characterised by lethargy, weight gain, reduced metabolic rate, hypotension and amenorrhoea. HRT gives some psychological benefit only, by withdrawal bleeding effects.
- *New growths* of the pituitary cause acromegaly and amenorrhoea, with signs of Cushing's syndrome due to effects on the suprarenal glands.

Other endocrine disorders

- *Adrenogenital syndrome* results from overactivity of the adrenal cortex due to the presence of a tumour or hyperplasia. Excessive production of androgens occurs, giving signs of virilism — a deepening voice, hirsuteness, an enlarged clitoris and the development of acne and amenorrhoea.
- *Cushing's disease* is caused by hyperplasia of the adrenal cortex, which leads to an excess of glucocorticoids, stimulating the conversion of protein into carbohydrate. Obesity, glycosuria, hypertension, increased androgen

activity and amenorrhoea from regressive changes in the genital organs are the main features of the condition.

The following endocrine disorders may also be accompanied by amenorrhoea:

- Addison's disease
- myxoedema
- thyrotoxicosis
- diabetes mellitus.

Emotional stress

PATHOPHYSIOLOGY

Emotional disturbance is likely to affect menstrual function through the hypothalamic–pituitary axis since the hypothalamus controls the output of gonadotrophins from the pituitary gland. Emotional distress caused by some traumatic event, such as receiving bad news or being involved in a major disaster, may contribute to amenorrhoea. If a woman has sexual intercourse without contraception, the fear of becoming pregnant may itself cause temporary amenorrhoea.

MEDICAL MANAGEMENT

Following discussion with the doctor, it is expected that the patient will understand and be reassured about the effects of stress on menstruation. When she makes a positive adjustment to the critical event that has preceded the problem, physical and mental relaxation will promote a spontaneous return of menstruation.

Anorexia nervosa (see also Ch. 5)

PATHOPHYSIOLOGY

Anorexia nervosa is a psychological illness, the distress being manifest as disordered eating behaviour. It is associated with dieting routines and distortion of body image and is characterised by extreme weight loss and dislike for foods, particularly carbohydrates. It occurs most commonly in adolescent girls with a peak age of 17–18 years and an incidence of 1–2 per 1000 (Fombonne 1995). There is failure in hypothalamic stimulation of LH release and amenorrhoea occurs.

MEDICAL MANAGEMENT

Women with anorexia nervosa are usually reluctant to accept they have a problem or to seek help. Their weight loss may be being investigated or they may present to their GP with another problem but when a diagnosis is made, care is usually maintained by a psychiatrist. A behavioural therapy programme is negotiated with the patient to ensure an improvement in food intake, while a cognitive therapist may assist her to think more rationally and improve her feelings of self-esteem and her body image. Positive physical and psychological changes can promote a return to menstruation.

Psychotic illness

PATHOPHYSIOLOGY

Psychotic illness may be a cause of amenorrhoea. The person with a schizophrenic reaction may not menstruate for many months or years. A life crisis can contribute to disturbances in the activity of neurotransmitter catecholamines in the brain. The chemistry of the hypothalamic– pituitary axis may be disrupted, resulting in amenorrhoea.

MEDICAL MANAGEMENT

The psychiatrist would check that a pregnancy has not developed in the patient with a psychotic reaction. A reliable source of information will be needed, whether the patient herself or her partner. A laboratory pregnancy test may be necessary. The acute symptoms of the patient's illness may be treated by neuroleptic medication or psychotherapeutic intervention. A return of the normal menstruation pattern would be expected when the body chemistry becomes more stable.

Severe general illness

PATHOPHYSIOLOGY

The stress of severe illness may induce ineffective functioning in multiple body organs and may temporarily suppress menstrual function. Stress, as experienced by prisoners of war or refugees, associated with malnutrition, minimal protein and vitamin intake, leads to amenorrhoea.

MEDICAL MANAGEMENT

The amenorrhoea is secondary to the general illness. Thus the particular illness condition must be treated before the amenorrhoea can be relieved. The influences of emotional and physical stress are complex, and sometimes assisting the patient to relax and lower anxiety levels may promote menstruation before the general illness is fully relieved.

NURSING PRIORITIES AND MANAGEMENT: Amenorrhoea

The nurse caring for a patient with amenorrhoea may do so in any of the hospital specialties or in the community — the nursing management will be similar in all of these locations.

Assessment

As part of the routine assessment of the patient, the nurse should enquire about the date of the last menstrual period and whether there are any problems with menstruation. The nurse should ascertain whether the patient has any knowledge of the reason for the absence of menstruation. As the patient shares information, the nurse should be able to establish how the patient feels about the amenorrhoea that is described. The patient may not regard amenorrhoea as a problem or, conversely, it may be a source of some distress. Assessment should take account of her lifestyle, including nutrition, eating pattern, body weight, level of exercise and any stressful life events.

Care planning

In negotiation with the patient, the nurse should plan time to give her information about the absence of menstruation. This can perhaps be associated with potential worries about the condition. The patient's level of anxiety should be documented in the plan. The nurse may wish to emphasise the need for self-relaxation and may teach a simple relaxation exercise. Relaxation audiotapes may be available from the physiotherapy department, occupational therapy or the department of clinical psychology.

If, following a medical assessment, puberty is deemed to be delayed, reassurance and counselling are part of nursing care. Nurses can encourage optimism, provide general information about diet, exercise and lifestyle, and offer support, but in some cases skilled counselling may also be of value.

Evaluation of care

The patient's long-term goal of 'a return of the menstrual period' may not be achievable within the early weeks of care and should be modified to include a short-term realistic target. This may include an evaluation of the level of anxiety experienced by the patient. Nurse and patient should negotiate and evaluate it, to check on the response to self-relaxation activity during the first 2 days of care. The patient may need more help from the nurse and new target times for evaluation of goal achievement will then need to be set.

The patient should be asked to report menstruation. Achievement of such a long-term goal may occur as a result of medical treatment, particularly if hormonal or anxiolytic sedative drugs have been prescribed.

Cryptomenorrhoea

This is a condition of concealed menstruation and it is important to differentiate it from amenorrhoea. Menstrual blood is unable to pass through the vagina due to an obstruction. This may be due to an imperforate hymen, a transverse vaginal membrane, or complete or partial vaginal atresia. Incomplete canalisation of the lower end of the Müllerian cords will result in atresia of the upper vagina. There may be a complete absence of the vagina or cervical stenosis after cautery to the cervix or amputation of the cervix.

PATHOPHYSIOLOGY

In this condition, the uterus, ovaries and the pituitary gland are functioning normally, but the menstrual outflow is obstructed. Conditions such as an imperforate hymen or a transverse vaginal septum will result in an accumulation of blood in the vagina (haematocolpos). In addition to vaginal distension, retrograde flow to the fallopian tubes (haemosalpinx) and accumulation of blood may cause pelvic congestion and displacement of structures. Symptoms are cyclical pain and lower abdominal swelling.

MEDICAL MANAGEMENT

The condition is relieved by surgical drainage. There is a risk that the fallopian tubes may be damaged due to retrograde flow and consequent distension.

NURSING PRIORITIES AND MANAGEMENT: Cryptomenorrhoea

Assessment

The patient will be admitted as an emergency for early transfer to the operating theatre. The nurse assessing the patient on admission will uncover the following symptoms:

- pelvic pain
- potential retention of urine from pressure on the urethra
- anxiety about the condition, the strange environment and unknown procedures.

Care planning

If time allows before transfer to the operating theatre, the relief of the patient's pain will be a priority, according to medical prescription. A comforting, positive attitude of open regard shown by the nurse may help to reduce the patient's anxiety. Giving information will prepare the patient for the procedures to be expected before surgery and in the first 24 h after the operation (see Ch. 26).

A urethral catheter may be introduced unless there is an obstruction of the urethra. This may be undertaken once the patient is anaesthetised. An empty bladder facilitates the work of the surgeon and reduces risk of injury to the bladder.

Postoperative care

This will ensure the patient's safe recovery from anaesthesia and that pain is fully relieved. The patient's vaginal blood loss will be observed and documented. The patient should quickly recover, without any complications of anaesthesia or surgery. Full information should be given about what the surgery entailed and expected future progress.

Evaluation of care

The patient should quickly achieve the following outcomes:

- freedom from pain
- minimal blood loss, reducing daily
- no nausea or vomiting
- return to self-care activities within 24 h
- no hospital-acquired infection
- able to explain, before discharge, the action to be taken if the condition recurs
- discharge within a day or two, with an outpatient clinic appointment for 1 month's time.

If these outcomes are not achieved then discharge will be delayed while care is modified, until the patient's condition improves. Surgical treatment should result in subsequent menstrual blood flow per vagina.

Dysmenorrhoea

Dysmenorrhoea is pain associated with menstruation. Many women experience minor discomfort associated with menstruation, but dysmenorrhoea is more disabling. Before the start of the period, the breasts may feel larger and ache; there may also be feelings of abdominal distension, constipation may be a problem, and the woman may feel unwell. The symptoms may persist for 1–2 days and are relieved or replaced by the symptoms of backache, frequency of passing urine and loose bowel action with the onset of menstruation.

For some women, the first hours or the first day are the most painful. Dragging sensations from the umbilical area down to the groins and thighs may be experienced, or the pain may be severe, colicky or spasmodic in nature across the abdomen and back. The pain may be so distracting as to interfere with the woman's usual daily activities. Dysmenorrhoea affects 40–95% of menstruating women, and has been reported as the most common cause of regular absenteeism among young women (Jones 2004).

Two types of dysmenorrhoea are described:

- primary dysmenorrhoea (spasmodic) is due to physiological activities of the menstruation, with muscle contraction
- secondary dysmenorrhoea (congestive) is associated with organic pelvic disease.

Primary dysmenorrhoea is seen in young women in their late teens and early 20s. At first they may have anovulatory, pain-free menstruation. Later, when ovulation becomes established, they experience pain 24 h before the flow begins. The pain is of the severe colic type over the lower abdomen, often radiating to the thighs and back, and lasts for at least 12 h. Nausea, fainting and diarrhoea may accompany the acute phase and the girl looks pale and drawn with a tense facial expression.

PATHOPHYSIOLOGY

Dysmenorrhoea is associated with an increased production of prostaglandin from the endometrium, resulting in intense uterine contractions. Arterioles in the uterus can go into spasm and the resulting muscle ischaemia can produce uterine pain similar to that of angina.

Misunderstandings about the physical changes of menstruation and the nature of dysmenorrhoea may underlie ineffective management (see Research Abstract 7.2). Education about the nature of dysmenorrhoea and its effective management should therefore be addressed with young girls and their parents as appropriate.

The excess prostaglandin (F2) circulating in the blood may cause nausea, vomiting, diarrhoea or faintness. Muscular incoordination may be the result of improper functioning of the autonomic nervous system. This may cause spasm of muscles of the uterine isthmus and of the internal os.

Rarely, dysmenorrhoea may be due to an obstruction to the flow of blood as a result of a clot being lodged in the cervix. Other possible causes include pelvic inflammatory disease, endometriosis and congenital abnormalities.

MEDICAL MANAGEMENT

Detailed interviews may be carried out with the girl and her mother, separately and together. In this way, shared and different attitudes to the subject can be identified and problems defined. Vaginal or possibly a rectal examination may be carried out.

Efforts are made to educate the girl and her mother, as necessary, about normal menstrual function. It is important to test their understanding by giving them opportunities for feedback about attitudes and old wives' tales. A period of rest and the application of warmth to the abdomen or back may be helpful. The need to rest should not be used as an excuse for avoiding school or work. Regular exercise, the avoidance of constipation and the prevention of anxiety and tension are emphasised. Exercise encourages the release of endogenous endorphins which have natural analgesic properties. A series of exercises to stretch the ligaments that support the uterus in the pelvis may relieve menstrual pain. Attention should be paid to maintaining good posture.

Treatment Non-habit-forming analgesics can be of value, particularly aspirin, which reduces prostaglandin synthesis.

RESEARCH ABSTRACT 7.2

How adolescents manage menstrual discomfort

Campbell and McGrath (1997) surveyed 386 adolescent girls, at public high school, aged between 14 and 21 years. Eighty-five per cent of the subjects were English Canadian. Two hundred and ninety-one cases were used for analyses. The Menstrual Distress Management Questionnaire (designed for their study to measure disability and medication use) and the Symptom Severity Scale were the measurement tools used. Ninety-three per cent of the subjects reported menstrual discomfort during the last three menstruations but there was great variability in the reported degree of menstrual discomfort and the treatments employed by the subjects.

Seventy per cent of those who reported dysmenorrhoea had used over-the-counter (OTC) medications to manage their discomfort. Users of OTC medications reported greater symptom severity and disability than non-OTC users. Seventy-five per cent of the OTC medication users took within the recommended dose of 1–2 pills, but 57% took medication less often than the maximum daily frequency. Seventeen per cent used prescription medication and reported significantly greater symptom severity and disability than non-prescription medication users. Of the prescription drug users, 71% took the prescribed amount, 13% took less and 16% took more.

The authors concluded that adolescent girls frequently suffer from menstrual discomfort and self-medicate with OTC medications. However, they may not be using these medications effectively or using prescribed medications appropriately.

Campbell M A, McGrath P J 1997 Use of medication by adolescents for the management of menstrual discomfort. Archives of Pediatrics and Adolescent Medicine 151(9): 905–913

An antiprostaglandin synthetase inhibitor such as mefenamic acid or naproxen may be prescribed to reduce the pain. Mefenamic acid can be taken three times per day, the analgesic effect persisting for longer than that of aspirin (Trounce 1997). Antispasmodic drugs such as hyoscine butylbromide may help with colicky pain. In cases of severe pain, the combined oral contraceptive pill may be taken for 6 months to suppress ovulation and reduce blood loss. This relieves pain for that period, and when normal cycles return, the pain should be less severe. Progesterone alone may be given to the young girl whose skeletal growth is incomplete. Progesterone from day 5 to day 25 will relax the arteriole spasm in the myometrium without inhibiting ovulation. It is thus also useful for those with pain who wish to become pregnant.

Dilatation and curettage may be performed to relieve cervical spasm or obstruction but is not advised as a routine intervention in dysmenorrhoea due to the risk of incompetence of the cervix. In severe cases, hysteroscopy may be necessary to exclude uterine pathology. A laparoscopy may be required to exclude endometriosis which can occur 3–4 years after the onset of menstruation (Hoshiai et al 1993). A pregnancy and vaginal delivery may improve or cure primary dysmenorrhoea.

NURSING PRIORITIES AND MANAGEMENT: Primary dysmenorrhoea

Assessment

An assessment should be made of the general health of the patient. The patient's own description of the nature of her painful periods should be recorded along with any observations she makes about her physical and emotional symptoms on particular days of the cycle. Any medication used for pain relief or contraception, and its effectiveness, should be noted. Dietary habits and exercise activities are also relevant. By sensitively questioning the patient as to whether she has any special worries or has recently experienced stressful events, useful information may be obtained for inclusion in the care plan.

Care planning

The care plan should be designed in collaboration with the patient. It may be necessary to help the woman recognise signs of impending menstruation so that analgesics can be taken in time to prevent pain. The nurse and patient should discuss strategies other than pharmacological interventions to relieve pain.

The stress of hospital admission or the illness condition may induce menstruation at an earlier date than expected. The nurse may then have to write up appropriate interventions to ensure the patient is 'pain-free' or 'pain is reduced to a tolerable level'. Where possible the patient's preferred methods of pain relief should guide the nursing actions planned.

A teaching plan should be completed in preparation for the patient's discharge as follows:

- Give a simple explanation of the functioning of hormones in the menstrual cycle and the effects of excessive prostaglandins; perhaps use diagrams.
- Discuss the beneficial effects of a diet adequate in fibre, vitamins and polyunsaturated fats, and low in sodium chloride.
- Compare the patient's present level of physical exercise with that of a more beneficial programme. Explain the effects of exercise and good posture in stimulating the function of all organs and the release of pain-relieving endorphins (see Ch. 19).
- Teach a simple relaxation exercise. Ask the patient to practise the exercise regularly. Explain the effects of muscular relaxation in counteracting anxiety or tension and muscle spasm. Refer to massage and local heat application.
- Discuss the use of drugs that reduce the development of prostaglandins, particularly any drug prescribed for the patient.
- Ask the patient to explain, in her own words, some of the changes she would like to make in future. Reinforce her understanding and resolve, and check whether she needs further explanation.

Evaluation of care

A pain verbal rating scale, such as the visual analogue scale, could be used by the patient (see Ch. 19). If the goal of optimal pain relief is not achieved it may be necessary to change the analgesic. Relaxation exercises should be used while the effects of analgesics are awaited. The achievement of the patient's goals will be her first step in a change of lifestyle. Further support and encouragement may be given by her mother, friend, partner, a school or practice nurse or the GP.

Secondary dysmenorrhoea

PATHOPHYSIOLOGY

Secondary dysmenorrhoea is experienced in later menstrual life by women in their mid-20s after previous years of painless menstruation. Women usually complain of a dragging pain in the lower abdomen, pelvic area and breasts, accompanied by headache. The pain occurs some days before the menstrual flow and may continue throughout the period.

The condition is usually associated with some pelvic pathology, although anxiety or depression can be an aggravating factor:

- *Adenomyosis* is a state of increased tension in the uterine muscles, due to accumulating blood in the cystic spaces.
- *Fixed retroversion of the uterus* can cause severe pain, especially if associated with a low-grade pelvic infection.
- *Partial stenosis of the cervix*, following cautery or cone biopsy.
- *Endometriosis* interferes with normal rhythmic contractions of the uterus.
- *Pelvic congestion*, due to increased blood supply to the uterus, and menorrhagia.
- *Pelvic inflammation*, particularly salpingitis, might contribute to pain.
- *Fibromyomata and polyps* interfere with normal rhythmic contractions of the uterus and cause muscular spasms as the uterus attempts to empty itself of the abnormal tissue.

MEDICAL MANAGEMENT

History and examination A detailed history of the problem is recorded and a full physical examination is completed. An accurate history of the pain is important, noting the age of onset, and the site, radiation, duration, character and time of onset in the menstrual cycle. The doctor seeks information about any related symptoms, possible abnormal uterine bleeding, pain on sexual intercourse (dyspareunia), pruritus and premenstrual tension.

Treatment Medical treatment may involve examination under anaesthetic (EUA), dilatation of the cervix and curettage of endometrium. A laparoscopy may be performed when endometriosis is suspected. The presence of fibroids or polyps will be treated appropriately (see p. 274). Pelvic inflammation can be treated by antibiotics. An analgesic drug can be prescribed that is suitable for inhibiting prostaglandin synthesis, e.g. mefenamic acid.

NURSING PRIORITIES AND MANAGEMENT: Secondary dysmenorrhoea

On assessment, actual or potential pain episodes will be identified as a problem. Goals and interventions will be

similar to those described for primary dysmenorrhoea, particularly education for the maintenance of personal health. Additional problems will be identified and appropriate nursing interventions planned depending on the specific underlying pathology and the treatment interventions recommended.

Social and psychological issues vary with women's individual circumstances and needs. Pre- and postoperative care planning will be needed if surgical procedures are planned. The nurse needs to be able to promote trust and develop a warm relationship with the patient in order to counteract the patient's fears and communicate effectively. At the time of discharge the patient's future prospects for an improved pattern of menstrual cycles should be much better.

ABNORMAL UTERINE BLEEDING

Abnormal uterine bleeding is described according to the rhythm or pattern of the blood loss episodes:

- *Menorrhagia* refers to heavy or profuse menstrual bleeding. The flow of blood occurs at normal intervals but is increased in amount or duration.
- *Polymenorrhoea* describes menstrual periods that occur with a frequency of less than 21 days.
- *Polymenorrhagia* refers to periods that are both heavy and frequent.
- *Metrorrhagia* describes irregular or unusual bleeding from the uterus between periods.
- *Dysfunctional uterine bleeding* is the descriptive diagnosis used when no organic cause for the abnormal bleeding can be identified.

When abnormal uterine bleeding occurs, the passing of blood clots from the uterus is significant. The menstrual flow is greater than normal if the usual anticlotting agents released by the endometrium are not able to control the volume or rate of flow of the blood.

Menorrhagia

PATHOPHYSIOLOGY

There is hormonal imbalance from any variation in the pattern of oestrogen and progesterone secretion; it is usually of endocrine origin with oversecretion of gonadotrophins. Emotional stress may result in excesses of these hormones being produced.

Ovarian lesions are of two types:

- *Polycystic growths* — may disturb the normal production of ovarian hormones and excessive endometrial growth occurs.
- *Immature follicles* — may fail to result in ovulation. The corpus luteum fails to form, so progesterone cannot be produced. Oestrogen levels continue to rise and there is a proliferation of the endometrium.

Uterine lesions consist of the following types:

- *Fibroids* — increase the surface area of the endometrium that bleeds with greater flow. They may prolong the flow by restricting or disturbing contractions.
- *Polyps* — increase the surface area of endometrium.
- *Adenomyosis* — interferes with contractions by infiltrating the myometrium with endometrial cells.
- *Multiparity* — may result in loss of tone in the uterine muscle fibres. These may be replaced by fibrous tissue which will interfere in the normal contractions.
- *Developmental disorders*, e.g. a bicornuate, septate or duplicated uterus — may impede contractions.
- *Endometriosis* — this is a condition in which ectopic endometrium deposits may be found in the muscle wall or in scattered areas of the pelvic cavity; it is accompanied by increased blood supply to the uterus.
- *Tumour formation* — increases blood supply and bleeding.
- *Intrauterine contraceptive devices* — cause some irritation of the endometrium. Excessive bleeding may be problematic during the first 3 months after insertion.
- *Fallopian tubal ligation* — involves some alteration in the course of blood vessels that increases uterine blood supply. Following the operation, menstruation is usually heavier and may lead to the need for hysterectomy in some women.

MEDICAL MANAGEMENT

Medical examination seeks evidence of stress, worry or tension in the patient and will try to establish whether bleeding is a problem of quantity or rhythm, or both. Pelvic examination may reveal tenderness, masses or irregularities. If no pelvic abnormality is found, then a provisional diagnosis of dysfunctional uterine bleeding is made.

Investigations Special investigation is made of haemoglobin level and full blood count to assess any anaemia present. An EUA and a diagnostic curettage can be performed to show the endometrial response to hormones, to identify any uterine polyps and to exclude carcinoma. Hope (2000), however, asserts that endometrial assessment is not required at an early stage. An estimation of urinary gonadotrophins, oestrogens and progestogens as indicators of hormonal activity may be completed.

Treatment This will depend on the amount of blood lost. Hope (2000) suggests either mefenamic acid 500 mg or tranexamic acid 1 g, three times daily on the first day of the period and on other days with a heavy flow, for a period of 3 months, followed by a review. A dilatation and curettage investigation may in itself relieve the problem, especially in cases of an endometrial polyp. In some instances it may be necessary to nurse the patient in bed and to administer an anxiolytic sedative medication as prescribed to encourage relaxation and reduce stress responses. Any anaemia identified should be corrected as appropriate.

Hormone therapy may be given. Progesterone may be prescribed to provide a balance with oestrogens and reduce excessive endometrial growth. One of the combined contraceptive pills may be given to suppress hormone production, e.g. norethisterone 10–20 mg daily for 10 days, from the 15th day of the cycle. Progestogen administration will modify flow in heavy, but regular, cycles in dysfunctional uterine haemorrhage.

Endometrial ablation is another treatment option for menorrhagia. The aim of this procedure is to remove the

endometrium and up to 3 mm of the myometrium. There are several methods of achieving this: transcervical resection of the endometrium (TCRE), laser ablation of the endometrium, rollerball endometrial ablation or thermal uterine balloon therapy (Rosevear 2002). If suitable for this treatment, the woman may be prescribed danazol 4–6 weeks in advance of the procedure to reduce endometrial thickening. The surgery can be performed as a day case. The procedure involves the use of a hysteroscope, inserted vaginally, and through which other instruments are passed to remove the endometrial lining. Following the procedure slight vaginal bleeding can be expected for a few days. Menstrual periods will become lighter or may cease, but dysmenorrhoea and premenstrual symptoms may continue. This procedure may require to be repeated at a later stage or a hysterectomy may eventually be necessary. Disadvantages of this procedure include the possibility of severe haemorrhage or uterine perforation which would necessitate hysterectomy at the time of TCRE. Women should therefore be aware of this before consenting to the procedure.

When a hysterectomy is deemed necessary it may be possible to undertake this without major surgery by means of laparoscopic surgery. This requires insertion of a number of small trocars through the abdominal wall, providing entry sites for instruments. The viewing laparoscope is inserted below the umbilicus, two other insertion sites will be positioned just above the pubic hair line and accessory insertion sites will be used for electrosurgical techniques, a stapling device or to insert sutures via the abdominal cavity. The procedure is performed using video monitoring. The woman can be discharged from hospital within 2 days.

If large fibroids or endometriosis exist, an abdominal hysterectomy is required. Alternatively, in the case of fibroids, a myomectomy may be appropriate. Here the fibroids are shelled out of the myometrium. This conserves the uterus for child bearing.

Metrorrhagia

PATHOPHYSIOLOGY

- *Lowered oestrogen level* may occur just prior to the formation of the corpus luteum, resulting in vaginal blood spotting at the time of ovulation.
- *Changes in the cervix*, e.g. inflammation, erosion, polyps or carcinoma, may cause slight bleeding, especially after intercourse or vaginal examination.
- *Changes in the vagina*, e.g. inflammation, ulceration and atrophy, may cause bleeding.
- *New growth*. Endometrial carcinoma is a major cause of irregular bleeding.
- *Complications of an early pregnancy*. As a fertilised ovum settles into the endometrium, slight bleeding may occur. This loss may be repeated during several months of the pregnancy. Haemorrhage might also occur in a pregnant woman due to 'placenta praevia', when the placenta has implanted abnormally low in the uterus.

MEDICAL MANAGEMENT

Investigations A visual examination with a vaginal speculum is an early investigation. A more detailed examination using the colposcope apparatus completes the colposcopy examination, where magnification of the cervix allows for diagnosis of cervical neoplasia through observation of the epithelial vascular pattern, surface contour and colour. In 95% of patients, premalignant intraepithelial neoplasia is visible through the colposcope.

Punch biopsies are taken for histological examination and examination of tissue complements the colposcopy observations. The Papanicolaou (Pap) smear test is a routine investigation to evaluate changes in cells shed or scraped from the cervix. A high vaginal swab of secretions will allow the identification of bacterial infection, or fungal or parasitic infestations.

The dilatation and curettage operation will provide evidence to support any further investigations.

Treatment Infections of the reproductive tract will be treated with the appropriate broad-spectrum antibiotic. Vaginal thrush (candidiasis) is relieved by nystatin pessaries. *Trichomonas vaginalis* is treated with metronidazole (Flagyl).

In ovulation spotting, small quantities of oestrogen may be given for 6–7 days, 3 days before ovulation.

Any malignant changes that are identified are usually treated by surgical excision, radiotherapy or cytotoxic medication as advised.

PREMENSTRUAL SYNDROME

Premenstrual syndrome (PMS) refers to physical and psychological symptoms occurring in the latter half of the cycle, 2–12 days prior to menstruation, and subsiding after the menstrual flow begins. As luteal phase symptoms, they are present for no longer than 16 days. There is a symptom-free week following menstruation. The symptoms vary from one woman to another, but also show variability from cycle to cycle in individual women with respect to severity, timing and duration.

In establishing a diagnosis, Reid (1991) stresses the importance of the severity of symptoms experienced by women. While mild physiological symptoms are experienced by approximately 95% of women in their reproductive years (Wyatt et al 1999), around 5% of women have symptoms severe enough to disrupt their lives (O'Brien 1993). Hylan et al (1999) estimate that 1.5 million women in the UK experience such symptoms, 35% of them seeking medical help. Symptoms of PMS frequently start after discontinuing the oral contraceptive pill or after a pregnancy, and become progressively worse with age.

Abraham (1987) subdivides symptoms as follows:

- nervous tension, mood swings, irritability and anxiety
- weight gain, swelling of extremities, breast tenderness, abdominal bloating and pelvic pain
- headache, craving for sweets, increased appetite, heart pounding, fatigue and dizziness or fainting
- depression, forgetfulness, confusion, crying and insomnia.

Leather et al (1993) found that symptoms of PMS had greatest effect in the home, with 82% of women reporting relationships with their partners to be seriously affected and 61% reporting relationships with their children to be severely affected, associated with disturbed body image and low self-esteem.

PATHOPHYSIOLOGY

Numerous theories have been suggested to explain PMS, but the precise cause remains unknown. PMS is concluded to be a multifactorial psychoneuroendocrine disorder (see Box 7.2).

Prostaglandins Prostaglandins are produced in response to changing levels of oestrogen and progesterone. They exert sedative effects on the central nervous system and affect both aldosterone and antidiuretic hormone (ADH) activity. If premenstrual changes are influenced by prostaglandins, it may be the balance between the prostaglandins that is of greatest importance.

Fluid retention or redistribution Since the 1930s it has been suggested that PMS might be related to hormones responsible for fluid retention, but research studies can only suggest that there may be a redistribution of body fluids in intracellular and extracellular compartments. They have failed to demonstrate a pattern of fluid retention in most women that suffer from PMS.

Hypoglycaemia Abnormalities of glucose metabolism in the luteal phase of the menstrual cycle that exaggerate glucose swings during the luteal phase might account for premenstrual hypoglycaemic symptoms. However, a causal relationship with PMS is inconclusive (Reid et al 1986).

Vitamin B_6 (pyridoxine) deficiency Vitamin B_6 increases inhibitory amines such as dopamine and serotonin, and also acts as a coenzyme in converting excitatory amino acids to corresponding inhibitory amino acids, with sedative effects. Vitamin B_6 can reduce the excitatory biogenic amines.

Research suggests a central neurotransmitter abnormality, causing a reduced platelet uptake of serotonin and reduced peripheral blood serotonin levels found in the luteal phase of the cycle in women with PMS (Menkes et al 1992, Sundblad et al 1992).

Progesterone withdrawal Although many researchers have suggested that PMS is the result of unopposed oestrogen effects, due to deficiency of progesterone production, many PMS patients have been shown to have adequate corpus luteum functioning. This suggests that it may be the rate of fall of progesterone level during the late luteal phase that is causative in PMS rather than a deficiency state.

Endorphin withdrawal Endorphins are a group of substances which are endogenous opioid peptides. They appear to be important in the physiology of pain and mood change. Studies have shown that there is a change in endorphin levels in women who experience PMS, endorphins declining as the cycle progresses or in the week preceding menstruation (Facchinetti et al 1987).

O'Brien (1993) suggested that PMS is probably related to ovarian function, which in turn is linked to gonadotrophins, which may well be dependent on endorphin function. The current state of knowledge suggests that the primary causal factor lies somewhere in the hypothalamus–pituitary–ovarian mechanism or in the higher centres which influence it.

Serotonin Serotonin is a neurotransmitter that influences mood, appetite and behaviour. In women with PMS it can be significantly lower in the luteal phase of the menstrual cycle than in control subjects, hence the serotonergic system has become a focus of study in PMS (see Research Abstract 7.3).

Box 7.2

Theories related to premenstrual syndrome

Imbalance
- Oestrogen/progesterone
- Prostaglandins

Excess
- Aldosterone
- Angiotensin II
- Oestrogen
- Androgen
- Antidiuretic hormone
- Endorphin
- Prolactin

Deficiency
- Progesterone
- Androgen
- Essential fatty acid
- Blood glucose
- Magnesium
- Endorphin
- Zinc
- Vitamin B_6

Physical changes
- Sodium and water retention
- Abnormal water distribution
- Leakage of albumin/tissue fluid
- Allergy related to progesterone
- Dietary abnormality
- Serotonin or aspartine neurotransmitter disturbance

RESEARCH ABSTRACT 7.3

Selective serotonin reuptake inhibitors in the treatment of premenstrual syndrome

Wyatt et al (2002) carried out a systematic review on the effectiveness of selective serotonin reuptake inhibitors (SSRIs) in the treatment of women with severe premenstrual syndrome (PMS). An electronic search of the Cochrane Menstrual Disorders and Subfertility Group specialised register of controlled trials, Cochrane Controlled Trials Register, MEDLINE, EMBASE and PsychLit was conducted. All trials in which women were randomised to receive SSRIs or placebo in a double-blind trial for the treatment of premenstrual syndrome were considered. Fifteen trials were included in the systematic review and 10 trials in the main analyses.

The findings indicated that SSRIs were very effective in treating premenstrual syndrome, both physical and behavioural symptoms. Side-effects resulted in some withdrawals (2.5 times more likely in the treatment group, particularly with high doses). The reviewers concluded that there is good evidence for the use of SSRIs in the treatment of severe premenstrual syndrome.

Wyatt K M, Dimmock P W, O'Brien P M S 2002 Selective serotonin reuptake inhibitors for premenstrual syndrome. Cochrane Database Systematic Review (4): CD001396.www.update-software.com/Abstracts/AB001396.htm

While researchers have been keen to find one reason for PMS, it is more likely that it is a combination of physical, psychological and social factors.

MEDICAL MANAGEMENT

Recommended treatment focuses on identifying and controlling individual symptom clusters. Drug treatments are used cautiously. Many research studies have shown marked placebo effects of 40–60% in PMS sufferers. The patient–doctor relationship is thought to be an important influence on some women, relieved that their condition is being taken seriously.

Investigations A thorough examination is required to diagnose PMS accurately and exclude or identify any underlying pathology. Other medical, psychiatric and gynaecological conditions must be excluded or be identified as coexisting with PMS.

Breast cancer must be excluded, as hormone-dependent cancers may be stimulated by hormone therapy. A patient with pelvic pain may have an inflammatory condition, or endometriosis, that needs further investigation. Some patients may have a depressive illness, as well as PMS. This may be referred to as secondary PMS, the depressive symptoms persisting through what is expected to be a symptom-free week in the cycle.

Estimations of oestrogen, progesterone, prolactin, gonadotrophin or electrolytes are not usually helpful in making a diagnosis of PMS.

Treatment An integrated treatment programme can be adopted whereby patients are asked to record in a diary, on a daily basis, personal experiences in mood, behaviour, thinking patterns and physical discomforts, for at least 3 months. Symptom clusters and symptom-free times can be thus easily identified.

In addition, women should be advised to:

- take regular exercise
- avoid coffee, tea and chocolate
- take a diet that is low in sugars and high in lean proteins
- take vitamin supplements B_6 and E_1 and the mineral magnesium
- restrict salt intake
- limit fluid intake
- chart their weight daily
- avoid alcohol and smoking
- avoid stress.

These general measures contribute to good health and can maximise physical and psychological well-being.

While some women have found evening primrose oil can relieve symptoms of PMS (Campbell et al 1997), the beneficial effects have not been substantiated in research (Khoo et al 1990, Robinson & Garfinkel 1990, Budeiri et al 1996). Robinson and Garfinkel (1990) included factors such as diet, exercise and stress control in their recommendations for effective management of PMS.

Some women find aromatherapy helpful for specific PMS symptoms, such as headache or fluid retention. A few drops can be added to bathwater or mixed in a massage oil. Rosemary or peppermint can be used to relieve headache; fennel, juniper or geranium to reduce fluid retention; bergamot and jasmine to elevate mood; and lavender and rose to help balance hormone production (Rich 1996).

Drug treatments used in PMS depend partly on the preference of the doctor providing care and the particular cluster of symptoms experienced by the patient. Many women who have already tried over-the-counter remedies expect or request hormonal treatment.

Hormonal treatment Hormonal treatment of PMS is as follows:

- Some doctors continue to use progesterone or progestogen for all PMS symptoms. The drug may be given orally, by injection, by suppository, in the combined contraceptive pill or by means of an implant. However, Wyatt et al (2001) present evidence from a meta-analysis that does not support the use of progesterone or progestogens in the treatment of PMS.
- The drug danazol, which inhibits pituitary gonadotrophin secretion, is prescribed selectively for some patients, particularly those with severe mastalgia and other PMS symptoms (Halbreich et al 1991). Danazol completely suppresses the menstrual cycle and reduces breast tenderness, but varying degrees of improvement in other symptoms have been documented. Patients are advised to use alternative, non-hormonal contraceptive methods. The major disadvantage of danazol is that high doses cause masculinisation (Deeny et al 1991). Other minor side-effects such as nausea, dizziness and rashes are troublesome to certain patients.
- Analogues of gonadotrophin-releasing hormone (GnRH), such as buserelin, will inhibit the release of gonadotrophins and so suppress follicular development, ovulation and the endocrine changes of the cycle. A 'medical oophorectomy' is thus created. Suffling (2001) claims that GnRH analogues are most effective if administered by depot injection and their use limited to 6 months, minimising the side-effects associated with sudden oestrogen withdrawal. The treatment is expensive and is generally reserved for women with severe symptoms, when other treatment options have failed.
- Oestrogen therapy, in the form of transdermal patches or subcutaneous implants, can be used to suppress menstruation. Natural oestrogen administered by this route avoids the liver and so prevents problems with clotting factors and lipid metabolism. For women with a uterus, the use of this percutaneous oestrogen therapy requires to be complemented by the use of cyclical progestogen, to prevent endometrial hyperplasia. Unfortunately some women experience mild PMS-like symptoms during this phase of the treatment.
- Bromocriptine is a stimulant of dopamine receptors in the brain and also inhibits the release of prolactin by the pituitary. The role of prolactin in PMS is poorly understood, but bromocriptine has been shown to be effective in the treatment of breast symptoms.
- Schellenberg (2001) suggests that one tablet daily of *Agnus castus* (dry extract) is well tolerated and can be effective in women's self-assessment of their symptoms, e.g. mood, headache, breast fullness and bloating.

Diuretic treatment In women who have a measured weight increase, the diuretic spironolactone may be prescribed. This medication blocks the body's use of the hormone aldosterone. Some investigators have found it to be useful for symptoms of depressed mood.

Analgesic treatment Where pain is a primary symptom, the anti-inflammatory analgesic and prostaglandin inhibitor mefenamic acid may be helpful, but research as to how many PMS symptoms this medication will relieve is contradictory. There is agreement that the medication is of benefit for some PMS symptoms.

Psychological support Supportive psychotherapy and techniques that improve coping skills and stress management should be part of the care programme. Women who experience secondary PMS, whereby their unhappy mood and agitated behaviours persist throughout their cycles, may need the clinical help of a psychiatrist. Wyatt et al (1999) suggest that vitamin B_6, up to a dose of 100 mg/day, can be helpful for premenstrual depression and other premenstrual symptoms.

Surgery In cases of severe PMS or those compounded by other gynaecological problems, hysterectomy with bilateral salpingo-oophorectomy followed by HRT may be considered. Oophorectomy must be included to prevent the ovarian cycle, otherwise the cyclical problems will persist.

NURSING PRIORITIES AND MANAGEMENT: PMS

Assessment

The nurse may encounter women who experience PMS symptoms not discussed with their doctors. Nurses have opportunities to provide such women with information suggesting daily recording of physical changes, discomforts, emotional feelings and behaviour.

Care planning

A supportive–educative approach combines the giving of information and advice, and also allows the woman to suggest how best the aims can be achieved in her particular circumstances. The nurse should discuss options with particular care to avoid causing any financial embarrassment to the woman who may have little money to spare from her family budget for vitamin supplements or evening primrose oil, which may be costly.

Useful advice includes the following:

- Undertake physical exercise as a stimulant to the circulatory system, improving functioning of all bodily organs and relieving congestion. As a result concentration and sleep should improve, and feelings of well-being may increase.
- Reduce fat, sugar, salt, coffee and tea consumption.
- Aim to eat five servings of fresh fruit and vegetables per day (Williams 1995).
- Reduce smoking and alcohol intake.
- Avoid stressful situations to reduce tension and feelings of frustration, particularly at trigger times in the cycle.
- Incorporate relaxation exercises.
- Obtain massage, carried out by a partner, nurse or therapist.

A counselling approach by the nurse can encourage the woman to verbalise her preferred choices. Information should be given to the patient about the nature of any drugs prescribed. Referral to a health visitor may be necessary if the patient requires continuing support at home. The possible value of self-help groups can also be discussed with the woman, but the value of family support, emphasised in some cultures, should not be undermined.

Evaluation of care

Some symptoms may have greatly improved, but there may be no feeling of improvement in other areas. Where unresolved problems remain, each planned action should be reviewed. Evidence of a sustained unhappy mood or other severe symptoms should be referred to the GP or PMS clinic doctor or the added interventions of a psychiatrist or psychotherapist.

DISORDERS OF THE MENOPAUSE

Physiological, psychological and social changes associated with the menopause have been described earlier. The long-term effects of oestrogen withdrawal on women's health will now be addressed.

Decreased oestrogen formation is associated with the development of osteoporosis and cardiovascular disease, resulting in an increased risk of bone fractures, myocardial infarction, angina and stroke. The literature suggests that there is some cultural variation in the experience of post-menopausal symptoms and in the incidence of disorders related to the withdrawal of oestrogen (Lock 1994, Robinson 1996, Chow et al 1997). Gasperino (1996) proposes that there is ethnic variation as well, suggesting, for example, that the greater bone and muscle mass and lower fat, as a percentage of body weight, in black women is relevant to the lower incidence of osteoporosis and cardiovascular disease in this ethnic group.

Factors contributing to an increased risk of osteoporosis and cardiovascular disease include:

- inherited factors
- sedentary lifestyle
- low calcium intake
- low body weight
- early menopause
- cigarette smoking
- excessive salt intake
- excessive stress
- high protein intake
- moderate to excessive alcohol intake
- caffeine
- pre-existing disorders of the kidney or thyroid, rheumatoid arthritis and diabetes.

Osteoporosis

Osteoporosis is a disease characterised by a decrease in bone density per unit volume, predisposing to fracture with even minimal trauma. The demineralisation and consequent weakening of bone are more marked in trabecular bone. The World Health Organisation (WHO) defines osteoporosis as bone mineral density of more than 2.5 standard deviations

below the mean value for young adults (WHO 1994). This definition has been used to diagnose osteoporosis based on bone mineral density assessed at the hip and spine using dual energy X-ray absorptiometry (DEXA). Peripheral densitometry devices have been introduced with the advantage of low cost and portability, allowing assessment at the heel or forearm. However, since bone mineral density is not consistent throughout the skeleton there is the potential for misdiagnosis if the WHO's definition is applied at all sites. Such discordance between sites is more common in younger women, and Miller et al (1998) recommend that more than one site is used in women younger than 65 years. Quantitative ultrasound at the heel can be used to assess bone strength (rather than bone density) and can provide a useful measure from which predictions can be made about the risk of future fractures in older women (Hans et al 1996, Hodson & Marsh 2003). The most common sites for fractures are the wrist, spine and hip, causing pain, deformity and possible hospitalisation.

Oestrogens play an important part in achieving a strong bone structure. They determine the sensitivity of bone to parathyroid hormone, limit resorption of bone and increase calcium absorption from the gut. In early adult life, the rate of bone formation exceeds that of resorption, thus building strong bone. When oestrogen levels decline prior to the menopause, bone resorption increases and bone loss accelerates after the menopause. This is most marked in the first years after the menopause when there is a significant decline in oestrogen. During the first 5–10 years after the menopause, bone density decreases significantly. Thereafter the rate of bone loss gradually decreases. Failure to achieve maximum skeletal mass in early adulthood will be aggravated by oestrogen deprivation after the menopause. HRT after the menopause, however, is not recommended as the first choice for preventing osteoporosis (Singh 2003).

Cardiovascular disease

Before the age of 50, deaths from breast cancer outnumber deaths from ischaemic heart disease and stroke in women, but in postmenopausal women the mortality rate for arterial disease greatly exceeds that of breast cancer. Payne (1997) suggests that cardiovascular disease is the most common cause of death among women in the UK. Withdrawal of oestrogen at the menopause causes changes in lipid and lipoprotein metabolism, resulting in a low high-density lipoprotein:low-density lipoprotein ratio. Such metabolic disturbances can contribute to the incidence of cardiovascular disease in this group (Stevenson 1996). Recent research suggests that HRT offers women no protection against ischaemic heart disease (Løkkegaard et al 2003). A consensus statement on HRT by the Royal College of Physicians (2003) indicates that its value remains controversial and that although effective in relief of vasomotor symptoms, mood changes and insomnia associated with the menopause, evidence is lacking to support the use of HRT in treating osteoporosis, heart disease or Alzheimer's disease. Grant (2003) suggests that this underestimates the dangers of HRT, indicating an increased risk of breast cancer (Rossouw et al 2002, Beral et al 2003), ischaemic heart disease (Rossouw et al 2002) and ovarian cancer (Gottlieb 2003).

MEDICAL MANAGEMENT: LONG-TERM EFFECTS OF THE MENOPAUSE

Hormone replacement therapy (HRT) Once bone loss has occurred it cannot effectively be replaced. There is evidence that oestrogen prevents bone loss in early menopausal women (Stevenson et al 1990) by decreasing the rate of bone resorption. Bone loss occurs most rapidly at the time of the menopause or shortly after. Prophylactic HRT has been recommended in the past for osteoporosis, but there is now the suggestion that side-effects outweigh the benefits (Singh 2003).

Other therapies which reduce the rate of bone resorption are calcitonin and bisphosphonates. Calcitonin can prevent postmenopausal trabecular bone loss (MacIntyre et al 1988, Overgaard et al 1989) by decreasing osteoclast activity, as do bisphosphonates (Reginster et al 1989). Gottlieb (2001) suggests that parathyroid hormone may offer short-term treatment in cases of established fractures (see Research Abstract 7.4).

Research in the 1990s suggested that oestrogen replacement after the menopause decreased the risk of cardiovascular disease (Hunt et al 1990, Stampfer & Colditz 1991) and stroke (Finucane et al 1993). The main beneficial effects on the cardiovascular system appeared to be on vessel walls, blood flow and lipid metabolism (Whitehead & Godfree 1992). Nabulsi et al (1993) suggested that taking oestrogen postmenopausally can reduce the risk of coronary artery disease by 42%, and if progestogen is included the benefits may be even greater. However, this remains controversial and further research is ongoing.

In hormone replacement therapy oestrogen is administered continuously. Progestogens are given for 12–14 days per month on a cyclical basis to women with a uterus, for endometrial protection, reducing the risk of erratic bleeding, endometrial hyperplasia and endometrial cancer (Whitehead et al 1990). This results in a withdrawal bleed. Tibolone (Livial) is a synthetic steroid with properties of

RESEARCH ABSTRACT 7.4

Parathyroid hormone in the treatment of established fractures

In a randomised controlled study of 1637 postmenopausal women with previous vertebral fractures (Gottlieb 2001) the women were given either 20–40 mcg parathyroid hormone or a placebo subcutaneously daily. In addition all patients took calcium and vitamin D supplements daily. The women receiving parathyroid hormone showed a significant reduction in the risk of new fractures when compared with those taking the placebo. Women in the treatment group also showed significant increases in vertebral, femoral and total-body mineral density. While there is some concern about the possible side-effect of bone tumours (identified in rats having high doses in earlier trials) this may prove to be a possible option for short-term treatment in cases of established fractures.

Gottlieb S 2001 Human parathyroid hormone may prevent osteoporosis. British Medical Journal 322(7296): 1200–1201

RESEARCH ABSTRACT 7.5

The effect of hormone replacement therapy on women's menopausal symptoms

Gelfand et al (2003) evaluated the effects of a regimen of constant-oestrogen, intermittent-progestogen hormone replacement on women's menopausal symptoms in a randomised, double-blind, placebo-controlled multicentre study conducted over 90 days. One hundred and nineteen postmenopausal women with vasomotor symptoms participated in the study. All the women still had their uterus and had reported amenorrhoea for at least 6 months. The active treatment group showed a marked reduction in menopausal symptoms as measured by the Kupperman Index when compared with the placebo group after 45 days of treatment and this was maintained until the end of the study (90 days). The active treatment group also showed greater improvement in quality of life as measured by the Menopause Quality of Life summary score. The authors concluded that the regimen of constant-oestrogen, intermittent-progestogen was effective in relieving menopausal symptoms and improving quality of life. The treatment was well received by the sample of women.

Gelfand M M, Moreau M, Ayotte N J, Hilditch J R, Wong B A, Lau C Y 2003 Clinical assessment and quality of life of postmenopausal women treated with a new intermittent progestogen combination hormone replacement therapy: a placebo-controlled study. Menopause 10(1): 29–36

oestrogen, progestogen and androgen; if taken continuously, it should not cause a withdrawal bleed.

Short-term HRT may be prescribed for specific menopausal symptoms such as hot flushes and atrophic vaginitis, for as long as treatment is required. Long-term HRT may be prescribed for women under 40 years who have had a premature menopause, occurring naturally, as a result of surgery or iatrogenically.

While HRT can confer benefits for women experiencing adverse effects of the menopause (see Research Abstracts 7.1 and 7.5), it can also have side-effects, and risks are associated particularly with long-term use. In addition, there are some contraindications to be considered regarding the use of HRT.

Although many preparations of HRT are available, the reported adherence rate is poor, with a significant number of women discontinuing therapy. Treatment is abandoned because of the side-effects experienced or because of fear of risks associated with the treatment. Possible side-effects include:

- breast pain/tenderness
- leg cramps
- vaginal discharge
- vaginal bleeding
- fluid retention/bloating
- mood changes
- increased appetite.

Such side-effects might be reduced or eliminated by changing to a different preparation. However, women are encouraged to persist with one form of therapy for at least 3 months as some of the early side-effects can be temporary.

While it is acknowledged that unopposed oestrogen increases the risk of endometrial cancer, Whitehead et al (1990) suggested that this risk can be eliminated if progestogens are administered for 12–14 days of the cycle. Wells et al (2002) demonstrated a degree of hyperplasia with sequential oestrogen/progestogen but, in most cases, this can be prevented with a regimen of continuous progestogen with oestrogen.

The link between HRT and breast cancer has been the subject of research for some time. Schairer et al (2000) indicated that an oestrogen–progestogen regimen increases breast cancer risk beyond that associated with oestrogen alone. Beral (2003) confirmed earlier findings that the present use of HRT is associated with an increase in breast cancer, the effect being substantially greater when oestrogen–progestogen combinations are used. There is a need for further research.

Contraindications to HRT are usually described as absolute or relative. Absolute contraindications generally include:

- pregnancy
- undiagnosed endometrial bleeding
- endometrial cancer
- breast cancer
- severe active liver disease
- porphyria.

While HRT is not recommended for women with these problems, individual women may still wish to take HRT for severe acute symptoms or for protective effects. Such women are referred to a specialist centre to be fully informed and closely monitored if they decide to embark on the therapy. Possible contraindications are identified to highlight the likelihood of complications, to ensure that underlying disorders are treated or monitored, and to monitor the appropriate therapy, which may differ from uncomplicated cases, if the woman and her doctor decide on HRT. Caution is therefore required in prescribing HRT in association with the following:

- endometrial hyperplasia, endometriosis or fibroids
- hypertension — treat prior to HRT
- clotting problems — refer to a haematologist (Whitehead & Godfree 1992)
- diabetes — monitor glucose levels to identify any change required in insulin
- gallstones — may be aggravated, rather than develop as a new disease (Whitehead & Godfree 1992); if treated, they are not of concern
- otosclerosis — Whitehead and Godfree (1992) recommend referral to an ENT specialist since they have anecdotal experience of increasing deafness in such patients.

Menopause clinics Some GPs prescribe HRT directly, whereas others refer women to menopause clinics which have become established in many hospitals throughout the

UK, staffed by a gynaecologist with a special interest in the management of problems associated with the menopause. Specially trained nurses and paramedic personnel contribute to the overall assessment and care of those attending the clinics. Treatments can be more easily controlled and supervised within such a clinic, protocols are established, dietetic and diagnostic facilities are more readily available, and screening, general health and patient education programmes can be introduced.

NURSING PRIORITIES AND MANAGEMENT: The postmenopausal woman

Women should be encouraged to make an informed choice about HRT. The role of the nurse involves the development of trust within the nurse–patient relationship and the giving of information to enable women to come to an informed decision. The educative and supportive aspects of the self-care nursing model (Orem 1991) are useful. Whilst not recommending HRT for all postmenopausal women, it is not justifiable to withhold treatment from a fully informed patient who requests it.

Since women worry about the risks of HRT, the nurse should raise these, both to allow a discussion of personal feelings and to clarify any misunderstandings. It is important to warn about the early side-effects of the sudden rise in oestrogen levels at the start of HRT. Women should understand that there are a range of medications, doses and types of HRT, so that if one is found to be unacceptable, another regimen may be tried.

The following is a guide for nurses interviewing women facing the menopause:

- Provide information and advice according to the problems and concerns of individual women and any ongoing postmenopausal symptoms.
- Encourage a healthy lifestyle and continuing health awareness.
- Give dietary information to encourage selecting low-fat, calcium-rich foods; explain physiological links to vascular conditions and the maintenance of bone mineral content.
- Check the patient's usual physical exercise pattern; reinforce the need for regular exercise, stressing the importance of the pull of muscle on bone for bone formation and health; discuss a weight-bearing exercise programme.
- Discuss the benefits and possible side-effects of HRT.
- Explain the need for self-examination of breasts and teach the technique.
- Provide opportunities for questions.
- Check the patient's understanding of the information given by encouraging feedback.
- Give the patient a copy of free booklets prepared by the health authorities relating to the menopause and a healthy lifestyle, for example the Health Education Board for Scotland booklets *The Time of Your Life, Well Woman, Eat to your Heart's Content, Look after Yourself.*
- Give the name and telephone number of a person to contact in the event of any problem occurring.

DISORDERS OF THE FEMALE REPRODUCTIVE SYSTEM

BENIGN TUMOUR OF THE OVARY

Benign cystic teratoma or dermoid cyst

Dermoid cysts may develop in women of all ages and comprise 25% of all ovarian tumours. There is a 3% possibility of such cysts becoming malignant.

PATHOPHYSIOLOGY

The dermoid cyst is believed to develop from the aberrant division of an unfertilised oocyte, but the cause remains uncertain (Lewis & Chamberlain 1995). It is formed from accumulated sebaceous material from the glands of the neoplasm. It is a thick-walled cyst, whitish-yellow in colour, lined with skin, hair follicles, hair and sweat glands. Teeth may be found emerging from primitive sockets, and bone cartilage, lung and intestinal epithelium can be identified within the cyst.

MEDICAL MANAGEMENT

The patient may present with abdominal pain. Following an abdominal and vaginal examination, she is referred to a gynaecologist for assessment. Pain may be caused by peritoneal irritation from the cyst. Peritonitis may result from rupture of the cyst contents into the abdomen. The cyst may become infected if salpingitis, appendicitis or diverticulitis is present. Dense adhesions may occur between an infected cyst and the peritoneum or bowel. Torsion or twisting of the pedicle or stalk of the cyst may develop and this may reduce the blood supply, particularly the venous return, to the cyst and cause pain. Malignant change may occur in any of the primitive tissues of the cyst.

Investigations A Pap cervical smear test may be completed at the time of vaginal examination by the GP. Any malignant cells present might be associated with an ovarian cancer. An ultrasound scan can identify the ovarian cyst.

Treatment Surgery will be undertaken by laparoscopy or laparotomy. The extent of surgery will vary according to the age of the woman. In younger women, with childbearing years ahead of them, the benign cyst alone may be shelled out of the ovary, leaving the normal ovarian tissue to continue functioning. Both ovaries will be assessed, as the cysts are often bilateral.

Women who already have a family or are over 50 years of age would be advised to have the ovary removed. In the event of malignancy of the dermoid cyst, both ovaries and the uterus would be removed. Involvement of the peritoneum in the spread of malignancy would necessitate the instillation of a cytotoxic agent, such as thiotepa (see p. 1053), into the abdominal cavity at the time of surgery.

NURSING PRIORITIES AND MANAGEMENT: Dermoid cyst

Nursing care will depend upon the extent of the surgery undertaken and will be described in the section on ovarian cancer (p. 286).

BENIGN TUMOURS OF THE UTERUS

Endometrial polyps

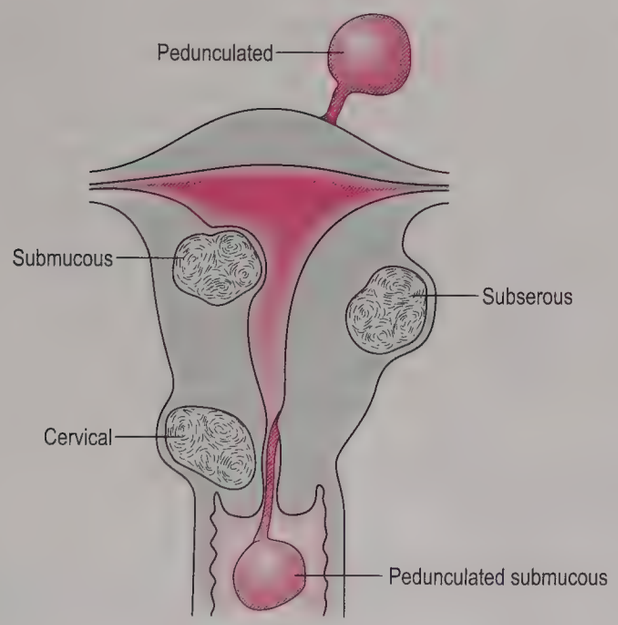
Polyps are benign neoplasms of the endometrium of the uterus. They may develop from an overgrowth of endometrial glands and stroma. The polyp may produce a stalk and may descend towards the vulva. Single or multiple polyps may occur commonly in women of any age group. Vaginal bleeding may be slight but occurs between menstrual periods or following coitus. Under anaesthetic the polyp can be removed from the uterus by twisting it off at its stalk or by curettage of the endometrium. Histological examination of all polyps is routine as recurrent multiple polyps may undergo malignant change.

Fibromyomata

Myomata or fibroid tumours of the muscle of the uterus can occur in women between 35 years of age and the onset of the menopause. The growth of fibroids is stimulated by ovarian hormones, particularly oestrogens. Women who have not had children are more liable to develop such tumours.

PATHOPHYSIOLOGY

The fibroid is spherical in shape and firm in consistency. Some fibroids are small, while others may grow large enough to fill the abdominal cavity. The tumour is encapsulated and the capsule contains the blood vessels supplying the tumour. As it grows, the centre of the tumour becomes less vascular and liable to degenerative change.



Multiple fibroids may be present, giving the uterus an irregular shape (see Fig. 7.7) or causing displacement of the uterus and uterine vessels.

Common presenting symptoms Menstruation becomes heavier and is prolonged when there are fibroids in the uterus. If the tumours are submucous then menstruation may become irregular and there may be bleeding between periods, but this is not common. Uterine pain may result as the uterus strongly contracts to attempt expulsion of the fibroid. Pressure upon pelvic nerves may cause back or leg pain; pressure on pelvic organs may lead to:

- frequency of micturition
- retention of urine
- obstruction of the gastrointestinal system
- oedema of a leg.

A fibroid may become infected and necrotic, causing a purulent vaginal discharge.

The most noticeable change is that of increasing girth of the abdomen; rapid increase may indicate that malignant change has taken place in the fibroid. Polycythaemia is associated with uterine fibroids but is a rare condition.

274 Fig. 7.7 Common sites of fibromyomata in the uterus.

MEDICAL MANAGEMENT

On abdominal and vaginal examination, the uterus is usually found to be symmetrically enlarged. It feels harder than it does in pregnancy, unless there is some degeneration of the fibroid(s) as occurs after the menopause. The uterus may feel nodular due to the presence of multiple tumours. The lower part of a tumour may be felt through the cervix and the difference between fibroid and carcinoma of cervix may be difficult to ascertain.

Investigations Pelvic X-ray and ultrasound scan may assist with diagnosis of fibroids. Diagnostic curettage may be performed to exclude endometrial carcinoma. An EUA is helpful in diagnosis. A sigmoidoscopy or barium enema may be performed to exclude carcinoma of the bowel.

Treatment Small fibroids may not be treated and any symptoms should disappear with the menopause. Medical treatment may be prescribed in the interim to relieve symptoms. Goserelin, a gonadotrophin-releasing hormone analogue, may be prescribed. In a woman who desires a future pregnancy it may be appropriate to shell out the fibroids from the myometrium (myomectomy); an older woman may be treated by hysterectomy. If the fibroids are small, a vaginal hysterectomy may be possible. Any anaemia experienced by the patient is rectified by blood transfusion before surgery.

Embolisation of uterine arteries has been introduced as an alternative treatment to hysterectomy (Thomas 1997). This involves cannulating the right femoral artery after administration of a local anaesthetic to the inguinal region. Under screening control, a catheter is passed through the arterial system and eventually to the right and then left uterine arteries which are individually embolised with polyvinyl alcohol solution. Contrast medium is injected to ensure effective arterial occlusion. Thomas (1997) stresses that patients require good opiate pain control following this procedure, but once pain is controlled patients can be discharged.

NURSING PRIORITIES AND MANAGEMENT: Fibromyomata

Nursing care will be prioritised depending upon the type of surgery completed. Observations of pulse, blood pressure

and vaginal blood loss are recorded to monitor internal bleeding from the operation site.

Care following hysterectomy will be similar to that described on page 280, but the patient will not have the worry of having a malignant disease that may continue to cause problems. Fibromyomata may recur in some women (Fedele et al 1995).

TROPHOBLASTIC TUMOURS

Trophoblastic tumours arise from the primitive tissues destined to develop into the placenta. They may be benign or malignant.

Hydatidiform mole (vesicular mole)

The hydatidiform mole results from hydropic degeneration and vesicle formation of the chorionic villi. These project from the outer mass of cells forming the trophoblast and are destined to become the placenta when the fertilised ovum settles into the endometrium. The uterus fills with grape-like vesicles which produce large quantities of chorionic gonadotrophin. The chromosomal pattern is 46XX, but all the chromosomal material is derived from the sperm, which doubles its chromosomes and takes over the ovum. No fetus develops.

PATHOPHYSIOLOGY

A hydatidiform mole is a benign tumour mass of chorionic cells in the uterus, which exists as though it were a developing pregnancy. Ovarian follicles are enlarged and there is an increase in blood and urine levels of human chorionic gonadotrophin (hCG). The uterus increases in size, sometimes faster than in a pregnancy. The villi of the trophoblast become swollen and the villi or vesicles cluster together like grapes.

Common presenting symptoms A woman may visit her doctor complaining of a vaginal discharge of fresh or altered blood which does not seem like normal menstruation. She may have noticed that some jelly-like mole vesicles have been expelled. She may be feeling unwell with some nausea and vomiting that resembles early pregnancy. Pelvic pain is not usually a problem.

MEDICAL MANAGEMENT

A general physical and vaginal examination will be performed. The uterus may be increased in size. A 'blighted ovum' might be suspected but the watery vesicles of the mole, if identified or reported, will alert the doctor to the condition.

Investigations A series of pregnancy tests will be completed. Pregnancy tests are positive, although there is no fetus present. The urine is diluted 1:10, 1:100 and 1:1000 — a positive pregnancy test in the 1:100 dilution is strongly suggestive of the mole. The diagnosis is confirmed by ultrasound investigation and by the finding of high levels of hCG in urine or serum. Choriocarcinoma is a serious complication following hydatidiform mole in 1 in 30 cases.

Treatment The uterus may be stimulated to contract by administration of oxytocin, in order to expel the mole, or it may be evacuated vaginally by suction apparatus. The uterus is in a soft, delicate state and is gently curetted to prevent perforation. A hysterectomy may be advised for a woman who has a family or is past child-bearing age. Thorough follow-up of the patient is necessary if hysterectomy has not been performed. At weekly or 2-weekly intervals for 2 years there must be measurement of urinary output of hCG by radioimmunoassay.

Complications A rising level of hCG with negative curettings of the uterine cavity suggests that the mole has become invasive of the muscle of the uterus and may even erode through the uterine wall. Deposits of molar tissue may be found in other parts of the body, in the peritoneum or in the lungs, and may cause death.

Choriocarcinoma

In 50% of cases choriocarcinoma of the uterine wall occurs after hydatidiform mole. The malignant condition may appear to arise spontaneously from the ovary but it is more likely to be associated with other neoplastic tissues, such as a teratoma. It may follow a normal pregnancy, an abortion or an ectopic pregnancy.

PATHOPHYSIOLOGY

The uterus becomes ulcerated, causing an offensive, blood-stained vaginal discharge. Metastatic spread of the cancer is speedy and extensive; the brain, lung, liver and other organs may be involved. Early deterioration is expected if the condition is not treated early.

Diagnosis is difficult but confirmed by hCG estimations in urine and plasma. The tissues contain malignant syncytioblast and cytotrophoblast cells.

MEDICAL MANAGEMENT

Follow-up arrangements after mole removal are usually stringent and early signs of development of the malignant tumour should become obvious, but there are greater risks if a woman delays consultation.

Investigations The tumour produces large amounts of hCG, used as a tumour marker. Uterine curettings provide histological evidence that confirms diagnosis and excludes a rare ovarian teratoma. hCG levels are also used to monitor the response to therapy.

Treatment Choriocarcinoma is highly sensitive to single-agent chemotherapy. If the tumour is confined to the uterus then intensive cytotoxic drug treatment is given using the drug methotrexate, toxic to the decidua, with almost 100% successful results. Folinic acid is given to protect the bone marrow. Special facilities are needed to protect patients who have a lowered resistance to infection because of diminished white blood cells.

If there is metastatic disease, methotrexate may be combined with other cytotoxic agents. The drugs induce marked side-effects during the treatment period and cardiac toxicity may occur. Early detection and treatment of the condition are advised, the disease being known to be curable even after systemic spread. Eighty per cent of patients may make a complete recovery if the disease is identified within

6 months of onset. Good prognosis from metastatic disease is associated with hCG titre levels of less than 40 000 mIU/mL before chemotherapy. hCG levels above 40 000 mIU/mL give a poor prognosis.

Some women may need a hysterectomy before treatment is completed but, as the condition occurs in child-bearing years, women may wish to become pregnant after a period of 2 years from recovery.

NURSING PRIORITIES AND MANAGEMENT: Hydatidiform mole/choriocarcinoma

Hydatidiform mole

Nursing care following evacuation of hydatidiform mole will be similar to that following curettage of the uterus. Recovery from anaesthetic should be speedy and the patient will become self-caring soon after returning to the ward. Following an anaesthetic, the nurse should check on the level of vaginal blood loss, which should be minimal within 24 h, diminishing quickly. Persistent bleeding should be reported to the doctor.

Minimal abdominal discomfort should be experienced by the patient. A mild analgesic will be prescribed, if necessary. If a patient experiences more severe pain, she should be closely observed. Intensive curetting of the uterus might, in rare cases, result in perforation of the uterus and even damage to the bowel. Any cause for concern should be reported to the doctor.

A series of postoperative urine and blood specimens will be required to estimate hCG levels. Specimens may need to be sent to one of the specialised centres in the UK where there is greater experience in assessing the significance of hCG levels and reporting results.

Choriocarcinoma

In the event of persistently high levels of hCG, a diagnosis of choriocarcinoma would require transfer of the patient to a specialised centre for chemotherapy. The patient may be very anxious, having to face up to the seriousness of her illness and the urgency of treatment. The nurse will reinforce the information already given to the patient by the doctor, emphasising the positive aspects of the care and the expertise of the staff at the specialised centre. The nurse must be prepared to cope with any outpouring of emotion and facilitate special wishes the patient may have. The partner can be fully involved in the events and can accompany the woman to the treatment centre.

Special facilities are available for reverse barrier nursing of the patient to protect her from infection as chemotherapy progresses and her immune system is compromised (see Ch. 16). Physical, psychological and social aspects of nursing care will be of primary concern. Many weeks of treatment may be involved before recovery is achieved and the patient returned to normal family life. Follow-up and further hCG monitoring are essential.

GYNAECOLOGICAL CANCER

The organs of the female reproductive system are susceptible to benign or malignant overgrowth of tissues. Cancerous or malignant tumours are generally differentiated from benign tumours by the following properties:

- they are not encapsulated and invade tissues in which they arise
- they show disorderly reproduction
- they tend to show loss of structural differentiation
- they can produce metastases.

The cervix, body of the uterus, ovary and vulva are potential sites for primary cancerous growth.

Carcinoma of the cervix

The cervical tissue is at particular risk of carcinomatous change. Hughes (2001) suggests cervical cancer affects 4200 women in the UK annually. Department of Health (1999) records indicate that 4000 new cases of invasive cancer of the cervix were registered in 1998–1999. In Scotland in 2002 there were 100 deaths from cervical cancer but over the most recent 10-year period there has been a fall in incidence and mortality (Scottish Health Statistics 2003).

Cancer of the cervix occurs most often in women between 30 and 50 years of age. It is preceded by a pre-invasive condition that can be simply and effectively treated if identified by cervical cytological screening. The peak age for pre-invasive lesions is 25–35 years and for invasive cancer 40–50 years. Although there is difficulty in providing a high-quality smear, and programmes can still be improved in terms of accessibility and education for all women, cervical cytology remains the most effective screening test in medical oncology, contributing to a reduction in the morbidity and mortality rates of cervical cancer (Masood 1997).

Pre-invasive cancer of the cervix

PATHOPHYSIOLOGY

The endocervical canal is lined with columnar epithelium one cell thick. Deep branching compound racemose glands exist within these cells and secrete alkaline mucus. Adenocarcinoma, which is relatively rare, arises within these cells (5–12% of cervical cancers). This type of cancer is not normally diagnosed from a cervical smear.

The area where the columnar cells of the endocervix join with the squamous cells of the ectocervix is called the squamocolumnar junction (SCJ). A natural physiological process exists whereby the columnar cells migrate down to the ectocervix, moving the SCJ to a new position and causing a red area of columnar epithelium around the cervical os (Hopwood 1990). The migrated columnar cells then start to break down in the acid environment of the vagina and the squamous cells beneath grow to replace them. The area where the normal replacement of the columnar cells with squamous cells takes place is called the transformation or transitional zone and is most commonly where precancerous changes occur. Cervical smears must therefore be taken from this area using specially shaped instruments.

A specific 'oncogene' has been identified as giving a cell its cancer potential (see Ch. 31). Adolescence, the time of menstruation, the first pregnancy and the prenatal period are times of maximum cellular activity in the cervix, when

the tissues are more sensitive to a carcinogen that has been sexually transmitted and more prone to genetic mutation.

The relationship between cervical squamous pre-cancer and sexual intercourse appears to be conclusive since the condition is virtually unknown in celibate women. Epidemiological observations indicate that the age of onset of intercourse and the number of sexual partners influence the development of cervical pre-cancer and cancer (Lewis & Chamberlain 1995). The condition is also more common in lower socioeconomic groups. The more sexual partners the woman has had, the more likely she is to be exposed to the unknown carcinogen(s). Two viruses have been proposed as possible carcinogens:

- the human papilloma virus (HPV) (Eluf-Neto et al 1994)
- the herpes simplex virus type 2 (Hildesheim et al 1991, Jones 1995).

The specific high-risk viruses thought to be linked with cervical cancer (HPV16, 18, 31 and 33) cannot be identified from a cervical smear test alone — the DNA needs to be examined.

Studies of the role of the male sexual partner suggest the possible transmission of viruses but also refer to the possible carcinogenic effect of human sperm. It is suggested that the basic proteins of histone and protamine fraction of the sperm heads may act as carcinogens. Barrier methods of contraception can offer protection.

There is a possible increased risk of cervical cancer associated with cigarette smoking although there may be several coexisting factors contributing to the risk (Phillips & Smith 1994, Szarewski et al 1996). Factors currently considered to be important are listed in Box 7.3. These factors may change as research continues.

Box 7.3

Risk factors and possible causes of carcinoma of the cervix

Risk factors
- Early intercourse (before 17 years of age)
- Multiple sexual partners
- Early pregnancy
- Living in an urban environment
- Low socioeconomic status
- Smoking
- Immunosuppression
- Use of oral contraception
- Previous abnormal smear
- Failure to participate in screening
- Nutritional deficits — vitamins A, C, folic acid
- High-risk male partner
- In utero exposure to diethylstilbestrol

Possible causes
- Human papilloma virus
- Herpes simplex virus
- Sperm from high-risk tissue-type male
- Smoking
- In utero exposure to diethylstilbestrol
- Immune deficiency

Reproduced with permission from Shingleton & Orr (1987).

Carcinoma of the cervix is now classified as a preventable disease if certain examinations are undertaken regularly by women. Cervical cancer that is identified in the pre-invasive stage is curable.

Common presenting symptoms The earliest knowledge of a malignant change in the cervix may be from a report on a cervical smear test. A clear vaginal discharge may occur in the early stages, whereas later the discharge may be bloodstained or have a bad odour. Irregular vaginal bleeding may be associated with prolonged menstruation, occur between periods, follow sexual intercourse, or be postmenopausal. Pain may be experienced when metastases are present or if there is nerve involvement.

Where there is advanced disease, venous or lymphatic obstruction may lead to extensive oedema within the pelvis. Blocked ureters may result in renal failure, and the spread of growth may lead to fistula formation between the vagina and rectum, or the vagina and the urinary bladder, in which case incontinence will be unavoidable. Massive haemorrhage may occur and death may be related to kidney failure or intestinal complications.

MEDICAL MANAGEMENT

Investigations The following procedures may be completed:

- traditional Papanicolaou smear test or a smear test using liquid based cytology
- Schiller test
- colposcopy and biopsy
- histological examination of smears and tissue specimens.

Papanicolaou (Pap) smear test Papanicolaou and Traut showed the value of smears in detecting cervical cancer as early as 1941, but it was not until 1964 that cervical screening was introduced in the UK. From the 1980s a number of initiatives were introduced in the UK to improve the organisation of cervical screening services and reduce mortality from cervical cancer. Women are generally recalled on a 3- or 5-yearly basis. On the basis of research, the Cancer Research Campaign (1994) and Ibbotson and Wyke (1995) recommended that women aged between 20 and 64 years should have a smear test every 3 years. However, for maximum personal benefit women may wish to have a Pap test every 1–2 years from the time they are sexually active until the age of 70. Cervical cancer remains a significant health risk for older women and it is suggested that a revision of the guidelines for cessation of screening may be appropriate (Colgan et al 2002). Women who are not or have never been sexually active are excluded. A woman who has had a total hysterectomy for benign reasons will not require subsequent smear tests, but if a hysterectomy has been performed for pre-cancer or cancer, subsequent vault smears should be taken. Women who have had a subtotal hysterectomy will still require to have cervical smear tests.

The cells identified from the cervical smears are classified as shown in Box 7.4. This information is supplemented as appropriate with the histological grade of pre-invasive disease, i.e. CIN1, CIN2 or CIN3 (see Box 7.5).

Women may be asked to have a smear test repeated where there is an inconclusive diagnosis or if minor cytological abnormalities are detected.

Box 7.4

Papanicolaou smear test results in graded classes

Class 1	Cells are normal in appearance
Class 2	Abnormal cells are present but are not malignant; the patient may have suffered from vaginal inflammation
Class 3	Abnormal cells are present and are suggestive of malignancy
Class 4	Abnormal cells are present and appear to be malignant
Class 5	Abnormal cells are present and definitely malignant

Box 7.5

Histology of cervical intraepithelial neoplasia (CIN)

Current terminology for cervical intraepithelial neoplasia describes three grades of change as part of a continuum of pre-invasive disease:

- CIN1 corresponds to mild dysplasia
- CIN2 corresponds to moderate dysplasia
- CIN3 corresponds to severe dysplasia and carcinoma in situ.

Liquid based cytology Liquid based cytology (LBC) is a new method of preparing a cervical cell sample. Samples are collected from the woman as for a Pap test but a brush-like device is used instead of a spatula. The head of the collecting device is rinsed or broken off into a small container of preservative fluid, most or all of the cells being retained. In the laboratory the sample is mixed to disperse the cells. Cellular debris is removed. A thin layer of the cervical cells is placed on a microscope slide and is stained for examination by a cytologist (NICE 2003). Following a pilot programme this method of obtaining cervical cells is now in operation across the UK. Advantages of this technique over the Pap smear are:

- improved slide preparation, allowing a more homogeneous sample for examination
- increased sensitivity and specificity
- improved handling procedures for laboratory samples.

Colposcopy and biopsy Colposcopy is recommended immediately for all women with a smear that suggests CIN2 or CIN3 and involves examination of the vagina and cervix using magnification and illumination to identify and assess pre-invasive changes. Saline may be applied to the cervix to identify blood vessel patterns. Acetic acid is applied to the transformation zone, mucus is removed with a cotton wool ball or a swab and the area is carefully examined for abnormal epithelium. Iodine can be used (the Schiller test; see Appendix 1) to outline abnormalities. Several biopsies are taken from abnormal areas. Histological examination of the biopsies will confirm the diagnosis of pre-invasive disease. If the transformation zone cannot be completely visualised because it extends too high in the cervical canal, a cone biopsy is performed for diagnosis.

A diagnostic biopsy method may be that of punch biopsy or low-voltage diathermy loop excision biopsy. The punch biopsy tends to crush the sampled tissue and may not include stroma which can lead to missing invasive disease. The diathermy loop excision method can provide tissue samples of better size and allows better control of bleeding.

Treatment options

Conservative treatment Pre-invasive cancer of the cervix that can be fully visualised within the transformation zone can be treated by destruction of the entire transformation zone down to a depth of 6 mm. This depth will ensure the destruction of diseased crypts and glands without destroying normal tissue. Accurate assessment of depth is difficult. Conservative treatment is important to the woman who has not yet started a family and who needs to avoid developing an incompetent cervix to prevent loss of a future pregnancy.

Destructive treatment The following destructive treatment methods may be used:

- *Cryotherapy*. Cryonecrosis is produced by crystallisation of intracellular water using nitrous oxide or carbon dioxide. Freeze–thaw–freeze techniques produce the best results. Little or no analgesia is required. Patients can expect a copious watery vaginal discharge after this procedure.
- *Electrocoagulation diathermy*. Temperatures of over 700°C are used to induce tissue destruction to a depth of at least 7 mm. Traditionally carried out under general anaesthesia, Chanen (1989) demonstrated that the procedure can be carried out successfully with intracervical infiltration with a local anaesthetic. Bleeding and discharge can be expected in the postoperative period.
- *Cold coagulation*. A thermasound heated to 120°C is applied for 20 s to five areas of the surface of the cervix. The procedure is completed under local anaesthetic and has a reported cure rate of 94% (Gordon & Duncan 1991).
- *Laser vaporisation*. The carbon dioxide laser (pulsed or continuous) may be applied to the cervix to ablate the pre-invasive cancer. The procedure can be performed under local anaesthetic. Postoperatively, primary or secondary haemorrhage may occur. A 94% success rate has been reported (Baggish et al 1989); however, Dey et al (2002) suggest that loop diathermy excision is a more effective treatment of CIN than laser vaporisation.
- *Excision of the transformational zone*. This procedure can be performed using laser or a diathermy loop. The latter method is easier to perform and more economical in terms of time. Large loop excision of the transformation zone (LLETZ) may be achieved under colposcopic guidance by low-voltage diathermy — an alternative to cone biopsy. The procedure is performed under local anaesthetic. A bloodstained vaginal discharge usually follows for 1–2 weeks. Severe secondary haemorrhage may occasionally occur.
- *Cone biopsy*. When a transformation zone is not fully visible for colposcopy then an excisional method of treating the pre-invasive cancer has to be used. The

entire transformation zone is excised, which provides a large specimen for histological examination and allows confirmation that all diseased tissue has been removed or that the disease was more extensive than originally diagnosed. The procedure, performed under a general anaesthetic, may be complicated by secondary haemorrhage, infection, cervical stenosis or incompetence. Care is required to prevent uterine perforation and pelvic abscess.

NURSING PRIORITIES AND MANAGEMENT: Pre-invasive carcinoma of the cervix

The person with pre-invasive cancer is treated as an outpatient or as a day patient. Diagnosis, treatment and follow-up are completed in separate visits to a colposcopy clinic. An appointment for colposcopy is given to correspond with the middle of the menstrual cycle, which is a favourable time for the procedure. The nurse will need to ensure at all stages that the patient understands the procedures planned and the expected outcome.

Anxiety levels amongst women presenting for colposcopy have been found to be higher than those of women going for surgery, concerns about the procedure being as great as those about the illness condition (Marteau et al 1990). Sensitive approaches are required to help the patient to express her feelings and think rationally about the future after treatment.

When the patient feels calmer, other information can be given, as it is more likely to be retained. The nurse should tell the person to expect vaginal discharge and some bleeding after the treatment, and explain what to do if bleeding becomes suddenly very heavy or if she suspects she has an infection. The opportunity for health promotion regarding avoiding smoking can be taken.

Arrangements for a follow-up cervical smear test are discussed as part of the pre-discharge routine, as well as the need for future annual check-ups.

Invasive carcinoma of the cervix

PATHOPHYSIOLOGY

Commonly, carcinoma develops from the vaginal surface of the cervix, and less often from the cervical canal. It may form an ulcer on the cervix or become a fungating cauliflower-type growth and is of the squamous cell type. Tissues become eroded and infected, forming an unpleasant vaginal discharge.

The carcinoma spreads by direct infiltration of surrounding tissues and via lymphatic vessels. Blood-borne metastases in more distant organs occur less often. The prognosis for cervical cancer relates to the extent of the growth at the time of diagnosis rather than to the histological type of the cancer. The international classification of carcinoma of the cervix is shown in Box 7.6 (see also Ch. 31).

Common presenting symptoms A woman may have no particular symptoms at the time a cervical smear result confirms that cancer of the cervix exists. On the other hand, she may visit the doctor because of irregular vaginal bleeding, perhaps associated with sexual intercourse, micturition or defaecation. An ulcerated area or an overgrowth of tissue on the cervix may be directly visible to the doctor on examination using a vaginal speculum.

A vaginal discharge becomes more continuous; a thin bloodstained loss may change to a thicker, brown, offensive discharge or heavier bleeding episodes. Lower abdominal pain develops as the growth increases in size, spreads and exerts pressure on surrounding structures. Very severe lower back and sciatic pain may occur and lymphatic nodes adhere to the sacral plexus. Pressure on the pudendal nerve and blood vessels causes obstruction to the venous return and oedema of the legs.

Incontinence of urine and faeces may occur as the bladder and rectum are inflated with growth or react to radiation side-effects. Ureters may become blocked and renal failure may ensue.

Box 7.6

International classification of carcinoma of the cervix

Stage 0	Pre-invasive carcinoma, also known as carcinoma in situ (CIN3)
Stage IA	Microinvasive carcinoma; less than 5 mm in depth
Stage IB	Neoplasm confined to the cervix
Stage IIA	Neoplasm has infiltrated adjacent parametrial tissue or upper vagina; if the carcinoma is endocervical then it has extended up into the uterus in this stage
Stage IIB	Tumour extending to the parametrium but not to the pelvic wall
Stage IIIA	Lower third of the vagina is involved or the parametrium
Stage IIIB	Involves lymph nodes as far as the pelvic wall or there are isolated metastases in the pelvis, often obstructing a ureter
Stage IVA	Spread of growth to adjacent organs
Stage IVB	Spread of growth to distant organs

MEDICAL MANAGEMENT

Investigations A number of investigations are required before any treatment is planned to establish the spread or otherwise of the disease. A chest X-ray and intravenous pyelogram are completed to gain information on obstruction of the flow of urine from the kidneys, which indicates involvement of the parametrium. A cystoscopy may be performed. A lymphangiogram and a CT scan will assist with identification of disease spread to lymph nodes.

The patient with carcinoma of the cervix requires a general physical examination and a thorough pelvic examination. Haematological and blood chemistry and nutritional studies will be completed. An EUA is carried out at the time of cone biopsy or the insertion of radioisotopes. The EUA increases the accuracy of identifying the stage of development of the growth. It allows better examination of the upper vagina and improved palpation of the abdomen, pelvis and enlarged pelvic, inguinal and para-aortic lymph nodes. Fine-needle aspiration of nodes under sonar or CT guidance may be performed to delineate the spread of the

cancer. The information gained is used to confirm, modify or extend treatment plans.

Serum markers Tumour-derived and tumour-associated markers in the plasma of patients with carcinoma of the cervix continue to be researched (Ngan et al 1996, Sliutz et al 1997). Individual marker levels may be used at the assessment stage, in the planning of treatment, when monitoring the response to treatment and in the follow-up years of care. Marker measurement values tend to increase with the stage of disease and decrease with effective treatment. Initial levels before treatment may be an aid to prognosis. The following are examples of serum markers that may be studied:

- *Carcinoembryonic antigen (CEA)* — squamous cell carcinoma and adenocarcinoma have significantly different capacities for CEA release.
- *Plasma histaminase* falls during radiotherapy with a value that is inversely proportional to the radiation response.
- *Tumour-associated antigen (TA-4)* provides a means for monitoring squamous cell tumours.
- *Immunosuppressive acid protein (IPA)* — patients with recurrent cervical cancer have shown elevated IPA, whilst 83% of patients previously treated but without evidence of recurrence did not have elevated levels.

Treatment

Surgery When the carcinoma is confined to the cervix, resection of the malignant tissue is necessary. This may be achieved by laser beam therapy, cone biopsy of the endocervical tissue or amputation of the cervix. Where there is extension of the growth up into the uterus, hysterectomy and removal of pelvic lymph nodes will be necessary.

Radical surgery may be planned for some patients who are at earlier stages of the disease and are more generally fit. This surgery may be combined with radiotherapy as tumours of the cervix are particularly radiosensitive. Care is jointly planned by the surgeon and radiotherapist. The Wertheim–Bonney–Meigs operation involves removal of the uterus, cervix, the upper third of the vagina, pelvic cellular tissue lateral to the uterus and vagina, and the uterosacral and cardinal ligaments. The lymphatic glands in the obturator fossae and along the external and internal iliac vessels are removed. The ovaries are preserved in premenopausal women.

To facilitate the excision of the cervix, vagina and supporting ligaments, the ureters are dissected free during the operation. Postoperatively there may be a breakdown of the ureteric anastomosis, leading to a urinary fistula. The autonomic nerve supply to the bladder may be disturbed, resulting in incomplete bladder emptying as a complication.

Pelvic exenteration Where there is extensive recurrent disease, an anterior pelvic exenteration may be performed, involving removal of all the reproductive organs and the urinary bladder. The ureters are implanted into an artificial bladder fashioned from a loop of ileum — a urinary diversion (see Ch. 8). If the rectum is also removed, a terminal colostomy is formed. This extremely radical surgery may be combined with cytotoxic drug therapy using cisplatin and other chemotherapeutic agents.

Radiotherapy Radiotherapy is initially to reduce the size of tumour, inhibit its growth and reduce its blood supply before surgical removal by hysterectomy. Caesium-137 rods may be inserted under general anaesthetic into the uterine cavity and vaginal vault to provide a radiation dose to the whole pelvis. The treatment will reduce the blood supply to the growth and exert a lethal effect on the cancer cells. Hysterectomy may be performed after local irradiation by caesium or standard supervoltage techniques. Stages III and IV of carcinoma of the cervix are usually inoperable. Palliative irradiation therapy is then indicated. Radiation may be administered via sophisticated machinery such as the Cathetron, which can pass high-intensity radiocobalt radiation from a protected store along ducts to applicators already positioned in the uterus and vagina. The patient is treated in a protected room, reducing radiation risks to others.

The dose of radiation necessary to kill the tumour cells may leave a very low level of protection for healthy tissue cells. Short- or long-term radiation reactions may be induced by therapy. The bladder and rectal tissue may become swollen, inflamed, friable or fibrosed and there is a risk of the development of a fistula. The patient may become distressed by urinary problems or diarrhoea. Symptoms are relieved as they occur. Minor surgical repair operations may be necessary. The patient's general comfort is of prime importance.

NURSING PRIORITIES AND MANAGEMENT: Hysterectomy

Preoperative care

Assessment

The assessment process will identify the patient's gynaecological details, individual problems and needs for nursing assistance and support. The patient who has previously been prescribed an oral contraceptive drug will have been advised to discontinue the contraceptive pill and use an alternative barrier method for 6 weeks prior to the operation to reduce the risk of thrombus formation during surgery or in the postoperative period. The nurse should check that this advice has been followed.

Identification of actual and potential problems

Anxiety

The woman may experience considerable anxiety related to surviving the operation and the illness condition. A change in body image may occur, a sense of loss and some alteration in sexuality and sexual identity may be feared. The woman's loving relationship with her partner may appear to be threatened by the surgery, particularly if her child-bearing potential is lost. Anxiety may also be focused on the family members who remain at home: how will the children and her partner cope whilst she is in hospital? She may be worried that her illness will affect her ability to work and support the family in future. A gentle approach by the nurse may help the patient to speak about her main concerns. Being able to do this at the time of assessment may be the first step towards making a positive adjustment and thereby reducing anxiety. The nurse will be able to plan to utilise opportunities to help the patient manage her anxiety during the hospital period.

The need for information

In preparation for surgery, the patient will need information about the events to be expected during both the lead-up to the operation and the recovery period. The benefits of planned information-giving preoperatively, based on nursing research findings, are described in Chapter 26. An information booklet explaining the operation and its resultant internal changes and answering many questions about the future should be provided for the patient to read at her leisure. This provides a permanent reminder of what she may have been told and reinforces her understanding.

The surgeon will advise when sexual intercourse may be resumed. Normally this will be several weeks after the operation, to allow internal healing and to reduce the incidence of infection. The patient will benefit from knowing that a sexual climax will again be achievable even though the uterus has been removed. The nurse can explain that the pleasurable sexual experience is achieved from the stimulation of the external clitoris within the vulva and the psychological experience associated with stimulation of the penis in the vagina. The patient may already be aware of this, but will be pleased to know that the experience should not change. It is helpful if the patient's partner can be included in the information-giving session. The patient may then approach surgery more calmly and confidently, and recover with minimal physical or emotional problems (see also Research Abstract 7.6).

Exercise

Patients will have limited mobility in the first 48 h after a hysterectomy. There will be a risk of venous stasis and pressure ulcer development. Patients should be encouraged to practise foot and leg exercises before the operation, so that they understand how to carry out the exercises while resting in bed after surgery. A short course of subcutaneous heparin may be prescribed prophylactically. Patients will also benefit from experiencing how it feels to be moved by nurses using a mechanical hoist, and from knowing what they can do to assist the process. This should help to reduce apprehension about being moved at a time when dependent. A visit by the physiotherapist will prepare the patient for moving, and for deep-breathing and coughing exercises to be used after the operation.

Protection from hazards (see Ch. 26)

The doctor is responsible for fully informing the patient about the planned operation and is required to obtain the patient's informed consent in writing. The nurse preparing the patient checks that the consent form has been signed before completing the other major surgery preoperative procedures. The patient will wear anti-embolism stockings to counteract venous stasis during the operation period. A premedication is given as prescribed. The patient leaves the ward escorted by her nurse who completes a safe transfer to the operating theatre staff.

Postoperative care

The patient's individual needs and actual problems will transfer from a preoperative care plan to a postoperative care plan, but a major new focus will be that of maintaining a safe internal and external environment for the patient.

RESEARCH ABSTRACT 7.6

A study of self-concept and social support after hysterectomy

Webb and Wilson-Barnett (1983) studied depression, self-concept and sexual life in 128 women during recovery from hysterectomy as part of a nursing study. At the time of operation, 103 were premenopausal and 102 were sexually active. The women were interviewed 1 week and 4 months after the hysterectomy. The results showed that women felt physically and emotionally much better, were less tired and irritable, had gone back to work and had resumed leisure and social activities. Responses showed that:

- 94% were happy to have no more periods
- 84% were glad they could no longer become pregnant
- 90% of those who were sexually active said their sex life was now as good as, or even better than, previously
- 92% were glad they had the operation.

The small numbers who gave 'negative' replies to these questions were still not completely recovered and gave this as the reason for their answers. They referred to physical complications of wound, urinary or vaginal infections which delayed recuperation rather than the psychological problems suggested in medical studies.

In studying the social support of these women results showed:

- 70% had been told 'old wives' tales' of pessimistic outcomes; 11% felt there was some truth in them after their own experiences
- 23% of partners (n = 103) had been given no extra help in the home.

The greatest area of dissatisfaction was in the lack of information from medical and nursing staff. Women would have liked guidance on what they could do, how they might feel as they progressed and what symptoms or complications could occur.

Webb C, Wilson-Barnett J 1983 Self concept, social support and hysterectomy. International Journal of Nursing Studies 20(2): 97–107

There are a number of potential problems that will feature in the care plan and will have been explained to the patient preoperatively. The general care of a patient following major abdominal surgery is described in Chapter 26, and in Nursing Care Plan 7.1.

Carcinoma of the body of the uterus

Carcinoma of the body of the uterus is more common with advancing age, most cases occurring in the sixth and seventh decades (Blake et al 1998). The condition is associated with infertility, diabetes mellitus, oestrogen replacement therapy, obesity and hypertension. An excess of oestrogen is common to all the risk factors. As women are living longer, the present rate is expected to increase.

PATHOPHYSIOLOGY

The columnar epithelium that covers the surface of the endometrium and forms the lining of the glands gives

Nursing Care Plan 7.1 Care of a patient following a hysterectomy

Potential problems	Expected patient outcomes	Nursing care	Rationale
1. Irregularity in vital signs	• Pulse and BP measurements are within acceptable limits for the patient • Blood loss through wound or drainage tubes is minimal in any 24 h	Record BP and pulse: _____ Inspect wound/drains Observe for any pv loss Record temperature: _____	Haemorrhage due to loss of haemostasis at operation site would result in hypovolaemia, requiring blood transfusion. Fine drainage tube is in position in wound. Pyrexia may occur due to infection in chest, urinary tract, wound or veins
2. Body fluid imbalance	• No sign of dehydration or fluid overload • Patient is adequately hydrated • Signs of fluid overload are detected from fluid balance record	Maintain intravenous therapy as prescribed Observe i.v. puncture site for signs of infection or fluid being given extravenously Record fluid intake and output Dress cannula site with: _____ Change giving set: _____	Major surgery depletes body potassium, sodium and water levels Fluid and electrolyte replacement is needed by the intravenous route
3. Patient to have nil by mouth	• Peristalsis returns within 48 h	Patient to be given no fluid or food by the oral route until prescribed by doctor Record any bowel activity	Peristaltic movement of the intestines stops when the abdomen is opened and the gut is handled. Food and fluid, if taken, could not be digested. Bowel sounds are heard when peristalsis returns. Patient passes gas
4. Urinary bladder is drained by a self-retaining catheter (suprapubic or transurethral) **Risk of bladder dysfunction after catheter removal** **Risk of urinary tract infection**	• Urine drains freely to minimise pressure on operation sites Urine is clear and has low bacterial count	Observe and record urinary output Obtain catheter specimen of urine: _____ for laboratory culture and sensitivity Complete catheter toilet: _____ Remove catheter on: _____	During the radical hysterectomy the ureter is either partially dissected to allow resection of the medial portion of the cardinal ligament, or more extensively dissected to sever the cardinal ligament at the pelvic side wall. There may be oedema and bruising of posterior urethral wall. Diminished bladder sensation, reduced bladder compliance and stress incontinence may occur. Urinary tract infection is a risk with a catheter in the urinary bladder

Nursing Care Plan 7.1 Care of a patient following a hysterectomy *(Continued)*

Potential problems	Expected patient outcomes	Nursing care	Rationale
5. Possibility of patient becoming distressed or uncomfortable due to postoperative pain	• Patient expresses verbally or by body language that pain has decreased to an acceptable level on a pain scale of 1 = 'low' to 5 = 'high'	Remind the patient of the availability of analgesia Reposition the patient as necessary for comfort Give analgesia as prescribed or supervise the patient-controlled analgesia system (PCA) Ask patient if analgesia is adequate using pain scale 1 = 'low' to 5 = 'high'	Patients have different pain tolerance levels. It may not be possible to keep the patient pain-free at all times. A degree of pain control that is acceptable to the patient should be planned
6. Limited mobility with risk of: • **venous stasis** • **pressure ulcers**	• No limb tenderness, pain, swelling or redness during hospital stay • Moves safely within limits allowed • Pressure areas remain intact	Supervise limb exercises whilst patient in bed, to be performed _____ -hourly Move patient to relieve pressure over bony prominences: 2-hourly Anti-embolism stockings to be worn until _____ Mobilisation programme: _____ _____	The patient who is immobilised by major surgery and confined to bed may experience reduced muscular stimulation to the venous system. The blood flow in the veins of the limbs is slowed down, increasing the potential for blood clot formation, inflammation of the vein and surrounding tissues (phlebitis and cellulitis) with accompanying swelling and pain and possible embolism. Body pressure exerted over pressure areas for more than 2 h will result in compromise of the blood supply to the tissues and the development of pressure ulcers. Exercising of limb muscles and the wearing of anti-embolism stockings are preventive measures that reduce risk. Measures to relieve pressure over pressure areas are effective in preserving skin and other tissue integrity

Continued ▶

Nursing Care Plan 7.1 Care of a patient following a hysterectomy *(Continued)*

Potential problems	Expected patient outcomes	Nursing care	Rationale
7. Needs information or new skills in readiness for discharge	• With information/instruction/practice will be able to function independently in: _____ _____ _____ by discharge on: _____	Patient preparation: _____ _____ _____	Depending upon progress during the hospital stay, the patient will need an individualised pre-discharge programme. Advice and counselling in areas of the activities of living may be needed. Personal care, including wound management, the importance of exercise and restricting of lifting activity, should be related to the surgical removal of ligaments and supporting structures in the pelvis and the slow healing of abdominal muscle and other tissues The patient may be discharged with a suprapubic catheter in situ. Practice will be needed in the management of the closed drainage system. The patient may have the support of a community nurse when at home to complement self-care. The patient will need to know what to do if problems occur, and who to contact: GP or hospital. The patient should be encouraged to ask questions and talk about any concerns. Information about a local group of the Hysterectomy Association should be provided should the patient feel in need of support and social contact. Medical staff will need to give specific instructions about when sexual intercourse may be resumed and what follow-up surveillance will be maintained in the observation for recurrence of disease; 20-year follow-up may be achieved

origin to carcinoma of the body of the uterus. The growth is usually an adenocarcinoma. In a small number of cases of adenocarcinoma, there may be a squamous metaplasia. This squamous element may be benign or malignant.

Endometrial carcinoma develops in an atrophic senile uterus. The lesion penetrates the endometrium, spreads laterally and grows slowly. With time it penetrates the myometrium deeply, reaching the peritoneal covering, and the lymphatic glands become involved. Secondary deposits may affect pelvic and aortic lymph nodes and the ovary. Metastases to the lung, bone, liver or brain may be late, blood-borne complications. There are different grading systems that can be applied to endometrial cancer. Staging relates to the tumour size, location and spread beyond the uterus. Walczak (2000) describes a system that coincides with recommendations of the International Society of Gynaecological Pathologists (see Box 7.7). Scholten et al (2004) claim that the most widely used grading system for endometrial cancer is the International Federation of Gynaecology and Obstetrics (FIGO) system. However, this three-tiered system is now being challenged by a binary grading system, based on the amount of solid growth, the pattern of invasion of the myometrium and the presence of tumour cell necrosis (Lax et al 2000, Scholten et al 2004). While both the FIGO and binary systems show good prognostic power, the binary grading system is said to have better prognostic power and greater interobserver and intraobserver reproducibility.

Common presenting symptoms From the age of 45 years, a woman expects changes in the menstrual cycle related to the menopause. The early signs of carcinoma of the uterus may be difficult to distinguish from the changes of the climacteric. Unexpected or irregular vaginal bleeding is a significant sign. Bleeding that is too heavy, occurs too often or happens after cessation of periods at the menopause needs to be investigated. Low abdominal pain may be a late experience for the woman with uterine carcinoma. The vaginal discharge may be clear or brown with an offensive odour.

Box 7.7

Staging of endometrial cancer

Stage IA	Tumour is limited to the endometrium
Stage IB	Tumour invasion to less than one-half of the myometrium
Stage IC	Tumour invasion to more than one-half of the myometrium
Stage IIA	Involvement of endocervical glandular tissue
Stage IIB	Invasion of cervical stroma
Stage IIIA	Invasion of serosa and/or peritoneum
Stage IIIB	Metastatic spread to pelvic and/or para-aortic lymph nodes
Stage IVA	Invasion of the mucosa of bladder and/or bowel
Stage IVB	Distant metastases — intra-abdominal and/or inguinal lymph nodes

Reproduced with permission from Walczak (2000).

MEDICAL MANAGEMENT

Investigations In some cases a routine cervical smear test may yield the first evidence of malignant endometrial cells. Initial investigations include a transvaginal scan (TVS) and endometrial biopsy. If the endometrial biopsy is insufficient for histological identification of malignant cells or if there is thickening of the endometrium shown on the TVS (indicative of pathology), the diagnosis can be concluded by a hysteroscopy followed by dilatation and curettage of the endometrium.

Treatment

Total hysterectomy Cancer of the uterus is usually treated by total hysterectomy and bilateral salpingo-oophorectomy, i.e. surgical removal of the uterus, cervix, fallopian tubes and ovaries. The abdominal or vaginal surgical approach may be used. A vaginal hysterectomy is suitable if the uterus is small and not distended with bulky tumour.

Extended hysterectomy An extended hysterectomy also includes removal of pelvic lymph nodes. Surgical treatment may be combined with radiotherapy to the pelvic wall. Alternatively, the uterine tumour may be irradiated to shrink it and deplete its blood supply before surgery. Postoperative radiotherapy may be given either as external beam only or in combination with vault caesium.

Cytotoxic and hormonal treatments Cytotoxic medication may be used as early as possible following surgery to counteract metastatic seeding. Carcinoma of the endometrium is often sensitive to hormone therapy. High doses of medroxyprogesterone acetate (Depo-Provera) or hydroxy-progesterone caproate (Delalutin) may suppress the progress of the disease in advanced cases and limit metastatic activity. The 5-year survival rates in women treated for early cancer of the uterus are 60–70%.

NURSING PRIORITIES AND MANAGEMENT: Carcinoma of the uterus

The nursing care of the patient with cancer of the uterus involves pre- and postoperative care for hysterectomy. Care will be individualised but will be similar to that for the patient with carcinoma of the cervix (see p. 276).

Total or extended hysterectomy does not involve dissection of the ureters, as in radical hysterectomy. The patient should therefore have less difficulty with recovery of bladder function postoperatively, as there will be no disturbance of the nerve supply or any bladder wound. A self-retaining urethral catheter may be used in the first few days, to avoid distending the urinary bladder and exerting pressure on the posterior urethral wall, which may be swollen and bruised.

A haematoma in the vault of the vagina is a potential complication of vaginal hysterectomy. This will result in prolonged abdominal discomfort, raised body temperature and a sustained feeling of being unwell, until the haematoma is diagnosed and drained.

The patient will need information about her progress at regular intervals in the postoperative period. Of particular concern may be the need to have cytotoxic drug therapy at an early, vulnerable stage after major surgery. The patient may feel greatly debilitated by the side-effects of nausea

and vomiting. Psychological support from the nurse should help the patient to view the chemotherapy as the final safety net in the treatment process. Positive improvements should be seen within 3 months of treatment being completed. Medical follow-up is essential to monitor progress and identify early signs of recurrent disease.

Malignant disease of the ovary

Ovarian cancer is the sixth most common cancer in women and the leading cause of death from a gynaecological malignancy. The incidence and mortality of ovarian cancer has shown little change in the past two decades, despite an increase in the proportion of women receiving surgical treatment to manage the disease (Laurvick & Semmens 2002).

Ovarian cancer is more common in developed countries (Lambert et al 1992). A relationship is said to exist between multiple ovulation in women in well-nourished communities and the incidence of ovarian cancer, the disease being more common in the better-nourished and upper social groups. Pregnancy and the oral contraceptive pill have a protective effect. The condition is more common in infertile and nulliparous women and in women who have not taken a sexual partner. A previous problem of endometriosis is linked to malignant change. The peak incidence is between 50 and 70 years of age (Blake et al 1998).

To date there is no effective screening procedure for early detection of this disease in the population. The tumour is often widespread before symptoms appear. As a result, late detection of the condition prohibits effective treatment and the mortality rate is higher than for other genital malignancies.

PATHOPHYSIOLOGY

Ovarian tumours comprise tissues of the normal ovary, most commonly arising from the epithelial lining. The tumour may occur unilaterally or bilaterally. Carcinoma developing in other organs can metastasise to the ovary. Carcinoma of the body of the uterus may spread directly to the ovary, although this is less common with carcinoma of the cervix or vagina. The pylorus, sigmoid colon, rectum, gall bladder, breast and kidney are possible sites of primary growth. The lymphatic channels and blood vessels facilitate the spread of ovarian cancer. Box 7.8 outlines the international classification of ovarian cancer.

Ovarian cancer is histologically classified according to the type of cell from which it originates, the most common source being surface epithelium, formed from embryonic mesothelium. Three types of tumour may develop:

- serous (tubal)
- endometrioid (endometrial)
- mucinous (endocervical).

Serous papilliferous carcinoma The malignant serous tumour is the commonest type of primary ovarian cancer and often affects both ovaries. The growth penetrates the capsule of the ovary and projects on the outside surface. Tumour cells are disseminated into the peritoneal cavity to form multiple seedling metastases. In most cases there is rapid spread in the peritoneal cavity secreting excessive amounts of fluid into the abdominal cavity.

Serous papilliferous cystadenoma The cysts of this serous new growth contain many papillary processes and are lined with a single layer of cubical epithelium on a vascular connective tissue base. The epithelium resembles that of the fallopian tube, the cells being ciliated.

Mucinous cystadenoma Mucinous tumours are formed from columnar epithelium, similar to the tissue of the endocervix. The tumours are described as multilocular, consisting of several cysts clustered together and separated from each other by a septum. The cysts have mainly fibrous tissue walls and contain viscid mucin, a glycoprotein. This tumour can grow to a very large size.

Mucinous cystadenomas may rupture spontaneously or be damaged during surgery, spilling epithelial cells into the peritoneum where seeding and further growth occur, with secretion of mucin forming a jelly-like mass in the abdominal cavity.

Mucinous carcinoma Approximately 10% of ovarian cancer is classified as mucinous and 5% of mucinous cysts are found to be malignant (Lewis & Chamberlain 1995). Many of these tumours are identified at an early stage of growth, which gives a better prognosis for the patient.

Endometrioid carcinoma In the ovary, this type of cancer resembles adenocarcinoma of the endometrium of the uterus. The tumour consists of tubular gland cells as found in the endometrium. It may be secondary to uterine disease or a primary ovarian growth that coexists with cancer in the body of the uterus.

Germ cell tumours Similar tumours may arise in the germ cells of either gender and may be benign or malignant. Benign conditions are very common; malignancy is rare. The commonest type of germ cell tumour is the dermoid cyst or cystic teratoma. Dermoid cysts usually occur in the ovary but are very rare in the testes; malignant teratoma is more common in the testes.

Amongst the malignant germ cell tumours, the highest incidence is of the dysgerminoma histologically resembling a seminoma of the testis. It shows large round cells separated by fibrous septa and is highly malignant, perforating its capsule and spreading cells into the blood and lymphatics.

MEDICAL MANAGEMENT

Ovarian cancer is insidious in its growth and the woman may be quite free from discomfort or suspicion of disease until an advanced stage. Approximately 70% of women have the disease diagnosed when it has spread beyond the ovaries (Blake et al 1998). Late symptoms are related to increased pressure in the abdominal–venous channels,

Box 7.8

International classification of ovarian cancer

Stage I	Disease limited to one or both ovaries
Stage II	Growth extending beyond the ovaries but confined within the pelvis
Stage III	Growth with widespread intraperitoneal metastases
Stage IV	Cases with other distant metastases and/or parenchymal liver involvement

causing oedema in the legs and pain from pressure on nerves to the legs. Metastatic growth in the peritoneum will contribute to extensive ascites, abdominal pain, frequency of micturition, nausea, vomiting, emaciation and breathlessness. A thrombosis may form in an iliac vein or in the inferior vena cava. If growth has spread to other organs then other symptoms may occur, such as obstruction of the small bowel or the colon.

Investigations A full pelvic examination is necessary, with palpation of the ovaries. Ultrasonic scanning and laparoscopy are useful diagnostic procedures. A Pap smear may show ovarian malignant cells in a specimen taken from the posterior fornix of the vagina. X-rays of the pelvis and vertebrae may show bony metastases. An intravenous pyelogram may be performed to assess the degree of involvement of the urinary system. A ureter may become obstructed, hydronephrosis occurring. A full blood count and serum biochemistry are included in investigations and tumour markers have a place in diagnosis. Ovarian tumours are always surgically removed. It is important that the ovary and peritoneal cavity should be fully assessed to define the spread of the disease.

Treatment When malignant disease of the ovary is diagnosed, both ovaries need to be removed and total hysterectomy completed. The tumour may involve the peritoneum and other organs. As much malignant tissue as possible will be removed. The infracolic omentum is removed since it is a common site for microscopic disease (Blake et al 1998). Adjuvant chemotherapy is normally given except in early stages of the disease. Radiation is generally confined to palliation. In advanced states, palliative treatment only may be possible. Abdominal paracentesis may be performed to relieve the pain and respiratory distress caused by ascites. Hospital admission is arranged as needed to make patients more comfortable. They may be cared for in a hospice or live their last months with their families at home.

NURSING PRIORITIES AND MANAGEMENT: Ovarian cancer

In addition to physical care, the patient with ovarian cancer will need much psychological support from the nurse. Anxieties associated with investigations, diagnosis and the effects of hysterectomy and cytotoxic drug therapy will need to be anticipated and managed in all aspects, as described earlier in the chapter. The patient may make a full recovery quite quickly or, if secondary disease remains, may be debilitated for longer. She may or may not be aware of the seriousness of the cancer condition, as full details of the illness may have been withheld in her best interests. However, openness is generally found to be more helpful for both the patient and her carers (Glaser & Strauss 1965, Hinton 1980, Knight & Field 1981, McQueen 1997).

The nurse will work towards helping the patient make physical and emotional adjustments. Attention will be given to the relief of pain, nausea and vomiting after surgery and chemotherapy. As physical problems are relieved, the patient may cope better emotionally, but in terminal cases, time is needed to adjust to the sad news. If a warm, trusting relationship has been developed with the nurse at the acute stage of treatment, it will sustain the patient who needs to return to the ward to continue with cytotoxic drug therapy or for palliative paracentesis. This can be emotionally demanding for the nurse but can also provide immense satisfaction, and patients appreciate the time and individualised attention given to their emotional needs (McQueen 1995). In caring for terminally ill patients, the nurse's empathetic feelings extend to the patient's family, and part of holistic patient care incorporates the giving of information and support to the relatives (McQueen 1997).

OTHER GYNAECOLOGICAL DISORDERS

Displacements of the uterus

The basic criterion of uterine normality is mobility rather than position. The cervix is laterally anchored but the fundus is free to move widely in an anteroposterior position. If the long axis of the endometrial cavity is hinged forwards in relation to the cervical canal, the body of the uterus is anteflexed in relation to the cervix. Similarly, if the long axis of the endometrial cavity is hinged backwards in relation to the axis of the cervical canal, then the body of the uterus is retroflexed in relation to the cervix (see Fig. 7.8).

Careful assessment of the position of the uterus is necessary to prevent perforation of the uterus during diagnostic or therapeutic curettage.

Cervicovaginal prolapse

The cervix can become prolapsed and elongated by the opposing forces of pull of the transverse and uterosacral ligaments against prolapsed vaginal walls. The cervix prolapses but the uterus stays in the pelvis.

Anterior vaginal wall prolapse

- *Cystocele* — the upper part of the vaginal wall prolapses due to underlying failure of the fascia and the bladder base descends.
- *Urethrocele* — the lower part of the vaginal wall prolapses and the urethra descends. This is caused by stretching of the urogenital diaphragm, which holds the urethra to the pubic bone.

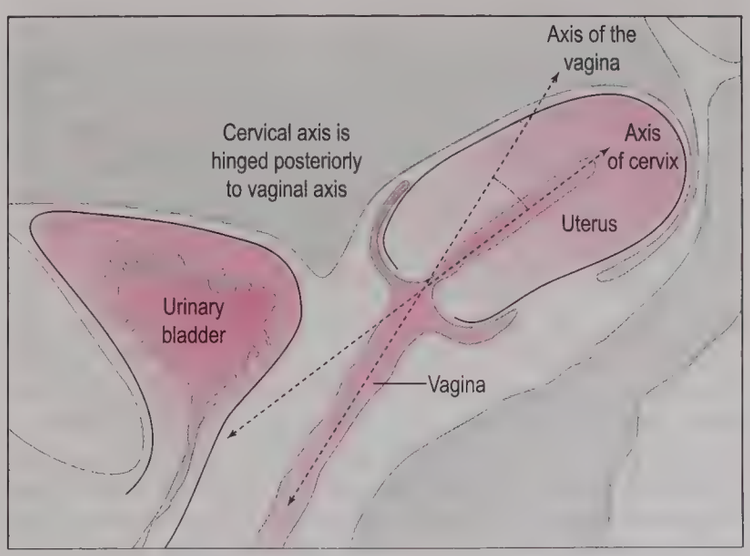

Fig. 7.8 The retroverted uterus.

Posterior vaginal wall prolapse

- *Rectocele* — if the prolapse is at the level of the middle third of the vagina, the retrovaginal septum is involved and the rectum prolapses with the vaginal wall. If the lowest part of the vaginal wall prolapses, the perineal body is involved rather than the rectum.
- *Enterocele* — if the upper part of the posterior vaginal wall prolapses, the pouch of Douglas is elongated and the small bowel or omentum may descend.

Both anterior and posterior vaginal walls may be involved in the prolapse. When a cystocele is present, bladder emptying tends to be incomplete, causing hypertrophy of the bladder. The uterus may become distorted, leading to reflux of urine and, ultimately, hydronephrosis. Urinary tract infection is inevitable and this contributes to hypertension and raised blood urea levels in women with prolapse.

Uterovaginal prolapse

When the ligaments and muscles supporting the uterus and vagina become ineffective, the genital tract descends, prolapses or herniates through the gap between the muscles of the pelvic floor.

The uterus descends in the axis of the vagina taking the vaginal wall with it. This prolapse is essentially but not exclusively a postmenopausal condition.

Three degrees of uterine prolapse are described:

- *first degree* — the cervix is still within the vagina
- *second degree* — the cervix appears at the introitus
- *third degree* — the uterus and vagina are completely prolapsed and lie outside the vulva. Rectal prolapse may also occur. This is sometimes called complete 'procidentia' or 'vault prolapse'. The vaginal rugae are smoothed out, and the epithelium becomes thickened and keratinised. The uterus becomes dry, sore, swollen, inflamed, congested and ulcerated from contact with clothing. Contributing factors are:
  - — stretching of muscle and fibrous tissue from repeated child-bearing. It is suggested that it is due to the action of progesterone relaxing muscles during pregnancy
  - — injury to the muscles of the pelvic floor during childbirth
  - — constitutional predisposition to stretching of ligaments with the long-term maintenance of an upright, erect body position that strains the transverse ligaments (the chief support of the uterus)
  - — increased intra-abdominal pressure, as experienced by obese women with a chronic cough or those engaged in heavy industrial work.

MEDICAL MANAGEMENT

History The woman is likely to be overweight and suffer from backache. She is aware of feelings of the internal organs coming down at a time when she is in an upright position. This is relieved by lying down or resting. Pelvic venous congestion occurs and the abdominal contents exert pressure on the inadequate, weakened pelvic floor. There is frequency of micturition, incomplete bladder emptying and the residual urine is a focus for infection. Stress incontinence may be a major problem for some women (see Ch. 24). There may be difficulty in voiding urine and in defaecation. The cystocele or rectocele may have to be supported or pushed upwards vaginally before urine can be passed or the bowel evacuated. Physical movements become difficult and uncomfortable.

Examination Severe prolapse may be diagnosed by inspecting the vulva with the patient lying on her back and straining downwards. A vaginal speculum is used to allow direct vision of a prolapsed anterior vaginal wall and any rectocele or enterocele formed by a prolapsed posterior vaginal wall. A rectal examination is needed to confirm the latter type of displacement. The degree of uterine prolapse is usually assessed before surgery when the patient is anaesthetised.

Investigations Apart from an EUA, no routine procedures are necessary to assist with diagnosis of uterine displacement. Preoperative assessment will usually involve a full blood count, urinalysis, and a midstream specimen of urine for culture and sensitivity. Other procedures, such as a chest X-ray, ECG or blood chemistry estimation, may be necessary to assess the patient's general medical fitness for surgery.

Treatment Surgical treatment is curative for prolapse but a small number of women may be unfit for surgery due to advanced age or poor physical condition. The uterus may be supported by the use of a ring pessary made from polyethylene or flexible vinyl. Such pessaries may have the disadvantage of acting as a foreign body in the vagina, causing some local inflammation. Pessaries are changed every 4–6 months when the vaginal walls can be examined for inflammation or ulceration. A course of vaginal oestrogen may be prescribed to diminish atrophic changes, inflammation, infection and discharge.

Surgery to conserve the uterus If there is only a first-degree descent of the uterus or if the woman prefers to retain her uterus, although prolapsed, then the Manchester (Fothergill) operation is performed. This involves partial amputation of the elongated cervix and the joining of the cut transverse cervical ligaments to the stump of the cervix. The shortened ligaments antevert and elevate the uterus. The vaginal walls are repaired as necessary.

Repair of uterovaginal prolapse Reconstruction of the pelvic floor involves restoring the pelvic aperture to its previous competent state. This is achieved by bringing together skeletal muscle between the anus, vagina and bladder, and approximating the medial borders of the pubococcygeus muscles. Childbirth can result in supporting structures being torn, separated and overstretched. These structures are identified at operation and reconstructed. An elongated cervix may be amputated. The fascia supporting the bladder and bladder neck is tightened across the midline. The parametrial tissues supporting the uterus are shortened to raise the uterus to its normal position.

Repair of cystocele is known as anterior colporrhaphy, supporting the urethra and urethrovesical junction. A rectocele is repaired by a posterior colpoperineorrhaphy, the repair of the perineal body. Bladder, perineum and vulva have an excellent capacity for repair, related to a rich

blood supply and good venous drainage. Surgery is usually very successful.

A complete uterine prolapse will usually be treated by hysterectomy.

NURSING PRIORITIES AND MANAGEMENT: Displacements of the uterus

Preoperative care

Preoperative assessment and care of patients for gynaecological operations has been fully described earlier in the chapter. Care is always individualised according to needs, but some problems and interventions are similar.

- *Information.* Information about procedures before and after the operation, in order to increase patient understanding and cooperation and to reduce anxiety and risk of venous stasis are required.
- *Potential embarrassment.* A woman admitted for repair of prolapse may experience embarrassment in having to identify that she has a problem of stress incontinence requiring her to wear some form of protection. The nurse will ensure that her special requirements are met discreetly.
- *Evacuating the lower bowel before surgery.* According to the surgeon's requirements, the patient will be given two rectal suppositories or an evacuant enema on the evening before the operation day.
- *Preparing the operation site.* An antiseptic vaginal douche can reduce the numbers of bacteria inhabiting the area and inhibit their multiplication, allowing healing of the vaginal wounds without infection.

Postoperative care

- *Risk of strain on internal suture lines from a full bladder.* An indwelling catheter is required and a continuous urinary drainage system is maintained. Precautions are taken to prevent the introduction of infection when collecting specimens or changing drainage bags.
- *Loss of bladder tone.* This is possible after catheter removal. Catheterisation is completed after the patient has passed urine once daily to assess the level of urine retained in the bladder. A residual urine of less than 60 mL is satisfactory.
- *Risk of wound infection.* The use of a bidet for perineal toilet twice daily can minimise the risk of infection.
- *Constipation.* This will potentially cause strain on the repaired posterior vaginal wall. A stool-softening agent can be prescribed to promote easy bowel evacuation.
- *Strain on healing ligaments and muscles.* The patient is advised to avoid jarring or lifting activities for 2 months.
- *Pre-discharge counselling.* An opportunity is created for the patient to discuss her feelings and worries about the level of recovery from surgery, bladder functioning, future return to sexual activity and work. An appointment is given for a medical follow-up in the outpatient department. The patient is given the name of the nurse to contact in the ward if further advice is needed.

Salpingitis

Infection of the fallopian tubes, salpingitis, usually affects both tubes simultaneously. It may result from an ascending infection from the vagina, cervix or uterus or it can occur directly from appendicitis, a pelvic abscess or bowel inflammatory disease such as diverticulitis. The ovaries may also be involved in the inflammatory process. Salpingitis may therefore be part of generalised pelvic inflammatory disease (PID).

Acute salpingitis may follow childbirth, abortion, diagnostic or operative procedures involving the uterus, or the insertion of intrauterine devices.

PATHOPHYSIOLOGY

Ascending infection of the fallopian tubes through the vagina, cervix and uterus is most commonly caused by the organism *Chlamydia trachomatis*. Gonococcal infection, which is sexually transmitted, may also be the cause. Streptococcal and staphylococcal organisms are associated with salpingitis following abortion, childbirth or the insertion of an intrauterine device. These causes may reflect reactivation of pre-existing disease. Intestinal tract commensals, *Escherichia coli* or *Streptococcus faecalis*, may be involved if the infection is linked to appendicitis or bowel infection. The blood-borne tubercle bacillus may unobtrusively inflame the reproductive organs.

The fallopian tubes become engorged and swollen, possibly filled with a seropurulent exudate. Epithelium cells are shed, damaging the delicate ciliated, transporting function of the tubes.

Common presenting symptoms The patient experiences a generalised feeling of being unwell, with:

- raised body temperature and associated sweating
- nausea
- vomiting
- aching joints
- severe pelvic and abdominal pain
- dyspareunia.

MEDICAL MANAGEMENT

Salpingitis may be identified for the first time at laparoscopic surgery, the tubes observed as red, oedematous, distended and blocked. Adhesions may form between the fallopian tubes and other pelvic structures and peritonitis may be evident.

Abdominal and vaginal examinations identify tenderness over the cornua of the uterus. Vaginal discharge may not be observable if the salpingitis has been from lymphatic spread and the muscle of the fallopian tube is mainly involved in the inflammatory process. Infection spread via the mucous membrane of the genital tract will affect the lumen of the fallopian tube, creating a purulent, foul discharge that is drained through the vagina. Scar tissue may form, causing narrowing or closure of the fallopian tube and the severe complication of sterility may result. Adhesions may form between the inflamed tubes and the peritoneum. Peritonitis may occur if pus leaks out of the tubes into the peritoneal cavity. Rarely, a pelvic abscess may form in the rectovaginal pouch or abscesses may form on the ovaries.

Investigations High vaginal or cervical swabs of discharge are pathologically investigated. Throat, urethral and rectal swabs may be taken. During surgery, exudates from the fallopian tubes or the pouch of Douglas may be obtained. Causative organisms are identified by cell culture or antigen detection, using immunofluorescence or enzyme immunoassay. Examination for specific antibody may assist in diagnosis. The antibiotic sensitivities of organisms are established.

Diagnosis may be confirmed by laparoscopy.

Treatment Antibiotic therapy is administered at the earliest opportunity. Analgesic medication will be necessary. Paracetamol, pentazocine or pethidine may be used at different levels of assessed pain severity.

Patients appreciate rest in bed in the acute phase of the illness. An upright position is considered helpful to promote simple downward drainage within the abdominal cavity, towards the uterocolonic pouch of Douglas, reducing the possible spread of infection to structures nearer to the diaphragm. Salpingitis may follow a chronic course and surgical removal of fallopian tubes, ovaries and uterus may be necessary.

NURSING PRIORITIES AND MANAGEMENT: Salpingitis

Nursing care will be organised to relieve the patient's pain, pyrexia and associated sweating, nausea, vomiting and potential dehydration. Analgesics and antibiotic drugs are administered as prescribed. Increased amounts of fluid, 3–4 L in 24 h, will require to be taken orally, or intravenously if vomiting is a problem. When the patient's pain is more tolerable, she may appreciate tepid sponging and a change of linen as a general comfort measure and to reduce body temperature. The doctor will usually explain to the patient the extent of her problem and the treatment given. In addition to giving information, a counselling approach may be helpful in giving support while encouraging the woman to look to the future. Information will need to be shared with her about the prevention of infection, the risk of infertility and the possibility of an ectopic pregnancy following salpingitis.

PATHOPHYSIOLOGY

A fallopian tube may fail in its usual function of transporting a fertilised ovum to the uterus, and the ovum will then implant in the tube. This delayed passage of the ovum, or obstruction, may be due to a deficiency in peristaltic movement, damage to the ciliated epithelium, a developmental abnormality or adhesions from an earlier inflammation. The trophoblast erodes through the epithelium and connective tissue, embedding itself in the muscle wall of the tube, where the pregnancy develops and erodes into blood vessels, causing bleeding around the embryo and into the muscle wall. Increased tension in the tube may lead to rupture.

Common presenting symptoms The woman experiences the early indications of pregnancy: amenorrhoea, breast changes, early-morning sickness and frequency of micturition. Amenorrhoea may not occur in one-third of women with a tubal pregnancy and this may result in delayed diagnosis.

The trophoblast slowly erodes the tubal wall, which results in gradual or sudden rupture of the tube before the 10th week of gestation. The woman complains of spasms of abdominal pain that are not too severe at first. Shoulder pain may be experienced. This is referred pain from the diaphragm, which is irritated by blood in the abdominal cavity.

Tubal rupture causes severe localised pain, which is followed by intense, more generalised abdominal pain. The products of conception are expelled into the peritoneal cavity and there is haemorrhage from the tubal placental site. Uterine bleeding may occur at this time. The patient is in a state of shock, with rapid, feeble pulse rate, lowered blood pressure, sighing respirations and pallor — an acute abdominal emergency exists. Diagnosis of the condition is difficult because similar symptoms and signs may occur in other abdominal emergencies such as perforation of a peptic ulcer or torsion of an ovarian tumour.

MEDICAL MANAGEMENT

Investigations

Pregnancy tests Standard immunological pregnancy tests are not helpful as a tubal pregnancy may not produce enough hCG to give a positive result. Estimation of the b subunit of hCG in the serum is of greater value. Absence of b-hCG excludes pregnancy. A level of 6000 mIU/L suggests a normal pregnancy in the uterus, whereas a level below 6000 mIU/L suggests a tubal pregnancy or a missed abortion.

Ultrasound scanning By the sixth or seventh week of pregnancy, a gestational sac can be identified within the uterus on ultrasound scanning. From the sixth week onwards, it may be possible to show a gestational sac and fetal cardiac echoes outside the normal uterus, directly confirming an ectopic pregnancy.

Laparoscopy Direct vision of the fallopian tubes using a laparoscope allows diagnosis of an ectopic pregnancy when there is uncertainty in clinical diagnosis. Laparoscopy involves giving the patient a general anaesthetic, which should be avoided if there is the possibility that a pregnancy exists in the uterus. The use of hCG estimations and ultrasound scanning may reduce the need for patients to undergo laparoscopy.

Treatment An ectopic pregnancy always requires urgent surgical intervention. The damaged tube is usually removed. An unruptured ectopic pregnancy may be removed from a linear incision in the tube, ensuring conservation.

A ruptured ectopic pregnancy quickly produces a state of hypovolaemia in the patient and a blood transfusion is necessary. This will sustain the patient through surgery and partially relieve the hypotensive symptoms. Immediate surgery is essential even though the patient is in a poor physical condition. Improvement is speedy once the intraperitoneal bleeding is controlled.

The ruptured fallopian tube is removed but the ovary is conserved if possible. Recovery after salpingectomy is usually rapid and uncomplicated. Prompt surgery ensures

a low mortality rate from a ruptured ectopic pregnancy. A woman who has suffered one ectopic pregnancy is at risk of developing a similar pregnancy in the second fallopian tube. It is usual for the patient to be encouraged to be optimistic about the future and having a normal pregnancy by means of the remaining fallopian tube.

NURSING PRIORITIES AND MANAGEMENT: Ectopic pregnancy

Preoperative care

Risk of hypovolaemia

The nurse assesses and monitors the patient's physical state intensively from the time of admission to the ward. There are life-threatening concerns as the patient is at risk of hypovolaemic shock and cardiac arrest if the tubal pregnancy ruptures. Vital signs are recorded every 15 min. Problems of increased pulse rate, lowered blood pressure and the patient's pain experience are communicated to the doctor. A state of readiness is maintained to resuscitate the patient if necessary.

Pain

Pain is a major problem for the patient. It may be moderate, but may become intense and intolerable if the pregnancy ruptures through the tube, with bleeding and spillage of gestational sac fluid into the peritoneal cavity. Analgesia is given as prescribed.

Preparation for general anaesthesia

Emergency surgery will be planned. Fasting from food and fluid by mouth prior to laparotomy will be as described in Chapter 26. In the case of emergency surgery it is important for the anaesthetist to know the last time the patient ate or drank and of any vomiting. It may be necessary to introduce a nasogastric tube prior to surgery to reduce the risk of regurgitation and inhalation of gastric contents when the patient is anaesthetised.

Anxiety and the need for information

The patient may be fearful about the operation to come and distressed about losing a pregnancy. She will need information about the surgery and postoperative care, and needs to be encouraged to talk about any worries she may have. It is possible that she may be too weak to talk and the nurse must show empathy and understanding of the patient's feelings and concerns. The nurse may indicate that she will talk with the patient some time after the operation and that she will accompany her to the operating theatre and be responsible for her care when she returns to the ward.

Postoperative care

Postoperative care will be individualised according to patient need, but will follow the general principles of postoperative care described in Chapter 26. Her condition will begin to stabilise as soon as the ectopic pregnancy is removed and bleeding is controlled. Her main problems will be similar to those of other patients who have had abdominal surgery, when organs and the peritoneum have been handled by the surgeon and tissues have been cut through, as follows:

- *Change in vital signs.* The nurse monitors pulse rate, blood pressure and body temperature. Wound, drainage tube and blood loss from the vagina are observed for more than minimal drainage. Primary and secondary haemorrhages are risks. Wound dehiscence may occur. Any causes for concern will be shared with the doctor.
- *Postoperative pain.* The level of pain can be assessed using a verbal rating scale (VRS 1–10). Analgesics are prescribed and administered to control pain.
- *Post-anaesthetic nausea.* This problem may be prevented or treated by giving an antiemetic medication with analgesics as prescribed.
- *Fluid and electrolyte imbalance.* Intravenous fluid and electrolyte replacement therapy is administered as prescribed, until oral intake is resumed. Fluid intake and output are recorded.
- *Venous stasis and pressure-area damage.* The patient is actively encouraged to exercise her legs hourly whilst confined to bed. Assistance is given to change the patient's position every 2 h to protect pressure areas. A programme of early mobilisation will be introduced.
- *Personal care.* Whilst intravenous therapy is in situ, assistance will be given to maintain the patient's preferred standard of personal care until fully mobile.
- *Loss and grieving.* Time is planned for counselling the patient. She needs to know that she can talk about her feelings and express emotion freely. Information should be shared about the possibility of future pregnancies. Details of local support groups for those who suffer loss should be given.

Further considerations

Psychological support

A woman who is suffering a second ectopic pregnancy will become infertile. She may become emotionally distressed at any time during her hospital stay and may show behaviour associated with a crisis of loss and a grief reaction. She will need support whilst expressing her feelings of regret and possibly guilt. Both the nurse and the patient's partner may be helpful in assisting the woman to be realistic about future options and limitations. Some reorganisation of the woman's life will emerge as she accepts her inevitable situation.

Special services

As a result of media coverage, the public are now aware of techniques such as in vitro fertilisation (IVF) and embryo transfer into the uterus (ET) and the possibility of surrogacy for infertile couples. Nurses need to know about such special services and policies within their own units, so that they are informed and can respond to the patient with appropriate caution and discretion and refer enquiries to the patient's doctor.

FAMILY PLANNING SERVICES

Birth control was considered 'social' medicine prior to 1950 and responsibility for family planning advice was established within the Family Planning Association (FPA) and its

clinics. The National Health Service Reorganisation Act of 1973 made provision for free family planning advice within the NHS. The FPA clinics and domiciliary services were merged into the NHS in 1974, when a completely free contraceptive service became available at clinics and hospitals and was extended into primary care in July 1975 (Loudon 1985).

Free contraceptive services are now available from general practitioners, family planning clinics in hospitals and the community, and voluntary organisations such as the FPA and Brook Advisory Centres. The voluntary groups receive grants from central government or from purchasing health authorities.

All contraceptive supplies are available free of charge from family planning clinics, and GPs provide prescriptions, except for condoms. Male and female sterilisations are available free in NHS hospitals. Vasectomies may be performed in some large family planning clinics and by some GPs in the surgery. Item-of-service payments are made to GPs and hospital staff.

Postnatally, community midwives, health visitors and GPs routinely discuss birth control methods with the new mother. This is invaluable in reminding women of their fertility and the possibility of another early pregnancy if precautions are not taken when resuming sexual activities.

Women who discontinue attending the GP or family planning clinic may do so because they have changed their birth control method. Women who have completed their family may have chosen sterilisation or their partners may have chosen vasectomy for a permanent form of birth control. Others may be abandoning contraception because the time is favourable for them to begin a family.

The contraceptive needs of young people

Provision of extra contraceptive services for young people after puberty, under 16 years and up to 20 years of age, is controversial and, in the past, was given a low priority. With more recent concern about AIDS and HIV transmission, young people have been specially targeted for health education and advice about their sexual behaviour. Grimley and Lee (1997), in a study of 15- to 19-year-old American females, found that subjects perceived the male condom to be acceptable for both prevention of pregnancy and sexually transmitted diseases. The Contraceptive Choices Survey (Family Planning Today 1996) commissioned by the Contraceptive Education Service showed condoms to be the second most popular method of birth control. The most popular method of contraception, especially for younger women, is still the contraceptive pill, used by 43% of those aged 16–24 years. The combined pill of progestogen and low oestrogen is favoured for high contraceptive protection and ease of use.

ABORTION

The term 'abortion' refers to the premature delivery of a non-viable fetus, spontaneously or by induction. The term 'miscarriage' is sometimes used when the pregnancy loss is spontaneous and is a term generally considered to be more acceptable to women who lose a wanted pregnancy. Debate surrounds the issue of 'non-viability' and the accepted stage at which a fetus is considered viable or capable of independent existence varies between countries. In the UK, a fetus is considered viable from the 24th week of pregnancy. This viability is recognised and safeguarded in the Infant Life (Preservation) Act 1929 and its amendment under the Human Fertilisation and Embryology Act 1990. It has been proposed that the fetus should be deemed viable as early as 18–20 weeks because of the possibility that life-support equipment can maintain the vital functions of such a small fetus and it has been argued that technological advances in medicine have the potential for saving the life of an infant weighing as little as 500 g. Such debates continue, reflecting different social attitudes and scientific developments.

Abortion may be discussed in terms of:

- the level of certainty of the abortion occurring
  - — threatened
  - — inevitable
  - — missed
  - — induced
- the cause or relative incidence of the abortion
  - — spontaneous
  - — habitual (recurrent)
- the degree of success in expulsion of the products of the pregnancy
  - — incomplete
  - — complete.

Threatened abortion

PATHOPHYSIOLOGY

An abortion is presumed to threaten when a woman known to be pregnant develops vaginal bleeding during the first 24 weeks of pregnancy. Some lower abdominal pain related to uterine muscle contractions may be experienced at the time of bleeding, but there may be no uterine contractions and no pain. The blood loss may be brown or red.

It is not unusual for a show of blood to coincide with the woman's regular date of menstruation. This type of bleeding is due to the fertilised ovum becoming more deeply implanted in the uterine wall. There is little risk of loss of the pregnancy if the bleeding settles quickly (see Fig. 7.9A).

MEDICAL MANAGEMENT

The presence of bleeding, slight uterine contractions and a closed cervical os established by medical examination assist in identifying threatened abortion; 70–80% of women can be expected to continue to full-term pregnancies and give birth to a healthy infant.

Treatment While the woman is continuing to lose blood vaginally, rest in bed is prescribed to ensure that the best possible adjustments can be made within the uterus and to allow a better blood flow to the uterus. Bed rest is usually maintained as long as the blood loss is bright red. One week of bed rest may result in considerable improvement for the patient.

NURSING PRIORITIES AND MANAGEMENT: Threatened abortion

The patient will be very concerned about the possible loss of the pregnancy. This may result in tearfulness, anxiety,

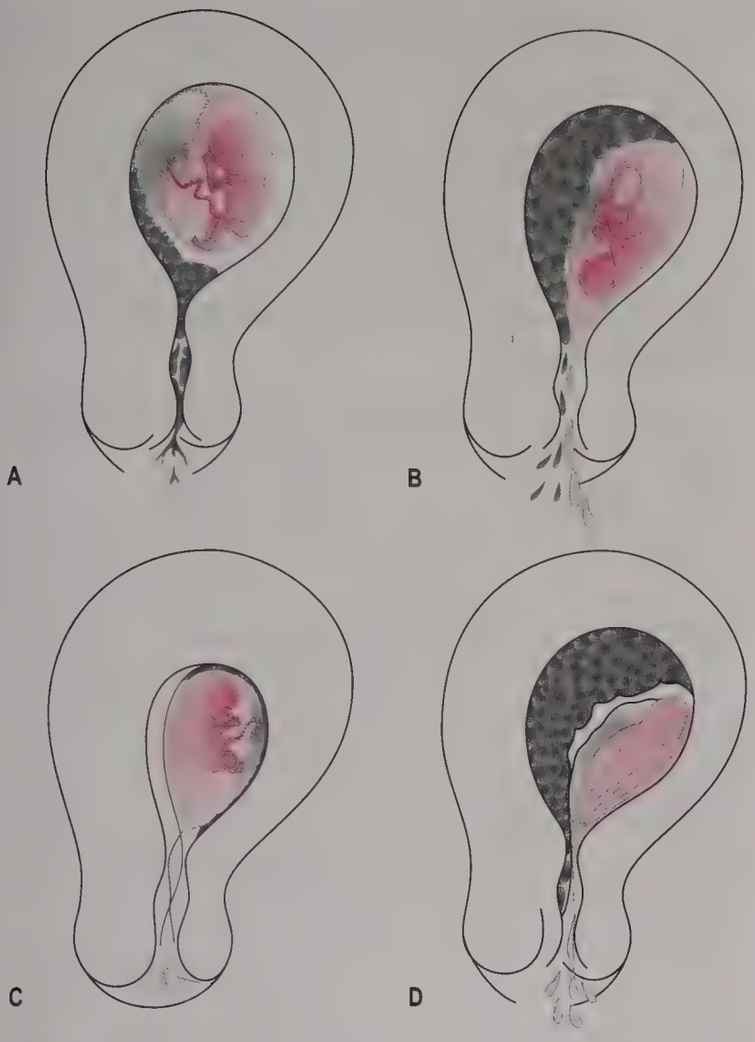

Fig. 7.9 The types of abortion that may be seen. A: Threatened abortion. B: Inevitable abortion. C: Missed abortion. D: Incomplete abortion.

irritability and feelings of frustration. The immediate and long-term future may be feared. The patient may be apprehensive of pain and uncertain of what to expect. Small doses of anxiolytic–sedative drugs and progesterone may be prescribed to encourage rest and to help sustain the pregnancy.

Nursing care will be planned with the goal of reducing anxiety and inducing relaxation in the patient. Vaginal bleeding will be observed and quantified. The patient's experience of abdominal discomfort or pain will be assessed and recorded. The supportive, counselling contact time with the nurse will be appreciated by the patient and her partner. When talking with the patient and partner, both doctor and nurse will usually refer to a threatened miscarriage of the pregnancy rather than using the term abortion.

Inevitable abortion

PATHOPHYSIOLOGY

A threatened abortion can progress to an inevitable abortion if bleeding continues. Inevitable abortions occur in 20% of all pregnancies. An abortion becomes inevitable, with no possibility of saving the pregnancy, when the following are present:

- vaginal blood loss
- strong uterine contractions
- pain
- dilatation of the cervix.

Contractions will increase, the fetal sac membranes will rupture and the uterine contents move through the cervical os. Part or all of the products of conception will be voided from the uterus (see Fig. 7.9B). An inevitable abortion may be complete if all products of conception are voided, or incomplete if some products are retained.

MEDICAL MANAGEMENT

The aborting process will involve blood loss. Estimation of blood loss, and assessment of pulse, blood pressure and appearance of the patient will indicate whether shock is developing. Blood transfusion may become essential and analgesic medication will be prescribed as necessary.

The fetus that has been expelled is retained and examined to assess whether the fetal sac and contents are intact or whether remnants have been retained. Ergometrine maleate 125–500 mg will be given intramuscularly or intravenously according to blood loss which will induce strong contraction of the myometrium, to exert and sustain pressure on the multiple open-ended blood vessels of the placental bed. Thus, bleeding will be controlled until the uterus itself reduces size gradually.

Ultrasonography can be useful to classify the type of abortion (complete, incomplete, missed, etc.) and, based on this, appropriate information can be given to the woman about the likely outcome and therapeutic options. If any of the products of conception are thought to have been retained, several treatment options may be available and it is recommended that women are involved in the choice of approach. The options are:

- surgical evacuation of the retained products from the uterus, an invasive procedure involving a general anaesthetic (GA)
- medical management that avoids a GA and invasive surgery
- expectant management ('wait and see'), whereby four out of five women with an incomplete abortion will complete their abortion within 14 days (Nielsen et al 1995).

NURSING PRIORITIES AND MANAGEMENT: Inevitable abortion

Assessments of vaginal blood loss may need to be maintained for a further period of 12 h. When the effects of ergometrine diminish and the uterine muscle relaxes, blood vessels open up and bleeding and blood clots continue as problems. Further doses of ergometrine, in tablet form, may then be prescribed to control the bleeding and expel blood clots. The blood clots will cause further pain for the patient until they are finally voided from the vagina.

The patient may be distressed by the blood loss, pain, sight of the fetus and the anguish of losing a pregnancy to which she had become emotionally attached. She is likely

to experience considerable physical and emotional distress and will need the nurse to be readily available to support, reassure, comfort and assist her through the procedures and experience of pregnancy loss. The patient will need to have the opportunity to talk about her feelings of loss. In this respect, time and empathy from the nurse will be appreciated (Leask 1991, Nazarko 1992). It may be that she has already had a previous miscarriage and will also be recalling that experience as part of her grieving process. The patient's sadness may be sustained for many months after the abortion occurs. To plan some continued support, the nurse in hospital can refer the patient to the community midwife, who is able to provide bereavement counselling until resolution of the grief reaction takes place.

Missed abortion

PATHOPHYSIOLOGY

The term 'missed abortion' describes the intrauterine death of a fetus that has not been expelled. The size of the uterus fails to increase over a 2-month period and the expected signs of a normally developing pregnancy will be missing. The death of the fetus may occur at any week of gestation. Some placental tissue survives to produce progesterone and prevent expulsion (see Fig. 7.9C).

MEDICAL MANAGEMENT

The woman may have experienced movements of the fetus in the uterus, but later reports that recently she has not felt the baby kicking. The doctor will no longer be able to hear the fetal heart beat on auscultation of the abdomen. The uterus may seem to have increased in size due to increased fluid level in the uterus, known as 'hydramnios'. The patient may state that she feels empty and has lost feelings of being pregnant. She is asked to record on a chart any sensation of the baby moving or kicking.

Investigations An ultrasound scan of the uterus and a cardiotocograph reading will assess the status of the fetus and the position of the placenta.

Treatment The diagnosis of a missed abortion will require the doctor to decide whether to allow some time for the fetus to be aborted spontaneously as a natural labour response or whether to evacuate the uterus immediately after diagnosis. The decision may be to let nature take its course and wait for labour to begin. However, the doctor is also likely to take account of the preference of the woman, who has already had to adjust to the loss of the pregnancy and may be further distressed by the dead baby within her.

A risk exists, with missed abortion, that hypofibrinogenaemia will occur. One-third of patients may develop defective blood coagulation due to lowering of fibrinogen levels. Death of the fetus leads to major utilisation of clotting factors at the placental site, and this reduces clotting factors in the woman's blood. Disseminated intravascular coagulation (DIC) is the mechanism that is said to bring about the change in the woman's systemic circulation from the release of thromboplastins at the site of the damaged placental tissue.

The missed abortion may be evacuated from the uterus by vacuum extraction under general anaesthetic if the pregnancy was less than 12 weeks. Chia and Ogbo (2002) acknowledge that this procedure does have a morbidity and mortality and suggest that medical evacuation using mifepristone and misoprostol is a safe and effective alternative for patients who do not require a hospital admission, general anaesthetic and surgery. Gronlund et al (2002) found that misoprostol, alone, effectively induced labour in most patients with missed abortion.

NURSING PRIORITIES AND MANAGEMENT: Missed abortion

A counselling approach will be necessary to provide the patient with opportunities to express her needs and feelings freely.

If evacuation of the uterus under general anaesthetic is planned, the patient will need the usual pre-anaesthetic care in terms of fasting, a shower, and precautions against mis-identification and maintenance of personal safety (see Ch. 26). Following treatment, observations of vital signs and vaginal blood loss will be required to assess recovery.

If the products of conception are to be evacuated, the products of pregnancy should be expelled 4 h later. The nurse must be available to observe the patient's vital signs and need for pain relief. The patient may experience side-effects of nausea, vomiting or diarrhoea, but these are usually transitory. The presence of the nurse can be comforting to the patient, reducing feelings of isolation while treatment progresses.

The way in which individual patients cope emotionally is unpredictable, but the nurse can anticipate that any patient may feel sad and angry about the lost pregnancy. Follow-up counselling can be arranged by the nurse with the community midwife or health visitor, when the woman's level of adjustment can be assessed.

Spontaneous abortion

PATHOPHYSIOLOGY

A spontaneous abortion is a response to a naturally occurring phenomenon such as hormonal problems, uterine abnormality, cervical incompetence, a genetic malformation in the fetus or psychological factors. Pearce (1991) estimated that 25% of all pregnancies terminate in miscarriage in the first trimester; reasons include both fetal and maternal factors. Some women may not be aware that they have aborted a blighted ovum. Congenital abnormalities of the reproductive tract or long-standing medical problems may have an unfavourable influence on the pregnancy. Abortions in the early weeks of the second trimester of pregnancy are often found to be due to an incompetent cervix that responds to the increasing weight of the fetus. The cervical os dilates, the membranes rupture and the pregnancy is lost.

MEDICAL MANAGEMENT

To counteract recurrence of abortion, it is necessary to identify the pregnancy and any incompetence of the cervix at an early stage. In the case of cervical incompetence, a Shirodker's suture can be inserted surgically, closing the internal os, to increase the resistance of the cervix until the pregnancy reaches full term. When the patient goes into labour, the suture is removed to enable delivery to occur.

NURSING PRIORITIES AND MANAGEMENT: Spontaneous abortion

The physical care of the patient with a spontaneous abortion is similar to that of the patient with an inevitable abortion. The patient will normally be distressed by the loss of the pregnancy and will need psychological support from the nurse. A counselling approach to communication will encourage the expression of feelings. Continued support should be arranged by referral to the community midwife.

Habitual (recurrent) abortion

Recurrent abortion refers to a spontaneous abortion that occurs in three or more successive pregnancies. Many factors may contribute to recurrent abortion.

PATHOPHYSIOLOGY

Genetic, hormonal, anatomical, infectious and immunological factors have been implicated in the causation of recurrent abortion.

Tumbo-Oeri et al (2001), in a literature review on the state of thinking among researchers and clinicians on recurrent spontaneous abortion, suggest that there is evidence of involvement of immunological factors in successful pregnancies. However, the underlying mechanisms are poorly explained and largely speculative. They conclude that more focused investigation is required to provide a complete understanding of the mechanisms involved in recurrent pregnancy loss.

MEDICAL MANAGEMENT

Treatment Patients with immunological problems have been treated with leucocyte transfusions with successful results. Identified hormonal deficiencies are treated by replacement hormones, thyroid preparations and progesterone. Vaginal suppositories of progesterone 25 mg, twice daily, beginning 3 days after ovulation, are given and continued throughout the luteal phase, until the 10th week of gestation. At this time the placenta should be sufficient to maintain the pregnancy.

The administration of antibiotic medication is routine, where culture and sensitivity of organisms are known. Otherwise, the tetracycline group is given to offset an infective focus that might disrupt the pregnancy. Reconstruction surgery has achieved considerable success in treating structural abnormalities of the uterus and eventual successful pregnancies.

NURSING PRIORITIES AND MANAGEMENT: Recurrent abortion

Physical and psychological care are paramount at the time that the abortion occurs. Sensitivity in responding to the woman's needs is central. Potential for future assisted maintenance of a pregnancy will be fully discussed by the doctor and reinforced by the nurse. The patient who is anxious can be helped to learn relaxation techniques that may be used for self-induction of relaxation as an everyday activity, and one that can be practised in future pregnancies.

Incomplete abortion

An incomplete abortion is one in which only part of the products of conception are expelled from the uterus (see Fig. 7.9D).

PATHOPHYSIOLOGY

Portions of placenta and membranes are retained, some bleeding continues and could possibly be heavy.

MEDICAL MANAGEMENT

The residual products may be voided spontaneously by the patient but usually a dilatation and curettage is required to clear away the retained remnants of the pregnancy. Ergometrine 500 mg is administered intravenously to control uterine bleeding. Heavy blood loss will necessitate blood transfusion.

NURSING PRIORITIES AND MANAGEMENT: Incomplete abortions

The patient may experience continuous abdominal pain while the uterus retains products of conception. Nursing care involves the administration of analgesics as prescribed to reduce the discomfort, which may continue until the curettage is complete. Vaginal blood loss will need to be observed. Heavy, continuous blood loss may reduce the patient's circulating blood volume, resulting in signs of shock. Observations of vital signs will facilitate early recognition of shock and prompt correction of the condition by transfusion.

The patient will normally be worried about her condition and the operation planned and upset about the miscarriage. Adjustment to the loss will be gradual over time. Counselling time spent with the nurse may help to begin the adjustment process, and continuity may be gained by follow-up support from the community midwife or health visitor.

Induced abortion: termination (voluntary) of pregnancy

An unwanted pregnancy creates potential anguish and difficulties for a woman. She may experience feelings of conflict about both wanting and rejecting the pregnancy. She may fear having to explain it to her family and admit to sexual activities and her incompetence with contraception. Family standards of behaviour, cultural norms and religious beliefs may appear to be violated both by the pregnancy and by the possibility of an abortion. The woman may feel very alone, may be indecisive and under pressure from a partner who may reject the pregnancy. The conditions of the Abortion Act require decision-making to be completed early in the pregnancy.

The Abortion Act 1967 and 1990 amendments

In the UK, the Abortion Act 1967 became operative in 1968 and applies to England, Wales and Scotland but not to Northern Ireland. The Act states that the termination of pregnancy by a registered practitioner is not illegal under certain conditions. Notification of a termination must be given on a prescribed form to the Chief Medical Officer of the Department of Health within 7 days of the termination.

The Human Fertilisation and Embryology Act 1990 has amended the Abortion Act 1967, recognising viability of the fetus at 24 weeks.

Conditions of the Act and statutory grounds

A legally induced abortion must be:

- performed by a registered medical practitioner
- performed, except in an emergency, in a National Health Service hospital or in a place for the time being approved for the purpose of the Act
- certified by two registered medical practitioners as necessary on any of the following grounds:
  - — the continuance of the pregnancy would involve risk to the life of the pregnant woman greater than if the pregnancy were terminated
  - — the continuance of the pregnancy would involve risk of injury to the physical or mental health of the pregnant woman greater than if the pregnancy were terminated
  - — the continuance of the pregnancy would involve risk of injury to the physical or mental health of any existing child(ren) in the family of the pregnant woman greater than if the pregnancy were terminated
  - — there is a substantial risk that if the child were born it would suffer from such physical or mental abnormalities as to be seriously handicapped
- in emergency, certified by the operating practitioner as immediately necessary:
  - — to save the life of the pregnant woman
  - — to prevent grave permanent injury to the physical or mental health of the pregnant woman.

The conscience clause of the Abortion Act 1967

The Act states that no-one shall be under any legal obligation to participate in any treatment authorised by the Act to which he or she has a conscientious objection unless the treatment is necessary to save the life or prevent grave permanent injury to the physical or mental health of a pregnant woman.

The conscience clause does not only apply to members of a particular religion or faith. In England and Wales, a person must prove conscientious objection in the event of any legal proceedings. The clause also makes it explicit that the conscientious objector is not exempt from participation in the emergency care of the patient should such a situation arise. This is affirmed in the *Code of Professional Conduct* (NMC 2002).

Counselling of the pregnant woman requesting termination

In many hospitals the woman who requests a termination of pregnancy is referred to the Assessment and Counselling Service. The social worker seeks to understand what the pregnancy and termination mean to the woman, identifies any contraindications to termination and provides evidence for the final decision-making and the best solution.

It is valuable to interview couples together for counselling. Adolescent girls are often accompanied by parents who may be angry and rejecting of their daughter's pregnancy. The risk is then that the girl passively acts in accordance with her parents' wishes. The counsellor would usually speak with them together and then separately.

Counselling clarifies the woman's conflicting feelings about the pregnancy and strengthens her capacity to face up to her responsibilities. She may be more confident in making a decision in an unpressured atmosphere. The counsellor may have established that contraindications to the termination exist or that the request for termination be supported. In either case the information is made available to the gynaecologist. The counselling service ensures that adequate assessment and advice are provided for the woman who seeks a termination. It is suggested that in this way she will experience less regret, guilt or long-term psychological problems.

MEDICAL MANAGEMENT

Vacuum aspiration (suction curettage) This is the most commonly used abortion method for early termination of pregnancy. It may be performed with a general anaesthetic or a paracervical nerve block with lidocaine 0.5%. The cervix is dilated, a flexible cannula is inserted and the contents of the uterus are aspirated by suction. The uterus is then curetted to ensure total removal of the products of conception, and to reduce haemorrhage and the possibility of infection. Ergometrine 0.5 mg is administered intravenously to promote contraction and involution of the uterus.

Medical termination The main treatment schedule consists of oral mifepristone 200–600 mg followed by oral misoprostol 0.4–0.6 mg, 36–48 h later for pregnancies up to 49 days' gestation and vaginal gemeprost 1 mg or misoprostol 0.8 mg for periods of up to 63 days amenorrhoea (Bygdeman & Danielsson 2002).

Following administration of misoprostol the patient remains under observation for a further 6 h. The nurse monitors pulse, blood pressure, blood loss and other signs and symptoms experienced by the patient. The medical abortion is usually complete within 4–6 h. Anti-D Rhesus immunisation is given before discharge and an appointment is made for the patient to return in 5–9 days to assess the outcome.

While this method of terminating a pregnancy has its advantages — the woman can carry on her daily activities following administration of the tablets and there is no anaesthetic or surgical intervention — there are also potential problems of which the woman should be made aware. These include:

- a 5% chance that the termination will be unsuccessful/incomplete, resulting in the need for surgical abortion
- the possibility of pain following administration of gemeprost, necessitating powerful analgesics
- possible psychological distress for the woman seeing the expelled fetus.

Dilatation and evacuation of contents Abortion that is induced in the second trimester of pregnancy may be completed by dilatation of the cervix with graduated dilators. Preoperatively the patient may have a prostaglandin pessary to soften the cervix and facilitate easier dilatation. A curette is introduced into the uterus and the products

of conception and the superficial layer of endometrium are curetted or scraped from the walls of the uterus. Care is taken to avoid damage to the pregnant uterus. Ergometrine 0.5 mg is administered and few side-effects to the procedure are expected. Patients are followed up at the clinic.

Prostaglandin abortion Prostaglandin may be used in young women in the second trimester of pregnancy (13–18 weeks), when the cervix is soft and more easily damaged, or in older women when the pregnancy is beyond 18 weeks. Prostaglandin can be administered intravenously, extra-amniotically, intra-amniotically or in the form of pessaries. If pessaries are used these can be administered 4-hourly (maximum five doses). Abortion can take place within 12–20 h but this varies. Observations of pulse, blood pressure, blood loss, uterine contractions, cervical dilatation and any side-effects of the medication are noted and treated as appropriate. This more prolonged procedure causes more side-effects and can be more traumatic for patients. Psychological care and emotional support constitute an important part of their care.

Intra-amniotic injection The instillation of prostaglandins or other substances into the amniotic sac to induce labour and expulsion of the fetus may be used between the 14th and 20th week of pregnancy but this method carries a higher risk of complications.

Since there appears to be no consensus as to the most efficient method of procuring late abortions, Paz et al (2002) compared the efficacy of intra-amniotic injection of prostaglandin F2 alpha (PGF2alpha) and intravaginal application of misoprostol in terminating second trimester pregnancies after pretreatment with intracervical laminaria in a randomised trial. Laminaria primes the cervix, reducing resistance and minimising trauma. Following intracervical laminaria, vaginal misoprostol was more effective and less painful, compared with intra-amniotic PGF2alpha, for the termination of second trimester pregnancies with live fetuses.

NURSING PRIORITIES AND MANAGEMENT: Termination of pregnancy

Preoperative care

The procedure is generally completed on an outpatient basis or as a day patient in hospital. There is only a short time available for the nurse to build a relationship with the patient whilst documentation is completed. Every effort must be made to show acceptance of the woman and understanding of the difficulties she has been experiencing. Opportunities must be created for her to express her feelings as she wishes and the nurse should be available to listen. A consent form is signed for the termination and consent for anaesthetic is given. Blood tests such as haemoglobin and haematocrit, ABO grouping and the Rhesus factor are necessary precautions prior to the procedure.

Postoperative care

Vital signs related to bleeding and abdominal cramping pain must be observed by the nurse. Inspection of vulval pads will indicate the degree of blood loss. Heavy bleeding will usually require further administration of ergometrine to sustain contraction of the uterus and to evacuate blood clots. Pyrexia may indicate the onset of infection. Mild analgesics may be ordered to relieve cramping pain and also for their antipyretic properties. Women with Rhesus-negative blood require an injection of anti-D immunoglobulin.

The patient is advised to avoid the use of tampons, douching, strenuous activities or sexual intercourse for 2 weeks to reduce the risk of infection and aid healing. The patient's contraception methods are reviewed with her so that any changes needed are understood and appropriate decisions made. A follow-up outpatient examination is completed 2–3 weeks after the abortion to exclude the possibility of a failed abortion, an ectopic pregnancy or other complications. It also allows for an assessment of the patient's acceptance of and comfort with her decision to terminate. Relief is often expressed. Sadness, regret and depression are sometimes short lasting but at other times prolonged. The patient's relationship with her sexual partner may also be discussed; it may have been strengthened or weakened by the abortion experience. Referral to a postabortion support group may be helpful, if there is one active in the area.

Complications of abortion/pregnancy termination

- Pelvic infection — inflammation of the endometrium (endometritis) and fallopian tubes (salpingitis) may occur
- Perforation of the uterus — may occur accidentally during insertion of cannula or use of the curette
- Haemorrhage — bleeding should not be more than a normal menstrual period
- Laceration of cervix, cervical incompetence and recurrent abortion
- Ectopic pregnancy — related to previous salpingitis
- Incomplete removal of uterine contents
- Hydatidiform mole
- Delayed menstruation
- A live fetus at the time of delivery
- Possible susceptibility to subsequent pregnancy loss and premature births
- Infertility.

With improved services, the numbers of complications to abortion can be greatly reduced. Effective networks of outpatient facilities with good access, to avoid delays in uptake of services and reduced travel for women in need, should be the aim of authorities responsible for service provision.

CHILDLESSNESS

While some couples living together choose not to have children, the majority clearly do raise a family. For many people this is an important role, and when childlessness is a reality it brings disappointment. In addition, many other feelings, associated with social and cultural expectations and religious beliefs, may be experienced.

Barbour (1997) suggested that, until recently, much attention relating to treatment and counselling in this area has been directed towards women. Her experience with infertile couples, however, suggests that the feelings and reactions of men also require to be addressed. Mason (1994) also

recognised the significance of fatherhood in the context of male infertility. Hjelmstedt et al (1999) found that women reacted more strongly to their infertility than men but distress experienced by men concerned their male role and the social pressure to become a parent.

Some couples choose not to have children in the early years of their relationship but later may experience difficulty in conceiving. It is well documented that one in six couples will seek specialist help for a fertility problem (Winston 1991, Templeton 1992). In one-third of couples experiencing subfertility, the problem lies with the woman, in one-third with the man and in the remaining third both the man and the woman contribute some causative factor (see Tables 7.1 and 7.2).

The provision of general facilities to investigate and treat subfertility and to assist in conception are well established at the endocrinology and gynaecological surgery level in the NHS, but the specialist in vitro fertilisation services have been slow to develop, hampered by lack of finance. This has led to an increase in the fertility business in private health care. The need for subfertility services is expected to grow due to the trend towards later first pregnancies and an increasing number of remarriages. Demand is increased due to raised public awareness of treatment possibilities (Effective Health Care Consortium 1992).

Childlessness is deliberately maintained in women who use birth control methods. This is regarded as voluntary childlessness. Sterility refers to an absolute factor preventing procreation in either the man or the woman. The condition may be induced by ligation and separation of the fallopian tubes or by vasectomy.

Subfertility

A couple is said to be subfertile if there is a lack of conception after a 12-month period of unprotected sexual intercourse (Thonneau et al 1991). Primary subfertility refers to those cases where a pregnancy has never occurred, and secondary subfertility to those cases where there has been a previous pregnancy, irrespective of the outcome. The literature suggests that 10–15% of couples have difficulty conceiving or having the number of children they want and seek fertility services (Evers 2002, Kolettis 2003).

The principal causes of subfertility are shown in Tables 7.1 and 7.2. In some couples there will be more than one cause of subfertility. In 5–10% of cases after thorough investigation the cause of the infertility is unexplained (Adamson & Baker 2003). As diagnostic testing becomes more accurate, the proportion of unexplained cases of subfertility may decrease. The contribution of psychological factors to prolonged subfertility is not yet clearly established by research. A small proportion of cases of subfertility may be preventable, particularly tubal damage associated with sexually transmitted diseases.

MEDICAL MANAGEMENT

The diagnosis and management of subfertility is complex. The couple may require to undergo a variety of tests and investigations which can cause embarrassment and stress (see Tables 7.1 and 7.2).

Female subfertility

Female subfertility may be due to failure to ovulate, irregular egg release from the ovary, obstructed fallopian tubes, hostile cervical mucus, endometriosis or uterine conditions which inhibit implantation.

Ovulation disorders

These are among the commonest causes of subfertility (Power 2001). Failure to ovulate is linked with the functioning of hormones from the hypothalamus, pituitary and ovary (HPO axis). Anovulation is categorised into five groups:

- Hypergonadotrophic hypogonadism — elevated FSH and LH to within the accepted menopausal range; no response to ovulation induction.
- Hypogonadotrophic hypogonadism — hypothalamic suppression of gonadotrophin-releasing hormone (GnRH) release causes very low levels of pituitary gonadotrophin and results in suppression of ovulation.
- Eugonadotrophic hypogonadism — functional disturbance of the HPO axis, generally with oligomenorrhoea.
- Polycystic ovarian disease — small cysts on the ovarian surface coupled with hormonal imbalance. Multiple small follicles partly develop but none reaches maturity.
- Hyperprolactinaemia — high levels of prolactin suppress pulsatile secretion of GnRH and oestradiol production mediated by LH.

Treatment seeks to remedy problems arising from imbalances in the HPO axis. Ovulation induction is aimed at encouraging development of one follicle, leading to a single pregnancy. Clomiphene citrate can be used in women with eugonadotrophic hypogonadism or polycystic ovaries. This anti-oestrogen stimulates gonadotrophin release by inhibiting the negative feedback of gonadal steroids on the hypothalamus.

Treatment should commence in the early follicular phase. In amenorrhoeic women or those with severe oligomenorrhoea, treatment begins after an induced withdrawal bleed. Generally 50 mg clomiphene is administered daily for 5 days. Ovulation is expected 5–10 days after the last clomiphene tablet and intercourse is best timed between days 10 and 16. In successive anovulary cycles, clomiphene can be increased by 50 mg/day to a maximum of 200 mg/day.

For women who do not respond to clomiphene therapy, human menopausal gonadotrophin (hMG) may be used for direct ovarian stimulation. Careful monitoring of the dose is required to reduce the risk of multiple pregnancy.

Pulsatile GnRH is a suitable therapy for women with hypogonadotrophic hypogonadism. This is administered as a pulse dose via an infusion device and stimulates pituitary gonadotrophin release, resulting in the menstrual cycle with positive and negative feedback loops.

Elevated prolactin levels can result in chronic anovulation by inhibiting GnRH release and LH-mediated oestradiol production. Bromocriptine, a powerful dopamine agonist, inhibits prolactin release and may therefore be a therapy considered for such patients.

Table 7.1 Subfertility: summary of causes, investigations and treatment in women

Causes	Investigations	Treatment
Disorders of ovulation		
Stein–Leventhal syndrome Failure of one or both pituitary gonadotrophins (trauma or vascular disorder) Failure of hypothalamic releasing factor (stress, anorexia nervosa) Primary ovarian failure Tumours of ovary Cysts of ovary Endometrial hyperplasia (causing upset ovarian function) XO karyotype Drugs — post-pill amenorrhoea, phenothiazines, tricyclic antidepressants Adrenal dysfunction Thyroid, hyper- and hypothyroidism	• History • Examination (bimanual) • Skull X-ray • Endometrial biopsy, histology and culture • Plasma progesterone level • Urinary oestrogens level • Ovarian biopsy • Cervical mucus specimen (can be used as a parameter of ovulation) • Full blood count and ESR • Thyroid function tests • Chromosome studies	• Clomiphene • Bromocriptine — for raised prolactin only • LH releasing hormone (LHRH) by pump injection • Pergonal and human chorionic gonadotrophin (hCG) • Buserelin with human menopausal gonadotrophin (hMG) is useful for those with polycystic ovaries • Surgical wedge resection of ovary under laparoscopy. May be effective when drug treatment failed • Gamete intrafallopian transfer (GIFT)
Disorders of fallopian tubes		
Congenital absence Blocked due to infection: — tuberculosis — recurrent appendicitis — gonococcal infection — septic abortion Hydrosalpinx Disturbance of tubal secretions	• History • Examination • Hysterosalpingogram • Laparoscopy • Biopsy of fallopian tube • Hormone studies (no oestrogen surge)	• Salpingolysis • Salpingostomy • Tubal reconstruction — by microscopy • Tubal excision and transplantation • Oral oestrogens • In vitro fertilisation (IVF) and embryo transfer (ET)
Endometrium lining of the uterus		
Not prepared due to disorder of ovulation Endometriosis Endometritis Fibroids Endometrial hyperplasia Endocervicitis	• History • Examination (bimanual) • Hysterosalpingogram • Endometrial biopsy • Evidence of discharge	• Treatment of disorders of ovulation • Dilatation and curettage • Myomectomy • Endometriosis IVF-ET/GIFT
Factors in the cervical mucus		
Hostile mucus Cervical mucus not prepared due to deficiency of oestrogen as a result of disorders of ovulation Sperm antibodies in cervical mucus	• Postcoital test • Mucus/sperm match test • Spinnbarkheit test • Fern test • Sperm invasion test	• Deficient oestrogen — clomiphene • Ethinyl oestradiol (0.01 u daily for a 3-day period before ovulation) • Refrain from intercourse for a set period or use condom during intercourse. At the end of this time, there may be a decrease in antibodies
Psychosexual problems		
Frigidity Vaginismus Stress-affecting hypothalamic function Decreased sexual libido	• History and interview	• Psychological referral • Use of vaginal dilators
Others		
Congenital abnormalities (e.g. bicornuate uterus) Obesity Retroverted uterus Hirsutism and virilism (disorders of ovarian or adrenal function, also by certain drugs)	• Examination • Hysterosalpingogram	• Lose weight • Ventro-suspension surgery • Surgical restructuring of genital organs as possible

Table 7.2 Subfertility: summary of causes, investigations and treatment in men

Causes	Investigations	Treatment
Testes		
Congenital absence of both Klinefelter's syndrome Cryptorchidism Trauma Testicular failure: — torsion — infections — unrestricted pituitary output	• History • Examination • Testicular biopsy • Urinary gonadotrophins • Chromosome investigations	• Cryptorchidism should be detected early in school career and requires surgical intervention • Hormone therapy
Vas deferens and epididymis		
Congenital absence of both Blockage due to infections: — partial — complete Venereal disease Vasitis Epididymitis	• History • Vasogram • Semen analysis • Postcoital test	• No treatment for congenital absence • Vaso-epididymostomy • Microsurgery — removal of blocked section of vas
Spermatozoa		
Oligospermia (less than 20 million in 1 mL) Varicocele Hernia Physical exhaustion and overwork Aspermia Factors in the testes, vas deferens and epididymis (see above) Endocrine abnormalities, failure of pituitary, adrenal and thyroid glands	• History • Examination — consistency of testicles, presence/absence of varicocele • Semen analysis • Postcoital test • Seminal plasma analysis for fructose content and its glycerol phospherol choline • Interstitial cell-stimulating hormone, follicle-stimulating hormone and testosterone levels • Testicular biopsy • Thyroid tests • Urine analysis — gonadotrophins, ketosteroids • Vasogram	• Surgical treatment of varicocele or hernia • Moderation with alcohol, tobacco and work • Wearing loose underpants • Intrauterine insemination by donor • Vaso-epididymostomy • Assisted conception techniques using partner sperm
Semen volume		
Too low — sperms fail to contact cervical os Too high — overdilution Quality	• Semen analysis • Postcoital test	• Pooling of two or more semen samples and intrauterine insemination by partner • High doses of gonadotrophins • Split ejaculate and intrauterine insemination by partner
Agglutination of spermatozoa		
Sperm autoantibodies Hostile mucus Sperm antibodies in cervical mucus (penetrate the mucus but become agglutinated and immobilised and die)	• Seminal fluid analysis • Rosette formation of head-to-head clumping, or a wheatsheaf formation of tail-to-tail clumping in seminal fluid • No sperm invasion is seen	• It may be possible to wash the antibodies off these sperm and then, after centrifuging, produce a concentrated specimen; they can be inseminated directly into the cervix • Corticosteroid therapy
Ejaculatory disorders		
Hypospadias Epispadias Retrograde ejaculation	• History • Examination	• Collection of semen and artificial insemination by partner • Surgical treatment

Table 7.2 Subfertility: summary of causes, investigations and treatment in men *(Continued)*

Causes	Investigations	Treatment
Sexual problems		
Impotence Premature ejaculation Stress Decreased sexual libido	• History • Interview	• Psychological referral • Help regain self-confidence • Apply local anaesthetic to penis before coitus. Treatment for premature ejaculation • Monoamine oxidase inhibitor drugs
Others		
Poor general health Febrile illness Emotional shock Acute allergic response	• History • Examination • ESR	• Full recovery ensues naturally

Tubal disorders

Where tubal factors are the cause of the subfertility, tubal surgery may be advised but this depends upon the nature, site and severity of the condition of the tube, the presence and extent of adhesions, and the skill of the surgeon. Diagnostic procedures will include laparoscopy and hysterosalpingography for full assessment of the condition.

Treatment Surgical procedures used to treat tubal infertility include fimbrioplasty, salpingostomy, salpingo-ovariolysis, tubotubal anastomosis, uterotubal anastomosis and tubal cannulation. Results of such reconstructive surgery show great variation depending on the degree of tubal damage and the adequacy of the surgery performed. Audebert et al (1998) suggested that results from a laparoscopic fimbrioplasty are as good as results from microsurgery.

The World Health Organization (WHO) (1997) cautions against quoting statistics to patients since the 'success' rates reported in studies are often not defined in terms of achieving an intrauterine pregnancy and delivery of a live baby. Reversal of sterilisation, however, is more likely to be successful if the occlusive technique used for sterilisation caused minimal damage to the tubes. Clips, for example, generally have minimal traumatic effect and are associated with the highest proportion of intrauterine pregnancies following reversal. Successful reversal can also depend on the site of occlusion (WHO 1997).

Endometriosis

The association between endometriosis and infertility is complex (Mahutte & Arici 2002). Many women with the condition conceive successfully without intervention.

Treatment There is controversy over the treatment of infertile women with endometriosis without distortion of the pelvic viscera. Martin (1995) suggests that surgery should only be performed where symptoms such as pain and deep dyspareunia are attributable to endometriosis.

The use of laparoscopic surgery in the treatment of minimal and mild endometriosis may improve success rates but further research in this area is needed (Jacobson et al 2002). Surgery, however, is recommended in cases of distortion of pelvic tissues. Surgery to remove endometrial tissue, correct anatomical relationships and enhance the possibility of fertility can be successful by laparotomy or laparoscopic techniques (Candiani et al 1991, Redwine 1991). Other options for women with endometriosis include in vitro fertilisation (IVF), embryo transfer (ET) and gamete intrafallopian transfer (GIFT) (Effective Health Care Consortium 1992).

Male subfertility

Iammarrone et al (2003) suggest there is an increasing incidence of male reproductive problems. Male fertility problems can be categorised into three therapeutic groups: untreatable sterility, treatable conditions and subfertility. Subfertility is the most common (Baker 1995). Impaired semen quality and sperm dysfunction can occur as a result of many factors. The cause may be unknown, but it may be associated with a previous infection or factors such as stress, excessive smoking or alcohol intake. Obstruction of the vas deferens will result in ejaculate without sperm. Antisperm antibodies which attack sperm or inhibit their motility may be present in semen. Iammarrone et al (2003) claim recent studies suggest an increased incidence of genetic disorder relating to male infertility.

Common presentations are:

- oligozoospermia — reduced number of sperm
- asthenozoospermia — reduced motility
- tetratozoospermia — abnormal morphology
- oligoaesthenotetratozoospermia — a combination of the above three
- azoospermia — absence of sperm.

Semen analysis includes an assessment of volume; sperm concentration, motility and morphology; and the number of white cells present. Sperm mucus interaction can be examined in a postcoital test.

Men presenting with subfertility should be fully investigated to ascertain the type of subfertility and identify any related health issues requiring independent treatment.

Treatment should be aimed at achieving natural conception. If male antibodies to spermatozoa are produced,

prednisolone has been shown to be effective as an immunosuppressant (Hendry et al 1990). When natural conception is not possible, assisted reproductive techniques (ARTs) offer another possibility. ARTs involve the collection of sperm and eggs and either the immediate placement of the gametes into the fallopian tubes (GIFT) where fertilisation takes place or in vitro fertilisation (IVF) and subsequent transfer of the embryos (ET). Microinsemination techniques such as partial zona dissection (PZD) or subzonal insemination (SUZI) may be appropriate in, for example, oligozoospermia or tetratozoospermia (Fishel et al 1993). Green et al (1997) suggest that almost all cases of male infertility can be treated by intracytoplasmic injection (ICSI) if viable sperm can be obtained; however, there is some concern that ICSI may result in transmission of defects to the offspring since the natural selection of the spermatozoa is bypassed (Iammarrone et al 2003). Recognising this potential problem, Tournaye (2003) recommends that all men for ICSI should be rigorously screened and fully informed about the limitations of current knowledge and screening methods available.

While ARTs allow many subfertile men to father children, these techniques do not meet the needs of men who do not produce sperm. Donor insemination (DI) may be an option in such cases. DI may also be considered by couples where the man is known to be a carrier of a genetic disease or where couples do not wish to take the risk of having a child born with a genetic disorder transmitted by recessive genes. Kovacs (1997) suggests that a reasonable conception rate from DI in most units is about 10% per cycle. The cumulative conception rate increases to approximately 40% over five treatment cycles.

Provision of information and counselling

The stressful nature of investigations and treatment of subfertility and the psychological impact of the condition on couples require information about the nature of investigations, the implications of and alternatives to treatment. Emotional support and therapeutic counselling should be easily available to the couple. The Committee of Inquiry into Human Fertilisation and Embryology (1984) recommended that 'counselling should be available to all infertile couples and third parties at any stage of the treatment'. Infertility counselling is recognised by counsellors as a specialised area (Jennings 1995) and Monarch (2003) emphasises the continuing role of counsellors in helping patients, and the conception team, deal with the difficult psychosocial and ethical issues they face in practice. Boivin (2003) also draws attention to the added value of group interactions that focus on education and skills training, e.g. relaxation, claiming that these approaches are significantly more effective in producing positive outcomes across a range of issues.

In vitro fertilisation and embryo transfer (IVF-ET)

The work of Edwards and Steptoe in 1978 (summarised in Edwards & Steptoe 1983) led to the birth of the first human infant after conception in vitro (IVF). In the intervening decades the success rate of IVF has improved as a result of advances in ovulation induction regimens, oocyte retrieval, embryo culture, embryo transfer and improved facilities of cryopreservation (Fauser & Devroey 2003). IVF is now widely accepted as a form of treatment for unexplained subfertility. However, the success rate, measured by the end result of live healthy babies, depends on many factors, including the age of the woman, duration of infertility, existing fertility problem(s) of the couple and previous pregnancy history (see Box 7.9). The estimated live birth rates per cycle are reported to be between 13 and 28% but effectiveness of IVF has not been properly evaluated against other treatments (Pandian et al 2002). Some pregnancies terminate with spontaneous abortion or ectopic pregnancy (Talbot & Lawrence 1997).

Box 7.9

Indications for selection into IVF programmes

- Husband and wife are generally healthy
- Ovaries are accessible
- The uterus is functioning normally
- Menstrual function is normal or correctable
- Age preferred below 40 years but a flexible individual approach is taken
- The couple have an uncorrected problem, e.g.:
  - tubal
  - inadequate sperm for normal reproduction
  - endometriosis
  - cervical hostility
  - immunological
  - anovulation
  - undiagnosed by available methods.

Ovarian stimulation Various protocols are in use to achieve controlled hyperstimulation of the ovaries. Agents used include clomiphene citrate, purified FSH, exogenous gonadotrophin and gonadotrophin-releasing hormone agonists (GnRHAs). Modifications to protocols depend on the patient's response.

Clomiphene citrate acts in a negative feedback system to increase endogenous gonadotrophin. A hypothalamic site of action has been reported with increased pulsatile release of GnRH. Clomiphene results in synchronous development of multiple follicles, allowing many oocytes to be retrieved. A disadvantage can be a premature rise in LH, resulting in premature ovulation. To avoid the patient's spontaneous ovulation, hCG is used to induce timed ovulation for ovum retrieval. Medication used to stimulate ovarian function have improved and the three gonadotrophins are now available as recombinant products. In some situations the near-100% pure FSH preparations can cause abnormally low LH levels. The addition of LH may be necessary in these cases and Ludwig et al (2003) believe that r-LH may become available in sufficient dosages to replace hCG for ovulation induction, reducing the incidence of ovarian hyperstimulation syndrome due to its shorter half-life.

The dose of exogenous gonadotrophin is determined on the basis of the patient's age and history.

GnRHAs have increased pregnancy rates per cycle (Hughes et al 1992) and can be used in combination with hMG for improved folliculogenesis. Fauser and Devroey

(2003) advocate a more patient-tailored approach to ovarian stimulation.

Harvesting of eggs Eggs (oocytes) for fertilisation can be recovered from mature ovarian follicles by:

- ultrasound scanner-guided follicle needle puncture and aspiration
- laparoscopy and needle aspiration.

The laparoscopy method requires a general anaesthetic. The ultrasound method can be completed with either a light general anaesthetic or with the patient sedated. The ultrasound probe is introduced into the vagina and the pelvis is inspected, noting the position of viscera and blood vessels. An appropriate pathway for the aspirating needle through the pelvis is selected. The laparoscopic method may be used when it is difficult to access the ovaries vaginally. Aspirated oocytes are transferred to the embryologist.

Laboratory procedures For maximum efficiency and effectiveness there must be close proximity between the operating theatre and the embryology laboratory. There must also be ease of communication between the surgeon and the embryologist; direct verbal and visual contact between the two is needed. Theatre time is usually booked in advance, with 24 h notice, but sometimes egg recovery may need to be done at short notice because of the patient's endogenous LH surge.

The embryologist examines the follicular aspirate for oocytes. The eggs are examined for the level of maturity, washed in clean culture medium and transferred to the culture container. On completion of the oocyte collection, they are placed in an incubator until insemination. This may be 3–6 h later for IVF. In GIFT the oocytes and prepared sperm are placed into a catheter to be inserted into the fimbrial end of the fallopian tube, where the gametes are deposited for fertilisation.

Collection of semen can be a stressful experience for the man, who needs to be assured of a secure private environment to produce a specimen of semen by masturbation (Jackson & Burden 1997). A toilet and hand basin should be available. Erotic video and literature may be helpful. However, some couples may wish to be together for this procedure, so a bed with washable covers should be in the room. Men may produce a semen sample in their own home if they are able to deliver it to the laboratory within 1 h.

Insemination involves mixing of sperm, prepared by the embryologist, and eggs in the appropriate concentration. Between 16 and 20 h later the oocytes are examined for fertilisation and once normal fertilisation has been established the embryos are returned to culture in fresh medium for another 24 h.

Embryo replacement This is usually performed 2–3 days after oocyte retrieval or about 48 h after insemination when the embryos are at the two- or four-cell stage. Placement of the embryos in the uterus is a delicate procedure that does not necessarily result in successful implantation and pregnancy. In some centres nurses are taught to perform this procedure, following a specified protocol, as part of their extended role (Peddie 1998). The incidence of pregnancy increases with the number of embryos replaced, but an attempt is made to reduce the risk of multiple pregnancy with the possibility of premature births. Usually two or three embryos are transferred, a painless procedure for the patient.

On discharge from hospital the patient is given instructions to send samples of urine to the unit on the 8th and 11th days after replacement so that pregnancy tests can be completed and to notify the unit if menstruation occurs so that she can be advised about future treatment. If her pregnancy is confirmed and develops, the unit will maintain an interest in the pregnancy and celebrate the success of childbirth.

Transport IVF

While there is an increasing demand for IVF treatment in the UK, a lack of funding limits the number of clinics able to offer IVF treatment. Transport IVF, however, makes this treatment more widely available to infertile couples. Here gynaecologists in local communities make arrangements with regional specialist IVF units to share the care of the patients (Kingsland et al 1992). The ways in which the services required at different stages of IVF are organised between the two centres vary. One possibility is for ovulation stimulation and oocyte retrieval to be undertaken at the satellite centre, with subsequent transfer of the oocytes to the central unit for insemination, fertilisation and embryo transfer.

Treatment of low-powered sperm in IVF-ET

Such treatments involve manipulating ovum and sperm together to improve penetration of the ovum by sperm in cases of sperm dysfunction such as poor motility. A deliberate injection of a single sperm into an ovum can be achieved using a sophisticated microscope and special instruments. The human embryos so formed have led to successful pregnancies for a few women.

See Green et al (1997) for further information regarding intracytoplasmic sperm injection.

Prenatal analysis of DNA for genetic abnormality

Prenatal diagnosis of genetic abnormalities is now possible by analysing DNA for a known gene defect (see Ch. 6). A single cell is removed from a 4–16 cell embryo. Information regarding a genetic defect can become available within a few hours, soon enough to allow the embryo to be implanted when it is known to be healthy. Diseases such as cystic fibrosis and Duchenne muscular dystrophy can thus be avoided. Some women have already been treated in this way, but long-term information is needed on whether the loss of a single cell from an embryo is likely to have any adverse effect.

Gamete intrafallopian transfer (GIFT)

GIFT offers an alternative treatment to IVF when women have at least one patent fallopian tube. It is primarily used in patients who have unexplained subfertility and cervical hostility. It is contraindicated in women with stage III and IV endometriosis, active infection and intrauterine abnormalities. GIFT can be performed in hospitals that do not have IVF facilities. However, where such facilities exist,

surplus oocytes can be fertilised in vitro and cryopreserved. Thus IVF and later ET may be an option if GIFT is unsuccessful. Wood (1997) demonstrated that between 1990 and 1993 the live birth rate from GIFT was double that from IVF.

The technique involves giving follicle-stimulating drugs to stimulate the ovaries. Retrieval of eggs follows, as in IVF. The eggs are then mixed with the freshly donated sperm and transferred into the fimbriated ends of the fallopian tube(s) (see Fig. 7.10). GIFT is normally performed laparoscopically but it can be achieved vaginally or by means of a colposcope. The eggs, being placed directly in the fallopian tube, have the opportunity to become fertilised more naturally and continue along the tube to implant in the uterus.

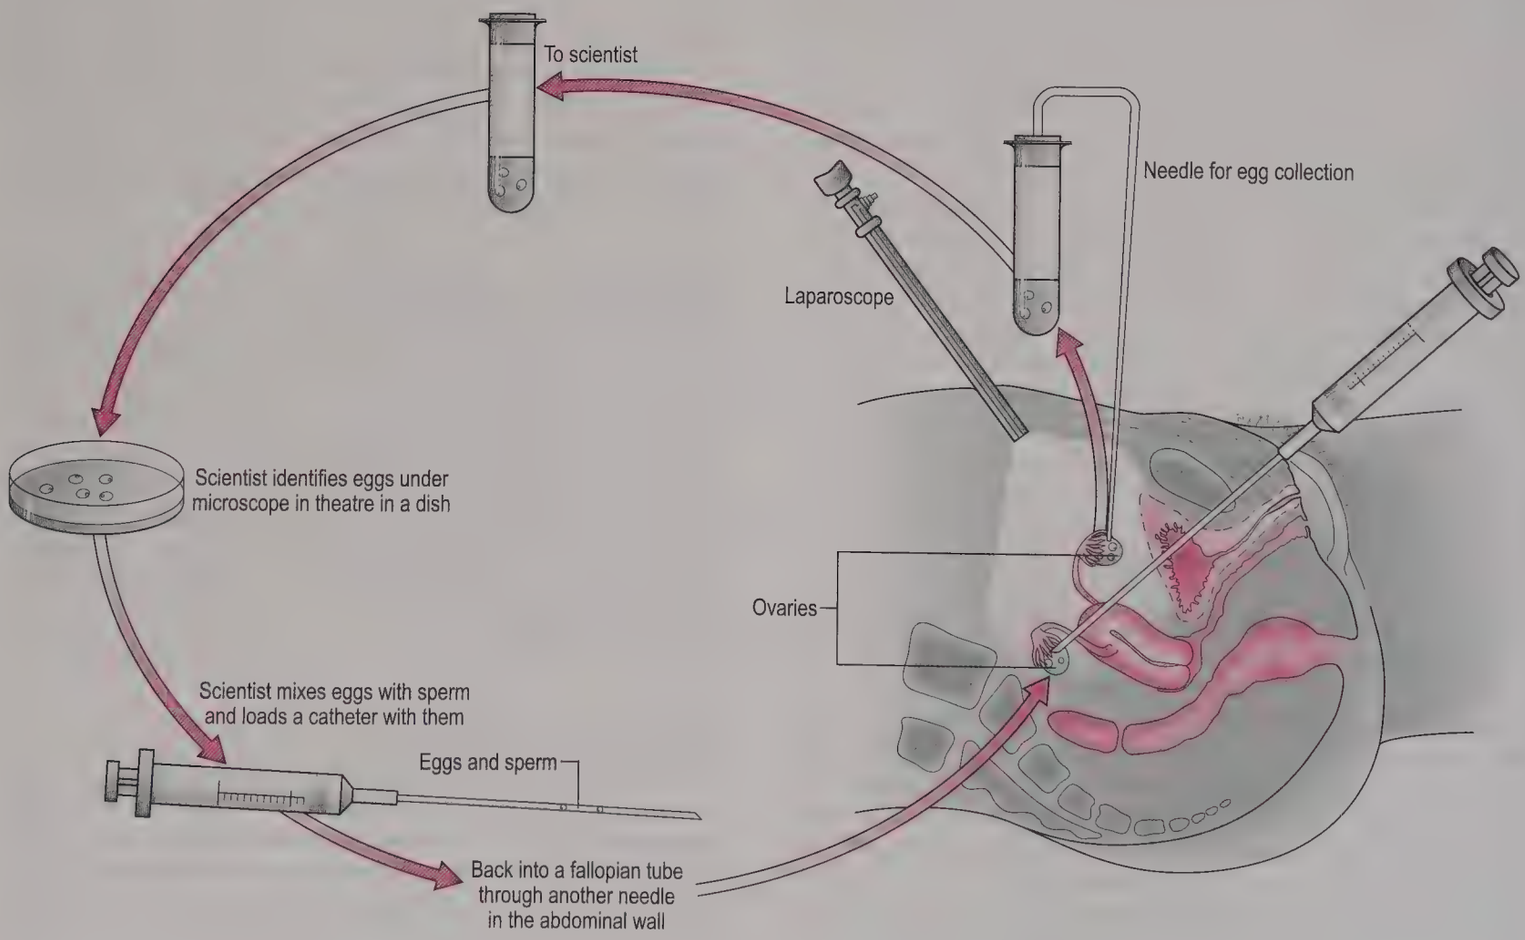
Zygote intrafallopian transfer (ZIFT)

Here the gametes are fertilised before transfer to the fallopian tube. In this treatment, therefore, fertilisation is known to have occurred and embryos have the opportunity to benefit from the tubal environment and to enter the uterine cavity naturally.

NURSING PRIORITIES AND MANAGEMENT: IVF

The couple may have experienced many tests, investigations and surgical interventions before being offered the opportunity to seek pregnancy by the IVF method, and, though always hopeful for success, must recognise that this is not guaranteed.

Pre-laparoscopy care



Reducing anxiety

Pretreatment counselling looks to give a realistic picture of the chances of cumulative success rather than encouraging the couple to focus on success of the first cycle (Anderson & Alesi 1997).

The nurse will need to prepare a plan of care that will minimise the stress level and help the patient to relax. High stress levels are well known to disturb hormone levels and activity. Planned counselling sessions may be needed. Similarly, information-giving sessions will need to be planned. Slides and videotapes can be invaluable supplements for group work when the special needs of individuals can be identified and met within a supportive group. A system of open communication is important, whether the information is favourable or disappointing.

Self-care in the follicular stage

The patient is not ill and her role in maintaining self-care can be explained. She will need to learn how to collect her urine, required for laboratory testing, and record the time and amount passed. Verbal instructions can be complemented by a written explanation available in the toilet area. A patient whose first language is not English will need written instructions in her own language.

304 Fig. 7.10 The GIFT treatment.

Blood and urine samples will be required for laboratory testing. Ovarian stimulants are given according to the individual patient's needs. Patients should understand that there are differences in need between individual women and the nurse's explanations can alleviate concerns.

Preparation for egg cell recovery

The procedure of ultrasound scanning should be explained in terms of checking the number of follicles maturing and their stage of development. Once the estimated time of ovulation is known, preparation for theatre begins. Blood is taken for haemoglobin estimation. Skin is prepared according to the policy of the unit; some surgeons still prefer the pubic area to be shaved prior to laparoscopy and oocyte recovery. Fasting arrangements are maintained according to protocol, in preparation for a general anaesthetic. No premedication drugs are prescribed, to avoid compromise of the patient's physiological balance and that of the ripened follicles.

The nurse should encourage the patient to relax and be calm for transfer to theatre. The eggs are generally recovered vaginally with ultrasound guidance but can also be retrieved via a laparoscope. Each mature follicle is carefully aspirated and the eggs are collected in the culture tube. The aspirate is immediately passed to the laboratory for examination and identification of oocytes.

Post-laparoscopy care

Recovery from the laparoscopy is rapid. Rest in bed for a maximum of 8 h is usually necessary to avoid referred pain in the shoulder from retention of residual gas in the abdomen. Mild analgesics such as paracetamol may be prescribed for relief of pain. The patient will be keen to know whether the laparoscopy was successful and how many eggs were recovered.

Sometimes the time of ovulation has been misjudged and the follicles have already ruptured prior to laparoscopy or the recovered eggs are too immature to be viable. During laparoscopy, adhesions may obscure the ovarian tissue, thus negating the procedure.

The nurse should adopt a sensitive approach when giving news of the failure of the procedure. The surgeon concerned may prefer to explain the difficulties to the patient and her partner. The nurse may have to repeat the information for the patient together with possible details of re-entry into the programme at a later date.

Preparation for embryo transfer

After a woman's eggs have been successfully recovered, it may be necessary to wait 2–3 days while the eggs are matured in vitro. 100 000 specially prepared motile sperm from her partner are added for each egg and fertilisation should occur within 18–24 h if there is no male problem. The embryos are observed in the laboratory as they develop to a two- or four-cell stage prior to transfer. Failures may also occur at this delicate laboratory stage and this is a further worrying time for the patient.

As soon as a positive decision is made for embryo transfer, the patient takes a shower and dresses in a clean gown. A bath is avoided to ensure there is no water in the vagina. The bed is prepared with clean linen and taken to the theatre. Once there, the patient is positioned in the modified lithotomy in the Trendelenburg position for the procedure of embryo transfer.

Following transfer the woman can resume her normal activities. Although resting does not increase the chance of pregnancy (Power 2001), the woman may prefer to have a quiet day.

7.1 Think about how the patient will feel if failure occurs at any of the stages of the IVF treatment programme.

7.2 Write down the patient's possible thoughts about failure:
- during the follicular stage
- at the oocyte recovery stage
- at the embryo development stage in the laboratory
- after embryo transfer into the uterus.

7.3 Write down a few sentences of what you might say to the patient at each of the above stages.

7.4 Discuss with your mentor whether what you have written down could be used as a guide to communication with the patient, with allowances made for differences between patients and their partners.

Continuing need for support and counselling

Nurses working in hospital or in the community must be prepared to use their counselling skills with clients who wish to enter, are involved in, or have terminated a programme of subfertility treatment. Community midwives may participate in the care of women who are pregnant following subfertility treatment and others who have experienced a miscarriage. Health visitors also have a role in counselling following the loss of a pregnancy or an infant after subfertility treatment. Couples may continue to need to talk about their feelings of inadequacy or failure and to be allowed to grieve for their losses (see Case History 7.1).

For some couples, treatment options for subfertility will not prove successful and it may be necessary for them to accept that they will not have children of their own. Other possibilities can be sensitively discussed.

EMBRYO RESEARCH

The main aim of human embryo research has been the prevention of genetically transferred diseases. Embryo research

CASE HISTORY 7.1

K

K achieved a pregnancy during her programme of subfertility treatments. Unfortunately, she aborted a twin-boy pregnancy and was devastated by the loss. She returned to the programme and became a mother with the birth of quadruplets: three girls and a boy. Unfortunately the boy subsequently died. K visits the unit with her lovely girls in a triple buggy but still grieves over the boys. She has asked to re-enter the programme because she still wants a boy. K has been referred to an independent counsellor.

improves the understanding and management of genetic diseases.

Pre-implantation diagnosis in embryos is possible by removing and examining a single cell, although it is not known whether this cell removal might cause a defect in the child. The treatment offers hope to those who carry genetic defects that can affect the well-being of the child. Further embryo research may help with the understanding of miscarriage of pregnancies, which involve 100 000 women per year, with consequent effects on health and future fertility. Further understanding of the way embryos implant might shed more light on contraception, miscarriages and ectopic pregnancies. It is also expected that embryo research will improve the understanding and treatment of cancer by the study of 'oncogenes' which control cell division and growth.

The Human Fertilisation and Embryology Act 1990

A consequence of reproductive technology and in vitro fertilisation is the production of surplus embryos. This has created public concern about the potential for undesirable experimental work on embryos.

The Human Fertilisation and Embryology Act 1990 prohibits certain practices and has established the Human Fertilisation and Embryology Authority (HFEA) to license and regulate the activities of IVF centres. The Act applies only to the creation of embryos outside the human body. The embryo is not to be kept or used after the appearance of the primitive streak, at the end of 14 days. The primitive streak, or groove, is formed by invagination from the ectoderm, in the formation of the mesoderm between the ectoderm and the endoderm of the embryo. Identification of this structure is used to denote the beginning of human life (Morgan & Lee 1991). Frozen embryos can generally be stored for 5 years and gametes may be stored for 10 years. There are, however, exceptional conditions when storage periods can be extended. All centres involved in IVF must prepare a code of practice, which is subject to inspection, and are required to send 12-monthly reports to the HFEA. The Act has a conscientious objection clause. Consequently anyone who can show a conscious objection to any of the activities governed by the Act is not obliged to participate in them (HFEA 2003). Nurses must make known any conscientious objection to the appropriate person as soon as possible (NMC 2002).

Surrogate motherhood

The Human Fertilisation and Embryology Act defines the woman who carries the embryo as the mother of the child. If the woman then gives the baby to a married couple in a surrogacy agreement, a parental order can be made by a competent court (in private) to make the couple the child's legal parents, providing specified criteria are met (Human Fertilisation and Embryology Act 1990). Regardless of any prior agreement regarding the surrogacy, the Human Fertilisation and Embryology Act renders surrogacy contracts unenforceable.

The right of any childless couple to have a child is generally accepted, but after infertility treatments fail to help the woman to conceive, there may be less support for her seeking another fertile woman to assist in developing a pregnancy. Financial inducement and contractual arrangements cannot guarantee that the surrogate mother will be prepared to hand over the newborn baby to the infertile couple. If the intended parents do not wish to accept the child the surrogate (legal) mother is responsible for its welfare. In the event of the child being rejected by the birth mother and the intended parents the child can be placed for adoption or fostering.

DISORDERS OF THE MALE REPRODUCTIVE ORGANS

The anatomy and physiology of the male reproductive system is described in Chapter 8.

MALDESCENT OF THE TESTES (CRYPTORCHIDISM)

PATHOPHYSIOLOGY

Cryptorchidism is a condition in which one or both testes have not descended into the scrotum before birth. It is a common condition seen in approximately 1% of boys after their first year and may be self-correcting or require surgery in the form of orchidopexy. Normal descent keeps the testes cooler in the scrotum and avoids the germ cell degeneration that is possible in the higher temperature of the abdomen, which carries a risk of malignancy. Three different grades of maldescent are described:

- a retractile testicle is normally found in the scrotum but on stimulation is pulled up into the superficial inguinal pouch by an active cremaster muscle
- an ectopic testicle is prevented, by tissue structures, from descending from the inguinal canal into the scrotum
- an undescended testicle is possibly abnormal: it remains in the abdomen and fails to enter the inguinal canal and pass into the scrotum.

MEDICAL MANAGEMENT

The aim of treatment is to promote normal function of the testicle. Treatment should be completed by the boy's eighth year, before the testicle starts functioning. Untreated cryptorchidism results in sterility, since the cells involved in the initial development of sperm cells are destroyed by the higher body temperature within the body. The testicle may migrate spontaneously, or hormone treatment may be prescribed to stimulate migration. Otherwise, an orchidopexy is performed to bring the testicle into the scrotum. It is held there by means of a suture passing through the wall of the scrotum and into the thigh. The suture is removed 7–10 days postoperatively.

More extensive surgery may be needed with actual removal of the abnormal testicle and repair of an inguinal hernia if this has occurred. In addition to the risk of

infertility, there is also a high risk of malignancy if the testes are left in the abdomen.

NURSING PRIORITIES AND MANAGEMENT: Maldescent of the testes

The nurse should identify any deficit in the patient's understanding of his condition and the operation to be performed. The patient who is still a child may feel embarrassed about asking questions and the nurse must judge where to begin and end when giving information and a health education programme. The facts of sexual life may need to be explained to the child with a parent present, or the parent may prefer to be the one to give the child the information. In some cases, the nurse may find it more relevant to focus on the parents' need for education, information and advice. While care should be taken not to cause undue anxiety, the suggested link with an increased risk of testicular cancer, at a later age, should be broached to encourage vigilance in adult life (see p. 308).

TORSION OF THE TESTES

Testicular torsion is an acutely painful condition caused by the twisting of the testicle on its spermatic cord. It may occur spontaneously or as the result of strenuous exertion. It commonly occurs in adolescents aged 12–18 years, but can also occur in adults. This condition is classified as a surgical emergency requiring immediate treatment.

PATHOPHYSIOLOGY

Testicular torsion results when an abnormality of the tunica vaginalis allows increased mobility of the testis and axial rotation of the spermatic cord above. The resulting ischaemia can lead to cell damage and infection within approximately 6 h.

Extravaginal torsion, a rare form, can occur in utero or in the newborn. In this case the testis is not painful but on examination is found to be a firm, large mass in the scrotum.

Common presenting symptoms The patient will present with sudden onset of acute pain in the groin, often radiating to the scrotum and abdomen. Exercise may be the precipitating factor, but the onset of pain can also occur at rest. Nausea and vomiting are common.

MEDICAL MANAGEMENT

The patient may give a history of previous, less severe episodes which resolved spontaneously. Examination of the testis may be hampered by the severity of the pain. The affected testis will be elevated, but abnormality of mobility ('bellclapper' deformity) may be present in the other testis.

Treatment Treatment is by immediate surgery to relieve the torsion and secure testicular fixation. However, if the torsion is detected at an earlier stage, it may be possible by gentle external manipulation to rotate the twisted testis in the appropriate direction. This may immediately resolve the emergency, but the testis should later be surgically secured to prevent recurrence.

NURSING PRIORITIES AND MANAGEMENT: Torsion of the testes

The patient will normally be young and fit and his stay in hospital brief. Although the surgery is not considered major, the acute onset of pain and the nature of the problem may give rise to considerable anxiety and embarrassment. Giving the patient adequate information will help to relieve anxiety and promote recovery. He should be informed that analgesics can be given immediately and that the acute pain will go away once the operation has been performed.

Postoperatively, the patient will have a small inguinal wound and perhaps some scrotal swelling. He will normally be able to return to school or to work in about 2 weeks, at which point he should feel comfortable walking and sitting. Lifting, heavy work and sports involving running, jumping or stretching should be avoided for about 6 weeks. An athletic support should always be worn when sports activities are resumed.

The patient who has received treatment in good time should also be reassured that no impairment to sexual function or fertility will result.

7.5 Write a care plan for a patient following surgery for fixation of the testes. Consider what problems the patient might have. The care plan should include:

- checking the wound for oozing, swelling and infection
- ensuring the wearing of a scrotal support to prevent swelling
- relieving pain by bed rest and analgesics
- ensuring that the patient passes urine within a specific time postoperatively (it may take him up to 24 h)
- checking temperature, pulse and blood pressure
- informing the patient when he may eat and drink again
- giving discharge advice.

HYDROCELE

PATHOPHYSIOLOGY

A hydrocele is a collection of serous fluid in the membranous sac (the tunica vaginalis) that surrounds the testes. It may occur spontaneously without any cause or it may be secondary to an acute or chronic inflammatory condition of the testis or epididymis. The hydrocele usually occurs on one side only, is painless, and can swell to a considerable size. It may accompany a condition that causes oedema of tissues, such as congestive heart failure or nephrotic syndrome.

Common presenting symptoms Hydrocele is usually asymptomatic, but an increase in scrotal size and associated discomfort will often prompt the patient to seek advice. The embarrassment caused by the swelling may be such that the individual curtails social activities, swimming, sunshine holidays and sexual relations.

MEDICAL MANAGEMENT

The presence of fluid within the scrotal sac is dull to percussion and provides a red glow on transillumination. A tense hydrocele can be differentiated from a tumour in

that the latter does not illuminate (Gillespie et al 1992). As a hydrocele can form around a testicular tumour, the possibility of cancer should be excluded.

Treatment The condition may be reducible by the wearing of a scrotal support, but it is often necessary to introduce a fine trocar and cannula to drain off the fluid. Bleeding and infection are common complications, and recurrence at 6–15 weeks is common.

VARICOCELE

A varicocele occurs when the veins draining the testes become distended and tortuous. This may cause enlargement of the spermatic cord. Palpation of the scrotum will reveal a mass of enlarged varicose veins. The condition most commonly occurs in men aged 15–30 years and sometimes resolves without intervention when there is regular sexual intercourse. A persistent varicocele may induce a raised temperature within the scrotum due to the increased blood supply and contribute to a subfertile state.

MEDICAL MANAGEMENT

The patient who complains of a dragging discomfort in the scrotum may find that this is relieved by the wearing of a scrotal support. If the condition is more severe, ligation of the veins may be needed. A small length of vein may be removed.

TESTICULAR CANCER

Testicular cancer is an uncommon condition, accounting for 1–2% of all cancers in men. It is, however, the commonest malignancy in men aged 20–34 years (Huyghe et al 2003). In the last 50 years, the condition has become more common among white racial groups but has remained only one-third as common among black racial groups. Its incidence is highest in Scandinavian countries and lowest in Asian and African countries. In Denmark, testicular cancer accounts for 6.7% of all cancers. In Japan, it accounts for 0.8%. There is a genetic component to testicular cancer; offspring of men with testicular cancer are 6–10 times more likely to develop the disease (Dearnaley et al 2001). Cryptorchidism (undescended testicle) and exogenous oestrogens have been linked with an increased incidence of testicular cancer. While exposure to exogenous oestrogens, in utero, can increase the risk of testicular cancer, Vessey (1989) indicated that such findings are not conclusive. Garner et al (2003) suggest the possibility of a link between testicular cancer and a high intake of dairy produce and Huyghe et al (2003) report an association with environmental factors and hormonal changes. More research is required to assess future trends and incidence rates and to identify risk factors.

As survival depends on early detection and treatment, Peate (1997) recommended that men should be encouraged to practise testicular self-examination at least every 6 months. The value of screening programmes for testicular cancer remains a matter for debate (see Research Abstract 7.7).

RESEARCH ABSTRACT 7.7

Testicular cancer screening

A report of a working party of the Royal College of Physicians (1991) concluded that as testicular self-examination has never been evaluated and because chemotherapy now achieves cure rates of 90% or more, even in advanced cases of testicular cancer, screening is probably unnecessary. Moreover, because there is no identifiable pre-invasive stage, screening cannot reduce the incidence but might even increase it by overdiagnosis of borderline tumours. Thus screening for testicular cancer is not indicated.

Royal College of Physicians 1991 Report on preventive medicine. RCP, London

PATHOPHYSIOLOGY

The cell types of testicular cancer are classified in terms of embryonal tissue rather than adult testes tissue. Almost all the cancers arise from the primordial germ cell, the multipotent cell found in the yolk sac of the embryo. This multipotent cell will have many varieties of cell types as offspring, and a primary testicular tumour may have a wide variety of cell types. The normal cells of the testis have high proliferative potential and can become malignant under the influence of an abnormal environment.

Testicular cancers are grouped as:

- Originating from germinal tissue (97%)
  - — seminoma (typical, anaplastic or spermocytic)
  - — non-seminomatous
    - i. embryonal
    - ii. teratocarcinoma
    - iii. teratoma
    - iv. choriocarcinoma
- Arising from stromal tissue (3%)
  - — interstitial cell tumour
  - — gonadal stromal tumour.

Germinal testicular cancer

PATHOPHYSIOLOGY

The germinal cancer types may develop from a single cell or a multifocus. The malignant growth is fairly rapid in one testis. Metastases may occur by extension locally or via the lymphatics to the retroperitoneal lymph nodes. Lymph node invasion may cause displacement of the ureters or kidneys. The ureters may become obstructed. By direct extension the tumour may invade the epididymis, extend up the spermatic cord or extend through the tunica vaginalis to the scrotum. Late metastases may be found in the lung, liver, adrenal gland or bone.

Common presenting symptoms The first sign of testicular tumour is painless enlargement of the testicle. This may be discovered by accident or by self-examination (see Box 7.10). A dragging sensation may be felt in the scrotum from the weight of the tumour.

MEDICAL MANAGEMENT

There is usually a lack of pain on palpation of the testis. Any painless lump in the testis that does not respond

Box 7.10

Teaching testicular self-examination

The nurse can make a valuable contribution to health promotion by teaching testicular self-examination. An effective teaching plan will explain the reasons for self-examination of the testes, the best time to perform self-examination, the steps to follow in self-examination and the types of abnormality that should be reported to a doctor.

Teaching plan

- Enquire about any previous information the patient may have gained about examination of the testes
- Respond to what the patient says about the topic and build on that knowledge. Give the patient the opportunity to ask questions and seek clarification regularly
- Use a simple diagram of the scrotum and testes to describe the structures involved
- Explain that it is necessary to be aware of the normal condition of the testes so that any later change can be recognised at an early stage
- Advise that the best time to perform self-examination is immediately after taking a shower or bath, when the body tissues are warm, the scrotum is relaxed and the testes easy to feel
- Emphasise the need to look at the scrotum for its colour, texture, any change in shape or any swelling that may be noticeable
- Instruct the patient that it is necessary to hold the scrotum in the palm of the hand and to examine each testicle by rolling the testis between his thumb and fingers:
  - — each testicle should feel smooth and be about the size of a small hen's egg
  - — the epididymis, which lies behind each testicle, should also be felt and should feel soft and slightly spongy to the touch.
  - — the spermatic cords, which extend upwards from the epididymis, should feel like round, firm tubes
- Explain that any abnormality in the shape of the testicle and any lump or swelling should be investigated by a doctor irrespective of how trivial it may seem
- Check that the patient knows why he is completing the self-examination. Help him to understand that a cancerous lump can now be successfully treated

promptly to antibiotics should be thought of as cancer until proven otherwise. Metastases may cause lumbar pain and abdominal or supraclavicular lymph node masses.

Investigations Laboratory studies of serum alpha-fetoprotein (AFP) and serum beta-human chorionic gonadotrophin (hCG) help in the diagnosis of germ cell cancer as tumour markers. AFP is high in aggressive non-seminomatous tumours; hCG is elevated in 30% of seminomas. These markers corroborate diagnosis but are also useful in monitoring treatment. Chest X-ray, chest CT scan, tomography, lymphangiography, abdominal CT scan, abdominal ultrasonography and intravenous pyelography may all be used diagnostically.

Treatment is by surgery with adjuvant radiotherapy and chemotherapy. The specific therapy will depend on the type of cancer and the stage of the disease.

Surgical intervention This involves a high radical inguinal orchidectomy. The testis, epididymis, a portion of the vas and parts of the gonadal lymphatics and blood vessels are removed. The remaining testis will undergo hyperplasia and produce enough testosterone to maintain sexual capacity, male characteristics and libido. The semen, however, may be of poor quality. Ejaculatory ability may be reduced.

Radiotherapy Following surgery, radiotherapy is recommended for seminomas. Standard treatment in the UK for stage 1 seminomas is adjuvant radiotherapy to the para-aortic area, over a period of 3 weeks, for lymph node treatment. In more advanced disease, radiotherapy is extended to the ipsilateral pelvic area and chemotherapy can also be administered (Dearnaley et al 2001). Fatigue, bone marrow depression and diarrhoea may be experienced as side-effects.

Chemotherapy In stage 1 non-seminomatous germ cell tumours there are two main approaches to therapy. When there is no vascular invasion a strict surveillance protocol can be followed; in cases of vascular invasion the patient can either have a surveillance protocol or immediate treatment with two courses of adjuvant chemotherapy. In more advanced disease additional courses of chemotherapy are employed (Dearnaley et al 2001). A number of cytotoxic agents are used as an adjunct to surgery and radiotherapy (e.g. bleomycin, cisplatin and etoposide). Cisplatin-based combined therapy has been a major advance in treating disseminated disease with a cure rate of 80% (Chaudhary & Haldas 2003). However, serious long-term complications from chemotherapy are now recognised and close follow-up of patients after completion of treatment is advocated. Significant side-effects include secondary leukaemia, azoospermia, nephrotoxicity, bone marrow suppression, neurotoxicity and vascular toxicities (Hawkins & Miaskowski 1996, Hilkens et al 1997, Chaudhary & Haldas 2003). Reduced sexual function and infertility are possible persisting side-effects following treatment for testicular cancer (Arai et al 1997, Jonker-Pool et al 1997). However, Taksey et al (2003) point out that a low sperm count does not necessarily prevent fatherhood.

NURSING PRIORITIES AND MANAGEMENT: Testicular cancer

The pre- and postoperative needs of a patient having orchidectomy are as for major surgery (see Ch. 26). The need for information, relief of anxiety, pain relief and protection from wound infection are primary. The young adult patient with insight into his cancer condition will undoubtedly be worried about the future, the course of the illness, his family responsibilities and his career.

Postoperatively the patient will require a short period of fully compensatory care whilst recovering from the anaesthetic. A short period of partially assisted care will follow. In the long term the patient will need planned educative and supportive care (see Case History 7.2).

CASE HISTORY 7.2
Mr W

Mr W is 32 years of age. He is married and has two young daughters aged 2 and 4. His wife looks after the children well but has always been very dependent on him for organising the family and helping with domestic chores and the shopping. They have usually enjoyed an average social life, babysitters permitting. Mr W works as a computer engineer. He likes to leave work promptly so that his wife isn't left too long on her own at home. She has had episodes when she has become reliant on alcohol, particularly when she is worried about the children.

7.6 Mr W had his left testis removed 48 h ago. He has extensive lymphatic gland metastases. The medical plan includes radiotherapy and chemotherapy over the coming months.

Consider the circumstances of the family described in Case History 7.2 and:

(a) identify Mr W's needs for education and support
(b) prepare a teaching plan
(c) list the ways in which you as the nurse can provide support for Mr W during the postoperative period
(d) explain the ways that Mr W can continue to be supported after discharge from hospital
(e) identify the needs of the family in the short and long term.

For further information, see Moynihan (1996).

VASECTOMY

Couples who have used a range of birth control methods over the years may decide that permanent sterilisation by surgical means would now be preferable. According to Amundsen and Ramakrishnan (2004) vasectomy is one of the most reliable and cost-effective permanent methods of contraception. When compared with other Western European countries, the UK has a high rate of sterilisation: 23% of couples of reproductive age use this method (Roberts 2000).

Preoperative counselling

Before such a decision is taken the couple should meet with their GP or family planning counsellor to discuss their needs and circumstances and their reasons for considering sterilisation as a birth control method. The counsellor should provide information about both female and male sterilisation and the risks, side-effects and failure rates of the procedures available. The long-term effects and prospects for reversal of the sterilisation should be explained. The couple should also be encouraged to consider the implications of a breakdown of their marriage or partnership, or the loss by death of one of the couple or of their children.

A man contemplating vasectomy may have particular anxieties about the effect of the procedure on his masculinity and sex drive. He must be assured that, as the testes will not be removed, his hormone production, virility and sex drive will be unaffected. The nature of the operation should be described with the aid of a simple diagram. It should be explained that the ejaculation fluid will be free from sperm and that unused sperm will be broken down and reabsorbed. Further information that the patient will require is summarised in Box 7.11.

Box 7.11

Information for the patient undergoing vasectomy

Every patient undergoing vasectomy should be given an information leaflet containing the following information:

- The type of anaesthesia that will be given (i.e. general or local)
- The operation will be completed via the scrotal sac
- A portion of vas may be removed on each side
- A dressing will be applied to the wound and a scrotal support will be applied and should be worn for 2 weeks
- Some swelling and bruising will occur around the operation site. This may extend down over the thighs or up towards the umbilicus
- Some pain will be experienced, but this can be relieved by paracetamol or codeine tablets
- Skin sutures will dissolve spontaneously within approximately 1 week of the operation
- Strenuous exercise should be avoided for 2 days
- The patient will not become infertile immediately after the operation due to sperm being stored upstream of the operative site. Therefore, he must continue to take contraceptive precautions until two successive sperm samples are proved to be free of sperm
- Normal sexual intercourse can take place from the third postoperative day. As the operation site may be tender, the individual may prefer to wait longer than this
- At least 12 ejaculations should have occurred before the first semen test to clear sperm. A second semen test will be completed 2 weeks later. In a small proportion of cases, sperm persists in the seminal fluid for many months
- There is a 0.5–1.0% failure rate associated with the operation:
  - — the ends of a vas may join up again early or late after operation
  - — the surgeon may remove some structure other than the vas
  - — some men have anatomical abnormalities, such as a double vas that is not fully removed
- Reappearance of fertility after two negative semen tests may mean that the tests were not accurately completed or the ends of a vas have reunited
- Severe, prolonged pain may indicate some slow seepage of blood into tissues from a small blood vessel. A haematoma may have formed, causing the scrotum to swell. Rest in bed should ease the condition. Otherwise the site may need to be drained at the clinic
- The wound may become infected, in which case the GP will prescribe antibiotics
- There is a reasonable chance that the operation can be reversed should this be desired. Reversibility cannot be guaranteed, however, and a return to the previous level of fertility may not be achieved.

MEDICAL MANAGEMENT

The surgical procedure Vasectomy is the ligation or division of the vasa deferens, the genital ducts that store and

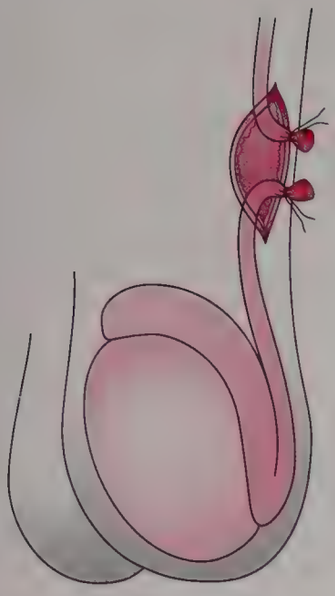


Fig. 7.11 The vas divided.

transport sperm to the urethra in the process of ejaculation (see Ch. 8), and is performed under either general or local anaesthetic. In the traditional method of vasectomy, the vas is palpated in the upper scrotum and an incision of 1 cm is made over the vas. The fascia around the vas is incised and the vas drawn out and ligated in two places.

The vas is then simply divided or a small segment is excised (see Fig. 7.11). One end of the vas is enclosed again in the fascia envelope. The other end of the vas is repositioned outside the fascia. Alternatively, the cut ends of the vas may first be cauterised or the cut ends looped back on themselves. The skin is closed with absorbable sutures and the procedure is repeated on the opposite side. The possibility for reversal of the operation is retained. Using this method there is some controversy over whether a section of vas should be removed. Roberts (2000) reports on observational studies that suggest an increased incidence of recanalisation after removal of segments less than 14 mm long. Hence, removal of 15 mm is recommended.

In 1974 a no-scalpel method of vasectomy was introduced by a Chinese surgeon. This procedure is carried out using a local anaesthetic. A vas-fixing forceps encircles the vas through the skin. A specially designed curved haemostat with sharp points is used to puncture the skin and vas sheath. The puncture hole is stretched to form a small opening in the scrotum through which the vas can be lifted out. It is then cut, tied or cauterised as in other vasectomy techniques. The midline puncture site can be used to isolate and interrupt the second vas. No skin sutures are required (Huber 1988). This procedure has been positively evaluated (Burket-Piccolino & Costa 1992, Holt & Higgins 1996, Black & Francome 2003), showing comparable intra-operative pain levels, less pain and bleeding postoperatively and fewer infections. These advantages are attributable to the minimal dissection and handling required for the procedure.

Outcome Following vasectomy the man should have two consecutive sperm analyses 2–4 weeks apart showing azoospermia to confirm effective contraception. The majority of men are pleased with the vasectomy operation. They usually consider it to have been minor surgery and to have caused no ill effects. They can approach sexual intercourse with greater relaxation and increased enjoyment. A minority experience regret after the operation, feeling that their sexual drive and performance have been reduced. Others who have taken new partners or remarried may regret being unable to have another child within the new relationship. A new wife who has no child may feel deprived and frustrated.

Reversal An increasing number of men are requesting reversal of their vasectomy. Surgeons are now attaining 70–90% success rates with such reversals, which are technically feasible, but the pregnancy rate achieved is disappointingly low: only one-third of the reversed vasectomies lead to pregnancy. This low rate may be due to the formation of sperm antibodies.

NURSING PRIORITIES AND MANAGEMENT: Vasectomy

Preparation for the procedure

The nurse may be responsible, jointly with the surgeon, for ensuring that the individual undergoing vasectomy and his partner understand what the procedure entails and its anticipated results.

Postoperative care

Postoperatively, the nurse on the ward will be involved in pain management and wound care and will have an important contribution to make in instructing the patient in postoperative self-care and in informing him about procedures for follow-up and assessment. The nurse should also alert him to the possible complications or problems that should be reported (see Box 7.12).

Many men are concerned about the development of scrotal swelling and haematoma in the postoperative period. Scrotal support, rest and analgesics are necessary for general comfort and to improve the condition over time. Any bleeding from the wounds may be relieved by the use of butterfly sutures to pull the wound edges together. Psychological after-effects of vasectomy should be few if preoperative counselling and information-giving have been adequate. Some men complain of an adverse effect on sexual performance after vasectomy, but they are usually those who have had similar difficulties before surgery.

The possibility of an association between vasectomy and prostate cancer has attracted some attention; however, studies suggest no increase in prostatic cancer in men who have had a vasectomy (Chacko et al 2002, Cox et al 2002) (see Research Abstract 7.8). There has also been some debate about a possible link between vasectomy and testicular cancer but Jorgensen et al (1993) and Moller et al (1994) have found no causal relationship. Jorgensen et al (1993) suggest that vasectomy might precipitate the development of testicular cancer from a pre-invasive carcinoma in situ lesion but Moller et al (1994) claim that vasectomy does not accelerate the growth or diagnosis of pre-existing testicular neoplasms.

Box 7.12

Inflammatory conditions of the male reproductive organs

Balanitis and balanoposthitis
The term balanitis refers to inflammation of the glans penis. The term balanoposthitis refers to inflammation of the prepuce or foreskin as well as the glans penis. Both conditions are the result of bacterial infection. They are painful, irritating and produce a discharge. They may be associated with inadequate hygiene and phimosis. A swab from the inflamed area is sent for pathological culture and sensitivity tests. Specific antibiotic therapy can be prescribed. Local treatment will involve bathing the affected areas with normal saline to relieve discomfort.

Epididymo-orchitis
In this condition, infection and inflammation of the testis and epididymis occur together. It may be caused by prostatitis, a urinary tract infection or a sexually transmitted disease. The testes are swollen, tender and painful. The patient is pyrexial and suffers from aches and pains. He may experience nausea and vomiting. Bed rest, extra fluids, analgesics and antibiotics are necessary. Cold packs applied locally to the scrotum and the wearing of a scrotal support will help to relieve discomfort and swelling.

Orchitis
This condition is most often caused by mumps occurring after puberty. It may result in atrophy of the testes and sterility. Males who have not had mumps in childhood should try to avoid contact with the disease. Early administration of gammaglobulin may reduce the severity of mumps in those who have been exposed.

Prostatitis
This is an acute or chronic inflammation of the prostate gland and is usually bacterial in origin. Urgency, frequency and pain with micturition are experienced. Acute retention of urine, cystitis, low back pain, chills and haematuria may occur. The prostate gland is enlarged and tender when examined. Midstream urine specimens are sent to the laboratory for culture and sensitivity. Antibiotics, analgesics and a high fluid intake are prescribed. The condition is liable to recur.

The nurse should take the opportunity to check whether the patient understands how to self-examine the testes for the development of a lump (see Box 7.10). The patient should accept the need to complete a self-examination at appropriate intervals. However, it would be inappropriate to associate the risk of tumour with vasectomy until more research data are available.

Occupational health nurses can take a significant role in promoting testicular self-examination in the working male population, the majority of whom seldom need to visit their general practitioner.

ERECTILE DYSFUNCTION

Erectile dysfunction (or impotence) is the persistent inability, due to organic causes, to obtain an erection sufficient for sexual intercourse. The word impotence has

RESEARCH ABSTRACT 7.8

Vasectomy and risk of prostate cancer

Vasectomy has become a popular method of contraception but concern has been raised regarding a possible association with prostate cancer. Cox et al (2002) investigated this with a national population-based case-control study in New Zealand, involving 923 new cases of prostate cancer among men aged 40–74 years. Controls were randomly selected from the electoral register with frequency matching to cases in 5-year age groups. Cases and controls were interviewed by telephone. Their findings suggest no association between prostate cancer and vasectomy, and no association with time since. The authors therefore concluded that vasectomy does not increase the risk of prostate cancer, even after 25 years.

Cox B, Sneyd M J, Paul C, Delahunt B, Skegg D C 2002 Vasectomy and risk of prostate cancer. Journal of the American Medical Association 287(23): 3110–3115

wide social and psychological connotations and it is recommended that the use of this term with patients is discouraged and the disorder referred to as erectile dysfunction or another appropriate descriptive expression (Bancroft 1993). It is difficult to show the true prevalence of erectile dysfunction because of the nature of this disorder and the shame, guilt or embarrassment associated with it, but Bancroft (1993) suggests 7–8% of men may be affected, the incidence increasing with age.

PATHOPHYSIOLOGY

Erectile dysfunction may be a primary or secondary condition. The former implies that the patient has never had an erection. This is rare and is usually associated with gross abnormality of the penis or with hormone deficiency from childhood. Secondary erectile dysfunction is much more common and may be due to psychological or organic factors, or to a combination of both.

Most men will occasionally fail to gain or maintain an erection attributed to stress, overwork or some other reason.

Causes Psychological causal factors have been categorised by Kolodny et al (1979) as follows:

- Developmental
  - — maternal or paternal factors
  - — conflict in parent–child relationship
  - — severe negative family attitude to sex
  - — traumatic childhood sexual experience
  - — gender identity conflict
  - — traumatic first coital experience
  - — homosexuality
- Affective
  - — anxiety about performance
  - — guilt
  - — depression
  - — poor self-esteem
  - — hypochondria
  - — mania

— fear of causing pregnancy
— fear of sexually transmitted diseases (STDs)
- Interpersonal
  — poor communication
  — hostility towards partner
  — distrust of partner
  — lack of physical attraction to partner
  — sex role conflict
  — divergent sexual preference, or sex value systems, e.g. time, place, type
- Cognitive
  — sexual ignorance
  — acceptance of cultural myths
  — performance demands
- Miscellaneous
  — premature ejaculation
  — isolated episode of erectile failure
  — iatrogenic influences.

Organic causes of secondary erectile dysfunction include:

- poor arterial inflow caused by atherosclerosis and aneurysm
- venous leaks between the corpora and venous system
- neurological diseases
- endocrine dysfunction
- drugs, including antihypertensives, narcotics and alcohol
- major surgery — cystectomy, radical prostatectomy (see Ch. 8).

For further information, see Bennett (1994).

MEDICAL MANAGEMENT

Investigations are carried out to provide an understanding of the problem (Gregoire & Pryor 1993):

- clinical interview to explore the nature of the problem, sexual behaviours and attitudes, relationship with a partner, personal and family history, medical history, psychiatric history and current therapy or medications
- physical assessment, including examination of penis, testes, prostate and seminal vesicles; neurological examination; vascular examination
- blood screen for evidence of endocrine imbalance, diabetes mellitus, renal failure
- assessment of penile blood flow by Doppler studies and angiography
- assessment of neurogenic factors by monitoring nocturnal penile tumescence (NPT), response to visual erotic stimuli, assessment of autonomic nerve function and neurophysiological studies
- psychological testing.

Treatment options:

Local injection A local injection at the base of the penis using the α-adrenergic receptor blocking agents, papaverine or a combination of papaverine and phentolamine can cause an erection. The action is by vasodilatation and vasocongestion within the spongy tissue of the penis. An erection can be maintained for a period of about 30 min. Patients can be taught to self-inject at home. Complications include fibrosis at the base of the penis and priapism requiring emergency hospital treatment. Priapism is persistent, painful erection of the penis, unrelieved by sexual intercourse or masturbation. Priapism lasting more than 4–6 h can result in necrosis and fibrosis of the cavernosal tissue as a consequence of ischaemia (King et al 1994).

Penile prosthesis There are various types of penile prosthesis available, ranging from semi-rigid, non-inflatable devices to multicomponent, inflatable implants. A full discussion with the patient (and his partner as appropriate) prior to surgery should include an explanation of the various types, the patient's expectations and possible complications.

The semi-rigid prosthesis consists of two semi-rigid silicone-covered or malleable rods inserted into the shaft of the penis, in the corpora cavernosum. It is important that the correct size is used by the surgeon if the prosthesis is to be effective. They give a permanent erection which is firm enough to allow the patient to have intercourse. A hinged prosthesis allows movement into the upward or downward position. Flaccidity and erection are possible with mechanical and inflatable prostheses.

Individual factors such as motivation, intelligence, dexterity and strength require to be considered in choosing an appropriate prosthesis, to avoid implanting a device that the patient cannot operate (Montague & Lakin 1994).

Infection and erosion are possible complications and usually require removal of the device. The probability of mechanical failure usually relates to the complexity of the device and failure generally requires re-operation.

Revascularisation of the penis This advance in surgery can help patients who have arterial problems. It involves anastomosing an abdominal artery to the penile vein to improve the blood supply. Although not considered major surgery, it does leave the patient with a fairly large abdominal scar. Infection may be a postoperative problem. This procedure has the advantage of restoring normality. Success rate is reported to vary from 50 to 81% (Sharlip 1994), depending on the selection of patients and the surgical procedure adopted.

Vacuum suction machine The machine produces a partial vacuum around the penis, causing it to engorge. An elastic band is then placed around the base of the penis to maintain the erection for a maximum of 15 min. The advantage of this treatment is that the patient can control the erection, but the duration of the erection is limited by the ischaemic effect of the tourniquet.

Psychotherapy Impotence judged to be psychological in origin may be helped by psychotherapy for the patient and his partner.

NURSING PRIORITIES AND MANAGEMENT: Erectile dysfunction

Psychological considerations

A man who develops erectile dysfunction is likely to be shocked and dismayed and reluctant to talk about the problem. This can become a complex matter, not only for the individual but also for his partner and family. Failure to accept or understand the problem can lead to the break-up of relationships. Moreover, organic causes of impotence,

such as multiple sclerosis, diabetes and circulatory problems, may have already caused the patient to change his lifestyle and placed the family under stress. The patient may be very reluctant to discuss the problem openly with a doctor or nurse. He may present to his GP ostensibly with another problem, only managing with difficulty to mention his real concern. Occasionally it is at an outpatient appointment such as a diabetic clinic that the subject is brought up. Medical and nursing staff must treat the patient with empathy and sensitivity. While the condition is not life-threatening, once the patient presents he will want something done quickly.

Practical considerations for the patient receiving a penile implant

The nurse should ensure that the patient is given sufficient information about the procedure and recovery. He should be told that his hospital stay will be 4–7 days, and that regular analgesics will be given to control any pain. Catheterisation will be required for at least 24 h. Bed rest will not be required, but the patient should not spend too much time walking around or sitting in a chair for the first few days, to encourage healing and reduce discomfort. A scrotal support for a few weeks will help prevent swelling and minimise discomfort.

The consultant will discuss how soon the prosthesis may be used, usually recommending that it is not used until after the first outpatient appointment in 6 weeks. Sutures are normally dissolvable. It is helpful to assure the patient that visitors or other patients on the ward will not know what procedure he is undergoing unless he tells them himself. Nor will other people know that he has a prosthesis, although it may be necessary to avoid wearing tight trousers or swimming trunks.

OTHER DISORDERS OF THE MALE REPRODUCTIVE ORGANS

Inflammatory disorders of the male reproductive organs are briefly described in Box 7.12, page 312. Disorders affecting the prostate, urethra and urinary function are described in Chapter 8.

CULTURAL AWARENESS IN REPRODUCTIVE HEALTH

Sociological change and economic progress have contributed to the integration of immigrants into the UK and some have been in this country for generations. Inevitably, when people move from their particular culture to another, they bring with them their own beliefs and values. Some of these will remain with them, giving direction to their life and practices. Older members of a family tend to rely on tradition and may be reluctant to adopt new ideas, whereas younger generations growing up in a new environment are more influenced by different cultural perspectives and more likely to adapt to or adopt some of the dominant views of the indigenous population around them. This can cause tension within families as views associated with sex, marriage and family affairs come into conflict.

If health care workers are to provide sensitive care to individuals from different cultural backgrounds, they need to be aware that the beliefs and values associated with a particular culture. While the views of some will conflict with those held by the nurse, a non-judgemental approach is required. In this respect, Item 2 in the nurses' *Code of Professional Conduct* (NMC 2002, p. 4) states that nurses, midwives and health visitors must respect the individuality of patients 'irrespective of gender, age, race, ability, sexuality, economic status, lifestyle, culture and religious or political beliefs'.

Nurses are not expected to have a wide knowledge of all cultural and religious beliefs but should find out about the customs relevant to the cultural groups presenting in clinical practice. In some cases, problems with communication can be exacerbated in cross-cultural interactions, not only because English may not be the first language of patients, but also because they may feel embarrassed to ask for clarification or further explanation. Obtaining leaflets with information in different languages is required when this is a potential problem. Younger members of a family may be more fluent in English than their older relatives and effective communication may be achieved by sensitively incorporating them for translation and clarification. The services of an interpreter may need to be employed.

While reproductive functioning, sexuality and health disorders affecting the reproductive systems are felt to be very personal and intimate issues in British culture, this attitude may in fact be much more exaggerated in other cultures. Open communication, required for the sharing of information and the giving of health care advice, may therefore be made more difficult. The performance of a necessary vaginal examination, for example, may be seen as a major procedure with significant emotional implications.

While it has been suggested that treatment of fertility problems should incorporate the couple, Muslim or Sikh men may be extremely reluctant to attend a fertility clinic with their wife and can feel humiliated or angry at the suggestion that they might be responsible for the fertility problem. The beliefs held about fertility and the sanctity of semen in its life-giving potential can have important implications for the way men and women view contraception and the options available to them for regulating their family. While the nurse may not be conversant with specific options acceptable in different cultures, an awareness of the existence of such restrictions on individual choice allows a more sensitive, exploratory approach with clients.

Different cultural and religious perspectives view marriage and the production of offspring in different ways. Similarly, family networks vary and the extended family may have a significant influence on younger members, showing a sense of responsibility with regard to provision of information and support.

Thus, both culture and religion can have a powerful influence on sexual practices, family support networks and how individuals feel about their own sexuality and self-concept. In introductory interactions with patients — taking a history and building up a rapport — the nurse can learn much from them by showing an interest in their beliefs and their perspective on life and encouraging them to discuss

these. This knowledge can then help nurses to be more aware and sensitive to cultural influences in health care and facilitate more individualised nursing.

Male circumcision — excision of the foreskin — is a procedure with religious connotations for those of Jewish or Muslim faith. This can be performed by a Jewish rabbi or by a family doctor. Harbinson (1997) indicates that circumcision is carried out in the USA for hygienic and social reasons, but in the UK the operation is only performed within the NHS for medical reasons.

Female circumcision is widely practised in some African and Egyptian ethnic groups, in parts of the Middle East and in South East Asia. In the UK, female circumcision is considered to be female genital mutilation. Female genital mutilation is a term used to refer to procedures resulting in different degrees of mutilation of the external genitalia of females (Royal College of Nursing 1996) and has been illegal in the UK since 1985. However, immigrant families can return to their home country to have this procedure carried out on the daughter (usually from the early days of birth to 16 years of age). The effects of the procedure are also seen in the UK amongst women who have been mutilated prior to arrival. Within the culture valuing this procedure, there may be difficulty in securing a husband for a female who has not been so treated.

Female mutilation can take various forms:

- Female circumcision involves excision of the hood of the clitoris.
- Clitoral excision may be performed with or without removal of the labia minora.
- Infibulation is a more extensive procedure involving removal of the clitoris, labia minora and some of the labia majora. The vulva is sutured together leaving only a small orifice for passage of urine and menstrual blood.

Although the risk of infection after these procedures is high, women may not present with problems until later in life. Problems may include recurrent urinary tract infections, vaginal infections, non-consummation, infertility and psycho-sexual problems. During pregnancy the women require sensitive care. Special antenatal care may be available to allow women to express their fears about labour and childbirth and for the provision of information and counselling. For some women a vaginal delivery will be feasible and de-infibulation may be possible to avoid a caesarean section (Toubin 1994). De-infibulation can be performed during a pregnancy or during labour but Omer-Hashi (1994) suggests that the earlier this is performed the better the outcome in terms of decreased pain during labour and a shorter recovery time after delivery.

Educating, advising and counselling people who have quite different beliefs, values and attitudes concerning health issues from those of the health professionals providing help and support requires tact and sensitivity. Understanding and empathy can help nurses to appreciate what others consider to be important. A balance is required between giving sound advice and respecting the social, cultural and religious views of others.

INTRODUCTION

The breast is the human organ of lactation which develops in puberty to enable a mother to feed her offspring. In Western society the breasts are strongly associated with femininity and sexuality as well as with motherhood. Images of femininity and sexuality presented in advertising and other media use breasts, often large and perfectly formed, as symbols of sexual desirability promoting an idealistic beauty which few women can attain. It is not surprising, therefore, that breast disease often has profound implications not only for a woman's physical health but also for her social and familial roles, body image and self-confidence. Women who suffer any alteration or disfigurement of the breast often experience anxiety, depression and loss of sexual satisfaction.

This chapter will begin by discussing the anatomy and physiology of the healthy breast before considering the benign disorders of the breast, mammary dysplasia, fibroadenomas, breast pain and breast infections. In addition, the rare condition of gynaecomastia will be described in view of its important psychological implications for the individual.

Breast cancer and its treatment will then be discussed in detail as breast cancer is one of the most common malignant conditions in the United Kingdom. Related health care issues such as breast reconstruction, care of the fungating breast lesion and the management of lymphoedema will be given particular attention. Consideration will also be given to measures for the early detection of breast cancer.

Finally, the significance of diseases of the breast for a woman's psychological well-being will be discussed. Patient education will be considered in relation to promoting breast health and the early detection of disease. The importance of involving the patient and her family in making informed treatment choices and in carrying out subsequent self-care will also be considered.

ANATOMY AND PHYSIOLOGY OF THE BREAST

Structure of the breast

The breast is made up of glandular, fatty and fibrous tissue which is covered by skin. Men and women both have breast tissue, but in the male it remains rudimentary and normally does not develop in puberty.

The glandular tissue of each breast is divided into 12–20 lobes or segments (see Fig. 7.12). Each is made up of hundreds of lobules which are activated during pregnancy to produce milk. They are connected by terminal ducts which join to form lactiferous ducts before ending in approximately 10 openings in the nipple. Breast tissue is supported by Cooper's ligaments, fibrous bands which connect the skin of the breast to the underlying fascia. These ligaments may contract when affected by tumour causing dimpling of the skin (peau d'orange). With increasing age and weight, these ligaments stretch, causing the breasts to droop, otherwise known as ptosis.

The nipple contains smooth muscle and becomes erect when stimulated, allowing a baby to suck more easily. It is surrounded by the areola, on the surface of which are Montgomery's tubercles, or glands which lubricate the nipple during breast feeding.

Blood and lymph vessels

The breast is highly vascularised. It is supplied by thoracic branches of the axillary arteries laterally, and medially by branches of the internal mammary artery. Venous drainage follows arterial supply, and the lymphatic channels follow the main blood vessels outwards, branching to the regional lymph nodes. Most lymph drainage of the breast is via the axillary lymph nodes, proceeding from there to the supraclavicular lymph nodes. Drainage from the medial part of the breast is via the internal mammary nodes which lie beneath the ribs and lateral to the sternum.

Nerve supply

Branches of the IV, V and VI thoracic nerves, containing sympathetic fibres, supply the breast. Many sensory nerve endings exist around the nipple. When touched, these cause reflex erection and, after childbirth, the release of milk.

Associated muscles (see Fig. 7.13)

Behind the breast and overlying the rib cage is the pectoralis major muscle. This large triangular muscle, which attaches to the clavicle, sternum and upper six costal cartilages, is

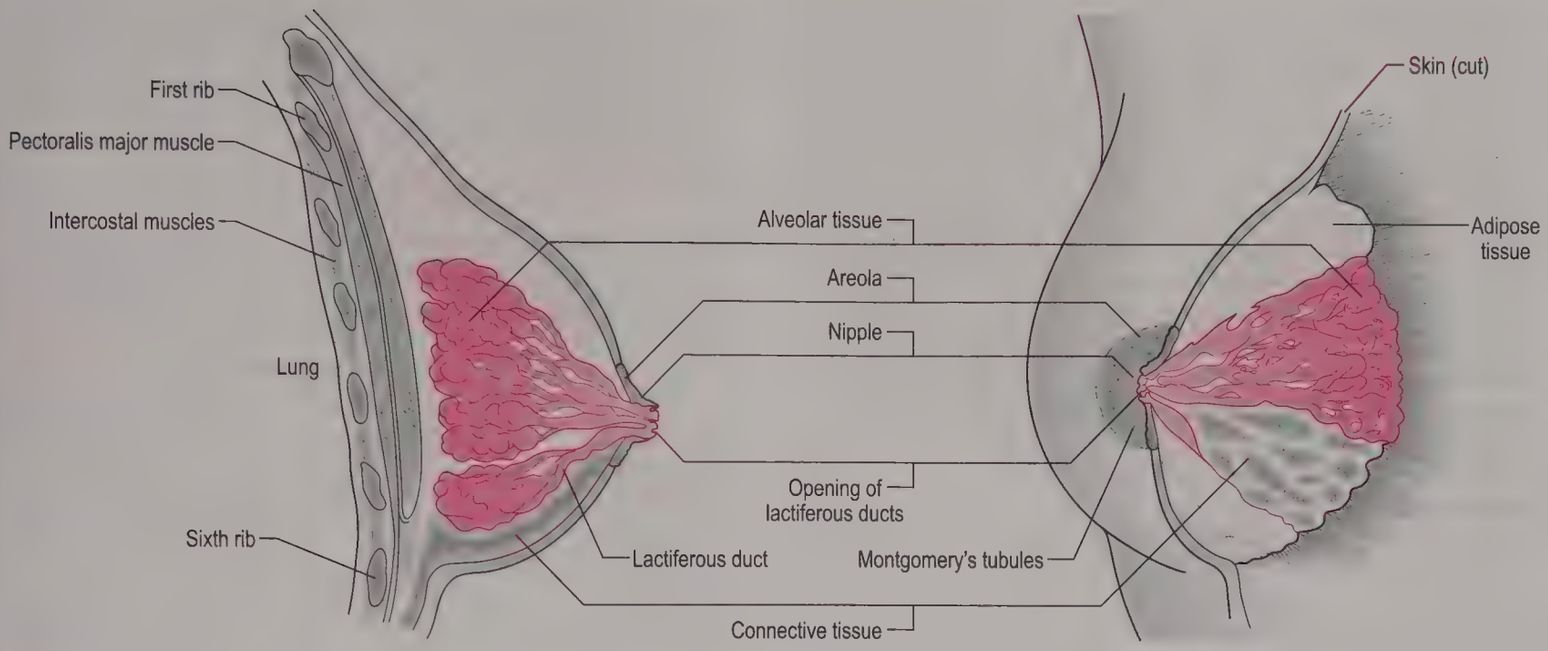

Fig. 7.12 Lateral cross-section of the breast.

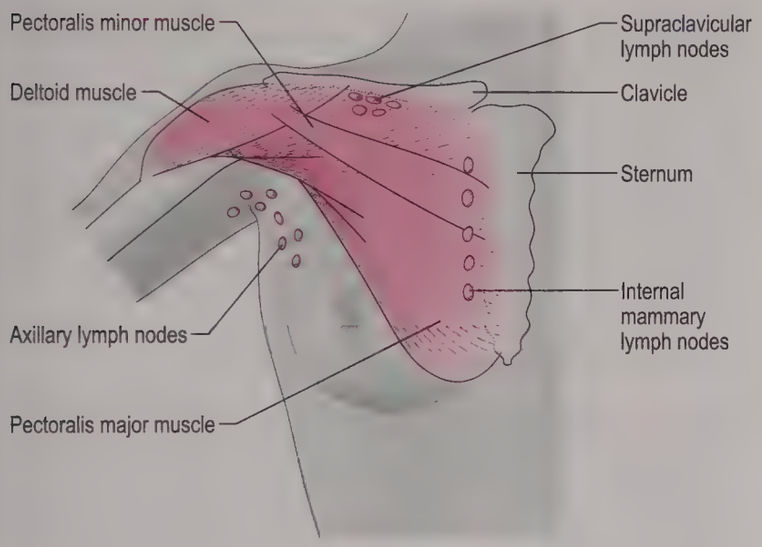

Fig. 7.13 The breast and associated structures.

used to adduct the arm. Behind the pectoralis major muscle lies the pectoralis minor. This muscle attaches to the third, fourth and fifth ribs and the front of the scapula. Its function is to stabilise the shoulder girdle, serratus anterior and the latissimus dorsi muscle from the base and back of the axilla, respectively. These structures and their nerve supply are important considerations when axillary surgery is performed.

Normal breast changes

The breasts constantly change as a normal consequence of ageing. Natural changes also occur with menstruation, pregnancy and lactation.

Puberty

A girl's breasts will begin to develop at puberty. The pituitary gland in the brain begins to produce the gonadotrophins, follicle-stimulating hormone (FSH) and luteinising hormone (LH). As the level of these hormones increases, egg follicles within the ovaries are stimulated to release oestrogens, which in turn stimulate an increase in the breast connective tissue, a lengthening of the ducts in the breast and the formation of the breast lobules.

Menstruation

At the start of each monthly cycle, blood oestrogen levels rise, causing the breast ducts and lobules to enlarge. After ovulation, the corpus luteum produces progesterone which causes further breast changes. At this time, tenderness and heaviness of the breasts may be noticed. If pregnancy does not occur, the hormone levels fall, the ducts and lobules regress, and the breasts lose their tenderness and swollen feeling. This usually precedes the onset of menstruation.

Pregnancy

If pregnancy does occur, the levels of oestrogen and progesterone continue to rise, causing the ducts and lobules to increase in size and number in order to prepare for lactation. The enzymes necessary for milk production are stimulated by prolactin (produced by the anterior pituitary gland) and by placental lactogen, but milk production is suppressed during pregnancy by high progesterone levels.

Milk production

After birth, progesterone levels drop and milk synthesis can begin. As the baby sucks, prolactin is released (from the anterior pituitary), initiating milk synthesis, and oxytocin is released (from the posterior pituitary), causing milk to be emptied from the ducts. The more the baby sucks, the more milk is produced. Sucking also inhibits the release of FSH and LH by the pituitary gland, so blocking ovulation. However, this effect is usually short lived and cannot be relied upon for contraception. When breast feeding stops, the ducts and lobules start to regress, and milk production slows and then ceases.

Once the baby is born, the breasts produce colostrum for 2 or 3 days before the true breast milk production begins. Colostrum is a yellowish fluid with a lower lactose content than milk and contains very little fat, but more vitamin A, protein and minerals. Like milk, colostrum is rich in IgA antibodies which protect the baby's gastrointestinal tract against bacteria and viruses (Newman 1995). Breast milk contains all that is necessary for an infant in the first few months of its life. Cells of the breast lobules extract amino acids, fatty acids, glycerol and glucose from the blood and build them into proteins, fats and lactose. Milk also contains calcium, phosphorus, vitamins A, B, C and D, and small amounts of iron, but the exact composition depends on the mother's dietary intake.

Menopause

As a woman approaches the menopause, changes in ovarian function and a subsequent drop in hormone levels cause glandular breast tissue to atrophy. This process of involution where breast tissue is replaced by fatty tissue causes the breasts to become softer and less lumpy. Consequently, the breasts are easier to examine and assess by mammography.

BENIGN BREAST DISORDERS

Benign breast disorders account for approximately 90% of all breast problems. The largest category of benign breast disorders occur as a result of 'anomalies of normal development and involution' (ANDI). The most common ANDI categories — structural disorders, benign mammary dysplasia, breast pain and breast infection — are considered here. Gynaecomastia is also mentioned because, although rare, it is the most common breast disorder in men.

ABNORMAL BREAST DEVELOPMENT

It is estimated that about 1% of men and 5% of women are born with one or more extra nipples. These extra nipples, or polythelia, usually develop whilst the foetus is in the womb, the most common site being along the milk line or the ectodermal ridge. Extra breasts can also develop and often occur in the lower axilla (Dixon & Mansel 2000).

Aberrations of normal breast development can cause the absence (amastia) or underdevelopment (hypoplasia) of one breast. This can occur in conjunction with a defect in the pectoral muscle and the upper limbs (Poland's syndrome). There is usually some difference in breast size for a woman, with the left breast being larger than the right, but the difference should not be extreme. If it is, then surgical intervention involving augmentation of one breast and reduction of the other breast is offered by many plastic surgeons (Reshef et al 1996).

Juvenile or virginal hypertrophy

Prepubertal breast enlargement is quite common and only requires investigation if it is associated with other signs of premature sexual development. The overgrowth of breast tissue can occur in adolescent girls whose breasts develop during puberty but then continue to grow. Usually no hormone abnormality can be detected. The treatment of choice for these women is a reduction mammoplasty, i.e. surgical removal of breast tissue from each breast (Dixon & Mansel 2000).

Epithelial hyperplasia

This is a common condition amongst women of all ages but particularly affects women between the ages of 30 and 55. This is often called fibrocystic disease but the term is misleading in that it is really not a disease but a natural occurrence in women as they approach the menopause. It is thought to be caused by the incomplete involution of breast tissue during each menstrual cycle, causing an increase in the number of cells lining the terminal duct lobular unit. This, in turn, leads to cystic changes, fibrosis and nodularity. If biopsied, the cells show hyperplasia, but with no alteration in individual cellular appearance. However, where atypical hyperplasia is present, the risk of breast cancer developing in the breast is raised, and regular screening may be advised.

Nodularity

This may present as diffuse lumpiness or thickening of the breast tissue which may contain single or multiple cysts. Commonly, it is bilateral, although it may occur in only one breast. Premenstrual tenderness is often experienced coinciding with an increase in nodularity. Cysts usually develop as a woman is nearing her menopause and they present as tender, fluctuant entities which, when examined under ultrasound, are shown to be fluid-filled. They may increase in size or stay the same and sometimes they just disperse.

MEDICAL MANAGEMENT

Investigations Assessment of a woman who complains of a lump or lumpiness within her breasts will involve clinical examination, mammography, ultrasound and sometimes fine-needle aspiration cytology or core biopsy. Cystic fluid is usually sent for examination if the fluid is bloodstained, as this may indicate cancer.

Whenever a cyst or area of nodularity is slightly suspicious in its presentation, excision biopsy will sometimes be recommended to exclude cancer (see p. 323). Follow-up examinations are not usually required unless histology reveals atypical hyperplasia in a younger woman or if there is a family history of breast cancer.

Nodularity is sometimes aggravated by oral contraceptive pills or the contraceptive coil. If this appears to be the case, a change in method of contraception may be recommended.

Fibroadenomas

Fibroadenomas are considered as aberrations of normal breast growth and are composed of both fibrous and glandular breast tissue. Under the same hormonal influences as the rest of the breast, a fibroadenoma grows as a centrifugal small nodule that is usually well circumscribed and freely movable within the surrounding breast tissue. They are very common, accounting for 13% of all palpable

breast lesions, and in women aged 20 years or less, they account for 60% of breast masses (Dixon & Mansel 2000). Juvenile or giant fibroadenomas are rare and occur in adolescence. They are characterised by a fast-growing lesion that can grow up to 5 cm in size and will distort the breast. These lesions require surgical excision for cosmetic reasons.

NURSING PRIORITIES AND MANAGEMENT: Excision biopsy of lesions and fibroadenomas

Major considerations

Assessment

Surgery is not usually undertaken for benign lesions unless a diagnosis is not possible. Fibroadenomas are not usually removed unless they are large or of particular concern to the patient. Nursing assessment should include the presenting symptoms and, in particular, the presence of any discomfort and any aggravating or alleviating factors. The nurse should determine the patient's knowledge about her condition, her fears and concerns, and the ways in which the condition is affecting her normal life.

Perioperative care

General pre- and postoperative nursing practices are discussed in Chapter 26. Surgery is usually minor. Reassurance that this is not cancer may be needed but the nurse should not give false reassurance where doubt exists as to the nature of the lump. As postoperative recovery is usually rapid, surgery is frequently performed on a day-case basis or may require a 1-night stay in hospital. Postoperatively, the priority of nursing will be wound management and pain control. Because the breast is very vascular, there may be bruising even though the surgery is minor. A wound drain is sometimes needed, but, if present, is usually removed the following morning.

The breast is likely to be very painful for several days. Paracetamol is usually sufficient for pain relief, but if bruising and oedema are very extensive, a stronger analgesic may be required, e.g. an opiate-based drug. Wearing a supportive bra is usually advised for the first 2 weeks postoperatively to improve comfort and avoid strain being placed on the wound. The woman should be encouraged to bring a good fitting bra into hospital with her so that she may wear it very shortly after the surgery.

Patient education

The nurse should take the opportunity to promote breast health by discussing breast screening and breast awareness. It may be appropriate to discuss how breast comfort can be enhanced by a correctly fitting bra. Women who have premenstrual breast discomfort may find reducing salt or omitting caffeine from their diet helpful. Others find that a course of evening primrose oil brings relief.

BREAST PAIN

Breast pain (mastalgia) has been reported in over 50% of women who attend benign breast clinics (Mansel 2000). For most women, some breast discomfort is accepted as a part of the normal changes in their breasts each month. However, some women suffer more intense pain which affects their quality of life, usually from mid-cycle onwards, and is often relieved by menstruation. The pain can differ from cycle to cycle and can continue for many years. Evening primrose oil and reducing caffeine and fat intake have been found to be of benefit for some patients. Hormone manipulation using danazol, bromocriptine or a luteinising hormone releasing hormone agonist have all been used to some effect. Such drug interventions should be medically supervised at a benign breast disease clinic (Purushotham et al 2000).

Non-cyclical breast pain, usually experienced in women over 40, is the main type of mastalgia. Often localised within the breast, this type of pain can be relieved by infiltrating the area with a local anaesthetic and steroid. For both cyclical and non-cyclical mastalgia, wearing a firm and well-fitted bra can help (Mansel 2000).

BREAST INFECTIONS

PATHOPHYSIOLOGY

Breast infections, such as mastitis, are relatively common, causing swelling, tenderness and pain, which may be associated with a breast abscess or nipple discharge. Breast abscesses are most commonly seen during or following lactation. Infection may arise from a cracked nipple, but often there is no apparent cause. Staphylococcal organisms are the most common causes.

MEDICAL MANAGEMENT

Systemic broad-spectrum antibiotics are the usual treatment. However, a persistent abscess may require surgical drainage and excision of the surrounding capsule. A persistent nipple discharge may be treated by a microdochectomy, which involves removing one of the major ducts behind the nipple, or a duct clearance which involves removing the major duct system behind the nipple. Surgery is usually through a circumareolar incision, and this surgery often can be performed on a day patient basis.

Duct ectasia

Duct ectasia occurs during breast involution when the major subareolar ducts dilate and shorten. Normal breast secretions are retained behind these blocked ducts. Women with duct ectasia present with nipple discharge, nipple retraction, inflammation or a palpable mass. Surgery is indicated if the discharge is a problem (Curling & Tierney 1997).

NURSING PRIORITIES AND MANAGEMENT: Breast infections

Giving psychological support

Until the presence of infection has been established, fear of a more serious problem, particularly cancer, may remain. An explanation of the nature and possible cause of infection will help to reassure the patient, particularly as recurrent infections are quite common and may cause frustration and distress.

Reducing discomfort

The discomfort and pain accompanying a breast infection are usually the most distressing features of the condition. A supportive bra, applications of heat or cold 'packs' and padding to protect a sore nipple may all reduce discomfort, but mild to moderate analgesic medication is usually necessary to achieve a satisfactory level of comfort.

Surgical management

Where surgical excision of the abscess is required, nursing management will be similar to that for a woman undergoing an excision biopsy (see p. 328). The nurse must be particularly vigilant in observing for signs of wound infection.

OTHER DISORDERS OF BREAST STRUCTURE

Duct papillomas

Duct papillomas are benign wart-like lesions which form in the lactiferous duct wall. Most of these occur beneath the areola. Papillomas present with pain or bloody discharge and are usually soft and difficult to locate. Surgical resection is usually the treatment of choice (Blackwell & Grotting 1996).

Lipomas

When examined, these fatty lumps can be mistaken for cysts within the breast tissue. They do not cause major problems and diagnosis by ultrasound and cytology should be all that is needed.

Mondor's disease

Caused by a superficial thrombosis of a vein in the breast, this condition is usually very painful, requiring analgesics. Malignancy should always be excluded, but no other treatment should be necessary and the condition usually resolves in 6 months (Curling & Tierney 1997).

Galactocele

This is a cystic lesion which occurs in the breasts of pregnant or lactating women. Once diagnosed, treatment is by aspiration. This may have to be performed on several occasions to allow the walls of the cyst to adhere (Curling & Tierney 1997).

Fat necrosis

Presenting as a painful mass, fat necrosis can imitate breast cancer and should be diagnosed with care. About half of the cases of fat necrosis are caused by a blow to the breast, although the other cases have no history of trauma. The treatment is surgical excision to be absolutely sure that the area is not malignant (Blackwell & Grotting 1996).

GYNAECOMASTIA

This is a rare benign disorder which occurs in men and involves overdevelopment of male breast tissue as a result of oestrogen production either in puberty (30–60% of boys aged 10–16 years) or at a later age. This may be due to idiopathic excess oestrogen, e.g. in choriocarcinomatous teratoma or cirrhosis of the liver, to decreased testosterone, e.g. in Klinefelter's syndrome (see Ch. 6), or to drugs, e.g. amfetamines, antidepressants, certain antihypertensives, digoxin, spironolactone or oestrogen administration.

MEDICAL MANAGEMENT

Surgery is not usually recommended, as 80% of cases resolve within 2 years, unless the gynaecomastia is mistaken for a possible carcinoma; in such instances a biopsy may be advised. If the condition has arisen following the administration of a particular medication, modification of that medication can be considered. Hormone manipulation may be of benefit where gynaecomastia is due to the oversecretion of oestrogen (Dixon & Mansel 2000).

NURSING PRIORITIES AND MANAGEMENT: Gynaecomastia

Giving psychological support

Breasts are considered to be a female characteristic, and for this reason the overdevelopment of breast tissue in a man may cause an altered body image and emotional distress. Some men with gynaecomastia believe they have lost their masculinity and experience anxiety and depression as a result. When gynaecomastia occurs in adolescence, such feelings may be particularly acute.

The nurse must be sensitive to such feelings and show an understanding of them. It may be difficult for a man to express these feelings to a female nurse, especially if she is relatively young, but he is more likely to do so within a professional relationship where trust exists. A clear explanation of why the breast tissue has developed and of any treatment that may be given is essential.

For more information, see Dixon (2000) and Purushotham et al (2000).

MALIGNANT DISORDERS OF THE BREAST AND THEIR SEQUELAE

BREAST CANCER

Incidence and mortality

Breast cancer is the most common malignancy in women, accounting for 25% of all of female cancers (Breast Cancer Care 2003). Approximately one in nine women in the UK will develop breast cancer at some time in their lives. There are 40 000 new cases of breast cancer and 13 000 deaths due to breast cancer each year (Breast Cancer Care 2003). Less than 1% of all breast cancers occur in men. It is important for nurses to be aware of the special problems that men may experience when they are diagnosed with a disease that almost exclusively affects women (Perkins & Middleton 2003).

Risk factors

The main risk factors associated with breast cancer are listed in Box 7.13. Of these, only increasing age is known to be of any substantial significance.

Box 7.13

Factors increasing the risk of developing breast cancer

- Early menarche
- Increasing age
- Family history of breast cancer
- Age at birth of first child
- Geographical location
- Late menopause
- Nulliparity (no pregnancies)
- Social class (class I has highest risk)
- Other possible factors under evaluation
- High alcohol intake
- High-fat diet
- Stress

Increasing age Breast cancer in women is very rare below the age of 35 years, but incidence rates increase steadily from then, reaching over 300 per 100 000 of the population by the time women are 85 years old. The largest number of women are diagnosed between the ages of 45 and 75 years (see Fig. 7.14).

Geography England and Wales have the highest standardised mortality figures per 100 000 for breast cancer in the world, followed by Scotland and Denmark, Northern Ireland and the Netherlands, Canada and the United States of America (McPherson et al 2000). Generally, incidence in Western Europe, North America and Australia is approximately five times higher than in Asia and Africa. Japanese women have low rates of breast cancer, but incidence rates are seen to rise by the second generation among Japanese–Americans. This suggests that environmental and social risk factors may exist.

Diet Populations with a high rate of breast cancer generally have a diet high in fat. Obesity has also been found to be associated with a slightly increased risk of breast cancer. However, a clear link between diet and the risk of breast cancer has not been established.

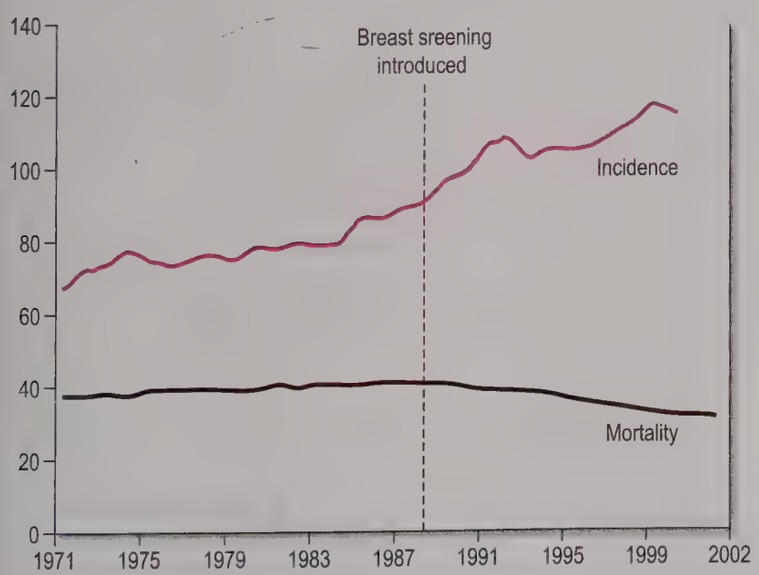

Fig. 7.14 Age-standardised incidence of and mortality from female breast cancer, England and Wales; rate per 100 000. From Office for National Statistics, www.statistics.gov.uk.

Social class Breast cancer is slightly more common amongst women in social class 1, suggesting that breast cancer is a disease of affluent societies.

Hormone-related factors Women who have their first child after the age of 35, those who experience early menarche, and those who have a late menopause are all found to have a slightly increased rate of breast cancer. This has led to the belief that the hormone oestrogen may be implicated in the development of breast cancer (Wren 2004). In recent years, there has been much speculation as to the effects of the contraceptive pill and hormone replacement therapy on the incidence of breast cancer. Studies do not give a clear picture as yet, as oral contraceptive use was not common until the early 1970s and any effect is thought to be long term. There is no increased risk for women in their early 20s who have used oral contraceptives to space their pregnancies. However, use of oral contraceptives for 4 years or more by younger women before their first pregnancy may increase the risk of premenopausal breast cancer. More research is needed, particularly as today's contraceptive pills contain lower levels of oestrogen or none at all (Hemminki 1996).

Family history Between 5 and 10% of breast cancers are due to genetic predisposition (Arden-Jones 2003). The likelihood of a woman carrying a genetic abnormality is higher if:

- there are several cases of breast cancer in a single family
- those affected in that family have an early onset of cancer
- there is a diagnosis of a different epithelial cancer in one family, e.g. bilateral breast cancer, ovarian cancer, colon or prostate cancer. The combination of ovarian and breast cancer is particularly common in families who carry a cancer predisposing gene (Page et al 2000).

In families suspected of having a cancer predisposing gene, it is important to get a family history, or pedigree, going back several generations to assess who developed cancer and the type of cancer it was. This information is usually taken by a geneticist or a genetics nurse who is working in a specialised genetics clinic (see Ch. 6, p. 235). These details will usually allow the geneticist to confirm that a cancer gene is present and to estimate the likelihood or risk that any member of the family has the gene. Family histories are often difficult to recall and sometimes it is necessary to extend and verify details of family histories by using public records of births, deaths and marriages, pathology reports and hospital records. Patterns in the family pedigree can then be clarified and the breast cancer predisposing genes such as BRCA1 or BRCA2 can be identified by genetic linkage analysis. This involves taking tissue or blood samples from family members and using specialised genetic techniques to search for the problematic gene.

Women who are at an increased risk of developing cancer because of a genetic predisposition will be offered genetic counselling and psychological support by the geneticist and specialist nurses who work in the clinic. Counselling

is a very important part of the process because of the implications for that individual and other members of the family who may not wish to know their risk of cancer. Family relationships can be seriously disrupted if risk assessment and genetic testing are not explored fully with all those involved (Arden-Jones 2003).

If the chance of the woman developing cancer is very high, this will be discussed with the woman and her future care will be considered. Interventions are regularly evaluated as this is a relatively new area of cancer care and there is uncertainty about the best way of screening or prevention for women (and men) at risk. Instituting regular clinical examination is debatable but contact with an established breast/genetics clinic is recommended for women at risk (Arden-Jones 2003). Regular mammographic screening commencing 5–10 years younger than the youngest relative already to have developed the disease is a current recommendation but this is not useful in women less than 35 years old. Both magnetic resonance imaging (MRI) and ultrasound are presently being evaluated as potential screening tools for women at high risk. Cuzick et al (2003), in an overview of the use of the oestrogen blocking tablet tamoxifen for women at risk, showed a reduction in breast cancer occurrence in high-risk women, so the use of this agent may be a future solution. Some women will have the BRCA1 or BRCA2 gene confirmed by DNA analysis and may then be offered bilateral subcutaneous mastectomy and bilateral oophorectomy as a preventive treatment, although this is clearly a serious undertaking (see p. 248). Research into this area of cancer care will continue far into this millennium. The implications for breast care are potentially very exciting, as women who are likely to develop breast cancer could be identified and treated prophylactically (McPherson et al 2000, Page et al 2000).

Prevention in the present

Over the last 30 years, advances in treatments, and more recently the multidisciplinary approach to breast cancer care, have made an impact on survival (Peto et al 2000). We also know that if women are diagnosed at an early stage in their disease, treatment is likely to be more effective (see Fig. 7.14). Therefore, taking measures to detect breast cancer earlier would appear to be one way of reducing breast cancer mortality.

Breast awareness

For many years there has been debate as to the value of monthly breast self-examination in the diagnosis of early breast cancer. Research has been unable to demonstrate that it alters survival from the disease. However, a woman who is aware of any changes that occur in her breast and, if she wishes, practises self-examination, is likely to notice any changes. This may aid diagnosis when a cancer is small, so enabling a wider choice of surgical treatment options to be offered. It also encourages an individual to participate in their own health care. Breast awareness helps a woman to know what is normal for her and to detect the following changes:

- A change in size of the breast, noticeably smaller or larger
- Newly inverted nipple or a nipple that has changed its shape
- Discharge from one or both nipples
- Change in colour
- A new lump or thickening in the breast that feels different from the rest of the breast tissue
- A rash or eczema-like changes around the nipple
- Pain in one part of the breast or in the armpit
- Puckering or dimpling of the skin of the breast (peau d'orange; see p. 328).

If a woman wishes to examine her breasts regularly she should do so when she feels comfortable although just after menstruation, e.g. day 8 of her cycle, can be convenient. Obviously, this does not apply to postmenopausal women. At this time, the breasts will be least lumpy and easiest to examine. Breast tissue can be lumpy and so each woman will need to become used to how her own breasts feel and learn to identify her ribs, which are often mistaken for lumps.

To carry out self-examination the woman should sit in front of a mirror and lift her arms above her head, noticing the shape and size of her breasts and any changes. She should examine her skin for dimpling and discoloration and the nipple for discharge, crusting and any new inversion.

Lying flat on a bed or when standing in the shower, with one arm behind her head, she should then examine her breasts using the flat of her fingers of the opposite hand. Breast tissue is very extensive, running vertically from the clavicle to the costal margin and the sternum to the axilla, and breast examination should cover all these areas systematically. Usually a hollow is noticed beneath each nipple. If any lumps, thickening or other changes are noticed, the woman should contact her GP immediately for an examination and advice.

Breast cancer screening

In 1986, the Forrest report (Department of Health and Social Security 1986) recommended the introduction of a national breast screening programme. Screening units are now in operation throughout the UK and women between 50 and 70 years are invited to attend for screening using mammography, i.e. X-ray examination of the breast.

The aim of breast cancer screening by means of mammography is to detect breast cancer at an earlier stage than is possible by clinical examination or breast self-examination, i.e. before a lump is palpable in the breast. In addition, it is hoped that more women with pre-invasive disease (in situ) cancer will be detected before the cancer cells have shown any evidence of spread. A research study by Sjönell and Ståhle (1999) questioned the mammography and screening programme in Sweden and this has raised fresh doubts about the effectiveness of the breast screening programme in the UK. Some clinicians involved in breast care would prefer to see the resources used for the screening programme invested in research into breast cancer treatment (Baum 1996). This debate is likely to continue until long-term evaluation of the effectiveness of the breast screening programme provides a definitive answer. There is much less evidence to support the screening of women aged 40–49 years, which is why, at present, the screening programme in the UK is offered only to women over the age of 50 (Kerlikowske et al 1995).

Mammography will detect 85–90% of all breast cancers in the women examined. It is most effective in postmenopausal women in whom breast tissue has been largely replaced by fat. For young women, in whom breast tissue is more dense, and detection of abnormalities therefore more difficult, mammography is frequently used in conjunction with breast ultrasound.

The success of the national screening programme will depend on a high uptake of the service. A Swedish study demonstrated an uptake rate of 70% (Tabar et al 1995) and this will have to be matched in the UK if the hoped-for 30% reduction in mortality is to be achieved. If fewer women participate in the programme, the cost per life saved increases and, although some women will clearly benefit, the cost-effectiveness of the programme will be called into question. Poor attendance at screening units may result from various factors, such as GP registers not being up to date, fears of discomfort or radiation, or a lack of understanding of the value of mammography. To further explain breast screening, all women invited into the programme are sent a leaflet entitled *Breast Screening – The Facts* (NHSBSP 2001).

Procedures Screening may take place in static or mobile units. The screening itself involves taking an oblique medio-lateral and a cranial–caudal mammogram. Mammograms are repeated every 3 years and, although the screening starts from age 50 years, a woman may not be called until she is 53 years old. The woman is notified by letter of the result. If an abnormality is detected, the letter will ask her to attend for re-screening at an assessment centre (see Fig. 7.15). Here, a fresh two-view mammogram may show the detected lesion to be merely an overlapping of normal structures or a benign lesion requiring no intervention. In some instances, further assessment of the suspicious area using ultrasound and fine-needle aspiration cytology or a core biopsy may be required.

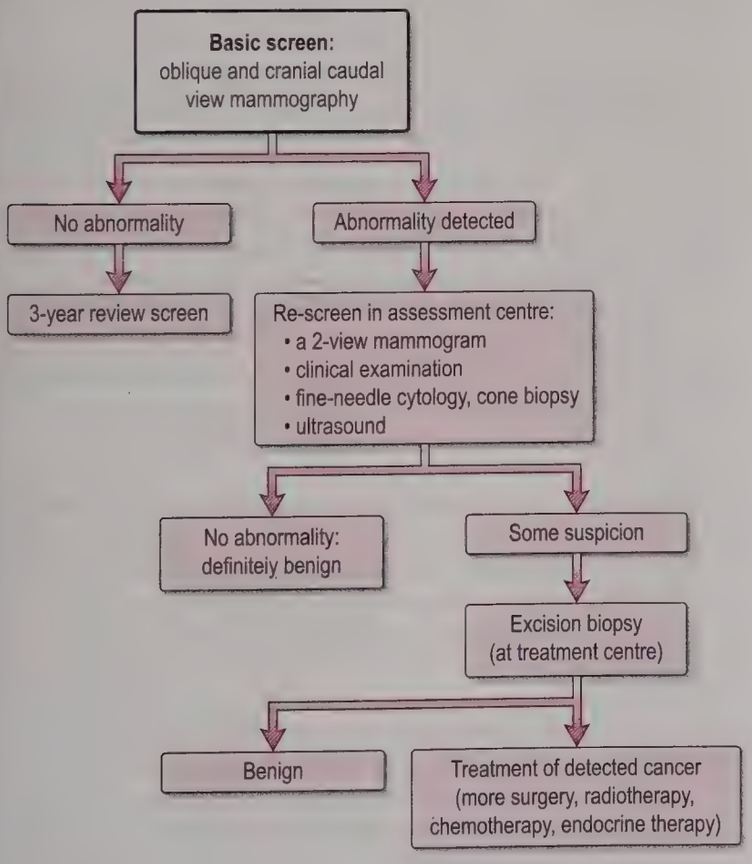

Fig. 7.15 Flow diagram of breast cancer screening procedure.

Psychological considerations Most women who present for breast screening are asymptomatic; apparently healthy people who, on the whole, come to be reassured that all is well. Inevitably, screening reminds the individual that breast cancer is a potential threat. It is therefore important that within the screening programme efforts are made to reduce anxiety where possible. It is particularly important that results are sent quickly. If the first screening is a positive experience, the woman will be more likely to attend 3 years later and may urge her friends to do likewise.

The nurse's role The Forrest report (Department of Health and Social Security 1986) recommended that qualified nurses should be available to support women who are undergoing screening. The report stressed the importance of having specialist nurses with an in-depth knowledge of breast disease and its treatment and with good communication skills to give support to women recalled to assessment centres following the detection of an apparent abnormality.

However, all nurses have a role in health education and should take every appropriate opportunity to raise women's awareness of the availability and benefits of screening programmes. Community nurses, in particular, can encourage women to attend for screening and can answer queries or discuss worries about breast screening as part of their general health promotion on an individual basis or through group discussion, e.g. in well woman clinics.

PATHOPHYSIOLOGY

Common presenting symptoms (see Table 7.3) Discovery of a non-tender, hard, usually irregular lump or thickening in the breast is the most common presentation of breast cancer. Increasingly, it is also diagnosed after a mass or microcalcifications are seen on a mammogram during routine breast screening.

Pain is not usually a presenting feature, but sometimes a sharp, pricking pain is the first symptom experienced. A change in breast size or shape may be noticed. Signs of inflammation and tissue oedema may also be present, and superficial veins may dilate and become more visible if partially obstructed by a tumour. If the tumour is advanced at the time of presentation, it may be fixed to the muscles beneath the breast. There may also be large palpable axillary lymph nodes or ulceration of the tumour through the skin, causing an infected, weeping, malodorous wound, although most women are sufficiently well informed to present to their GP before this advanced stage. Oedema of the arm may result if the cancer in the axilla is blocking the drainage of blood and lymph from the arm.

Histology Breast cancers may be classified according to the type of tissue from which they arise and their appearance under the microscope. The histological type of a cancer is often relevant to the choice of treatment.

Carcinomas arising from the epithelial cells of the ducts are known as ductal carcinomas and account for

Table 7.3 Signs and symptoms of breast cancer

Sign/symptom	Comment
Breast lump	Usually hard and irregular
Change in breast size or shape	
Impalpable mammographic abnormality	Mass/microcalcifications
Pain	Sometimes
Skin dimpling	Retraction of Cooper's ligaments
Peau d'orange	Thickening and oedema of skin
Nipple discharge	Usually bloodstained
Nipple retraction	Due to disease in main ducts
Nipple crusting	Usually Paget's disease of nipple
Dilatation of superficial veins	Result of partial obstruction of veins by tumour
Palpable axillary lymph nodes	Usually in advanced cancer
Ulceration of skin	Usually in advanced cancer

the majority of all breast cancers (Sainsbury et al 2000). Medullary, colloidal and tubular carcinomas are all types of breast cancer arising from ductal tissue. They usually arise in one area of the breast, but they can be multifocal; they are rarely bilateral. Cancers arising from cells of the breast lobules are known as lobular carcinomas. These account for approximately 15% of breast cancers and are more commonly multifocal and bilateral than ductal carcinomas (Crowe & Lampejo 1996).

In Paget's disease of the nipple, malignant cells are found in the epidermis of the nipple and are usually associated with small multifocal areas of ductal cancer behind the nipple and deep in the breast. Other breast cancer types, such as squamous cell or inflammatory carcinomas, are less common. Sarcomas and lymphomas may also arise in the breast, as may metastatic cancer tumours, although these are rare.

Breast cancers are classified as non-invasive or in situ (located only in the ducts or lobules) or invasive (having the ability to invade the basement membrane of the duct or lobule). This distinction has a bearing on prognosis and treatment. Ductal carcinoma in situ represents a very early stage of breast cancer which is often seen as microcalcifications on a mammogram. It cannot be predicted when, or if, a non-invasive breast cancer will become invasive.

Cellular differentiation, i.e. the degree to which cancer cells resemble their tissue of origin, is another important histological factor in determining prognosis: cells are described as well-differentiated, moderately differentiated or poorly differentiated, or grades I, II or III. Poorly differentiated cancers tend to be more aggressive, with the ability to metastasise at an earlier stage, and hence carry a poorer prognosis.

For more detailed information on the histology of breast cancers, see Dixon (2000).

MEDICAL MANAGEMENT

Investigations Once a breast abnormality has been detected, further diagnostic investigation will be carried out following referral to a specialist. This may involve:

- clinical examination of the breast
- mammography (see p. 326)
- ultrasound to distinguish solid from cystic lesions
- fine-needle aspiration to drain cysts and to obtain samples for cytological study
- biopsy.

Fine-needle aspiration cytology of the breast In this procedure, a syringe with a small-bore needle is inserted into the breast mass and suction is applied. The contents are withdrawn, placed on a slide and sent to the laboratory for cytological studies. Where a mass is found to be a cyst and a large amount of fluid is aspirated, it is usually discarded, unless it is found to be bloodstained, in which case a sample will be sent for examination. Cytological results are graded C0–C5:

- C0 represents an insufficient specimen
- C1 and C2 = benign cells
- C3 and C4 = cells suspicious of carcinoma
- C5 = carcinoma.

Fine-needle aspiration cytology is a useful diagnostic tool but is not conclusive on its own. A benign result may simply indicate that the needle missed the target; where other signs are suspicious, a biopsy will still be recommended. This method of gaining a provisional diagnosis can be very fast and is often used in clinics where the woman (or man) is given a diagnosis by the end of the clinic visit.

Biopsy On the basis of the investigations listed above, a decision is made as to whether a biopsy should be performed to confirm diagnosis. Biopsy may be of the following types:

- *A core biopsy* — removal of a core of tissue using a special large-bore needle which is spring loaded, and when guided by ultrasound, can accurately obtain good specimens of the suspicious lesion. This is often undertaken in the outpatient department using a local anaesthetic and the woman returns for her result several days later. Considerable pathological information can be gained from a biopsy, including the type of breast cancer, which can be very useful when planning the next stage of treatment.
- *Mammotome* – an X-ray-guided outpatient biopsy, useful for the investigation of calcifications in the breast. Many samples of tissue can be taken from a defined area.
- *Excision biopsy* — excision of the lump in its entirety, usually under general anaesthesia, requiring a 1-day hospital stay.
- *Localisation biopsy* — where a mammographic abnormality has been detected but there is no associated palpable mass. A wire may be inserted into the abnormal area under X-ray or ultrasound control. This tissue, once surgically excised from the breast, will be X-rayed to ensure that the surgeon has removed the area of abnormality.

Box 7.14

Staging of breast cancer tumours using the TNM and UICC classification system combined

Stage I	Tumour ≤2 cm, not fixed, no axillary node involvement
Stage II	Tumour ≤5 cm, with/without axillary node involvement. No detectable metastases
Stage IIIa	Tumour >5 cm, or chest wall involvement
Stage IIIb	Any tumour with supraclavicular node involvement, fixation to the chest wall, inflammation, ulceration
Stage IV	Any size tumour, positive lymph nodes and presence of distant metastatic disease

Treatment The choice of treatment in breast cancer will depend on several factors, including:

- the size, position and type of tumour (see Box 7.14)
- the spread of the disease
- the woman's general health
- the woman's priorities and wishes.

Surgical intervention Surgery is still considered to be the most effective treatment for early breast cancer. Formerly, radical mastectomy was the treatment of choice, but for many women, less extensive surgery followed by radiotherapy can be just as successful (Fisher et al 1990, Veronesi et al 1995).

Surgical procedures that may be used are as follows:

- *Lumpectomy* — removal of the breast lump with very little surrounding tissue. May be equivalent to an excision biopsy.
- *Wide local excision* — removal of the abnormal areas together with a 1–2 cm margin of normal tissue to reduce the possibility of incompletely excising the cancer. When the pathologist indicates that excision may be incomplete, re-excision is usually recommended. The amount of tissue removed in this operation can be considerable, depending on the size and location of the tumour in relation to the breast and may leave the breast smaller and somewhat altered in contour.
- *Partial mastectomy* — removal of a portion of the breast, usually the nipple and areolar complex. Invariably the breast is left smaller and its contour is changed.
- *Simple mastectomy* — removal of the breast tissue and overlying skin and nipple; all muscles are left intact and the scar is horizontal.
- *Mastectomy* — removal of all the breast tissue, overlying skin and the nipple. The pectoralis major and minor muscles remain and the axillary skin fold remains intact. The scar is oblique but less extensive than with a radical mastectomy.
- *Radical or Halsted's mastectomy* — this is rarely used nowadays unless there is extensive local spread of the breast cancer. This operation involves the removal of the pectoralis major and minor muscles, as well as the breast tissue and overlying skin, the nipple and the axillary lymph nodes. A long, oblique scar remains. The axillary skin fold is usually removed and the chest wall may appear concave and the ribs more prominent.
- *Axillary dissection* — this is usually performed if the patient has a confirmed *invasive* breast cancer to determine whether the cancer has spread to the lymph nodes or glands. When the tissue is examined pathologically the presence of cancer cells in these nodes indicates that micrometastatic spread is likely and hence adjuvant drug therapy is indicated. Where possible, axillary dissection, removing some or all of the lymph nodes, may be undertaken through the same incision as that made for the breast surgery. This would include some mastectomy and wide local excision procedures.
- *Sentinel lymph node biopsy* — axillary dissection can lead to chronic swelling, lymphoedema, of the affected arm in approximately 10–20% of individuals. Sentinel node biopsy is a new diagnostic procedure used to determine whether there is spread to the axillary lymph nodes. The procedure requires the removal of only one to three nodes for close review by the pathologist. If the sentinel nodes do not demonstrate cancer cells, this may eliminate the need to remove additional lymph nodes in the axillary area (see Appendix 1).

Primary or neoadjuvant chemotherapy For a woman who presents with a tumour greater than 3 cm in size many breast units across the UK are now offering primary chemotherapy, sometimes called neoadjuvant chemotherapy, to shrink the tumour prior to surgery (Mansi et al 1989, Richards & Smith 2000). In rare circumstances, often for the older patient, hormone therapy is used to achieve the same result. Any micrometastases that may have spread from the original tumour in the breast are also systemically treated by the chemotherapy or hormone therapy.

Throughout the chemotherapy (up to eight courses), the tumour will be assessed clinically by measurement, and radiologically by ultrasound and mammogram. When the maximum response to the medication has been achieved, surgery is considered and a mastectomy should be the surgery of choice. Sometimes, at the end of the chemotherapy, the tumour is no longer detectable radiologically, but limited surgery in the previous location of the tumour is recommended as small lesions are not always seen radiologically. Radiotherapy is then given to the breast or the chest wall to complete the local treatment.

Radiotherapy Otherwise known as teletherapy, this local treatment is usually advised following a wide local excision to reduce the risk of cancer recurrence in the remaining tissue and to protect the woman from the disease recurring systemically. Research has demonstrated that women with high-risk breast cancer survived significantly longer if they were treated with both chemotherapy and radiotherapy, supporting the use of radiotherapy as a local treatment (Overgaard et al 1997). If the axillary lymph nodes are not all removed and are found to contain cancer, they are also commonly irradiated. The supraclavicular region may also be irradiated. Radiotherapy is not always considered necessary following a mastectomy although it may be used if the tumour was large or multifocal.

Treatment is given at a measured dose of 2.0 gray/day to 25 doses, or fractions, or at 2.67 gray/day in 15 fractions (see Ch. 31). Radiotherapy is usually given to the breast

over a period of 3–6 weeks, three to five times a week. Radiotherapy travels in straight lines only and is given at different angles to protect the delicate lung tissue and the heart from receiving high doses of radiation. The potential side-effects are erythema and soreness of the skin over the treated area, and a general feeling of tiredness towards the end of the treatment period. All patients should be given clear advice about skin care during their radiotherapy treatment. They should be encouraged to use aqueous cream or E45 to moisturise the area that is receiving the radiotherapy and should wash or shower the area during the treatment period using tepid water and a very mild soap. Patients should wear loose-fitting, cotton clothing next to their skin and avoid wearing underwired bras. Towards the end of treatment some women may need to wear a loose tee-shirt or an unstructured bra support. The College of Radiographers has produced helpful guidelines on the assessment and care of skin reactions and how to look after them (Glean et al 2001).

Psychologically it may be quite distressing for the woman to attend an oncology/radiotherapy department several times a week, as this is a continual reminder that she has had breast cancer. Tiredness seems to be a problematic issue for women who are undergoing breast radiotherapy and support for the woman during this time is important (Faithfull 1998).

Radiotherapy may be administered wholly or partly by iridium wire implants, otherwise known as brachytherapy. The patient may be nursed in an isolation room for around 5 days until the required dose of radiotherapy has been given. The radioactive wires are then removed. The main advantage of this method is its ability to deliver high doses of radiotherapy to the area from which the tumour was removed. Radiotherapy is discussed in more detail in Chapter 31.

Adjuvant chemotherapy Over 50% of women who present with an invasive breast cancer will already have micrometastatic spread, so adjuvant systemic medical therapy should be given with the aim of destroying the cancer cells that have escaped from the original tumour (Powles et al 1998). When breast cancer is present in the axillary lymph nodes, the chance of a woman developing distant metastases is high. Systemic medication circulating to all areas of the body have been shown to reduce the chance of metastases developing or to increase the length of time before metastases become apparent.

Premenopausal women who have positive axillary lymph nodes are likely to benefit from cytotoxic chemotherapy. A commonly used regimen was cyclophosphamide, methotrexate, 5-fluorouracil (CMF) although this has been superseded by the combination of CMF with epirubicin. Eight courses of this chemotherapy given over 7 months have been shown to be more effective in the adjuvant setting than the classic CMF regimen (Poole et al 2003).

Postmenopausal women are also being offered chemotherapy, particularly if they have positive axillary lymph nodes. Pre- and postmenopausal women whose axillary lymph nodes are free of cancer have traditionally not received adjuvant therapy. However, some doctors are now advising adjuvant chemotherapy or endocrine therapy, as studies have indicated improvements in survival and time to recurrence (EBCTCG 1998a). More detailed information on chemotherapy and its management is given in Chapter 31. The common side-effects of chemotherapy for breast cancer are listed in Table 7.4.

Table 7.4 Possible side-effects of chemotherapy regimens used in the treatment of breast cancer

Side-effect	Comment
Lethargy	All drugs to some degree, but especially doxorubicin, epirubicin, cyclophosphamide
Anorexia/altered taste	Usually only temporary with most regimens
Nausea and vomiting	More common with doxorubicin
Mouth ulceration	Particularly methotrexate, epirubicin and doxorubicin
Diarrhoea	Rarely, but more commonly with 5-fluorouracil (5FU)
Bone marrow depression, specifically neutropenia	Greater where doxorubicin and taxanes used
Alopecia	CMF: some; doxorubicin, epirubicin and taxanes: complete (but scalp cooling may reduce this if available)
Red urine	Doxorubicin
Reactivation of radiotherapy sites	Doxorubicin
Nail pigmentation	5FU
Hypersensitivity reaction	Taxanes

High-dose chemotherapy In some solid tumours there is a direct correlation between the dose of chemotherapy and the response of the tumour. Giving higher doses of chemotherapy can lead to greater cell kill, but it will also cause more side-effects and toxicities. High-dose chemotherapy was assessed as part of several randomised trials throughout the world for women with a high number of involved lymph nodes. As it was not demonstrated to be very effective, it is not used routinely at present (Lake & Hudis 2004).

Further research will be necessary to determine if this treatment provides a real survival advantage.

Endocrine therapies Many breast cancers are thought to be stimulated by female sex hormones, particularly oestrogen. Endocrine therapies act by interfering with the synthesis of oestrogen or preventing it from exerting an effect on cells.

The medication tamoxifen, which competes with oestrogen receptors in the cytoplasm of the cell and so blocks oestrogen from stimulating breast cancer cell growth, has been found to be effective in many women with breast cancer. Tamoxifen is generally more effective in women who are postmenopausal and who have high levels of oestrogen receptors. When the woman's tumour is biopsied or removed, it is stained immunocytochemically for oestrogen receptors. A percentage value is given for the number of

receptors that stain positive, e.g. 75%, and this indicates whether the tumour is particularly sensitive to oestrogen. Because it is fairly well tolerated, tamoxifen is given to most post- and premenopausal women as an adjuvant therapy, regardless of whether there is spread to the lymph nodes.

A selection of aromatase inhibitors are now being offered to women as alternatives to tamoxifen. As selective inhibitors of the aromatase enzymes involved in the synthesis of oestrogen, anastrozole (Arimidex), exemestane (Aromasin), formestane (Lentaron) and letrozole (Femara) are all available for clinical use. By preventing oestrogen formation these drugs may cause oestrogen withdrawal symptoms such as hot flushes and night sweats. There is also the potential problem in the long term of musculoskeletal changes causing aching joints and possibly a loss of bone density (Fenlon 2003).

Ovarian suppression is particularly relevant for women who are still menstruating and have an oestrogen-positive tumour. Suppression may be achieved by surgical removal of the ovaries or radiotherapy to ablate the ovaries. For younger women who have not had a child, luteinising hormone releasing hormone (LHRH) analogues such as goserelin (Zoladex) can be used. Goserelin is given as a subcutaneous bolus injection and prevents the ovaries producing oestrogen. Once the injections are stopped, the effect is usually reversed.

Biological therapies New therapies for the treatment of cancer are regularly discovered. Trastuzumab (Herceptin), a monoclonal antibody that binds to the cell surface receptor human epidermal growth factor receptor 2 (HER_2) has recently been utilised for treating metastatic breast cancer. The cancer must be tested for the overexpression of HER_2 (Lewis et al 2004) and, if present, trastuzumab is administered as a weekly i.v. infusion. Trastuzumab targets the cancer cells and binds to the HER_2 cell surface receptors, preventing the cell from dividing. The medication also stimulates the immune system further to kill the breast cancer cells. Side-effects may include infusion-related chills and fever, usually following the first infusion, for which antihistamines usually prove effective treatment. Trastuzumab may cause cardiac dysfunction, particularly if given with anthracycline chemotherapy. Trastuzumab is now given as a single agent or with taxane chemotherapy.

7.7 When is a woman likely to be advised that a mastectomy would be the best treatment for her?

NURSING PRIORITIES AND MANAGEMENT: Breast cancer

The pretreatment phase

The period prior to admission to hospital is usually characterised by anxiety and uncertainty. Diagnosis has often been confirmed by biopsy and so the patient's concerns are focused on her cancer, how far it has spread and the physical effects on her body of the impending surgery, chemotherapy, radiotherapy and hormone therapy. Nursing intervention at this time will include assessing the patient's situation, helping her to cope with anxiety, providing education and psychological support and assisting her in making informed choices with regard to treatment options.

Assessment

There may be limited time available for assessment at this stage, but where possible the nurse should try to identify the following:

- The woman's reaction, and that of her family, to the diagnosis or potential diagnosis of breast cancer
- The major fears and concerns of the woman and her family
- The woman's feelings about body image changes that may result from any proposed treatments
- The woman's knowledge of breast cancer and cancer generally, how much information she has been given by medical staff, how much she has understood and how much she wants to know
- Whether the woman has any previous experience of another member of her family having breast cancer or any other kind of cancer
- The kind and degree of support available to the woman through family and friends. Northouse et al (1995) found that patients and their partners who reported high levels of social support also reported fewer adjustment difficulties after surgery. Husbands consistently reported that they received less support than their wives from friends, nurses and doctors
- Concurrent stressors, e.g. recent bereavements, divorce, financial difficulties
- Previous anxiety/depression. Watson (1991) found that women who had experienced previous anxiety/depression were more likely to re-experience this following diagnosis and treatment.

The treatment phase

Assessment

On the patient's admission to hospital, the nurse should undertake a more comprehensive assessment, including medical history, family history and a full physical and psychological assessment. In particular, the factors relevant in the pretreatment phase should be reassessed to determine if the woman's needs and concerns have changed. Particular note should be made of preoperative shoulder function if axillary surgery is to be performed. Good communication between the patient, ward nurses and the specialist breast care nurse will help to identify any particular psychological or social issues important to the patient that may affect her coping abilities and recovery from the surgery.

Preoperative preparation

The reader is referred to Chapter 26 for a detailed discussion of clinical considerations in preoperative care.

Giving psychological support

The nurse should give each patient the opportunity to discuss her fears but must respect her wishes if she prefers not to disclose her feelings. Where possible, a quiet, private room should be set aside for patients to spend some time in solitude or to talk privately with a nurse, doctor or family members.

Relaxation tapes can be comforting at a time when the patient may feel isolated and insecure. A relaxed but professional atmosphere on the ward will also help, as

will allowing women to remain in their day clothes, open visiting and permitting them to go out for meals or a walk.

Patient education

In addition to the issues discussed in the pretreatment phase (see above), the preoperative routine should be explained, including the approximate time of surgery and the timing and type of premedication to be administered.

The patient should be told that she may have drainage tubes in situ on return from theatre, sometimes in the breast wound and often in the axilla to prevent the collection of blood and serous fluid beneath the suture line. The patient should be advised that she can pick up the drains and walk around with them in place and reassured that it is difficult to dislodge the tubing as it is sutured in place. Sutures to the breast and axillary wound are usually subcutaneous and dissolvable, with paper stitches such as Steri-strips to the skin holding the wound edges together. A light dressing is all that is needed to cover the breast scar, although surgeons may have their own dressing preferences. It is worth telling the woman what sort of dressing to expect as she may think that the breast wound will be exposed on her return from theatre, which might be distressing.

A patient undergoing axillary dissection should be warned that she may experience discomfort on moving her arm for a few weeks postoperatively. The nurse should stress the importance of postoperative exercises and should refer the patient to a physiotherapist who can assess shoulder function preoperatively and teach exercises that can be used following surgery. Written information about the arm exercises is provided so that the woman can continue with them after she has been discharged. Because the axillary lymphatic system has been compromised by the surgery, nursing care should include informing the patient about their risk of lymphoedema and how to take preventive measures. Advice should address the following:

- Taking care not to develop infection in the affected arm by avoiding injections and vein puncture in that arm. An infection in the arm could further compromise the lymphatic system by causing localised swelling and inflammation.
- Avoiding the affected arm when blood pressure is manually recorded.
- Trying to avoid cuts and scratches in the arm and if damage to the arm does occur washing the area carefully with soap and applying an antiseptic cream to the wound.
- Reporting any signs of infection to the GP or the hospital.
- Wearing protective gloves when gardening.
- Avoiding insect bites by using insect repellent.
- Using a thimble for sewing.
- Avoiding the use of a wet-shave razor for removal of underarm hair by using depilatory cream or an electric razor instead.
- Taking care not to burn in the sun and using protective sun cream.
- Using the arm as normally as possible as regular movement will help lymph drainage.

The possibility of an intravenous fluid or blood transfusion in the immediate postoperative period should also be explained so that the patient does not become alarmed at finding one in place.

Patients often find it helpful to be told of the expected appearance of the surgical scar. Wound size and position, and the type of suturing to be used can be mentioned. Drawings and photographs may be helpful aids. It is important to warn the patient that, because the breast is so vascular, bruising and swelling are expected postoperatively. She should be reminded of this when she first looks at the scar.

Postoperative care

The nursing care of patients following surgical intervention is discussed in detail in Chapter 26. The following discussion will focus on considerations that are particularly relevant to breast surgery. The reader is also referred to Nursing Care Plan 7.2.

Wound management (see also Ch. 23) The size and position of the wound will depend on the operation performed. Generally, a low-suction drain is placed beneath the breast wound and another to the axillary region to reduce the likelihood of a seroma (see p. 343) forming. Initially, the drains and the wound dressing should be observed frequently for signs of excessive blood loss. Undue blood loss should be reported to medical staff immediately.

The wound drains will remain in situ for 2–5 days until the wound drainage is minimal, usually less than 50 mL/day. The nurse should ensure that the drains are patent and that, unless informed otherwise, suction is maintained; drainage volume should be recorded. Removal of the drains can be painful; this should be explained to the patient and removal should be preceded by the administration of oral analgesics or Entonox.

Some breast units permit patients to go home with the axillary drain still in situ. The woman, and a member of her family, are given instructions on management of the wound drain and wound care. The district nurses should be involved in the patient's early discharge, and will empty and finally remove the surgical drains at home (Chapman 2001). Close contact is usually maintained with the hospital and patients are asked to notify the hospital should the drain become loose or blocked or cause pain. Early discharge with the axillary drain still in situ is a new area of research. The work that has been done shows that, with good support, it is safe and does not cause any greater psychological distress for patients (Bundred et al 1998, Chapman 2001).

The wound should also be observed for signs of infection, i.e. redness, swelling, pain and discharge. Temperature and pulse should be monitored 4- to 6-hourly and a raised temperature brought to the attention of the medical staff.

Wound dressings should be changed only if they are being saturated by wound exudate. Unnecessary dressing changes reduce the rate of wound healing and increase the risk of infection. The wound dressing can be removed 48 h after the surgery if the wound is clean and dry (see Ch. 23). The patient can have a shower or bath at this point, providing that the wound is not soaked and the patient carefully pats the area dry with a clean towel.

The nurse must also consider other factors, such as nutritional intake, medication, stress and concurrent illness

Nursing Care Plan 7.2 Care for a woman who has undergone a mastectomy

Nursing considerations	Action	Rationale	Expected outcome
1. Potential problem of wound complications (infection, haematoma, seroma) and delayed wound healing January 10	• Check drains half-hourly for blood loss. Change drainage if necessary and record volume of drainage. Check wound for swelling	Haemorrhage may occur, compromising patient's health, and may necessitate return to theatre	Prevention of infection where possible and early detection of problems and promotion of wound healing
	• Observe wound for signs of infection (erythema, oedema, heat, pain, discharge)	Infection may delay wound healing and compromise general health. Medical treatment may be needed to control infection	There will be no signs of infection or bleeding
	• 4-hourly temperature and pulse	Increased temperature and pulse may indicate infection	
	• Aseptic dressing change only when absolutely necessary	Wound will heal more quickly if undisturbed, providing drainage is not excessive and there is no infection. Remove dressing 48 h after operation to allow air to get to the wound. Paper stitches to be removed at 10 days postop unless there is a wound infection or haematoma	
	• Assess nutritional intake and encourage balanced diet with plenty of vitamin C and protein	Vitamin C and protein are particularly important in wound healing	Patient will eat a balanced diet while in hospital
	• Assess amount of sleep and rest patient has had postoperatively. Where inadequate, consider anxiety reduction, pain control, night sedation to promote rest	Adequate sleep and rest are important in promoting wound healing	She will have at least 6 h sleep each night and report feeling stronger each day

Evaluation

January 11

Returned from theatre 12.30 h. All vital signs stable, now checked 4-hourly. Wound drainage 40 mL in last 4 h. Wound covered by light adhesive dressing.

January 12

Slight pyrexia of 37.4°C, but no other sign of infection. Wound discharge was 100 mL in 24 h (axilla 60 mL; breast 40 mL). Not sleeping well at night but managed to sleep a little today and does not wish for night sedation to be given.

January 13

Apyrexial and wound drainage reduced to 40 mL in 24 h. Slept better last night. Did not want early discharge with axilla drain in situ despite district nurse making contact prior to patient's admission.

January 14

Both wound drains removed today and wound dressing replaced. Wound is moist close to axilla and has oozed a little serous fluid but temperature remains normal.

January 15

Wound still a little moist close to axilla. Going home today so discussed signs of infection and advised visit to GP if they occur. Also advised that a seroma could form in axilla and to contact ward if this happens and arrange for an aspiration. Patient stated that she was worried about anything happening to her wound, particularly that it would open up, but said she was reassured following our discussion.

DISCHARGED

Nursing Care Plan 7.2 Care for a woman who has undergone a mastectomy *(Continued)*

Nursing considerations	Action	Rationale	Expected outcome
2. **Anxiety/distress due to altered body image as a result of mastectomy and diagnosis of cancer (Salter 1988)** January 12	• Give patient time and opportunity to express and explore feelings concerning cancer diagnosis and breast loss	Expression of feelings may help patient to clarify how she feels and relieve anxiety	Some anxiety will be alleviated
	• Encourage patient to discuss feelings with partner where appropriate	Partner may then be more easily able to understand and support and give reassurance that she is still attractive	Patient will have more acceptance of changed body image
	• Give information about scarring, e.g. bruising, sutures, position (photos shown pre-op may help)	May help to have realistic expectations of wound and know that bruising etc. will fade	
	• Offer to remain with patient when she first looks at wound, assess reaction and give support in discussing feelings afterwards	Moral support may help patient to sum up courage to look at the wound	Patient will be able to look at scar before discharge
	• Fit temporary prosthesis after removal of the drains and show how to use. Show silicone prosthesis if desired and make fitting appointment	A prosthesis may increase a woman's confidence to face the outside world and regain a healthy body image	Patient will be able to fit temporary prosthesis into bra before discharge
	• Discuss possibility of breast reconstruction if not previously mentioned	Breast reconstruction is known to be helpful for some women in coping with breast loss. Woman herself is best one to judge value for her	Patient will understand types of reconstruction possible
	• Refer to specialist nurse if one exists	Specialist nurses have been shown to aid rehabilitation and may lower anxiety and depression postoperatively	
	• Offer written information on breast cancer, prostheses, clothing, etc.	Practical help may increase a woman's confidence to take up her usual social activities and feel she is still the same as ever	
	• Ask if she would like voluntary visitor to be put in touch and arrange if desired	Some women find others who have had similar operations a great help and encouragement	

Evaluation

January

Stated that she is very frightened that cancer may recur in the future. Her friend died 2 years ago from breast cancer metastases and this fills her with fear.

Temporary prosthesis fitted today and appointment made for 6 weeks after discharge. Mrs X also looked at her scar for the first time. She found it was better than she imagined. She has asked that the nurse stay with her tomorrow whilst she shows her husband before she goes home.

Mrs X showed her husband the scar today. He also told her it was much better than he had imagined and that having her was much more important than her having two breasts. Breast reconstruction was mentioned again but Mrs X is sure she will not want this. To be followed up by clinical nurse specialist who saw her again today and gave her a booklet from Breast Cancer Care.

Nursing Care Plan 7.2 Care for a woman who has undergone a mastectomy *(Continued)*

Nursing considerations	Action	Rationale	Expected outcome
3. Difficulty moving arm due to discomfort following axillary dissection	• Refer to physiotherapist • Analgesics before physiotherapy • Encourage to practise arm exercises four times a day	Shoulder exercises are known to decrease the problems of reduced shoulder functioning that can result after an axillary dissection	To achieve and maintain full shoulder movement in 4 weeks and prevent 'frozen shoulder'
January 11	• Give written information sheets to reinforce what exercises to do and when	Written information will reinforce that given verbally and serve as a reminder after discharge home from hospital	Will be able to demonstrate physiotherapy exercises and perform four times each day
4. Pain January 10	• Regular analgesics initially postop. Assess effectiveness. Particularly important prior to physiotherapy	Regular analgesics more likely to be effective than PRN medication	Patient will report that pain is under control
	• Use pillow to support arm on affected side postop	Pillow provides a soft, comfortable support and encourages drainage of fluid back from arm	
	• Consider relaxation techniques and massage to relieve tension	Tension is known to increase experience of pain	

Evaluation

January 14
Seen by physiotherapist and commenced exercises. Patient says that she is able to move arm quite freely without much discomfort.

January 15
Has been practising arm exercises but a little more uncomfortable today and requested paracetamol prior to exercises this afternoon. She said this helped.

January 10
i.v. analgesic had been given in recovery but Mrs X has declined any further analgesics since returning to the ward.

January 11
Particularly uncomfortable when moving her arm. Had declined analgesics this morning but was persuaded that regular paracetamol for 2 or 3 days will not harm her and will help her move her arm, which is important.

January 14
Much more comfortable today and has again refused analgesics.

January 15
Requested analgesics prior to exercises today as arm feeling stiff and sore.

Nursing Care Plan 7.2 Care for a woman who has undergone a mastectomy *(Continued)*

Nursing considerations	Action	Rationale	Expected outcome
5. Potential problem of lymphoedema of the arm, postoperatively or at some time in the future January 11	• Explain what lymphoedema is, how it is caused and when it may occur • Explain signs of lymphoedema and encourage to report to doctor as soon as it occurs	Information will help the patient to understand the pathological basis of lymphoedema and encourage early detection of lymphoedema should it occur	Risk of lymphoedema occurring will be reduced The patient will understand what lymphoedema is, and what to do if it occurs
	• Discuss hand and arm care: – Avoid lifting heavy objects with affected arm – Avoid injections, blood tests, blood pressure recordings in affected arm – Use gardening gloves when gardening, kitchen gloves with abrasive cleaners, thimbles when sewing – Clean any cut on hand or arm very thoroughly and apply antiseptic. If any signs of infection appear see GP for antibiotics – Use depilatory creams to remove hair under arm, rather than a razor – Elevate arm whenever possible, particularly initially after surgery – Use a gentle moisturising cream on arm to prevent cracking if skin is dry	Following removal of lymph nodes by surgery and radiotherapy, there is an increased risk of infection in the arm. These precautions reduce the risk of infection, and also the risk of infection precipitating lymphoedema	She will be able to recount how to look after her hand and arm
	• Encourage arm and shoulder exercises	Exercise is thought to reduce the possibility of lymphoedema occurring	

Evaluation

January 14

Long discussion in preparation for discharge. Her friend had lymphoedema so she is very concerned this shouldn't happen to her.

Very keen to have advice on hand and arm care and has been given a leaflet about this. Stressed that she can contact clinical nurse specialist at any time if she is concerned that her arm is swollen.

(e.g. diabetes mellitus), which may affect the rate of wound healing and resistance to infection (see Ch. 23).

Alleviating discomfort Pain from the wound will always be experienced to some degree, but pain on shoulder movement is often more of a problem. Pain is sometimes more intense a day or so after the operation when the initial numbness has faded. Patients should be encouraged to take analgesics regularly for the first 48 h, but many women find that the wound is less painful than they had expected and require oral analgesics infrequently beyond this period. It should be stressed, in any event, that it is preferable to take analgesics and continue arm exercises than to take no analgesics and avoid the exercises.

The experience of pain is influenced by many factors, such as anxiety and emotional distress (see Ch. 19). These must be considered by the nurse in her efforts to promote the patient's comfort after surgery.

Women who have had a mastectomy may experience phantom breast and nipple sensations at some point following surgery. This may be very distressing and requires the nurse to reassure her that these sensations will not continue for long. In rare cases damage to the intercostal brachial nerve may occur during surgery. If the nerve has only been bruised patients may complain of an uncomfortable tenderness (neuropraxia) but this sensation should fade over a period of weeks to months. Referral to a physiotherapist and a review of the patient's oral analgesics may help. As the bruising subsides so will the symptoms of pain and altered sensation although this may take several weeks to months.

Promotion of shoulder movement Patients who have undergone surgery involving dissection of the axillary lymph nodes are at risk of developing problems with shoulder movement. This risk is greater if radiotherapy to the axilla is given postoperatively (Lichter 1998). Postoperative exercises will help to ensure that a full range of shoulder movement is attained following surgery.

Ideally, exercises should be taught by a physiotherapist. The nurse must know what they involve, however, so that she can encourage the patient to practise them. Generally, gentle exercises are begun on the first or second postoperative day and gradually increased in extent and frequency as drainage from the wound diminishes and the axillary drain is removed.

Preparing the patient for discharge

Looking at a breast scar for the first time is often very difficult and may confirm a woman's fears about breast loss and intensify her grief. However, others find the scar neater and less distressing than they had imagined. Women who have wide local excisions may have a similar range of reactions.

The nurse should encourage a woman to look at her scar before she goes home, as this represents a significant step in rehabilitation (Denton & Baum 1983). The woman may wish to be accompanied by her partner or a nurse when first seeing her scar and this may also be the first time she talks about the loss or alteration of her breast. The woman must never be forced to look at her wound and it may not be until the first postoperative outpatient visit that she is able to take this step.

Rehabilitation proceeds at different rates, but the nurse should explain to each woman that it may take several months before she feels that her energy has returned to normal. Persistent fatigue may cause frustration and may give rise to anxiety that the cancer has returned. Fatigue is more likely if chemotherapy or radiotherapy is given postoperatively, but where it is profound, depression should also be considered as a possible contributing factor.

Most women can begin driving again in 2–3 weeks, providing they feel confident, their arm movement is not too uncomfortable and the seat belt is not pressing on the scar line. They must be confident enough to perform an emergency stop if necessary. Light household duties can be undertaken when the woman feels well enough, usually 2–3 weeks postoperatively, and she may return to work at around 6 weeks. This will, of course, depend on the extent of the surgery, the particular individual and the type of work she does.

Pain and discomfort from the wound will steadily reduce, but some discomfort often remains for 2–3 months. Paraesthesia around the scar and axilla may fade over several months, but some may always remain and can be made a little worse by local radiotherapy.

A collection of serous fluid in the breast wound or the axilla may occur postoperatively and is called a seroma. Some women believe that the large lump they can feel is cancer that has suddenly grown after surgery. Prior explanation of this and the possibility of seroma formation is likely to reduce any anxiety. The problem can be resolved by the aspiration of the fluid and may be performed as a simple outpatient procedure. Many specialist breast care nurses and nurse practitioners have been trained to carry out this intervention and patients should be informed who to contact should this problem arise.

Lymphoedema, or swelling of the arm with lymph fluid, is a possible long-term complication that can occur in anyone who has axillary surgery or radiotherapy. Women should be advised to contact their GP or hospital if they notice any swelling, and not to leave it until it becomes a problem. Lymphoedema following breast surgery is discussed on pages 344–346.

Prior to discharge, any woman who has had a mastectomy or a significantly wide local excision should be given a temporary prosthesis, shown how to position it in her bra and alter its shape, and advised how to wash it (see Box 7.15).

7.8 Prepare a 10-min teaching session for your ward colleagues or fellow students on the subject of breast prostheses, including what types are available and why they are important for the patient.

Adjuvant therapy

Postoperatively, the woman will probably attend a surgical outpatient clinic where she will hear the results of her surgery, i.e. the number of lymph nodes involved with cancer, the size and grade of the tumour and the oestrogen status, all factors that will determine the need for adjuvant treatment. Following two meta-analyses published in *The Lancet*, many more women are now being offered adjuvant hormone and chemotherapy treatment. The first analysis showed that chemotherapy given to a woman with early breast cancer meant a statistically significant longer time to recurrence and a small but significant increase in survival (EBCTCG 1992). The second analysis showed that premenopausal women who are treated for an early breast cancer with adjuvant therapy have a 7–11% absolute improvement in 10-year survival (EBCTCG 1998a).

Information on radiotherapy and drug therapies should be given, as relevant, both verbally and in writing. The patient should understand why adjuvant treatment has been advised, for what period and at what intervals it will be administered, and what the side-effects may be. At this point the woman may be invited to join a research study, as several current national trials looking into effectiveness of different types of chemotherapy and hormone therapy are ongoing. The timing of this decision may put yet another strain on a woman who is already facing up to having cancer, so the support and information she receives from her oncologist, ward nurse and breast care nurse will be crucial at this time.

Box 7.15

Breast prostheses

The fitting of a breast prosthesis is an integral part of the rehabilitation of a woman who has had a mastectomy or partial mastectomy. The aim of the prosthesis is to match as closely as possible the woman's other breast in terms of size, shape, weight and feel, so that she may look natural and feel confident in clothing. This is important in helping her to resume her normal social activities and regain a healthy body image.

Temporary prostheses

A temporary prosthesis (sometimes known as a cumfie) is fitted as soon as the wound drains have been removed and is worn until a permanent prosthesis can be fitted. It is soft, light and washable, and can be pinned securely into the cup of a bra. If a bra cannot be worn because of discomfort, the prosthesis can be pinned into a camisole or slip. The woman may find that wearing loose clothing helps to achieve a balanced appearance. However, it is important that the nurse spends time fitting this prosthesis well, as it is with this that the woman will first face the outside world again.

Permanent prostheses

A permanent prosthesis is usually fitted 5–6 weeks after surgery or 2 weeks after the completion of radiotherapy, when the wound is well healed. The fitting may be undertaken by a specialist nurse, surgical appliance officer or visiting prosthesis company fitter. A private room with a full-length mirror is necessary and it is essential that each woman is treated with respect and sensitivity.

Today most permanent prostheses are made of silicone gel which feels soft and comfortable next to the skin and takes on the body's temperature. Many shapes and sizes are available; it should be possible for all women to be fitted with a prosthesis that gives a balanced appearance in a bra. Partial prostheses are available for women who have breast conservation. Silicone prostheses generally last for 2–3 years, but a woman is entitled to a replacement whenever the prosthesis begins to show signs of wear and tear or if she loses or gains weight or changes shape.

Special 'mastectomy bras' are not necessary, but the bra does need to be supportive and of the correct cup size, covering all of the tissue of the remaining breast. It is helpful if the nurse can give basic advice about bras and instruct a woman where she may be fitted for a bra locally, if her previous bras are now inappropriate. Volunteer organisations such as Breast Cancer Care give helpful advice about bras, swimwear and other clothing (see 'Useful addresses', p. 356).

Table 7.5 Possible side-effects of adjuvant radiotherapy used in the treatment of breast cancer

Side-effect	Comment
Erythema and soreness of the area treated	Not easily predictable
General tiredness	Especially toward the end of the treatment period
Photosensitivity	See Chapter 12; sun barrier creams should be worn for a year after therapy
Moist desquamation	Now rare because of the improved delivery of radiotherapy
Breast becomes firmer to the touch	Long-term effect due to fibrosis of tissue
Narrowing or blockage of lymph vessels	Increases risk of lymphoedema

Radiotherapy The possible side-effects of adjuvant radiotherapy in breast cancer are listed in Table 7.5. The nurse should also give advice on skin care for women undergoing radiotherapy.

Chemotherapy A variety of chemotherapy regimens are used and the woman may have already received chemotherapy treatment prior to her surgery. The nursing care for patients on chemotherapy regimens will be discussed separately.

Neoadjuvant (primary) chemotherapy These treatment regimens often contain an anthracycline-type drug and may need to be administered (see p. 337) via a pliable central venous catheter, sometimes known as a Hickman line. This central line is inserted through the chest wall and into the subclavian vein whilst the woman is under light sedation (see Fig. 7.16 and Box 7.16).

Peripherally inserted central catheters (PICC lines) are also a useful way of administering chemotherapy (see Ch. 31). Inserted through the antecubital fossa, the PICC line has the advantages of the Hickman line in that it can help prevent long-term damage to veins, relieves needle phobia and allows easy access for blood sampling. Central lines can represent a significant assault on the woman's body image as they protrude out of the chest wall or arm for the duration of the treatment (see Ch. 31 for the nursing care of patients receiving chemotherapy and p. 501 for disorders of white blood cells and lymphoid tissue).

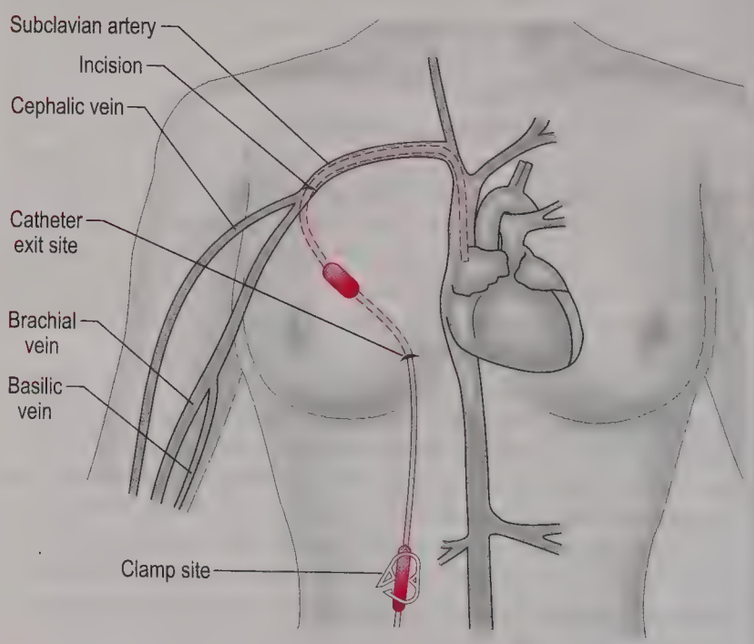

Fig. 7.16 Central line insertion.

Box 7.16

The central venous catheter for the administration of chemotherapy for breast cancer

Insertion of the central line may involve the woman having light sedation. The line is usually inserted by an anaesthetist but specialist nurses have extended their role to include this skill. The line is X-rayed after the operation to ensure that it is positioned correctly. The incision wounds will be covered with a light gauze dressing or an occlusive plastic dressing. The wound site must be cleaned and dressed regularly either by the woman herself or by the practice or community nurse; the frequency of the dressings is decided locally. The stitches should be removed from the incision site 7–10 days after the line has been inserted and from the exit site 6–8 weeks after insertion, but only if the central line was cuffed. This timing allows scar tissue to form around the line and to anchor it within the subclavian vein if it is a Hickman line. If the line is uncuffed, the exit site stitches remain in for the duration of treatment.

The woman (and often another member of her family or a close friend) will have been taught how to care for her central line. Community back-up is essential to continue the care that has been started in the hospital and to assist with the central line dressing. Infection of the exit site of the central line is common and this should be recognised quickly and treated with antibiotics, as septicaemia can develop. If this occurs, the line should be removed and the woman should be treated with i.v. antibiotics. Thromboses forming around the central line in the subclavian vein can be a problem and are indicated by blockage of the line, sometimes swelling of the arm on the side of the line and pain at the site of the thrombosis or referred into the side of the neck. An ultrasound scan or X-ray will be taken of the line for a definitive diagnosis and the woman will be started on anticoagulants. The line will be kept in situ unless the woman does not respond to the anticoagulants in which case it will have to be removed.

Provided that the site has completely healed, the woman can continue with some of her physical activities but should first check with her clinician. She can lightly shower over the central line site but, if receiving chemotherapy via a portable pump, should not get the pump wet. The line should be long enough with an extension to leave the pump outside the shower. Written instructions are often given by the hospital, including contact numbers should any problems occur.

Adjuvant therapy The patient should be reassured that the adjuvant chemotherapy regimens used in breast cancer tend to have milder side-effects than those used in the treatment of other cancers and can usually be managed by the outpatient department.

Nausea is commonly experienced but is normally mild and can be controlled by the range of antiemetics, including 5-HT_3 antagonists such as ondansetron or granisetron that are now available. Vomiting should be rare.

Thinning of the hair is to be expected in at least three-quarters of patients receiving CMF (Fisher et al 1990), though scalp cooling might help. Other breast cancer chemotherapy regimens containing an anthracycline such as adriamycin or epirubicin will cause total hair loss and the whole experience can be very stressful. Cooling the scalp with the use of ice caps can restrict the amount of chemotherapy reaching the hair follicles in the scalp and so may prevent complete hair loss, although the hair may thin and become drier and of poorer quality. Gentle shampoos should be used, and perms, colourants and the use of heated rollers and tongs should be avoided.

Bone marrow depression occurs with all cytotoxic drugs, but it is rare for neutropenia to be severe or for septicaemia to result. Nevertheless, every patient should be advised about good oral hygiene and the avoidance of obvious sources of infection. If the woman's temperature rises above normal she is usually advised to contact the hospital and to have a full blood count taken to ensure that her white cells are at an acceptable level. If the white cells are low and she is neutropenic, she may be prescribed oral antibiotics or, if necessary, admitted to hospital for intravenous antibiotics.

Fatigue is the most common problem and can be quite debilitating for the woman. Generally it is worst in the middle of a month's treatment cycle, when blood counts are at their lowest level.

A sore mouth and a susceptibility to mouth ulcers can be helped by using a soft toothbrush, salt water or medicated mouth washes.

Menstruation is usually affected, with periods becoming irregular or stopping, and this is yet another assault on the woman's body. Menopausal symptoms, e.g. hot flushes, may be experienced, but if the woman is in her early 30s, menstruation has a 90% chance of returning after chemotherapy finishes. Women in their early 40s are much more likely to go into early menopause.

Endocrine therapy Adjuvant tamoxifen is widely given in view of its relatively few side-effects and its proven efficacy (EBCTCG 1998b) although anastrozole is now being given in certain circumstances. Both pre- and post-menopausal women will usually experience menopausal symptoms, which can be very distressing. These may include fatigue, hot flushes, night sweats, joint pain, headaches and difficulty sleeping (Carpenter & Andrykowski 1999). There are vitamin and mineral preparations, often containing evening primrose oil (gamolenic acid), that can help with such symptoms; otherwise the woman's consultant or GP can prescribe medication to reduce the hot flushes. Unfortunately, these are not without side-effects and many women prefer to manage without such intervention.

Gastric upsets are uncommon but may occur, particularly if the tamoxifen tablets are not taken with food. Very occasionally, thrombocytopenia is a problem. The individual should be advised to report increased bruising or bleeding from her gums. A small increase in deep vein thrombosis and pulmonary embolus has also been noted with tamoxifen use (Fisher et al 2001) and women must inform their clinician of any new pain and swelling in their calves or sudden and unusual shortness of breath. Many women complain about an increase in weight, particularly around the abdomen, soon after starting the tablets. This may be due in part to fluid retention and in part to a reduction in physical activity following surgery. Other rare and more serious side-effects include endometrial cancer and cataract formation. Any abnormal vaginal bleeding should be investigated as well as any rapid deterioration in eyesight (Bruzzi 1998).

METASTATIC BREAST CANCER

Metastatic disease is sometimes obvious at the time of diagnosis but can occur months or many years later. Women in whom the cancer has spread to the axillary lymph nodes at the time of diagnosis are known to be at a greater risk of developing metastases at a later date. Often these metastases are too small to be detected by scans or other investigations. The rate at which breast cancer grows and metastases to other areas of the body varies and it is difficult to assess the long-term prognosis of an individual woman or to say that she is cured of the disease. It is estimated that over 50% of women who present with a breast lump already have metastatic spread (Richards & Smith 2000).

Once breast cancer has metastasised systemically, the oncologists will aim to put the disease into remission and to improve survival for the woman. The disease is no longer considered curable and the challenge for the oncologist is to give the woman prolonged life without distressing side-effects. The decision to treat should be considered carefully with the woman and her partner.

PATHOPHYSIOLOGY

The spread of breast cancer appears to be by direct invasion into the surrounding tissue and via the lymphatic and arteriovenous systems to distant areas, although this has not been proven absolutely. If untreated, local invasion of the breast cancer will cause ulceration, fixation to the chest wall and oedema of the arm. It may also, in extreme circumstances, erode blood vessels, causing haemorrhage, and invade the ribs or lungs and pleura, causing pleural effusion. Invasion of the brachial plexus can cause severe pain with functional and sensory loss in the arm. Invasion of the cutaneous nerves causes irritation and burning pain in the affected area. Because such aggressive local disease is not necessarily accompanied by metastatic spread, a woman may survive for many years with these problems.

Spread of breast cancer to distant sites is a common occurrence but may not become apparent for months or many years after the initial diagnosis and treatment. Metastases can occur anywhere and do not follow a systematic course. However, metastatic spread may be first discernible in the axillary and then supraclavicular lymph nodes, following the pattern of lymphatic drainage from the breast. The most common sites of metastases are bone, lungs, liver and brain. Less frequently, they occur in the ovaries and mediastinum and, rarely, in the stomach, oesophagus and intestine. The problems most commonly caused by metastasised breast cancer are listed in Table 7.6.

MEDICAL MANAGEMENT

Surgery rarely has a part to play in the management of metastatic breast cancer but can help with locally recurrent disease. Chemotherapy and endocrine therapy are the treatments of choice, given their systemic effectiveness. Radiotherapy plays an important role in the relief of bone pain and in the oncological emergencies of spinal cord compression, cerebral metastases and superior vena cava obstruction, where tumour pressure must be reduced quickly. In these contingencies, steroids are used in conjunction with radiotherapy to reduce the oedema in tissues surrounding the tumour and hence relieve pressure further.

The menopausal status of the patient, the site of the metastatic spread and the apparent aggressiveness of the tumour will determine which drug therapies are considered most appropriate.

Table 7.6 Common problems caused by metastatic disease in patients with breast cancer

Site of disease	Problem	Treatment
Bone	Bone pain	Non-steroidal anti-inflammatory drugs, opiates, radiotherapy to site, chemotherapy
	Hypercalcaemia	Emergency: hydration, bisphosphonates, chemotherapy
	Spinal cord compression	Emergency: radiotherapy and steroids
Bone marrow	Pancytopenia	Supportive blood + platelet transfusions. Chemotherapy (may cause further problems)
Lung/pleura	Pleural effusion	Pleural aspiration ± pleurodesis
	Reduced expansion/shortness of breath with persistent cough	Low-dose morphine, codeine cough suppressant Chemotherapy/endocrine therapy
Liver	Liver pain	
Ascites	Opiates, steroids, chemotherapy Paracentesis, chemotherapy	
Skin	Ulceration/fungation Pain/irritation	Radiotherapy, chemotherapy, endocrine therapy, dressings, analgesia. For nerve pain, steroids and anti-inflammatory drugs
Brain/CNS	Confusion, headaches, nausea, vomiting, altered behaviour, convulsions	Emergency: radiotherapy and steroids Intrathecal methotrexate
Mediastinum	Superior vena cava obstruction	Emergency: radiotherapy and steroids
Axilla/supraclavicular fossa	Lymphoedema	Chemotherapy, endocrine therapy, radiotherapy
	Brachial plexus pain and paraesthesia/paralysis of arm	Anticonvulsants, steroids and non-steroidal anti-inflammatories

Chemotherapy Disease that appears to be advancing rapidly or which involves the liver is most likely to be treated by chemotherapy. Regimens, including the taxanes paclitaxel (Taxol) and docetaxel (Taxotere), are given as outpatient infusions in conjunction with a premedication of steroids and chlorphenamine maleate (Piriton) to prevent hypersensitivity reactions. Currently, both paclitaxel and docetaxel are undergoing clinical trials as single agents or in combination with other chemotherapy agents and the short-term results are promising (Crown et al 2004).

The anthracyclines, alkylating agents, antimetabolites and vinca alkaloids are all effective at treating metastatic breast cancer and can all be given as single agents or in combination, depending on the previous treatment the woman has received.

The side-effects of chemotherapy regimens are described in Table 7.4 (p. 330).

Endocrine therapy Disease that is progressing more slowly may respond to endocrine therapies. These work more slowly but have fewer side-effects. Endocrine agents that may be used include the following:

Tamoxifen (see p. 331) This can be used in both pre- and postmenopausal women if it has not been used before as a neoadjuvant or adjuvant therapy.

Luteinising hormone releasing hormone (LHRH) analogues, e.g. Zoladex These interfere with the production of luteinising hormone and therefore oestrogen. Side-effects are the symptoms of menopause, e.g. amenorrhoea and hot flushes. These drugs are administered by subcutaneous injection every month and are only used for premenopausal women.

Anastrozole This medication inhibits aromatase enzymes that help to convert androgens to oestrogen and thus prevents the production of oestrogen. Other aromatase inhibitors can also be used (see p. 331).

Aminoglutethimide This medication inhibits the synthesis of aromatase, an enzyme needed to convert androgens produced by the adrenal glands to oestrogen. Allergic rashes are common but usually resolve if treatment continues. This is given only to postmenopausal women.

Progestogens, e.g. medroxyprogesterone acetate and megestrol acetate These are usually used as a third-line treatment when others have failed. Side-effects include an increase in appetite and euphoria. This can be helpful if a patient is depressed, nauseated and has lost her appetite; however, the steroid-type 'moon face' can develop (see Ch. 5). Weight gain is a problem, as is fluid retention, making progestogen a medication to be given with caution to any patient who has a history of cardiac disease. Glucose intolerance may be a problem so the patient should be monitored for the development of diabetes mellitus.

NURSING PRIORITIES AND MANAGEMENT: Metastatic breast cancer

Major nursing considerations

Assessment

Nursing assessment should address the physical, psychological and social impact of the disease, with particular consideration of the patient's own perception of these problems. The difficulties faced by the patient are likely to be determined in part by the site(s) of cancer spread. It should be remembered that medical priorities will not necessarily match the personal priorities of the patient and the decision to treat should be discussed carefully.

The reaction of the patient and her family to the news of progressive disease should be sensitively explored, and the nurse should assess how well they are coping. For many, the diagnosis of metastatic disease is more devastating than the original diagnosis of breast cancer, as the realisation dawns that treatment is now aimed at controlling rather than curing the illness. The patient and her family may once again experience shock, anger, denial, depression and despair as they try to come to terms with the implications of the diagnosis. They may feel that they had 'paid the price' at the time of the original diagnosis and that disease recurrence is very unfair (see Case History 7.3).

Even where cure is no longer possible, the philosophy of rehabilitation will remain at the centre of care, so that the highest quality of life can be maintained for as long as possible.

Palliative care

For a fuller discussion of the various aspects of long-term and palliative care that will be relevant to the patient with metastatic breast cancer, the reader is referred to Chapters 31 and 33. The important contribution of the nurse in controlling and managing symptoms such as pain, nausea and vomiting, fatigue, sexual problems, anxiety and shortness of breath is described in Chapters 3, 19 and 33.

7.9 Consider the following questions with reference to Case History 7.3:

(a) Mrs J has extensive metastatic disease of her lumbar vertebrae. What implications does this have for nursing care?
(b) What side-effects is Mrs J likely to experience with chemotherapy?
(c) What information should the nurse give to Mrs J to prepare her for her first course of chemotherapy?

CASE HISTORY 7.3
Mrs J

Mrs J is a 54-year-old married woman with two adult children. She has a part-time job in a school, but spends a large part of each day looking after her elderly mother, who is disabled with rheumatoid arthritis and is unable to move around.

Mrs J was diagnosed as having cancer of the right breast 4 years ago. This was treated by a wide excision of the tumour with axillary clearance. Adjuvant radiotherapy was also given. At this time four axillary nodes were found to contain cancer, and Mrs J was prescribed four courses each of epirubicin and CMF chemotherapy and subsequently tamoxifen 20 mg, which she has been taking ever since. She was well until a month ago, when she began to experience pain in her back; this has since increased in intensity. On admission to hospital, a bone scan revealed extensive metastatic cancer in her lumbar spine, and a chest X-ray showed pulmonary metastases. Doctors have advised a course of taxane chemotherapy, to which she has agreed, but she is 'devastated' by the news of cancer recurrence and is extremely frightened by the thought of chemotherapy. Her other major concern is how she will manage to continue to look after her mother.

(d) Discuss other ways in which the nurse can help to allay Mrs J's anxiety about chemotherapy.

BREAST RECONSTRUCTION

Breast reconstruction may be achieved by several surgical methods but frequently includes the insertion of silicone breast implants or the transfer of a skin and tissue flap from another part of the woman's body (autologous). It may be undertaken for cosmetic reasons when women feel their breasts are too small, where one breast has failed to develop at puberty, or following breast cancer surgery which has removed part, or all, of a woman's breast. However, only the latter will be considered here.

Immediate breast reconstruction can be undertaken at the time of the mastectomy, or as a delayed reconstructive procedure. The aim of breast reconstruction following breast cancer surgery is to create a breast form which resembles the woman's other breast as closely as possible in size, shape and consistency. Complete symmetry when the woman is naked is not possible to achieve but the aim of the surgery should be that any differences are slight when she is wearing a bra.

As far back as 1986 the King's Fund Forum consensus committee statement on breast cancer treatments suggested that 'the possibility of reconstructive surgery should be discussed with all women in whom a significant loss of breast tissue will be necessary'. The recent National Institute for Clinical Excellence (NICE) guidelines on the treatment of breast cancer state that every woman should be offered the opportunity of breast reconstruction, delayed or immediate, if they need a mastectomy as part of their breast cancer treatment (NICE 2002). Breast reconstruction may help to reduce the psychological or emotional problems experienced by women after surgery or it may enable a woman to undergo a mastectomy which she would have otherwise found intolerable (Hart 1996).

The presence of bone metastases should not prohibit a woman from having reconstructive surgery if she perceives that this will improve her quality of life and she is generally well enough to undergo surgery. Only uncontrolled metastatic breast cancer is considered an absolute contraindication to breast reconstruction.

MEDICAL MANAGEMENT

Routine surgical preparation involving blood tests, chest X-ray and ECG will be undertaken prior to surgery. Photographs will be taken to aid the reconstructive surgeon during the surgery and afterwards when trying to match the shape and symmetry of the woman's reconstructed breast to her remaining one.

Several surgical techniques can be used to achieve breast reconstruction. The most common are described below.

Submuscular implant This involves inserting a silicone implant beneath the muscle overlying the chest wall. Generally this can be done only where the remaining breast is small and droops very little.

Tissue expansion An inflatable double-lumen silicone bag is inserted beneath the muscle overlying the chest wall and gradually inflated with sterile saline over a period of several weeks via a port valve and connecting tube which lie just beneath the skin. The aim of this is to slowly stretch the skin until the tissue expander is larger than the other breast. It is left overexpanded for several months and then some fluid is removed to create the natural ptosis of a breast. If the surgeon has used a 'Becker' type implant the port and the connecting tube are surgically removed, leaving a sealed prosthesis in the same 'pocket'.

Tissue expansion methods are useful when the breast reconstruction is delayed, i.e. the woman has chest wall skin that is good quality but inadequate quantity.

There has been much debate about the side-effects of using silicone because of recent claims that silicone prostheses can cause connective tissue disorders such as rheumatoid arthritis (Lipworth et al 2004). Because of the uncertainty surrounding its use many surgeons in the UK favour implants that contain sterile saline rather than silicone gel. Research into the use of silicone implants has been implemented and a study, conducted in Sweden, using a large nationwide cohort showed no association between breast implants and connective tissue disease (Nyren et al 1998).

Myocutaneous flap This involves transposing part of the latissimus dorsi muscle and overlying skin from the back, or the transrectus abdominus muscle (TRAM) and overlying skin from the abdomen, to the chest wall. If necessary, an implant can then be placed behind this. Oval scarring on the breast form results, as well as scarring on the abdomen or back and there is often a bulge where the attached muscle is folded over as it is moved to form the reconstructed breast (West 2003).

A newer surgical technique similar to the TRAM technique uses the abdominal fat and tissue only. The deep inferior epigastric artery and veins are identified and disconnected with the fat and tissue flap and then reanastomosed with the internal mammary artery and vein. This means that the patient has less abdominal weakness than with a TRAM flap and, thus, very little risk of hernia.

These methods are generally used where a larger breast form is desired, following a radical mastectomy in which all chest wall muscle has been removed, or where radiotherapy has been given to the chest wall, causing the skin to lose its elasticity.

Reduction mammoplasty Surgery to the remaining breast may be advised if it is very large or pendulous in order to achieve as much symmetry as possible. Scarring following this procedure may be extensive and nipple sensation may be lost. These effects must be discussed with the woman beforehand.

Nipple areola reconstruction Sometimes the surgeon is able to do a subcutaneous mastectomy and leave the nipple intact. More often the nipple is not saved because of fear of cancer being present there. If this is so, a nipple areola reconstruction can be undertaken. Generally, this is done around 3 months after the initial reconstruction. The nipple may be created from the skin overlying the reconstruction, saved from the other nipple or a graft taken from the labia. The areola is usually created from an upper inner thigh skin graft. Some women do not want to undergo further surgery and opt for adhesive silicone nipples.

Breast augmentation following partial mastectomy This is usually carried out, if desired, at the time of the original surgery as it is more difficult after radiotherapy has been given. The implant is inserted into the area where tissue has been removed to reduce any alteration in breast size and shape and hence problems associated with altered body image.

Potential postoperative complications

Seroma/haematoma formation This is more likely to occur after an immediate reconstruction than if reconstruction is delayed. Serous fluid and blood may build up behind the implant in spite of the presence of wound drains, increasing discomfort and the risk of infection. Aspiration may be necessary and, occasionally, removal of the prosthesis.

Wound infection If wound infection occurs, antibiotics will be prescribed. If the infection fails to respond to these, it may be necessary to remove the prosthesis and re-attempt insertion after a 3-month recovery period. To try to avoid infection, prophylactic antibiotics will be prescribed at the time of surgery.

Necrosis This uncommon problem occurs where blood perfusion of the skin flap is inadequate and some of the tissue dies. It is more likely to occur when myocutaneous flaps are used.

Potential long-term complications

Capsular contracture A fibrous layer of tissue forms around the implant and, over time, will contract. If this contracture is severe, the implant will become hard to the touch, uncomfortable and cause the reconstructed breast to change in shape. Manual compression under local anaesthetic may break the capsule; the only alternative is to remove the implant and scar tissue and insert a replacement prosthesis. The incidence of capsular contracture requiring removal is difficult to ascertain but is likely to be around 15%; this figure increases significantly if radiotherapy is given to the breast after the reconstruction. There is some evidence that new textured implants result in a lower incidence of capsular contracture (Mulata et al 1997).

Abdominal herniation This infrequent problem may follow a TRAM flap reconstruction. The weakness in the abdominal wall resulting from this surgery is strengthened by the insertion of surgical mesh to reduce the possibility of herniation.

NURSING PRIORITIES AND MANAGEMENT: Breast reconstruction

Preoperative considerations

Assessment

Nursing assessment prior to breast reconstruction should address the following points:

- The woman's reasons for wanting a breast reconstruction. These may include wanting to eliminate the need for an external prosthesis, a desire to improve self-confidence and self-esteem or to 'feel more whole', and a desire to have greater freedom in choice of clothing (Goldberg et al 1984, Watson et al 2002, West 2003).
- The woman's expectations of breast reconstruction. A woman who has realistic expectations is more likely to be satisfied with the overall result of her reconstruction. Expectations for both physical appearance and quality of life should be assessed as, however good the reconstruction, it will not be an identical replacement for the breast that has been lost.
- The woman's knowledge of breast reconstruction and her understanding of what the surgeon has told her about the procedure and possible complications.

Giving information

The nurse has an important role in promoting realistic expectations of breast reconstruction. Showing photographs of breast reconstructions is one way of helping women to imagine what it will be like. Photographs that show the effect of the reconstruction unclothed, in a bra and under clothing are useful, but photographs should not show only the very best results.

It may also help to arrange for the patient to talk to another woman who has undergone a reconstruction, preferably by a similar method. Breast Cancer Care may be able to put the patient in touch with someone in her area if no-one is known to the nurse or consultant. Some women may also like to see an implant.

Giving psychological support

The woman who is undergoing breast reconstruction at the same time as her breast cancer surgery will be dealing with her recent diagnosis of cancer as well as with the idea of reconstruction. It may be particularly difficult for her to come to a decision about reconstruction at this time and so it should be made clear to her that refusing an immediate reconstruction does not prohibit surgery at a later date. The woman needs to have time to make her decision and should have access to a specialist nurse to go over what has been discussed (Reaby 1998).

Women considering a delayed reconstruction frequently have second thoughts about undergoing further surgery. The nurse can help by taking time to clarify with the patient her worries and concerns and her desire for reconstruction. Concurrent stresses and the woman's family situation should also be assessed and discussed, as these may influence how she feels about undergoing reconstruction and how she will cope postoperatively.

Postoperative considerations

Wound management

The aims and principles of wound management are described in detail in Chapter 23.

The following points are of particular relevance to wound healing following breast reconstruction.

The nurse should observe the wound for signs of necrosis, haematoma, seroma and infection. Wound drainage should be observed and the volume recorded every 30 min

for the first 2 h after return from theatre and then at gradually increasing intervals. Circulatory perfusion of skin flaps should be checked with the same frequency. The skin flap should be gently pressed using a blunt tongue depressor; it should blanch and then quickly return to a pink colour once the pressure is released. This is particularly important where an autologous flap has been used in reconstruction and where tissue expansion is placing the wound under some tension. If the colour returns slowly, the flap looks blue or feels cold to the touch, the doctor should be informed in case it is necessary to take the patient back to theatre.

Temperature and pulse should be recorded 4-hourly. Dressings should be changed only if they become saturated with wound exudate or if it becomes essential to view the wound. Frequently, pressure dressings are applied in theatre and remain in place for 1–3 days. When these are removed, transparent dressings such as OpSite or Tegaderm are useful. Subcutaneous sutures are normally used and remain in situ for 10–14 days unless they are of the dissolvable variety. Discomfort from wounds will vary. Immediate reconstructions involving the removal of axillary lymph nodes and the more complicated surgical procedures involving raised tissue flaps will be the most uncomfortable. Opiate analgesics may be required by i.v. injection or continuous infusion pump for the first 2 days; after this time, oral analgesics are usually sufficient. Promoting comfort will increase rest and sleep and so encourage healing and general rehabilitation.

Patient education

Postoperative exercises should be taught, preferably by a physiotherapist, to all patients that have undergone breast reconstruction. Some surgeons prefer shoulder movement to be restricted to 90° flexion and abduction for 2–3 weeks, particularly if the scar is very tight or if they fear movement of the implant. Because the silicone implant is usually placed behind muscle, as the muscle contracts, tightening or discomfort may be experienced. This should disappear as the muscle accommodates the implant.

Advice about bras is commonly sought. Some support is likely to increase comfort and sports bras are usually the best option. Underwired bras should be avoided for the first few months. Surgical breast supports may be recommended for a few weeks. A partial prosthesis will need to be fitted to obtain a symmetrical appearance during tissue expansion and sometimes following reconstruction.

Giving psychological support

Although having a reconstruction after a mastectomy may help a woman to cope and foster rehabilitation, research indicates that many women mourn the loss of their breast and suffer from anxiety and depression following surgery (Dorval et al 1998). The nurse should not assume that a woman who has had an immediate reconstruction will have no problems related to a changed body image.

Women undergoing tissue expansion often experience frustration at the length of time the process takes to complete reconstruction. Some find it difficult to cope with an inequality in breast size and shape during this time (Goin & Goin 1988). Acknowledgement of these feelings, adequate opportunity to discuss them and access to counselling may help the woman to cope.

When complications do occur and an implant has to be removed, the individual may suffer further psychological distress. A wait of about 3 months is generally required before another implant can be inserted; during this time the woman will have to cope with another alteration in body image. Anxiety, depression and feelings of anger or despair may result. Some women may decide that they do not wish to undergo a further attempt at reconstruction. The nurse should support the patient whatever her decision and encourage her to express her feelings about the reconstruction and what it means to her.

LYMPHOEDEMA IN BREAST CANCER

Lymphoedema is the accumulation of a high-protein fluid in the interstitial spaces between cells in the tissue of a limb or other area. It is the result of a defective mechanism of lymph drainage due to tissue fibrosis, disease or a congenital disorder.

Approximately 28% of women with breast cancer will develop some degree of lymphoedema (Mortimer et al 1996), characterised by a swollen arm, often with some swelling of the adjacent chest and back. This condition can cause considerable physical and psychological distress (Woods 2003).

PATHOPHYSIOLOGY

All women with breast cancer who have axillary surgery to remove some or all of their axillary lymph nodes, or those who receive radiotherapy to the axillary region, are at risk of developing lymphoedema of the limb on the affected side. Scarring from these treatments will result in the closure or narrowing of many lymph vessels and so reduce the efficiency of lymphatic drainage from the arm. For most women, the drainage remains adequate and collateral vessels may develop to increase the pathways for drainage. However, lymphoedema may develop weeks, months or years after surgery or radiotherapy, sometimes following a wound complication, cording, infection or injury, but often without an obvious reason. It may remain mild or gradually progress until the arm is so heavy that it is difficult to lift and to use. Over time, fibrosis within the tissue of the arm may occur, causing hardness. There is also a higher risk of infection and cellulitis, as the high-protein fluid is an ideal breeding ground for bacteria.

Disease within the axillary area which causes an obstruction to lymph flow will also cause lymphoedema. This may be seen when cancer has recurred or when a woman presents with an advanced carcinoma of the breast. Signs of venous obstruction are sometimes seen. These are commonly a pink colouring of the arm and distended veins visible on the upper arm and chest wall.

Brachial plexus nerve damage is rarely seen, but may also result from radiation fibrosis or cancer infiltration of the nerve plexus, causing weakness, paraesthesia or nerve pain.

MEDICAL MANAGEMENT

Treatment Options for medical management are at present limited. The choice of treatment depends on whether the lymphoedema has been caused by fibrosis or by axillary disease. Assessment may include CT scanning and colour

Doppler ultrasound to determine the amount of scarring, venous obstruction or disease.

Previously, attempts to reduce the size and weight of the arm by surgically removing a large amount of tissue have had very little success and have frequently caused further problems with infection, swelling and pain as well as extensive scarring. Where venous obstruction is due to a thrombosis, anticoagulation therapy with warfarin may be used.

In the case of axillary disease, surgery to remove as much of the cancer as possible may be of use by reducing the obstruction of lymph and venous flow. However, chemotherapy or endocrine therapies, which have the advantage of not causing the same disruption to normal structures as surgery, are more likely to be used.

Pain relief Analgesics ranging from paracetamol to opiates will be used as required. If, however, the pain is due to brachial plexus damage by disease or radiotherapy, it is unlikely to respond adequately to opiates since nerve pain is only partly opiate responsive (Twycross 1996). Anticonvulsants, serotonin reuptake inhibitor antidepressants, steroidal and non-steroidal anti-inflammatory drugs (NSAIDs) and, in some cases, anti-arrhythmics may be effective. These should be used under the guidance of the palliative care team (Twycross 1996).

Cellulitis The risk of infection in a swollen limb is high. A small cut or insect bite may provide an entry point for infection and result in severe cellulitis requiring treatment by antibiotics. If cellulitis is recurrent, patients are often given a prescription to have on hand so they may obtain antibiotics as soon as infection occurs.

NURSING PRIORITIES AND MANAGEMENT: Lymphoedema

Major considerations

Treatment effectiveness is measured in terms of the reduction in size and weight of the arm, and for most people this is possible. However, sometimes all that can be done is to increase the softness and movement of the arm and to reduce the discomfort, but these improvements can represent a substantial increase in the quality of life for the patient.

Assessment

Nursing interventions must be preceded by an assessment to identify the physical and psychosocial needs of the individual patient.

Physical assessment should address the following areas:

- General information such as medical history, particularly of any surgery or radiotherapy, disease in the axilla and any information that the patient feels is relevant to their limb swelling
- Physical examination of the limb including the condition of the skin of the arm: colouring, presence of cuts/infection, previous cellulitis
- The size of the arm. Both arms should be measured at 4-cm intervals from a fixed point at the wrist to the root of the limb so that a comparison can be made and the severity of the oedema estimated to form a baseline for treatment. There are specialised calculators available that can take these circumferential measurements and convert them into a volume, providing a more accurate estimate of lymphoedema swelling
- The duration of the oedema and any precipitating or aggravating factors
- Presence of oedema in the adjacent tissue of the chest wall
- Any previous treatment for lymphoedema
- The type and severity of any discomfort experienced
- The individual's range of shoulder movement and ability to use the arm in activities of daily living.

Psychosocial assessment should include:

- how the lymphoedema has affected the woman's self-esteem and body image
- how the lymphoedema has altered the woman's lifestyle, work and social role and how she feels about this
- whether the swelling has affected the type of clothing she can wear.

Nursing interventions

The aim of nursing interventions in the management of lymphoedema are:

- to reduce arm size
- to improve the use of the arm
- to improve the comfort of the arm
- to improve the shape of the arm.

All treatments involve compression of the limb to try to push more fluid back into those lymph vessels that are patent.

There are now four recognised elements to the treatment of lymphoedema: (1) skin care, (2) exercise and movement, (3) lymph drainage and (4) external containment using compression sleeves or bandaging (Woods 2003).

Patient education is very important to explain clearly the aim of each treatment regimen and to promote a realistic expectation of outcome. Although therapy is aimed at control rather than cure, the patient who is given sufficient information and is encouraged to participate in treatment is likely to adopt a more positive attitude towards her situation.

The main treatment methods are related to the degree of severity of the lymphoedema:

1. *Skin care.* Treatment would begin with emphasis on the importance of skin hygiene and care. Advice given at the time of the axillary surgery should be re-emphasised. Any infection should be treated with antibiotics and the skin of the arm should be moisturised and kept as healthy as possible.
2. *Exercise and movement.* Lymph drainage can be promoted through movement and appropriate exercise of the arm as the muscle contraction and expansion stimulates the superficial lymphatics to drain (Woods 2003). Hughes (2000) identified swimming as an ideal as the water supports the body and provides some resistance to the muscles.
3. *Lymph drainage.* Manual lymph drainage (MLD) involves specialised movements of the thumbs, fingers and hand. This type of massage can only be carried out by trained

MLD therapists. Simple lymphatic drainage (SLD) has been developed from MLD for use by patients and their relatives. The aims of SLD as with MLD are:

- to stimulate normal lymphatic drainage
- to 'milk' fluid away from the congested areas
- to improve superficial lymphatic drainage (Woods 2003).

This type of massage is light, aiming to stimulate the lymphatic vessels in the skin. Deeper massage would cause increased blood flow to the muscles causing more fluid to accumulate in the tissues and would thus be counterproductive.

4. *External containment.* This would include the use of compression sleeves or enclosing the limb with pressure bandages.
   - For women with severe lymphoedema, lymphorrhoea (leakage of lymph fluid), skin problems or difficulty using a sleeve, *compression bandaging* is the treatment of choice. Low-stretch bandages are used to bandage the fingers and hand before the arm is encased. The pressure applied should be graduated, greater pressure being applied at the lower end of the limb. The bandages should be reapplied daily. Due to the large size of the arm and of the bandages required, this may need to be undertaken on an inpatient basis which also affords an opportunity for the provision of physiotherapy, occupational therapy and psychological support. However, community nurses experienced in this technique can undertake compression bandaging in the patient's home. This is particularly helpful for those who have advanced disease and feel unwell. Bandaging of a large arm may provide great comfort and relief from pain even if it offers little hope of reducing arm size.
   - *Compression sleeves* are often used for lymphoedema management. Several specialised ready-made varieties are available, e.g. Medi, Pan-Med and Sigva. Compression must be fairly strong (around 40 mmHg) if it is to be effective. Supports such as Tubigrip are not adequate. Sleeves may be difficult to put on but once fitted are supportive and comfortable. They should be worn during the day when the patient is most active. The sleeves should not be allowed to form creases, as this will cause ridging in the swollen tissue. The sleeve, easily laundered, may need to be worn for several weeks, during which time the patient must be monitored regularly to assess the effect. If the oedema is modest, it may be possible for the arm to return to its normal size.

Lymphoedema of the arm is a difficult condition for any patient to face, particularly if they have been treated for breast cancer. With the specialist care now available, patients should be quickly assisted to manage this chronic condition (Woods 2003).

MALIGNANT FUNGATING BREAST TUMOURS

Breast cancer is the most common cancer to cause ulceration. The result can be an unpleasant, weeping, malodorous, infected wound which is psychologically very difficult to cope with. Women often express feelings of disgust and revulsion and curtail social activities because of their embarrassment. An altered body image may lead to anxiety, depression and sexual problems.

Nurses have an important role to play in supporting women with fungating tumours. By rising to the challenge of wound management and controlling symptoms such as odour and excessive wound exudate, they can help to improve the quality of life for these women. Frequently it is the community nurse who has the greatest involvement with these women and their families (see Case History 7.4).

CASE HISTORY 7.4

Mrs S

Mrs S has been referred by her GP to the community nurse for management of a large ulcerating left breast carcinoma and for psychological support. She is 65 years old and a retired civil servant. She lives with her husband in a large house, which they own. She visited her GP ostensibly to have her blood pressure checked but broke down in tears and told him that she had had a breast lump for 3 years. She hadn't told anyone, including her husband, because she 'feared the worst'. Now the lump was smelly and oozing and she could no longer hide it from her husband, who had made her visit the GP.

On visiting Mrs S for the first time, the nurse finds a withdrawn and depressed lady who has stopped going out. She is embarrassed to show the nurse her breast, which is a large ulcerating mass with nodules extending to the surrounding tissue on the chest wall. The wound is malodorous, with a large amount of necrotic tissue and a profuse discharge. Mrs S has been covering it with gauze pads but has not cleaned it for some time, as she cannot bear to look at it.

Mrs S describes her husband as supportive and loving, but she will not allow him near her any more because she feels that she is 'disgusting'. She has taken to sleeping in a separate room and avoiding him when she can.

The nurse is able to speak very briefly to Mr S, who appears caring but very anxious about his wife's condition. He is not allowed by his wife to be present during her discussion with the nurse.

PATHOPHYSIOLOGY

Ulceration occurs when breast cancer infiltrates the epithelium and causes a breakdown of the skin. The resulting wound may be superficial or deep; it may affect a small area of the breast or may be very extensive, involving part, or all, of the chest wall. Frequently, as a tumour grows, its blood supply becomes inadequate, causing central tissue death and necrosis. When such a tumour ulcerates, a large necrotic mass is revealed, providing an ideal environment for infection to develop. This in turn will increase exudate and cause odour.

As the disease progresses, ulceration becomes more extensive and may erode blood vessels, causing haemorrhage but also occlusion of the blood vessels. A lack of oxygenation of the tissues leads to tissue breakdown and a build-up of bacteria at the tumour site causing the classic malodour associated with fungating lesions (King 2003). The severity of bleeding will depend on the size of the blood vessel. Capillary bleeding causing a slow loss of blood

is commonly seen, but blood loss may be life threatening if a large vessel is eroded.

Tumour involvement of the cutaneous nerves can cause pain and irritation. There is often tenderness due to inflammation in the surrounding tissues. Whilst many women have remarkably little pain from these wounds, some have severe pain.

MEDICAL MANAGEMENT

Treatment will depend on the extent and position of the tumour and on what therapy for breast cancer, if any, the woman has previously received. Management may be considered in terms of treatments to try to control the disease and interventions aimed at symptom control.

Surgery For women who have an ulcerating tumour that appears confined to the breast region, it may be possible to remove the tumour surgically by performing a mastectomy (sometimes, unfortunately, called a toilet mastectomy). Where the tumour extends to the chest wall or a large area of skin, the surgery will be more extensive and surgical closure will require a skin graft or the use of a muscle and skin flap from the abdomen or back. These have been successfully used in some women to increase their quality of life, but careful discussion with the patient beforehand is important to ensure that she understands what the surgery entails, what benefits can be expected and what risks are involved. If the woman's general health is reasonable and she has a life expectancy of more than a few months, she may feel that this approach is the best for her even if recovery is protracted.

Radiotherapy can be used with great success in controlling some breast tumours. Complete remissions are occasionally seen, but more commonly radiotherapy achieves a reduction in tumour size and in the wound symptoms.

Chemotherapy and endocrine therapy may also be used, sometimes in combination with radiotherapy. Systemic drug therapies have the added advantage of treating disease elsewhere in the body as well as in the breast.

Symptom control measures are as follows:

- Analgesics may need to be provided frequently to alleviate constant pain or to make dressing changes more comfortable. The choice of analgesic will depend on the type and severity of the pain (see Ch. 19).
- Antibiotics may be required in the fight against infection.
- Supportive transfusion may be indicated where blood loss has caused anaemia.
- Surgical debridement may be very useful in removing necrotic tissue from the wound, but it is often not possible to carry out in view of the risk of haemorrhage. Streptokinase and streptodornase have also been used in combination for the debridement of necrotic tissue, although this treatment is time consuming and there is little evidence to support their use (King 2003).
- Diathermy can be helpful in controlling bleeding points but should be used with caution, given the necrosis it causes. In severe cases of bleeding, topical adrenaline may also be applied; this too should be used with caution.

NURSING PRIORITIES AND MANAGEMENT: Fungating breast tumours

Major considerations

Assessment

The nursing assessment of a woman with a fungating breast tumour must include far more than an assessment of the wound itself. It must consider psychosocial factors such as age, concurrent disease and disabilities, drug therapies and pain. All of these factors may influence the possibility of wound healing or infection.

The woman's psychological state, her reaction to the wound, her ability to cope with it and the way it has affected her life and her family are all equally important. The nurse should bear in mind that anxiety and depression can have a significant impact on treatment outcome. Frequently it is the community nurse that has the greatest involvement with these women and their families, as hospitalisation is rarely required. Women often live for many years with a slowly progressing fungating tumour, which makes it all the more important that every effort is made to improve their quality of life.

Wound management (see also Ch. 23)

Malignant breast lesions have a pathological cause, i.e. cancer. Unless this cause is being treated, wound healing is unlikely to occur. It is important that the nurse promotes realistic expectations in the patient, so that, if she is not receiving treatment for breast cancer, she is not hoping for complete healing of the wound.

The general aims of wound management are:

- to control the symptoms produced by the wound
- to minimise possible complications, e.g. infection
- to maximise comfort and minimise discomfort
- to promote healing where possible.

Many types of wound dressing are available. In order to choose products which are likely to be most effective for a given wound, the nurse must first identify the problems that are present. The most common problems associated with ulcerating lesions are discussed below (see also Nursing Care Plan 7.3).

Tissue necrosis Where tissue necrosis exists it is likely to increase the risk of infection. Debriding the wound of dead tissue will reduce this risk. Although it may be possible to remove the bulk of necrotic tissue by surgical debridement, the risk of haemorrhage sometimes prohibits this, making topical preparations, such as the hydrogels or the hydrocolloids, the preferred treatment, even though it is a slower process.

Infection is suspected where there is a purulent wound discharge, odour, inflammation and a raised body temperature. A wound swab should be taken by the nurse so that the appropriate systemic antibiotic can be prescribed. Preparations such as metronidazole gel may be applied topically to help fight infection (King 2003). The pharmacist and the infection control team will advise about the use of particular cleaning solutions when there is wound contamination by particular organisms such as *Pseudomonas*.

Nursing Care Plan 7.3 Caring for a woman with an ulcerating breast tumour (see Case History 7.4)

Nursing considerations	Action	Rationale	Expected outcome
April 6 **1. Ulcerating left breast cancer: the wound is malodorous, necrotic, and has a profuse discharge**	• Take wound swab for culture and sensitivity	Odour and discharge may be due to infection in wound	By April 13: A reduction in wound odour
	• Twice a day: – Cleanse wound with saline using syringe and quill – Remove any areas of *loose* necrotic tissue with forceps and sterile scissors – Apply thick layer of natural live yoghurt and leave for 15 min, covering patient with sterile towel – Remove yoghurt using saline in syringe again	Quill allows gentle but thorough cleansing (no cotton wool fibres may be left which act as focus for infection). This will increase speed of debridement but should only be done on loose dead tissue and should not be painful Natural *live* yoghurt very good at deodorising but need to leave 15 min to work	Reduction in necrotic tissue Amount of wound drainage will be reduced and controlled by wound dressings Mrs S will state that she finds her dressing comfortable and that the symptoms have improved
	• Apply Hydrogel wound dressing		
	• Cover with dressing, taking care to protect sore and friable areas with petroleum jelly	Dressing necessary to ensure Hydrogel is kept in place	
	• Apply absorbent secondary dressing containing charcoal, e.g. CliniSorb	Absorbent secondary dressing used because of profuse discharge. Charcoal helps to deodorise	
	• Keep in place with Netelast	Using Netelast reduces trauma to friable skin on chest wall	
	• Suggest change bedclothes frequently and open windows each day	These measures will help to prevent the odour lingering in the house	
April 10	• Apply Sorbsan instead of Hydrogel. Continue with rest of dressing	Sorbsan has a haemostatic action. Though more gentle than Varidase, it is also very absorbent	

Evaluation

April 10

Hydrogel debriding wound well but wound bleeding close to medial edge. Using Sorbsan to stop bleeding. Will continue with yoghurt.

April 13

Discharge reduced and now controlled by Sorbsan dressing. Odour much less obvious but still present, therefore will continue with yoghurt, Sorbsan and charcoal dressings.

Wound swab indicates *Staph. aureus* infection. GP will visit tomorrow and prescribe a course of antibiotics.

Nursing Care Plan 7.3 Caring for a woman with an ulcerating breast tumour (see Case History 7.4) *(Continued)*

Nursing considerations	Action	Rationale	Expected outcome
April 6			
2. Embarrassment and disgust at wound causing: (a) Difficulty in communicating with husband (b) Social isolation (c) Reduced self-esteem	• Dress wound to control symptoms of odour and discharge	If symptoms of odour and discharge are controlled Mrs S will be more likely to go out again and not feel so self-conscious	
	• Encourage Mrs S to express her feelings about her wound and the way it is affecting her life	This may help Mrs S to 'let go' of tension, to see her situation more clearly and to allow her to accept support from the nurse. It will also help the nurse to identify specific problems/concerns	Mrs S will verbalise her feelings about her wound
	• Encourage her to talk about her relationship with her husband and how it has altered	This will help the nurse to understand how they used to communicate and how close their relationship was. This will help her to plan intervention which may improve communication and mutual support	She will identify how her relationship with her husband has changed
	• Assess her social support and what sort of activities she used to do	This will indicate what the norm was for Mrs S and how things have changed. It will allow the nurse to know what activities and relationships she might encourage Mrs S to take up again	
April 10	• Suggest that Mr and Mrs S sit down together and discuss how they feel about the cancer, the wound and how it has altered their life	This would allow Mr and Mrs S to begin communicating again and to break down barriers so that they can support each other	Mr and Mrs S will discuss together how they both feel about Mrs S having breast cancer and an ulcerating lesion
April 13	• Suggest Mrs S should go out to her daughter's next week for tea	Mrs S is close to her daughter. As her wound is improving, this is an appropriate first step in taking up her social life again	She will arrange to go out to visit her daughter by April 20
	• Arrange for Mrs S to visit hospital for partial prosthesis to be fitted	Mrs S has voiced concern about her appearance in clothes. A partial prosthesis will enable her to regain a balanced appearance	
	• Discuss the choice of loose clothing to minimise the altered shape due to the dressings

Nursing Care Plan 7.3 Caring for a woman with an ulcerating breast tumour (see Case History 7.4) *(Continued)*

Evaluation

April 10

Mrs S says she feels very down today. Expressed feelings of guilt that she hadn't sought help before and believes she has let her husband down. She knows that he loves her but believes he cannot possibly want to be near her because of her wound's odour. She describes her marriage as previously very strong. They used to talk about most things but both find it difficult to express their feelings to each other and have not spoken of the cancer diagnosis or what will happen now. She has spoken to her daughter, who has said they should all talk about it. She would like to, but doesn't feel she can. I reinforced that I felt it would be a good idea and offered to be present if that would help. She will think about it.

April 13

Mrs S is feeling better. She is very pleased that her wound is more manageable and particularly that it is less smelly. I suggested she might consider going out. She is hesitant about this but I suggested perhaps a couple of hours with her daughter. She is still conscious of the wound and feels everyone will know something is wrong because her appearance is not balanced due to the dressings and tumour itself distorting her breast shape. I suggested partial prostheses may help this and she is very keen on this idea.

Nursing considerations	Action	Rationale	Expected outcome
April 6			
3. Fear of breast cancer	• Assess Mrs S's information needs by finding out what her knowledge of breast cancer is and identifying misconceptions she may have	Providing appropriate information may help to allay anxiety and remove misconceptions	Mrs S will specify the fears she has about breast cancer
	• Encourage Mrs S to express and explore her feelings concerning breast cancer	This is often therapeutic in itself but also allows the nurse to more accurately identify her fears	She will define her information needs concerning breast cancer and its treatment
	• Offer literature about breast cancer	Written information reinforces verbal information	
April 7			
4. Fear of dying in pain. Fear of nausea and vomiting	• Reassure Mrs S that effective pain control is available. (Discuss worries about taking opiates if this is a problem for her.) Stress that nausea and vomiting can normally be controlled by medication		Mrs S will understand that pain from cancer can be effectively controlled and that nausea and vomiting, if they occur, can also be controlled by medication

Evaluation

April 7

Very upset today. Feels very guilty that she didn't go to the GP before. Feels she has let her husband down. Has always been frightened of having breast cancer, although she doesn't know anyone who has had breast cancer. She knows that it is likely that she will die from this, in spite of any treatment she may be given, and she is frightened about how this will happen. She equates cancer with a painful death and cannot bear the thought of pain or feeling nauseated.

April 10

Given booklet by Breast Cancer Care. Suggested that she should let her husband read it too. Also wanted to know about possible treatments for breast cancer of this stage. Discussed chemotherapy, radiotherapy and hormone therapy.

Continued ▶

Nursing Care Plan 7.3 Caring for a woman with an ulcerating breast tumour (see Case History 7.4) *(Continued)*

Nursing considerations	Action	Rationale	Expected outcome
April 6	• Arrange a time to sit down and talk to Mr S	This will ensure the nurse has time specifically with Mr S	By April 13, Mr S will define areas of anxiety
5. **Anxiety of Mr S due to Mrs S's condition and withdrawn behaviour**	• Encourage him to express and explore his feelings and define the particular anxieties he has regarding his wife and any other areas of stress	Expression and exploration of feeling are therapeutic in reducing anxiety and will enable the nurse to assess the home situation more fully	Mr S will discuss his feelings concerning Mrs S's illness, behaviour and the ulcerating cancer
	• Assess the support systems that Mr S has and emphasise that the nurse is concerned for his welfare as well as his wife's	Many carers do not consider their own needs and consider the nurse only as a support for the patient	
	• Provide information about breast cancer and its treatment	Appropriate information may help to reduce anxiety by enabling Mr S to feel more involved and more in control of the situation	

Evaluation

April 6

Arranged to speak to Mr S tomorrow following visit to his wife.

April 7

Reluctant to discuss his feelings about his wife, preferring to dwell on his wife's problem and her feelings. Mr S fought back tears when discussing the future. However, he did say he feels angry with himself and his wife that the cancer got to this stage before medical help was sought. He feels guilty he didn't know about it and frustrated with his wife's withdrawn behaviour as he believes she will just give up and die. We discussed how control of the wound problems may give her the confidence to go out again, and how she will require his support, which he appears very willing to give.

Mr S appears to have very little support, only talking to his daughter on rare occasions about his wife. He used to talk over everything with his wife but now she won't allow this.

April 13

Seen briefly. Looks more relaxed. Has talked to GP about possible treatments and appointment to see consultant oncologist has been made for next week. Also believes that his wife is brighter because her wound has improved.

Excessive wound exudate is often due to a wound infection and hence the first action would be to treat the infection and to debride the wound as necessary. The aim of wound dressing is to absorb the maximum volume of exudate with the minimum bulk of dressing. This requires the use of a high-absorbency primary dressing, e.g. Kaltostat or Sorbsan, alginate hydrofibres, and a high-absorbency secondary dressing, e.g. CliniSorb, which has the added benefit of containing charcoal to reduce odour from the wound.

It is important to remember that once there is 'strike-through' of the secondary dressing (i.e. saturation of the dressing) a pathway exists for bacteria to move from the outside through the dressing into the wound. This should be prevented by frequent changes of the outer dressing. Waterproofing is also important. Dressings such as OpSite or Tegaderm may sometimes be used as a tertiary dressing as are disposable nappies where greater absorbency is needed.

Hydrocolloid or hydrogel dressings, available in sheet or gel format, may have an important role to play. Their high water content allows the rehydration of the wound and they have high absorption qualities for wound exudates. They do, however, promote a moist environment which can encourage the growth of bacteria, so constant evaluation of their use is necessary (King 2003).

Odour Despite the lack of research to legitimise the use of natural live yoghurt in reducing wound odour, it is in fact widely used and appears to be effective. It is thought that the application of yoghurt creates an acid medium which inhibits the growth of bacteria, and that the lactobacilli in the yoghurt also act directly on the bacteria within the wound.

Yoghurt is usually applied thickly for around 20 min before it is removed with saline or gently showered off in the bath. A further dressing such as Kaltostat or Sorbsan can then be used on the wound. Where odour is a severe problem, yoghurt can be applied three or four times a day to try to reduce the odour as quickly as possible. A secondary dressing containing charcoal can also be used.

Metronidazole gel is also effective, but the problem of bacterial resistance to antibiotics must be considered.

External deodorisers may be helpful, e.g. Ozium, Neutradol, Nilodor, but sometimes the smell of air fresheners or deodorisers is unacceptable to the patient or her family, and may even cause nausea. Fresh air is probably the most effective agent for removing odours from a room, and changing clothes daily will help to prevent odours from penetrating clothing.

Haemorrhage/capillary bleeding Capillary bleeding is commonly seen in malignant wounds and is often difficult to stop. Again dressings such as Kaltostat, an alginate hydrofibre, have a haemostatic property and are particularly useful where capillary bleeding exists.

It is extremely important that dry dressings are not applied to wounds that bleed, as removal is likely to cause further bleeding. To reduce trauma, adherent dressings should be removed only after soaking. Dressings such as Kaltostat and Sorbsan absorb exudate and turn to a gel which is then easily removed by syringing the wound with saline or when the patient showers. Where possible, wounds which are liable to bleed should be irrigated, for even the gentle use of cotton wool may be enough to cause bleeding.

The use of pressure may help to control bleeding, but if a major vessel is eroded, bleeding may be very difficult to control and alarming to the patient. Weak solutions of adrenaline may be advised by medical staff in such a situation, but these should be used with caution because of the possibility of systemic absorption.

Care must also be taken when using tape to hold dressings in place. The skin around an ulcerated wound is often inflamed, tender and delicate. As tape may cause trauma, it is a good idea to rotate the sites to which tape is applied. In fact, it is preferable for dressings to be held in place by net body bandages such as Netelast, which obviates the need for tape.

Pain Wound pain can range from very slight to severe. The nurse must assess the severity and type of pain being experienced and whether it is always present or affects the patient only during dressing changes. Pain assessment should be ongoing so that the effectiveness of pain control measures can be evaluated (see Ch. 19). Where dressing changes cause discomfort, analgesics should be offered to the woman at least 30 min before each change. The use of Entonox during the dressing procedure may also be helpful. The use of non-adherent dressings and, where possible, cleansing of the wound by irrigation will also reduce discomfort.

Patient education

Wound care As much information as the woman requires concerning her wound, dressings and general condition should be given. The degree to which the patient and her family are involved in wound management will depend largely on their own wishes and sensitivities. Some women prefer to be taught how to dress their own wounds completely at home, with only minimum supervisory involvement by the community or hospital nurse. This may originate in a desire to be independent or it may be prompted by embarrassment. Some patients feel unable to have anything to do with their wound and do not want family members to intervene either. No woman should be made to look at her wound if this is intolerable to her; to do so may destroy the only way in which she knows how to cope.

Diet Dietary advice may be appropriate if a woman is malnourished, has an infection, is anorexic or is considering starting a 'cancer diet'. The nurse should be able to give basic advice about a balanced diet (see Ch. 21) but may wish to refer the patient to a dietitian for further advice. The decision to go on to a cancer diet rests with the patient. There are many such diets: some are reasonably well balanced, but others are likely to cause extreme weight loss. Where this is likely to be detrimental to the individual, the nurse should discuss this with her. Ultimately, however, the nurse should support the patient in whatever decision she makes.

Prostheses and clothing Practical advice about clothing may be appreciated if the disease has radically altered the contour of the chest or where a large amount of absorbent dressing is necessary to control the wound exudate. The use of partial prostheses fitted over the dressings may restore a more normal breast contour. A larger soft bra may enable the dressing to be held in place comfortably but securely whilst maintaining a normal appearance in clothing. Where a bra cannot be worn due to discomfort, loose clothing will help to disguise any altered shape without causing any restrictions around the wound.

7.10 Consider the following questions with reference to Case History 7.4:

(a) Identify the main problems that Mrs S has.
(b) Consider the effects a fungating lesion might have on a woman's body image.
(c) It is important that Mrs S does not feel that her nurse is disgusted by her wound. Consider how the nurse might demonstrate both verbally and non-verbally that this is not the case.
(d) How might the nurse endeavour to reduce Mr S's anxiety about his wife?
(e) What properties should the wound dressing have? Can you suggest any appropriate products for such a wound?

THE PSYCHOLOGICAL IMPACT OF BREAST DISEASE

Nurses have a particularly important role to play in supporting patients through the traumatic experience of breast disease. Although many women with breast cancer will face similar problems, no two individuals will respond to their diagnosis and treatment in exactly the same way. As this chapter stresses, ongoing assessment is the key to

providing psychological and emotional support that is genuinely responsive to each woman's needs and priorities.

For most women, a diagnosis of breast cancer is devastating. They may have to cope with the prospect of mutilating surgery to a part of the body associated with femininity, sexuality and motherhood, the prospect of several months of intensive medical treatment and the possibility that they may eventually die of the disease. Some women with breast cancer discover their lump when washing or during self-examination whilst others are not aware that anything is wrong but find out when they attend for a screening mammogram. Symptoms of acute anxiety, panic, palpitations, tachycardia, loss of concentration and insomnia may be experienced in the period when a medical opinion is sought and a diagnosis awaited. Some women describe this time of flux as the most agonising period of their illness. For some women, the fear of cancer or its treatment is so great that they deny the presence of a lump or delay seeking medical help.

Some of this fear may be based on misconceptions about the nature of cancer treatments. It is important for nurses, especially those in community practice, to dispel myths about cancer therapy, to raise awareness of the success rate of breast cancer treatment, and to emphasise the importance of early detection.

Some women who undergo surgery for breast cancer initially experience euphoria that the cancer has been removed. Others deny the removal of their breast or find themselves unable to talk about it or to look at the scar. Much research has been carried out into the psychosocial sequelae of breast surgery. It has been reported that one-third of women develop severe anxiety or depression within a year of their diagnosis (Maguire 2000). It was thought that this was related mainly to the altered body image of mastectomy, but Fallowfield et al (2000) found that women who had a wide local excision had levels of anxiety and depression similar to those experienced by women who had chosen to undergo mastectomy. In their study, Dorval et al (1998) found that having a partial or total mastectomy did not significantly affect quality of life but that the individual's response to the surgery was affected by her age. Their study suggested that having a partial mastectomy may have lessened the negative effect of breast cancer for younger women.

Following diagnosis and surgery, a period of adjustment occurs which is characterised by fluctuating emotions. Northouse (1989) found that following mastectomy the major concern for most women and their partners surrounded issues of survival, in particular the extent of the cancer and the possibility of recurrence. Patients may also be worried about changes in lifestyle, treatment regimens and altered appearance.

For the majority of women who have undergone breast surgery, anxiety begins to reduce after about 3 months and the activities of normal life will be resumed. Some women, however, will continue to experience great anxiety, show signs of depression, withdraw from social contact or have sexual problems. These women are likely to benefit from more in-depth counselling and psychological support. Nurses, particularly those in the community and in outpatient departments, should be able to recognise emotional problems and, where necessary, suggest referral to a counsellor, psychiatrist or psychologist via the GP or hospital medical staff.

PATIENT EDUCATION

Being a recipient of the bewildering treatments for breast cancer can take self-determination away from the woman and this can lead to psychological morbidity. Research has shown that many patients find that information helps them to make sense of their situation, and hence to feel more in control, less vulnerable and less anxious (Fallowfield et al 2000). Most women have some general knowledge of breast cancer, but will not be familiar with the details of the tests or treatments they are to undergo. Many will, in fact, have misconceptions about breast cancer and its prognosis because of the misinformation that may be found in the popular media. Research by Macleod et al (2004) has demonstrated that different groups of women receive differing amounts of information from the available sources, the affluent group accessing more information than the deprived group. They state that health care professionals need to be aware that there may be greater psychological distress in the deprived group of women, perhaps not helped by the lack of informational support (see Research Abstract 7.9).

The nurse must bear in mind that the amount of information each woman wants about her disease or proposed treatment will vary. As too much information is likely to cause confusion and anxiety, it is important for the nurse to find out what each individual wants to know, and to

RESEARCH ABSTRACT 7.9

Psychosocial aspects of care in breast cancer: affluent vs deprived women

A postal questionnaire was sent out to affluent (n = 158) and deprived women (n = 263) with breast cancer to compare their psychosocial aspects of care with the purpose of understanding the balance of care and to explain why deprived women have poorer outcomes. Data were collected regarding reported sources of information, SF-36 scores and ongoing causes of anxiety. The results demonstrated that affluent women were more likely than deprived women to have received information from their hospital specialist (94.8 vs 76.0%) and from a breast care nurse (70.1 vs 40.0) than deprived women. They were also more likely to have received information from magazines (50.6 vs 33.0%), newspapers (45.5 vs 22.0%) and television news (45.5 vs 26.0%). Deprived women had poorer SF-36 scores than affluent women, and reported greater anxiety about money (12.2 vs 2.8%), other health problems (22.1 vs 8.2%) and family problems (17.5 vs 6.9%).

Personal and professional support is clearly important for patients with breast cancer. Health professionals need to be aware of the greater psychological distress demonstrated by deprived women, even some years after diagnosis with breast cancer, and seek to address it.

Macleod U, Ross S, Fallowfield L, Watt G C M 2004 Anxiety and support in breast cancer: is this different for affluent and deprived women? A questionnaire study. British Journal of Cancer 91: 879–883

clarify what has been understood. It is also important to remember that, in times of stress, information is more difficult to assimilate and remember. It is often necessary for the nurse to repeat information.

If the nurse feels unable to answer any questions, she should either find someone who can do so or arrange a further consultation with medical staff. The nurse may be able to facilitate communication by helping the patient to articulate her concerns and by clarifying concepts or terminology unfamiliar to the patient.

Areas of information that are likely to be relevant include:

- how breast cancer is and is not caused, e.g. it is not caused by a knock on the breast
- the aim of treatment and what outcome may realistically be expected
- the nature and likely cosmetic effect of any proposed surgery
- the possibility of breast reconstructive surgery if all, or a large part, of the breast is removed
- if axillary lymph node removal is advised, the effects of removal and the postoperative exercises necessary to ensure the return of full shoulder movement (see p. 332)
- staging tests that will need to be performed prior to or following surgery
- the availability of prostheses, when this is appropriate.

The nurse should ensure that the patient understands what the operation involves and the likely pre- and post-operative experiences, including the presence of wound drains, i.v. infusions, pain, scarring and any possible short- or long-term complications. Photographs or diagrams may be useful to demonstrate likely scarring or alteration in breast shape or size, and patient videos are becoming a popular way of reinforcing what has already been said.

Information given verbally may be reinforced in written form. Booklets on breast surgery and breast cancer can be obtained from Breast Cancer Care (BCC) and the British Association of Cancer United Patients (BACUP) if local literature is not available (see 'Useful websites', p. 354). These publications can also be useful for family and friends to read. Admission booklets providing information about the hospital, its facilities and visiting hours are also helpful.

Women who wish to have more in-depth knowledge about breast cancer may find Sampson & Fenlon (2000) useful. This book is written for the informed lay public.

THE ISSUE OF INFORMED CONSENT

The patient's rights

In order to give informed consent to an operation or treatment, a patient must be told what the procedure or therapy entails and its consequences, and must understand the information that she is given. Since the Alderhey tissue retention scandal (Hunter 2001), most centres now present women with individualised consent forms that clearly state in detail the type of surgery they will undergo and the expected effect of that surgery. The retention of tissue specimens for research is also made explicit and the woman has the right to refuse to donate her tumour tissue for research.

A woman who is diagnosed as having breast cancer has the right to be told of all the possible medical options and to decide which, if any, of these options she will take. She may wish to seek a second opinion from another specialist and to gather information to help her make a decision as to which is the best treatment for her. Research about particular aspects of treatment is becoming the norm in breast cancer care and most women being treated for cancer will be approached about entering one or more studies. In this event the study should be clearly explained and written information given as back-up. The woman must be assured that she has the absolute right to refuse entry without incurring any detrimental effect to her future care.

The nurse's role

The issue of informed consent is an important one for all nurses who aim to give truly patient-centred care. Doctors have the responsibility for obtaining informed consent, but nurses, including research nurses and specialist breast care nurses can help to ensure that this occurs by asking patients to explain what they understand is to happen to them and by providing any additional information that is desired. Often patients feel very vulnerable when consulting a doctor and a nurse may act as advocate by representing the patient or supporting her in meetings with the doctor.

For many women with breast cancer, the consultant will be able to give treatment options. In order for the woman to make an informed decision, she must understand what each operation or treatment involves, and any side-effects which may result. Most women find the thought of losing a breast very distressing and will prefer a wide excision of the cancer, while preserving the breast, if this is a safe option. However, mastectomy may be a better choice for tumours which are multifocal or involve a large portion of the breast. Mastectomy may also be preferred by women with small tumours to reduce the risks of local recurrence and the need for adjuvant radiotherapy.

A tumour that is multifocal (i.e. occurs in several areas of the breast) cannot safely be removed by conservative surgery as the risk of local recurrence would be unacceptably high. The cosmetic result of removing a large tumour from a small breast or removing a tumour that is centrally sited beneath the nipple could be so poor that a mastectomy would be more acceptable, although only the individual woman will know how she feels about this.

Some women facing breast surgery are not aware of the possibility of reconstructive surgery. In part, this reflects the lack of facilities and skills in many areas to undertake such surgery. The long waiting lists at centres where breast reconstructions are done may cause professionals to hesitate in disclosing the possibility of this surgery. Nonetheless, in fairness to the woman, all options should be explained so that she can decide whether breast reconstruction is right for her in light of the benefits and the possible complications.

THE ROLE OF THE CLINICAL NURSE SPECIALIST IN BREAST CARE

The role of the clinical nurse specialist in breast care has developed largely in response to the recognition that women with breast cancer benefit from the support and expertise of nurses specialising in this area (Watson et al 1988, McArdle et al 1996, Maguire 2000, NICE 2002). It must be stressed that

the clinical nurse specialist provides an additional service to that provided by hospital and community nursing staff, and not an alternative to that service. The clinical nurse specialist functions as a resource for patients, their families and other nurses.

Ideally, the clinical involvement of the nurse specialist with the patient will begin at the time of diagnosis and prior to hospital admission. This may involve meeting patients in screening assessment units, and requires the cooperation of outpatient nurses and doctors in informing the nurse specialist of new patients. Many specialist nurses follow a limited intervention strategy of seeing patients in hospital before and after their surgery and then visiting them at home or making contact by telephone postoperatively to assess how they are coping. Where problems arise, referral for more in-depth psychological support can be made, but the nurse is likely to continue her involvement with the patient and her family. Because of the increasing complexity of the treatments available, the larger centres may employ more than one nurse specialist, and each is then able to focus her expertise on different aspects of the woman's care.

The nurse specialist also provides a contact point for patients and their family should they require advice or support at any time. She should facilitate communication between the community care team and the hospital but should also be able to use discretion on the patient's behalf if a large number of carers become involved. She will resume contact with patients should metastatic breast cancer develop. Many breast care nurse specialists also provide prosthetic and lymphoedema services.

INTRODUCTION

The practice of urology as a specialty in its own right is commonplace in many general hospitals. Most patients who once would have been treated by a general surgeon are now referred to consultants in urology. This has come about partly in response to advances in technology, especially in the field of endoscopic and laser surgery. It is accepted that patients with urological disorders deserve the same level of understanding and sensitivity as those with gynaecological problems.

The movement within nursing towards patient-centred care in combination with the evolution of new, less traumatic and non-invasive treatments has allowed more individuals to be treated as outpatients or day cases. The appointment of clinical nurse specialists, including stoma care nurses and continence advisors, has also done much to improve standards of care.

It is important for nurses to bear in mind that patients with urological disorders often suffer from intense psychological distress. Nurses in this area of practice must develop good interpersonal skills so that they can discuss problems openly, sensitively and non-judgementally.

This chapter begins with a brief overview of the anatomy and physiology of the urinary system and of the male reproductive organs. With respect to the latter, this chapter complements the anatomy and physiology described in Chapter 7. Common disorders of the urinary tract and their treatment are then described, including infections, obstructive disorders, disorders of the bladder and some of the more significant renal disorders. With regard to the male urinary system and reproductive organs, only prostatic disorders and conditions primarily affecting the urethra are considered here. Conditions more directly affecting reproductive and sexual function, such as testicular cancer and impotence, are discussed in Chapter 7.

ANATOMY AND PHYSIOLOGY

The urinary system comprises the kidneys, the ureters, the urinary bladder and the urethra. Its function is to excrete the waste products of metabolism in the form of urine.

The kidneys

Structure

The kidneys are a pair of slightly lobulated organs which lie on the posterior abdominal wall, extending from the twelfth thoracic vertebra to the third lumbar vertebra. Because of the position of the liver, the right kidney is normally slightly lower than the left. Anteriorly, the kidneys are covered by the peritoneum and the contents of the abdominal cavity. Three layers of supportive tissue surround each kidney: an inner fibrous capsule, a middle fatty layer and an outer fascia. This fatty encasement is necessary for maintaining the kidneys in their normal position. Beneath this, a dark outer cortex surrounds a paler medulla, which consists of pale conical striations called the renal pyramids (see Fig. 8.1).

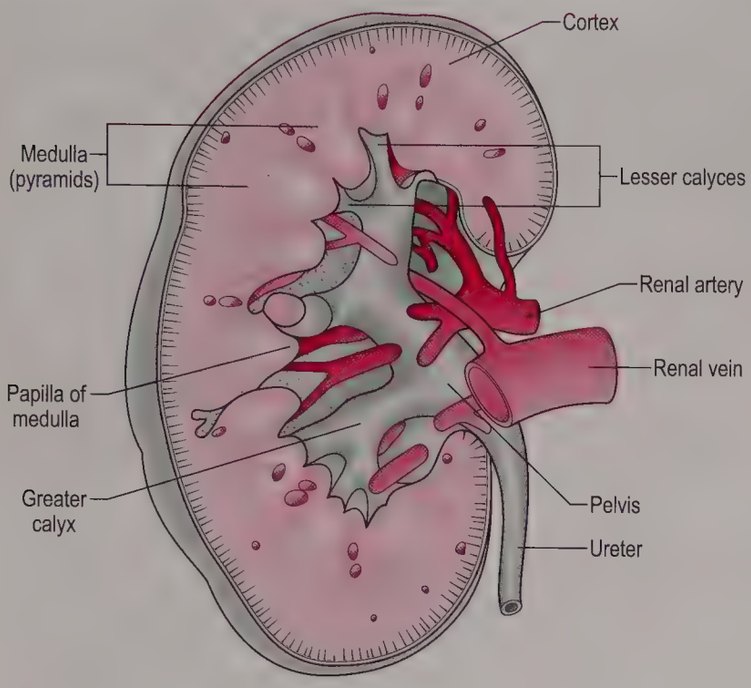

Fig. 8.1 Longitudinal section of the right kidney.

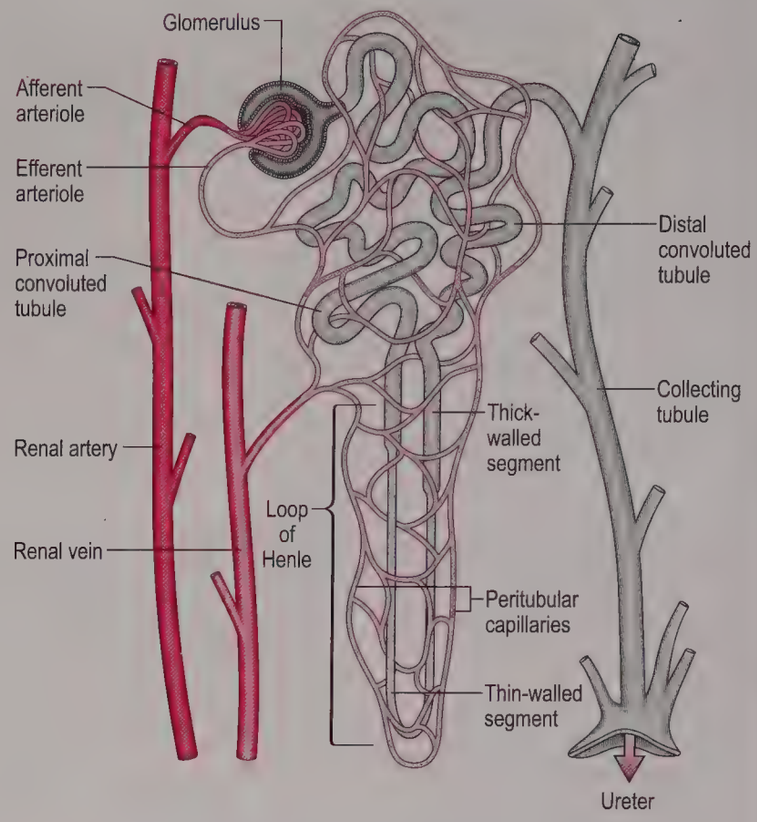

Fig. 8.2 Nephron with long loop of Henle (deep nephron).

At the hilus, i.e. the concave medial border of the kidney, blood vessels, lymph vessels and nerves enter and leave the organ. Medial to the hilus is the flat, funnel-shaped renal pelvis, which is continuous with the ureter leaving the hilus. Extending from the pelvis into the medulla are the cup-shaped calyces; these receive from the renal papillae the urine that has been formed in the nephrons and has passed through the collecting tubules. From the calyces the urine passes into the renal pelvis, which acts as a reservoir.

The nephron Each kidney is composed of approximately 1 million functional units called nephrons, which produce and channel urine into collecting tubules. A nephron consists of a convoluted tubular system and a tuft of capillaries known as the glomerulus. The glomerulus is enclosed in the cup-shaped upper end of the tubule (Bowman's capsule; see Fig. 8.2).

The tubule has three sections: the proximal convoluted tubule, which is the longest segment; the loop of Henle, which forms a hairpin-shaped curve; and the distal convoluted tubule. The distal convoluted tubules merge to form straight collecting tubules; these ultimately terminate at the renal papillae. Cortical nephrons are found in the cortex and have short loops of Henle. Juxtamedullary nephrons have long loops of Henle, allowing them to concentrate urine effectively.

Blood supply The kidney is supplied with blood by renal arteries arising directly from either side of the abdominal aorta immediately below the superior mesenteric artery. The renal arteries branch into smaller and smaller vessels, ultimately becoming afferent arterioles which lead into the nephrons. Each afferent arteriole subdivides further into a glomerulus. These capillaries then merge again to form an efferent arteriole which leaves the capsule and subdivides into a second network of peritubular capillaries which supplies the proximal and distal tubules, the loop of Henle and the collecting ducts. The capillaries merge into venules and then veins, eventually joining the renal vein, which in turn flows into the vena cava.

Function

The kidneys process about 180 L of blood-derived fluid daily. Of this, only about 1–2 L actually leave the body as urine, the remainder is returned to the blood. The kidney's basic function of producing urine takes place in the nephron. Here, the processes of glomerular filtration, selective reabsorption and tubular secretion result in the removal of wastes and toxins from the blood as it passes through the kidney and in the maintenance of fluid and electrolyte balance (Thomas 2002). The characteristics of normal urine are summarised in Box 8.1.

Glomerular filtration The initial filtration of blood takes place across a semi-permeable membrane in which fluid, electrolytes and certain non-electrolytes pass into the Bowman's capsule. Filtrate formation is a passive process and follows the same principles that account for all tissue fluid formation (see Ch. 20). However, the renal corpuscle is much more efficient because the filtration membrane is highly permeable and the glomerular pressure much higher than in other capillary beds. Hence the kidneys are able to filter the above mentioned 180 L of fluid daily, as compared with the 3 L/day produced by other capillary beds in the body.

The chemical composition of the glomerular filtrate is identical to that of plasma, i.e. plasma proteins are absent (the presence of protein in the urine can therefore be an indication of abnormality).

Box 8.1

Physical characteristics of urine

Volume (24 h)	1500 mL, but varies greatly according to fluid intake and insensible losses
Clarity	Transparent or clear; on standing, becomes cloudy
Colour	Amber or straw-coloured; varies according to amount voided; diet may change colour
Odour	'Characteristic'; on standing, develops pungent odour from formation of ammonium carbonate
PH (normal range 4.6–8.0)	Acidic when freshly voided, stale urine has an alkaline reaction from decomposition of urea forming ammonium carbonate. May become alkaline if diet consists largely of vegetables; a high-protein diet increases acidity
Specific gravity	1.015–1.020; highest in morning specimen

Chemical composition

Urine is approximately 95% water, in which is dissolved several kinds of substances. The most important of these are:

- Nitrogenous wastes from protein metabolism such as urea (most abundant solute in urine), uric acid, ammonia and creatinine
- Electrolytes, mainly the following ions: sodium, potassium, ammonium, chloride, bicarbonate, phosphate and sulphate — the amounts vary according to diet and other factors
- Toxins. During disease, bacterial poisons leave the body in the urine; this is an important reason for 'pushing' fluids on patients suffering from infectious diseases, as a high fluid intake dilutes the toxins that might damage the kidney cells if they were eliminated in a concentrated form
- Pigments
- Hormones
- Abnormal constituents such as glucose, albumin, blood, casts or calculi are sometimes found.

Adapted from Thibodeau & Patton (1999).

In order for glomerular filtration to take place, there must be adequate blood volume in the intravascular space and sufficient glomerular hydrostatic pressure. It is the glomerular hydrostatic pressure that essentially forces the water and solutes across the filtration membrane. This pressure (55 mmHg) is opposed by the colloid osmotic pressure exerted by the glomerular plasma proteins (30 mmHg) and the capsular hydrostatic pressure (15 mmHg). Thus the net filtration pressure responsible for filtrate formation is 10 mmHg. The rate at which fluid filters from the blood to the glomerular capsule is directly proportional to the net filtration pressure. The normal filtration rate is 120–125 mL/min.

Selective reabsorption The greater part of reabsorption takes place in the proximal convoluted tubule. Sodium, chloride, bicarbonate and potassium are returned to the blood by passive or active transport. Glucose is actively reabsorbed. Normally, all of the glucose is reabsorbed such that none appears in the urine. However, if blood levels of glucose are too high, some will be excreted in the urine.

About 99% of the water in the filtrate is reabsorbed. The continuous removal of sodium, chloride, bicarbonate, glucose and other materials from the tubule increases the osmotic forces such that water follows the dissolved materials. This is often referred to as obligatory water reabsorption.

One of the major functions of the kidney is to maintain a constant concentration of body fluids by regulating urine concentration. It is still uncertain exactly how this is achieved, but it would appear to be the result of the function of the loop of Henle, which may act as a 'counter-current multiplying system' in which the concentrations of sodium and negative ions move through a gradient, being greatest at the base of the loop. This allows the urine to be more dilute when leaving the loop of Henle than when it left the proximal tubule. This urine remains essentially unaltered unless the need to conserve fluid results in the release of antidiuretic hormone (vasopressin) by the posterior pituitary.

For further information, see Thomas (2002).

Tubular secretion In the distal convoluted tubule and in the collecting duct, sodium is reabsorbed from the tubular fluid while hydrogen and potassium ions are secreted into the fluid. This helps to regulate acid–base balance and rid the body of excessive potassium. In addition, tubular secretion can eliminate substances such as urea and uric acid, which may have been returned to the blood by passive processes, and can also dispose of substances not already in the filtrate, e.g. certain drugs.

Hormonal control of the kidney

Two hormones, antidiuretic hormone (vasopressin) and aldosterone, are important regulators of renal function.

Antidiuretic hormone (ADH) (vasopressin) is produced in the hypothalamus and stored and secreted by the posterior lobe of the pituitary gland. It affects water permeability in the distal convoluted tubule and the collecting ducts, allowing sodium, other ions and water to be reabsorbed, making the urine more concentrated. In the absence of ADH, sodium and other ions are reabsorbed, but not water. This makes the urine more dilute.

Pain, exercise, emotion and the use of narcotics or barbiturates can increase the secretion of ADH. Factors that decrease output are low plasma osmotic pressure, venous distension and alcohol consumption.

Aldosterone is produced in the outermost layer of the adrenal cortex. It acts on the distal tubule, where it increases the reabsorption of sodium (see Ch. 5, p. 176).

Other functions of the kidney

In addition to its role in removing waste products from the blood, the kidney has the following functions:

- Regulation of blood pressure through the maintenance of fluid volume.
- Production of the hormones renin, erythropoietin and 1,25-dihydroxycholecalciferol.

Renin is liberated through the juxtaglomerular cells and acts on angiotensinogen (a glycoprotein made in the liver and normally found in plasma), converting it into angiotensin I. Another enzyme in the pulmonary capillary bed acts on angiotensin I to convert it into angiotensin II. Angiotensin II has the following functions:

- Stimulation of the release of aldosterone, which helps to enable sodium reabsorption and therefore water reabsorption. This in turn helps to maintain plasma volume.
- A powerful vasoconstricting effect, acting on the arterioles and precapillary sphincters to shut down the capillaries, allowing blood volume to be maintained.

Erythropoietin is produced in response to lowered O_2 in the blood. It acts on the bone marrow, stimulating the production of red blood cells (erythropoiesis; see Ch. 11, p. 481).

1,25-dihydroxycholecalciferol is synthesised in the renal tubule cells and is the active form of vitamin D which enables calcium uptake from the small intestine (see Box 5.2, p. 175).

The ureters (see Fig. 8.3)

Urine is conveyed from the pelvis of each kidney to the bladder via the ureters. The ureters are tubular structures approximately 25–30 cm long, ranging in diameter from 2 to 8 mm at various points along their length.

Each ureter descends behind the peritoneum from the renal hilus to the level of the bladder and comes obliquely through the bladder wall before opening into the bladder cavity on its posterior inner surface. This arrangement is such that, when the bladder fills or empties, it is compressed, closing the distal ends of the ureters; in this way, there is no back-flow into the ureters.

Each ureter is composed of three layers of tissue:

- an outer fibrous layer which is continuous with the fibrous renal capsule
- a middle layer consisting of muscle fibres spiralling clockwise and anticlockwise; contraction of the muscle layer produces peristaltic movement of urine along the ureter into the bladder
- an inner mucosa of transitional epithelium.

The urinary bladder

The bladder is a muscular sac which acts as a reservoir for urine before it is expelled from the body. It lies behind the peritoneum in the pelvic cavity, with its anterior surface located just behind the symphysis pubis. In males, the bladder lies in front of the rectum, inferiorly to the urethra and the prostate gland. In females, it lies just anterior to the ureters and the superior section of the vagina.

Structure

The bladder is composed of four layers: an outer fibrous adventitia (except where the peritoneum covers the superior surface), a muscular layer, a submucosal layer of connective tissue and a mucosal layer of transitional epithelium. The muscle layer consists of intermingled smooth muscle arranged in inner and outer longitudinal layers and a middle circular layer and is called the detrusor muscle.

The interior of the bladder has three orifices, two for the ureters and one for the opening of the urethra. This forms a triangle called the trigone (see Fig. 8.4).

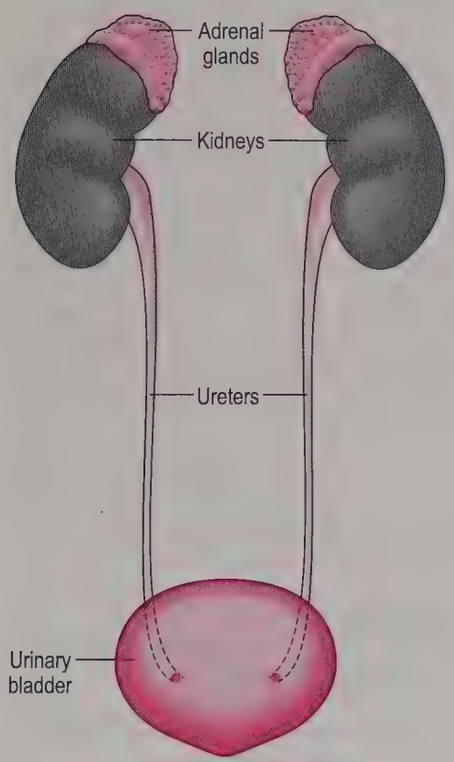

Fig. 8.3 The ureters and their relationship to the kidneys and the bladder.

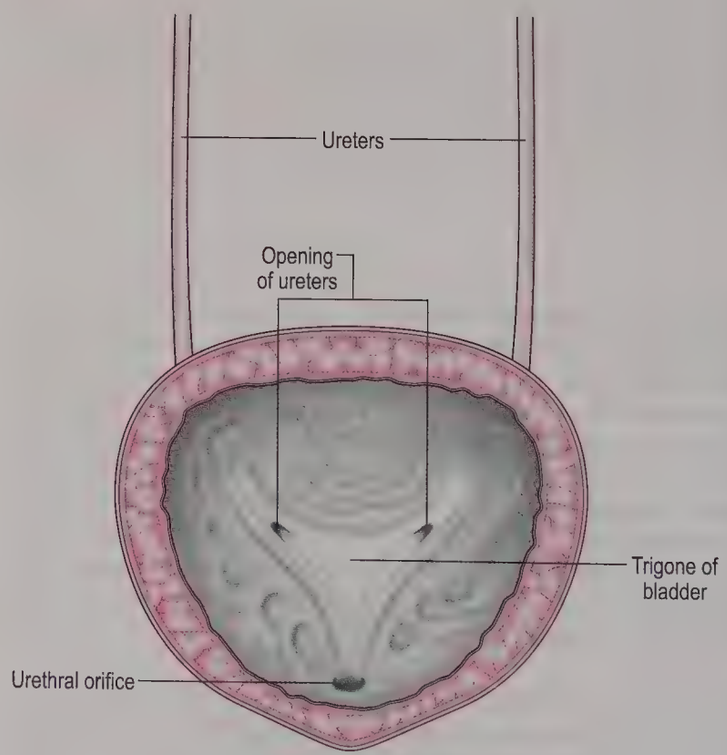

Fig. 8.4 The trigone.

Nerve supply to the bladder is both sensory and motor. Sympathetic nerves arise from T9 to L2 and parasympathetic and somatic nerves from S2 to S4. The motor innervation involves the parasympathetic supply to the detrusor muscle and the sympathetic supply to the trigone. Pudendal nerves under voluntary control supply the external sphincter and muscles of the perineum.

The urethra

The urethra is a tube 8–9 mm in diameter which extends from the neck of the bladder to the exterior. In males, it is about 21 cm long and in females about 4 cm long. It has an outer layer of smooth muscle continuous with that of the bladder. Beneath this lies a thin, spongy layer supplied with blood vessels, lymph vessels and nerves. The innermost layer is a lining of mucous membrane continuous with that of the bladder.

The male urethra is a shared pathway by which both urine and semen reach the exterior. Originating at the urethral orifice in the bladder neck, it is surrounded by the prostate gland and ends at the tip of the glans penis. It is lined with a large number of small mucus-producing glands (Littre's glands). It has an internal sphincter composed of smooth muscle which responds to parasympathetic and sympathetic stimulation. The external urethral sphincter lies at the point where the urethra leaves the prostate; this sphincter is composed of skeletal muscle and is hence under voluntary control.

The female urethra runs behind the symphysis pubis, opening at the external urethral orifice (the meatus) located between the clitoris and vagina. The passage of urine from the bladder through the urethra is governed by two sphincter muscles. At the opening from the bladder is an internal sphincter composed mainly of elastic tissue and smooth muscle and controlled by autonomic nerves. Near the external urethral orifice the smooth muscle is replaced by striated muscle to form an external sphincter under voluntary control.

Micturition

Micturition, the act of passing urine, is a complex physiological process governed by a number of neural controls. The bladder is very distensible, to allow for the storage of urine. An empty bladder is pear shaped and its walls are thick, falling into folds. As urine fills the bladder, it expands and becomes more oval to accommodate the increasing quantity of fluid. The muscle walls stretch and become thinner such that the bladder can comfortably hold 500 mL of urine. In extremis the bladder could hold more than 1 L. If this occurs it can be palpated above the symphysis pubis.

When the bladder contains 300–400 mL of urine, nerve fibres in the wall which are sensitive to stretch are stimulated (Downey 2000). In the infant or young child, this triggers a spinal reflex which results in contraction of the bladder muscle and relaxation of the internal urethral sphincter. When the nervous system is more mature, the individual is aware of a desire to pass urine and can inhibit the reflex action for a time.

Micturition is normally a painless function that occurs four to six times during the day. Decreased bladder capacity and weakened sphincter and detrusor muscles can, in older people and others, necessitate voiding once or twice during the night.

The composition of urine is given in Box 8.1.

8.1 Keep a fluid balance chart for yourself over a 24-h period. Record all your fluid intake and the amount and frequency of all urine output. In addition, record your activities for this period. Then compare your results with those of your colleagues. If possible, also compare your results with a patient's fluid balance chart.

The male reproductive organs

The male reproductive organs are those structures responsible for the production, maturation, and delivery into the female reproductive tract of spermatozoa necessary for the fertilisation of ova. The essential organs of this system are the two testes, in which spermatogenesis occurs. The accessory organs which support the reproductive process include:

- the genital ducts — the epididymis (2), vas deferens (2), ejaculatory ducts (2) and urethra, which convey sperm to the exterior
- the glands — the seminal vesicles (2), the prostate gland and the bulbourethral (Cowper's) glands (2), which produce fluid as a vehicle for sperm
- the supporting structures — the scrotum, penis and spermatic cords.

The essential organs

The testes are paired oval organs 4–5 cm in length weighing 10–15 g each. They are suspended in the scrotum by the spermatic cords and are encased in three layers of tissue, as follows:

- the tunica vaginalis, or outer layer — a down-growth of the abdominal and pelvic peritoneum
- the tunica albuginea — a layer beneath the tunica vaginalis which consists of fibroelastic connective tissue containing some smooth muscle cells
- the tunica vasculosa — an inner layer made up of delicate connective tissue supplied by a network of capillaries.

Each testis contains 200–300 lobes, within which are tightly coiled seminiferous tubules. It is here that the primitive sex cells (spermatogonia) present in male babies at birth become transformed into spermatozoa (spermatogenesis). This process starts at puberty and continues throughout life.

A spermatozoon provides one-half of the genetic material required to create a new life. Each spermatozoon has a head, neck, body and tail, each with a specialised function. The head contains a highly compact package of genetic material encased in a specialised covering, called the acrosome, which contains digestive enzymes that can penetrate the ovum during fertilisation. The body contains mitochondria and the tail adenosine triphosphate (ATP); these provide energy for sperm locomotion.

The testes also produce androgens (masculinising hormones), the most important of which is testosterone,

which is produced by interstitial cells (Leydig's cells). Testosterone promotes:

- maleness and male sexual behaviour
- the development and maintenance of male secondary sex characteristics and the functions of the accessory organs
- protein anabolism
- growth of bone and skeletal muscle and closure of the bony epiphyses
- a mild stimulant effect on the kidney tubule, with reabsorption of sodium and water and excretion of potassium
- inhibition of anterior pituitary secretion of the gonadotrophins follicle-stimulating hormone (FSH) and interstitial cell-stimulating hormone (ICSH). FSH stimulates the seminiferous tubules of the testes to produce spermatozoa. A negative feedback mechanism operates whereby, when testosterone levels are high, FSH and ICSH production is inhibited.

At the upper pole of the testis, the tubules combine to form the rete testis and then penetrate the tunica vaginalis to empty into the epididymis. The epididymis leaves the scrotum as the deferent duct (vas deferens) through the spermatic cords. The testes are well supplied with blood, lymph vessels and nerves from both divisions of the autonomic nervous system.

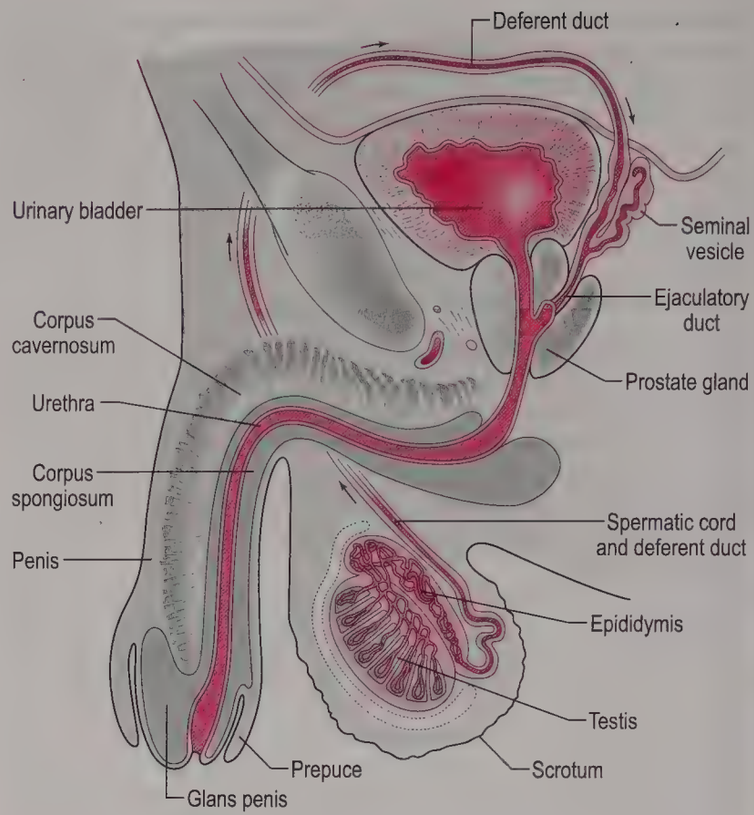

Fig. 8.5 Section of male reproductive organs. Arrows show the structures through which the spermatozoa pass.

The ductal system

The epididymis is the first part of the ductal system and forms a collection of tubules arising from the testis. The vas deferens, which is continuous with the epididymis, loops through the inguinal canal and joins the ejaculatory ducts, which pass through the prostate gland and lead into the urethra (see Fig. 8.5).

Sperm undergo a ripening process as they pass through the ductal system before ejaculation. They remain in the vas deferens for varying periods of time, depending upon the individual's degree of sexual activity. Sperm may remain in storage in the vas deferens for more than a month with no loss of fertility.

The accessory glands

The seminal vesicles are small, lobulated glands lined with secretory epithelium which lie to the posterior of the bladder at the base of the prostate. The lower end of each vesicle opens into a short duct, which joins with the deferent duct to form the ejaculatory duct.

The seminal vesicles secrete a thick, nutritive alkaline fluid that mixes with sperm on ejaculation. This fluid accounts for 30% of the volume of the seminal fluid and contains fructose and protein, which are essential to sperm motility and metabolism.

The prostate gland is a lobulated structure which lies in the pelvic cavity in front of the rectum and behind the symphysis pubis, surrounding the uppermost part of the urethra. It is palpable on rectal examination. The prostate gland secretes a thin, milky, alkaline fluid that makes up 60% of the seminal fluid; this fluid creates an environment more hospitable to sperm by giving protection from the normally acidic environment of the male urethra and female vagina. A neutral or slightly alkaline medium also increases sperm motility.

The prostate is susceptible to hyperplasia, which, because the urethra passes through it, can lead to urinary problems (see p. 375).

The bulbourethral glands are two pea-sized glands opening onto either side of the urethra. They produce a lubricating alkaline mucus that is expressed into the urethra during ejaculation, further reducing its typically acidic state, and contribute less than 5% to the volume of seminal fluid.

The supporting structures

The penis is a pendulous, soft tissue structure with a root and a body. The root lies in the perineum and is attached to the anterior and lateral walls of the pubic arch. The body, which surrounds the urethra, consists of three elongated masses of erectile tissue and involuntary muscle.

The erectile tissue is supported by fibrous tissue and covered with skin. The three elongated masses, which are longitudinal in shape, consist of an encompassing central column (the corpus spongiosum) containing the urethra, and two parallel columns (the corpora cavernosa) which provide the organ's main structural support. These structures are richly supplied with blood vessels.

At the distal end of the penis, the corpus spongiosum and the corpora cavernosa expand to become the glans penis, which surrounds the urethral meatus. The covering of skin folds upon itself at the glans penis to form a movable double layer called the prepuce.

Coitus and fertilisation The penis is supplied by autonomic and somatic nerves. Tactile, visual or mental stimulation causes a parasympathetic reflex leading to engorgement of the penis with blood and consequent erection. In the next phase, emission, sperm and secretions from the accessory glands are deposited in the posterior urethra. Finally, during ejaculation, the bladder neck closes and is followed by relaxation of the distal sphincter mechanism and spasmodic contraction of the bulbourethral muscles. This forces semen out through the urethra in spurts and is accompanied by the intensely pleasurable sensation of orgasm. Once ejaculation has taken place, the corpora cavernosa and the corpus spongiosum empty their excess of blood and the penis resumes its flaccid state.

The sperm, although anatomically complete and highly motile, undergo a further maturation process referred to as capacitation after introduction into the vagina. This enables the head of the sperm to use its hydrolytic (splitting) enzymes to penetrate the encasing membrane (the zona pellucida) of the ovum.

The millions of sperm ejaculated act collectively to produce hyaluronidase to liquefy the intracellular substance surrounding the ovum. This mass action is necessary for a single sperm to penetrate the ovum and bring about fertilisation.

The scrotum is a thin-walled pouch continuous with the abdominal wall. It is deeply pigmented and divided into two compartments, each of which contains one testis, one epididymis and the testicular end of the spermatic cord. The temperature of the testes is 2–3°C below body temperature, which helps to preserve sperm viability.

The spermatic cords Leading from each testis is a spermatic cord consisting of a testicular artery, a testicular venous plexus, lymph vessels, a deferent duct (vas deferens) and nerves; these are all surrounded by a fibrous connective sheath.

DISORDERS OF THE URINARY SYSTEM

URINARY TRACT INFECTIONS

Urinary tract infections are second only to respiratory infections in incidence. Infection can occur in both the upper and lower urinary tracts. The risk of developing a urinary tract infection varies throughout life. In childhood and adulthood, urinary infections are common in females; in women, infections are often precipitated by sexual intercourse (O'Callaghan & Brenner 2000). In healthy individuals, bacteriuria of the lower urinary tract increases transiently following sexual intercourse. In men, urinary infections are often associated with bladder outflow obstruction and/or in the presence of a urinary catheter.

PATHOPHYSIOLOGY

Normally, the anterior urethra and, in women, the entrance to the vagina contain microorganisms. The posterior urethra and the urinary tract are sterile. The urethral mucosa has antibacterial properties and is frequently washed by sterile urine, which discourages the passage of bacteria up the urethra to the bladder, ureters and kidneys. The female ureter is short, wide and straight, and allows the passage of organisms into the urinary tract more readily than does the longer male ureter.

The predisposing factors for urinary tract infections are as follows.

Vesico-ureteric reflux (the retrograde flow of urine) This can be:

- *Congenital primary reflux*. This occurs when there is a defect of the muscles around the vesico-ureteric junction (i.e. junction of the bladder and ureter). Abnormalities such as duplication and ectopic ureters can give rise to vesico-ureteric reflux which is often a cause of primary and recurrent infections in children (Downey 2000).
- *Acquired reflux*. This may be seen in patients with neuropathic dysfunction, urethral valves and (more rarely) in those with bladder outflow obstruction due to strictures. Injury to the ureteric orifice during surgery may also result in reflux. Tuberculosis and interstitial cystitis are other causes.

Obstruction Stones or strictures can prevent the free flow of urine and interfere with the ability of the kidneys to decontaminate themselves of organisms:

- *Tumours* of the prostate, bladder and kidney can give rise to urinary tract infections.
- *Pregnancy*. Hydroureter (distension of the ureter with urine) and hydronephrosis (distension of the kidney pelvis) can occur during pregnancy and persist for some months after childbirth. It is caused by relaxation of the muscles due to the high level of progesterone and by the obstruction of the ureters by the uterus.
- *Intubation*. Nephrostomy tubes inserted into the kidney pelvis, urethral or suprapubic catheters and other drainage tubes that communicate with the urinary tract predispose the individual to infection.

Fistulae Abnormal communication between the urinary tract and other structures (especially between the bladder and the colon) will allow organisms to enter the urinary tract.

Sexual trauma During sexual intercourse the female urethra can be traumatised. The movement of the penis in the vagina may also milk organisms along it into the bladder and cause infection. Varied sexual practices, inadequate personal hygiene and the use of foreign bodies can all play a part.

Iatrogenic factors Surgical and diagnostic procedures such as urethral and ureteric catheterisation, cystoscopy and other endoscopic instrumentations may exacerbate existing infections or send infection further up the urinary tract.

Pyelonephritis

Pyelonephritis, or inflammation of the renal pelvis, may occur in one or both kidneys. Bacteria may enter the urinary tract, especially the kidneys, via the bloodstream, or more commonly the bladder. Most organisms causing urinary

tract infection — *Escherichia coli, Klebsiella, Proteus, Pseudomonas, Streptococcus faecalis* and *Staphylococcus albus* — are found in the bowel and the perineum.

Acute pyelonephritis

PATHOPHYSIOLOGY

In acute pyelonephritis, the kidney is usually swollen and soft and the pelvis and calyces may contain pus. The mucosal lining of the pelvis may be congested and oedematous.

Common presenting symptoms The patient typically experiences a sudden onset of severe pain in the loin (the area of the back immediately above the buttocks) radiating to the iliac fossa. Other common features are pyrexia, rigor, nausea and vomiting.

Where cystitis (inflammation of the bladder) coexists, dysuria, frequency of micturition and discoloured urine will be noted.

MEDICAL MANAGEMENT

Investigations Procedures will include the following:

- The collection of a midstream specimen of urine (MSU) to be cultured for evidence of a causative organism and antibiotic sensitivity. The specimen must be collected in clean conditions to prevent the introduction of contaminants (Inglis 2003).
- A full blood count and urea and electrolyte estimation. A raised white blood cell count and erythrocyte sedimentation rate (ESR) may be revealed in response to infection.
- An intravenous urogram (IVU) to locate any obstruction in the urinary tract (see Box 8.2). An ultrasound scan may also be performed for the same purpose.

8.2 What might the nurse do or say to reduce anxiety and help the patient to understand the reasons for the investigations being performed?

Treatment The main aim of treatment is to eradicate the infection by means of antibiotic therapy. This may be commenced even before organism sensitivities are known. A more specific antibiotic can then be used following urine culture results. Analgesics, antiemetics and antipyretics may be prescribed. Oral fluids are recommended, up to 3 L/24 h.

In addition, the doctor will endeavour to determine and resolve any predisposing cause. Urine cultures will be repeated at 7 days to ensure that the infection has been eradicated.

NURSING PRIORITIES AND MANAGEMENT: Acute pyelonephritis

Major considerations

The patient with acute pyelonephritis of sudden onset will feel lethargic and is likely to require a period of bed rest.

In the acute phase, nursing priorities will include the administration of prescribed antibiotics and other medications. Attention should be given to the patient's personal hygiene and comfort, as well as to maintaining an accurate fluid balance record. Increasing fluid intake to as much as 3 L/24 h is to be encouraged (Thomas 2002) as this may reduce the osmotic pressure in the renal medulla and thereby decrease the proliferation of bacteria.

As the patient recovers, the nurse should focus on giving advice regarding hygiene. The importance of attendance at outpatient appointments for assessment of renal function and investigation of further urine infection should be stressed. Follow-up may be particularly problematic if the patient feels well and is symptom-free.

Box 8.2

Intravenous urogram or pyelogram (IVU or IVP)

This investigation, which involves the i.v. injection of an iodine-based contrast medium which is then excreted by the kidneys, allows a series of X-ray pictures of the kidneys, ureters and bladder to be taken.

Prior to the IVU, a control X-ray of the kidneys, ureters and bladder (KUB) is taken. The patient is requested to abstain from food for several hours and fluids for 1 h before the start of the X-rays. This helps the contrast medium to be excreted more quickly. The patient is also given an aperient to clear the bowel and thus ensure a clear image of the contrast medium on the X-ray. The patient should void beforehand to prevent the contrast medium becoming overdilute, resulting in a poor picture. Following the investigation, the patient is allowed to eat and drink again. The contrast medium will be passed when the patient voids urine, with no after-effects or change in the colour of the urine.

The IVU X-rays may show:

- absence of kidney
- obstruction of kidney
- obstruction of the ureter
- irregularities of the bladder wall — this finding may indicate the presence of a bladder tumour, diverticulum, calculi or foreign body.

8.3 Mrs V is 6 months pregnant and has been admitted to the antenatal ward for investigation and monitoring of a raised blood pressure. Early one evening she complains of feeling very unwell and feverish and is visibly shivering. She is known to have a history of recurrent urinary tract infection. Refer now to Chapter 22. What would be your priorities for Mrs V's immediate care?

Chronic pyelonephritis

Chronic pyelonephritis results from recurrent urinary tract infection. In children, vesico-ureteric reflux is often present.

PATHOPHYSIOLOGY

Chronic pyelonephritis is focal and irregular and may affect both kidneys. Progressive infection causes fibrosis and scarring, which gradually destroys the parenchyma. Eventually, the kidney becomes small, granular and infected.

Common presenting symptoms This condition may be asymptomatic until the patient finally presents with features associated with renal failure. These include uraemia, lethargy, hypertension and proteinuria. Urinary frequency and dysuria may be reported.

MEDICAL MANAGEMENT

Investigations As with acute pyelonephritis, diagnosis can be made by IVU. Urine culture should be performed and urinary tract obstruction excluded.

Treatment Antibiotic treatment can be administered as either a short course in response to organism sensitivities or a long-term course where chronic infection proves difficult to eradicate. Where inflammation persists, renal impairment may progress to end-stage renal failure requiring treatment by dialysis (see p. 391).

NURSING PRIORITIES AND MANAGEMENT: Chronic pyelonephritis

Major considerations

Where the patient experiences acute episodes of inflammation, priorities may be the same as for patients with acute pyelonephritis. However, some individuals with chronic pyelonephritis only experience feelings of tiredness or of being 'under the weather'. Nevertheless, recurrence of infection is common and disturbances of renal function and end-stage renal failure are possibilities that must be taken seriously. The nurse should educate the patient regarding the condition, treatment and potential long-term complications and should emphasise the importance of attending outpatient clinics for assessment even when there are no symptoms. Where long-term antibiotic therapy is required, the patient may have concerns about the necessity for such treatment and the chronic nature of the condition. The nurse should provide opportunities for the patient to ask questions and voice concerns.

In the event that progressive renal failure occurs, the nurse should help to prepare the patient and family for the treatment options available and for the lifestyle adjustments that will need to be made.

For further information, see Wagenlehner & Naber (2000) and Nicolle (2002).

Cystitis

Cystitis may be chronic or acute and is characterised by severe inflammation of the bladder walls. More commonly affecting women, cystitis may result from predisposing factors such as the presence of foreign bodies or stones, obstruction, tuberculosis, carcinoma in situ, chronic urinary infection and schistosomiasis.

PATHOPHYSIOLOGY

Common presenting features are scalding pain on micturition, often followed by bladder spasm, resulting in an urge to pass urine a second time. Frequency, urgency, nocturia and incontinence may also be present. The patient may have a fever and complain of fatigue and abdominal discomfort.

MEDICAL MANAGEMENT

Investigations Urine culture will identify the causative organism, although antibiotic therapy may be commenced before sensitivities are known.

Treatment Repeat urinary cultures should be examined. Persistent infection may require long-term antibiotic treatment. The patient should be encouraged to increase their fluid intake during the day, thereby increasing the flushing effect of the urine flow. The measurement and recording of fluid balance, temperature and pulse are necessary until the patient's clinical symptoms are eradicated.

Many people, however, suffer from recurrent cystitis over several years and attempt to manage the associated problems, often depending on such things as lemon barley water, over-the-counter preparations and advice found in popular magazines. This is an example of a condition for which self-help often plays an important role.

For further information, see Wagenlehner & Naber (2000) and Nicolle (2002).

OBSTRUCTIVE DISORDERS OF THE URINARY TRACT

Disorders that cause obstruction to the flow of urine (see Fig. 8.6) are not uncommon. Although the early stages may cause only mild symptoms which are easily ignored, the progressive damage caused by abnormal pressure, infection and stone formation can lead to renal failure. The importance of early detection and intervention cannot be overemphasised.

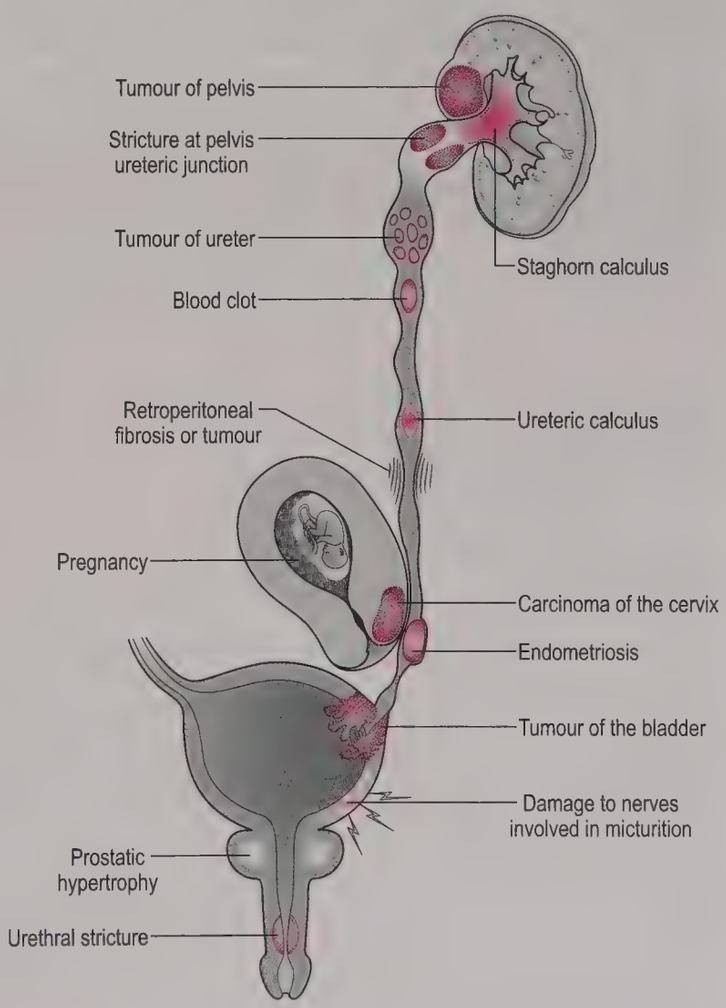

Fig. 8.6 Conditions causing obstruction to the urinary tract.

Urinary stones (renal calculi)

The formation of stones or calculi in the urinary tract is common in Europe, North America and Japan. According to Brewster et al (2001), in the developed world, 1–13% of the population is affected. The increasing incidence of calculi reflects affluence and a diet rich in refined sugar and proteins, but it is acknowledged that a wide variety of aetiological factors influence stone formation (Blandy 1998). Stone formation is more common in men than in women (M:F = 3:1). Interestingly, children and people of black African extraction are rarely affected.

PATHOPHYSIOLOGY

Table 8.1 summarises the features of the main types of stone that can form. In the majority of cases, however, unless there is an underlying disorder, no cause is evident. Box 8.3 identifies the predisposing factors.

Clinical features Stone formation may occur at any point in the urinary tract. Presenting symptoms and features will depend on the stone site:

- Stones that have formed in the renal calyces are often asymptomatic, but obstruction can occur at the calyx neck, resulting in infection and giving rise to pyrexia and pain. Scarring, renal atrophy and pyocalyx can occur.
- Stones found in the calyx can travel to the renal pelvis, causing pyrexia, nausea, vomiting and renal colic.
- The main presenting symptom of upper ureteric stones is colicky pain extending across the abdomen. Haematuria (gross and microscopic) may also be noted.
- The main presenting feature of mid-ureteric and lower ureteric stones is colicky pain radiating towards the scrotum in men and labia in women, together with urgency, frequency and abdominal distension.
- The main presenting symptoms of stone formation in the bladder are pain, dysuria, frequency and urgency.

Box 8.3

Predisposing factors in stone formation

- Idiopathic (most common)
- Stasis of urine, e.g. congenital abnormalities, chronic obstruction
- Chronic urinary infection (urea-splitting organisms, e.g. *Proteus*, cause alkaline urine and the development of magnesium-ammonium-phosphate stones, typically the 'staghorn' calculi of the renal pelvis)
- Excess urinary excretion of stone-forming substances, e.g. idiopathic hypercalciuria (calcium stones), hyperparathyroidism (calcium stones), hyperoxaluria (oxalate stones), gout (uric acid stones), cysteinuria (cysteine stones), xanthinuria (xanthine stones)
- Foreign bodies, e.g. fragments of catheter tubing, self-inserted artefacts, parasites (*Schistosoma* ova)
- Diseased tissue, e.g. renal papillary necrosis
- Multifactorial, e.g. prolonged immobility, children in developing countries

Reproduced with permission from Burkitt et al (1996).

Table 8.1 Chemical composition, clinical features and aetiology of urinary tract stones

Chemical composition	%	Clinical features	Aetiology
Calcium oxalate	40	Three types of stone are described: — small smooth 'hempseed' stones — small irregular 'mulberry' stones — small spiculate 'jack' stones	Most cases are idiopathic; predisposing factors include urinary stasis, infection and foreign bodies. Some are due to metabolic disorders: — hyperparathyroidism causing hypercalcaemia rather than hypercalciuria — hyperoxaluria (rare inherited disorder)
Mixed calcium oxalate and phosphate stones	15		Some are due to disorders associated with hypercalcaemia, e.g. sarcoidosis, multiple metastases, multiple myeloma, milk–alkali syndrome, overtreatment with vitamin D
Calcium and phosphate (hydroxyapatite)	15		Some patients excrete abnormally large amounts of calcium (idiopathic hypercalciuria, but without hypercalcaemia)
Magnesium ammonium phosphate	15	Typical of large 'staghorn' calculi of the pelvicalyceal system and some bladder stones	Caused by chronic infection by organisms capable of producing urease. This enzyme splits urea, forming ammonia if the urine is alkaline
Uric acid	8	Stones tend to absorb yellow and brown pigments. Pure stones are radiolucent	Occur in primary gout and also hyperuricaemia following chemotherapy for leukaemias and myeloproliferative disorders. Childhood urate bladder stones occur in some underdeveloped countries when urine pH is low
Cystine or xanthine	2	Excess urinary excretion of cystine or xanthine. Pure stones are radiolucent	Autosomal recessive inherited disorders

Reproduced with permission from Burkitt et al (1996).

MEDICAL MANAGEMENT

Treatment Small calculi (5 mm or less in diameter) may pass unobstructed through the urinary tract and be excreted in the urine. Intervention is indicated if there is evidence of anaemia, infection or hydronephrosis.

Conservative management The use of calcium-chelating agents and limiting calcium and sodium intake in the diet may be indicated where increased absorption of calcium is responsible for calculi formation. Acidification or alkalination of urine may prevent stones which form in these conditions. Fluid intake should be enough to ensure a urine output of 2 L/24 h. The drinking of large quantities of fluid serves no useful purpose. The rationale behind this practice is to produce sufficient urine flow to flush out the stone, but in practice the presence of a continued obstruction will simply result in further distension of the collecting system and make matters worse. Normal hydration is therefore recommended.

For further information, see Blandy (1998), Brewster et al (2001) and Tiselius (2003).

MANAGEMENT OF ACUTE RENAL COLIC

Investigations Procedures are listed in Table 8.2.

Treatment The patient with renal stones may be acutely ill, suffering from excruciating pain arising in the loin and radiating to the groin, which can last 5–6 h. Pain is caused by small calculi being moved along the ureter by peristaltic movements, by impaction and by obstruction of urine. Bed rest, warmth to the site of pain (Haslett et al 2002) and analgesics are the first line of treatment.

Medications include the opioid morphine (10–20 mg) intramuscularly. Pethidine should be avoided as it is associated with a higher incidence of vomiting (Holdgate & Pollock 2004). Diclofenac sodium (100 mg per rectum, usually at night) is a prostaglandin synthetase inhibitor which reduces renal blood flow and urination. It has an antispasmodic and anti-inflammatory effect and is long acting. Nausea may be relieved by an antiemetic such as i.m. prochlorperazine (12.5 mg) (Trounce & Gould 2000).

Flush-back of calculi and stenting This procedure affords temporary relief when a calculus causes obstruction and pain in the ureter. The stone is flushed back to the pelvis of the kidney. A small silicone tube, called a stent, is positioned in the ureter from the pelviureteric junction to the bladder. This stent is left in position to hold the stone in place. Further treatment to remove the stone can now be planned. The stent should not be left for more than 6 weeks. If the planned treatment cannot be carried out by the end of this period, the stent should be changed.

Insertion of a nephrostomy tube is indicated when obstruction in the kidney or the ureter cannot be relieved by flush-back and stenting (see Fig. 8.7 and Box 8.4). This is carried out under X-ray control, usually with a local anaesthetic. A small silicone tube is placed percutaneously into the collecting system of the kidney. The tube is held in place by a suture and connected to a closed-system drainage bag.

Ureteroscopic removal of calculi This procedure is suitable in the treatment of small calculi in the ureter. The ureteric orifice is dilated cystoscopically and a ureteroscope, to which a 'stone basket' is attached, is introduced into the ureter. The basket is opened out to ensnare the stone. The basket and stone are then withdrawn.

Rigid ureteroscopes are now available which can be inserted under direct vision. The surgeon is able to see the stone and can disintegrate it in situ before removing the smaller fragments in a 'basket' (Underwood et al 2003).

Extracorporeal shock wave lithotripsy (ESWL) This procedure is the treatment of choice for the majority of calculi, both renal and ureteric (Downey 2000). It effectively treats 70–80% of cases. Large calculi are broken up by means of this technique before percutaneous removal.

There are several lithotripsy centres in the UK, but some patients have to travel some distance for this treatment. Second-generation lithotripsers allow most patients to be

Table 8.2 Some investigations used for patients with renal calculi

Type of investigation	Test	Purpose
Investigation of urinary tract	Examination of urine for protein, RBC, WBC	Indicates abnormality of urinary tract
	MSU	Urinary infection
	Plain film abdomen	Shows opaque calculi, nephrocalcinosis
	IVU	Shows all calculi obstruction and abnormalities of urinary tract
Investigation of renal function	Blood urea, plasma creatinine	
	Creatinine clearance	
Investigation to determine underlying cause	Chemical analysis of calculus	Provides information as to what investigations to pursue
	Plasma calcium, phosphate	Hypercalcaemia
	Plasma parathyroid hormone	If hypercalcaemia is present to investigate possible hyperparathyroidism
	24-h urine calcium (2)	Hypercalciuria
	Plasma urate, 24-h urine urate (2)	In patients with urate stones or calcium stones
	24-h urine cystine (2)	In patients with cystine stones
	24-h urine oxalate (2)	Hyperoxaluria

Box 8.4

Stenting

The stents used by most surgeons are called 'double-J' or 'pigtail' stents and have small holes down most of the length of their tubing. These stents are self-retaining and must be removed endoscopically.

Some surgeons use an infant feeding tube as a stent following pyeloplasty, pyelolithotomy or ureterolithotomy. Infant feeding tubes are self-retaining to a degree, but the patient will need a urethral catheter in situ to keep the tube in place. When the catheter is removed the patient may pass the feeding tube without intervention. If this does not happen within 24 h, endoscopic removal will be required.

treated without anaesthetic. Depending on the density of the stone more than one treatment may be required. The patient lies on a special table, which allows shock waves produced by the lithotriptor machine to pass through it. The force of the shock waves causes the stone to disintegrate and fragment. The position of the patient on the table is dependent on the location of the stone. The whole procedure is performed under specialised X-ray and ultrasonic control. The disintegrated or powdered calculus is then allowed to pass down the ureter over the next few days.

Percutaneous nephrolithotomy (PCNL) This procedure is used to remove calculi lying within the kidney. Large staghorn calculi may need to be broken up first, using ESWL.

PCNL is performed under X-ray and ultrasound control. The patient will normally have a general anaesthetic. The kidney is punctured and the tract into the kidney is dilated to allow the nephroscope and a variety of grasping instruments to be inserted. The stone can then be removed or broken down into fine powder by ultrasonic probes (see Fig. 8.8). This powder can be aspirated through the centre of the probe.

Sometimes an electrohydraulic probe is used. This produces shock waves in the irrigating fluid to the kidney and results in the stone splitting into several fragments.

At the end of the procedure, a large nephrostomy tube with a smaller tube running down its centre is left in position to allow drainage and to prevent haematoma formation. This also allows access for a nephrogram 24–48 h postoperatively to assess the effectiveness of treatment.

Nephrogram No anaesthetic is required for this procedure. A contrast medium is injected down the smaller tube of a nephrostomy tube into the kidney. X-rays can then be taken and any fragments of calculi identified. Provided that there are no fragments left, the tubes can be removed.

Ureterolithotomy This open surgery is appropriate in the treatment of calculi occurring mid-ureter and causing obstruction that cannot be dealt with in any other way. An X-ray to identify the position of the stone will determine the incision to be made. The ureter is exposed and opened and the stone removed. The ureter is repaired either by removing a small section or by suturing the opening. A stent is usually left in place, positioned along the length of the ureter. This allows the ureter to heal and prevents leakage.

A wound drain will be left in position to prevent haematoma formation. The stent will normally be removed after 7 days.

Pyelolithotomy This open surgery can be used for the removal of calculi in the pelvis of the kidney which are causing an obstruction that cannot be removed by ESWL or PCNL. The procedure involves first exposing the affected kidney and then opening the pelvis of the kidney to remove the stone. Sometimes it is not possible to remove all of

a staghorn calculus (see Table 8.1) in this way, in which case further incisions into the surrounding renal tissue (nephrolithotomy) are necessary. A stent will be left in place for 7 days.

NURSING PRIORITIES AND MANAGEMENT: Acute renal colic

Major considerations

A patient admitted with renal colic can often do little more than cope with the excruciating pain, and is often unable to answer questions or to follow advice and instructions until the pain is relieved. Once the acute attack has subsided, the patient should be allowed to rest since only then will it be possible to absorb all the necessary explanations relating to investigations and treatment. Nursing Care Plan 8.1 outlines the priorities of nursing care for a patient admitted with acute renal colic.

Following specific interventions

Flush-back and stenting

Medium-sized stones in the upper half of the ureter are associated with obstruction. Under direct vision the calculi are flushed back into the renal pelvis and a stent is inserted;

Nursing Care Plan 8.1 Nursing care for a patient admitted with acute renal colic

Potential problem	Action	Desired outcome
1. Pain of a potentially excruciating nature	• Administer prescribed analgesics • Evaluate effect of analgesics: return to patient in 30 min: – ask if she is pain-free and record a pain score using an appropriate pain assessment tool – observe for evidence of pain, e.g. raised pulse rate, sweating and evidence of neurogenic shock (see Ch. 18)	Pain is relieved
2. Frequency and urgency of micturition	• Locate urinal within reach of patient	Sensations decline as pain is relieved
3. Nausea and vomiting	• Administer prescribed antiemetics • Evaluate effect of treatment: return to patient in 30 min • Locate vomit bowl within patient's reach	Patient obtains relief from feelings of nausea and from vomiting
4. Fluid and electrolyte imbalance	• Institute i.v. fluids if patient is unable to take adequate fluid orally	Fluid and electrolytes are maintained at satisfactory levels
5. Ureteric obstruction	• Check and record blood pressure • Observe BP trends and report elevations • Measure urine output; report reduction in volume • Observe for haematuria and passage of stones	Any obstruction is recognised immediately
6. Urinary tract infection	• Check and record temperature; report pyrexia • Check and record pulse rate; observe trends and report elevations	Infection is prevented or immediately recognised
7. Non-passage of small calculi	• Encourage normal volumes of fluid intake • Alleviate nausea and vomiting • Check urine for presence of calculi (use plastic urinal to prevent sticking of calculi)	Passage and collection for analysis of small calculi
8. Inability to perform personal hygiene	• Offer wash and change of bed gown as required, particularly if sweating is profuse	Patient is clean and comfortable Self-esteem is maintained
9. Difficulty in finding a comfortable position in bed	• Assist patient to find a comfortable position • Evaluate position regularly; ask the patient if she is comfortable	Patient is relaxed and comfortable
10. Anxiety	• Give patient the opportunity to voice concerns • Provide information about the condition, investigations and treatment • Ensure the nurse call system is close at hand at all times	Patient has an understanding of the condition and has reduced anxiety about outcome

ESWL can then be performed. The patient should be prepared for a general anaesthetic as discussed in Chapter 26. Normally, only a short-acting anaesthetic is required. Priorities in postoperative nursing care are as follows:

- To record observations, temperature, pulse and blood pressure and to watch for signs of infection.
- To monitor urine output and record volume and colour of urine on the fluid chart. A decrease in volume may indicate obstruction. Haematuria may indicate trauma, but some haematuria is to be expected.
- To encourage a fluid intake of 3 L daily to prevent infection.
- To administer analgesics if the patient is in pain. Severe pain must be reported to medical staff, as this may indicate trauma, a misplaced stent or return of obstruction.

Discharge advice The patient should be advised:

- to continue to drink 3 L daily
- to take mild analgesics such as paracetamol or co-proxamol if in pain
- to seek help from the GP if urine output is bloodstained or 'burning'.

The patient should also be advised when follow-up treatment will take place and what this will entail. If treatment is not within 6 weeks, it must be impressed upon the patient that it is very important to have the stent changed. If it is not changed, sediment and crystals will build up around it and form more calculi.

Extracorporeal shock wave lithotripsy (ESWL)

The role of the nurse in the ESWL unit includes giving reassurance to both the patient and the family, explaining what to expect, administering any prescribed medication, encouraging the patient to drink following the procedure and giving discharge advice.

The patient may receive an oral premedication such as diazepam or temazepam prior to treatment. The treatment is not normally painful. Anxiety may be experienced due to the noise from the shock waves and the requirement to lie still for 1–1.5 h. Playing recorded music may help to alleviate anxiety and boredom.

The patient will normally stay in the ESWL unit until urine has been passed. Prophylactic antibiotics and analgesics may also be given.

Most patients will be able to return home and continue with their normal daily activities. However, a small percentage will need hospital admission during the first week post-treatment because of colicky pain, oedema and, occasionally, obstruction of the ureter. This will sometimes settle with no further treatment, but a stent may need to be inserted to allow the oedema to subside.

Discharge advice The patient should be advised:

- to drink 3 L of fluid a day, to help prevent infection and to help the gravel to pass down the urinary system
- to expect some haematuria and gravel when passing urine
- to take prescribed analgesics, but if pain increases to see the GP or report back to the hospital
- to attend a follow-up appointment about 6 weeks later to have further X-rays taken to assess the effect of the treatment.

Percutaneous nephrolithotomy (PCNL)

Preoperatively, the patient should be prepared for a general anaesthetic (see Ch. 26). Postoperatively, the patient is likely to return to the ward with:

- a urethral catheter in situ
- an i.v. infusion of clear fluids
- a nephrostomy tube in the affected kidney.

The nephrostomy tube is a large-bore tube with a narrower tube running down its centre. These tubes will normally be sutured into position and enclosed in a urostomy drainage bag attached to a large 2 L drainage bag.

Priorities in the management of the nephrostomy tube are to maintain a closed drainage system in order to prevent infection, and to monitor drainage. The nurse responsible must:

- check the position and the placement of the nephrostomy tube
- help the patient into a position that is comfortable and allows the tube to drain
- empty the drainage bag when necessary and record the volume and colour of output
- remember that the urine will take the path of least resistance, so most of the output from the affected kidney will discharge via the nephrostomy tube.

The urethral catheter is normally removed 24 h following surgery. The i.v. infusion is discontinued at the same time, if the patient is able to drink normally. A nephrogram is carried out 48 h following surgery, and the nephrostomy tube removed if treatment has been successful. Following removal of the nephrostomy tube, the patient may continue to pass urine via the puncture site. This will normally cease after 12–24 h.

The patient may have colicky pain following the removal of the tube, as the urine must now redirect itself via the correct route. Analgesics can be given, and the patient should be asked to lie on the affected side. This will take the pressure off the affected kidney, and the drainage will pass via the puncture site.

Once drainage from the puncture site has ceased, a small, dry dressing can be applied and the patient discharged home. Occasionally the nephrostomy tube may need to be left in situ for a prolonged period because further treatment may be necessary. In this case, the patient may be discharged home into the care of the GP and community nurse.

Ureterolithotomy or pyelolithotomy

Preoperative preparation is as normal, including skin preparation and any necessary shaving of the area to be operated upon (see Ch. 26).

If there has been an uneventful 2- or 3-day postoperative period, and a double-J stent or pigtail stent has been used, the patient may be discharged home into the care of the GP and community nurse, returning as a day case to the hospital for removal of the stent. The community nurse will check the wound and take note of the patient's temperature and urine output. Sutures are removed from the wound

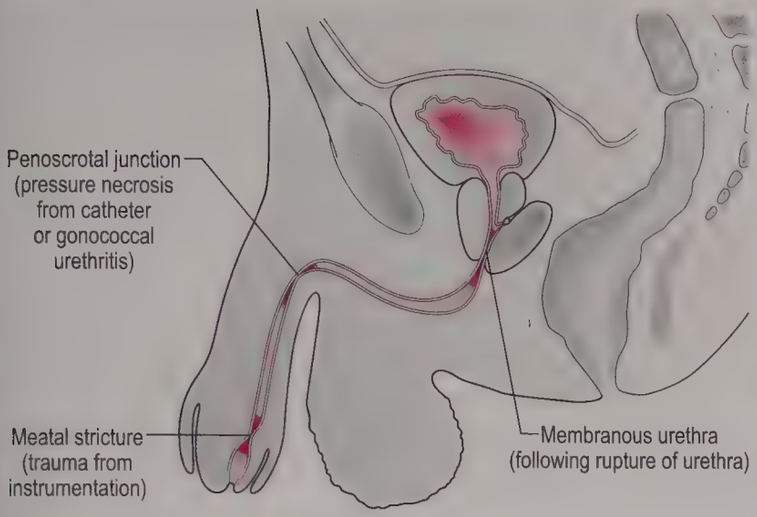

Fig. 8.9 Common sites and causes of urethral stricture.

at 7–10 days. If an infant feeding tube has been used as a stent (see Box 8.4), then the urethral catheter will remain in situ for 5–6 days. In this case, the patient may need to stay in hospital until the stent and sutures have been removed.

Urethral strictures

PATHOPHYSIOLOGY

A stricture is a narrowing within a structure which may arise from inflammation, muscular spasm or neoplastic occlusion. Urethral strictures can be congenital, caused by trauma, as in pelvic fracture, as a consequence of investigative instrumentation of the urethra (e.g. cystoscopy) or result from the presence of an indwelling urethral catheter (see Fig. 8.9). Infections such as non-specific urethritis and gonorrhoea may also result in stricture formation. It is a condition that more commonly affects men because of the length and structure of the male urethra.

Common presenting symptoms which can prove to be both distressing and frustrating are poor urinary flow, a feeling of incomplete bladder emptying, frequency, dysuria or haematuria, and dribbling incontinence, secondary to chronic urinary retention.

MEDICAL MANAGEMENT

Tests and investigations required are flow rate studies, retrograde urethrogram, urethroscopy, and full blood screening.

Treatment options include the following:

Urethrotomy The optical urethrotome allows the surgeon, under direct vision, to divide the urethral stricture. A silicone catheter would normally be left in place for a specified period to allow healing. However, the length of time it will be left in situ is variable.

Self-dilatation Often used in conjunction with urethrotomy, this technique involves the patient using a self-lubricating urethral catheter on a regular basis to increase the urethral diameter and keep the urethral passage open.

Urethroplasty Usually performed in two stages, this procedure involves excision of the stricture and anastomosis. In some cases a graft is required to replace the excised urethral tissue. This surgery requires a longer stay in hospital and is normally performed only after other treatments have failed.

NURSING PRIORITIES AND MANAGEMENT: Urethral strictures

8.4 As a nurse looking after Mr E (see Case History 8.1), what could you do to help him come to terms with the idea of performing self-dilatation and to feel more positive about it?

Major patient problems

In many cases urethral strictures are difficult to correct and recurrence is likely, thus the person must learn to live with the condition.

Self-dilatation

The patient faced with the prospect of needing to perform self-dilatation on an ongoing basis will need moral support and encouragement from the health care team. A specialist nurse will explain and demonstrate the procedure initially and then guide the patient through it, ensuring that continuing support is provided as needed. It will also be helpful for the nurse to emphasise the following points:

- No-one need know that the individual is using this technique.
- Although the idea may be difficult to accept, this treatment will minimise the risk of further admission to hospital and time off work.
- There is always a risk of infection, but this can be minimised with good hygiene, washing of hands and meatus, and adequate intake of fluids.

CASE HISTORY 8.1
Mr E

Mr E, a 35-year-old fireman, was having difficulty in passing urine. Two years previously, he had been involved in an accident in which he suffered crush injuries to his pelvis and urethra. At that time he had had a suprapubic catheter (i.e. a catheter inserted into the bladder via the abdominal wall) for 6 weeks.

On the more recent occasion, he was referred to the urologist by his GP for two reasons: firstly, Mr E had had repeated urinary tract infections over the last year; secondly, he had noticed that for the last 6 months there was a difference in the time it took him to pass urine and that the stream was thinner than usual.

After a full investigation, the surgeon decided that the best course of action would be to perform an optical urethrotomy, followed by the patient being taught to perform self-dilatation. Mr E agreed to have the operation, although he did not like the idea of performing self-dilatation. When given the opportunity to discuss this, he expressed the following concerns:

- 'What if my friends and relatives find out?'
- 'I don't want to put a tube up there. How do I do it?'
- 'What about infection?'
- 'How often will I need to do this?'
- 'I work shifts. How can I do this?'

- Dilatation will be necessary once a day at first, but as time goes on it can normally be reduced to once a week depending on individual needs.
- Irregular working schedules should not pose a problem, and the patient can work out a routine that is convenient.

Fibrosis

PATHOPHYSIOLOGY

Fibrosis is the formation of excessive fibrous connective tissue within a structure. Fibrosis around the ureters predisposes them to obstruction. The cause of the fibrosis is often unknown. This condition, known as retroperitoneal fibrosis, is not neoplastic but can result in damage to renal function. Other external causes of fibrosis are post-radiotherapy treatment, scarring arising from other surgical procedures, and aortic aneurysm. Fibrosis within structures (e.g. ureters/urethra) is usually secondary to instrumentation.

DISORDERS OF THE PENIS AND MALE URETHRA

Phimosis

In this condition, the foreskin or prepuce of the penis is too tight to be retracted over the glans penis. It is most frequently due to balanitis xerotica obliterans, a fibrosing condition of unknown aetiology (Brewster et al 2001). Other causes include infection, trauma as a result of early attempts to draw back the foreskin before it has naturally separated or developed fully in size, or a poorly performed circumcision operation.

PATHOPHYSIOLOGY

The natural separation of the two layers of skin from the glans penis normally occurs by about the age of 2 years. Following separation, daily bathing is necessary to ensure hygiene is maintained. Poor personal hygiene can give rise to inflammation and infection and has been implicated as a cause of carcinoma of the penis (Downey 2000).

Box 8.5

Circumcision

Circumcision, the surgical removal of the prepuce (foreskin), may be indicated for penile carcinoma, balanitis, candidal infection, phimosis or adherent prepuce. These conditions generally affect adults. Circumcision may also be performed in accordance with religious beliefs, in which case the procedure is usually performed in childhood.

The main complications of circumcision are infection and bleeding. Painful erections in the immediate postoperative period can usually be relieved by the application of a local anaesthetic gel. Postoperative swelling or oedema may make micturition difficult. Dribbling or urinary leakage to the wound area can delay or prevent wound healing and cause secondary infection. The insertion of a urethral catheter may be necessary to relieve this problem in order that wound healing may take place.

Common presenting symptoms Phimosis often causes balanoposthitis, i.e. inflammation of both the glans penis (balanitis) and the prepuce (posthitis). Presenting features include itching, a white discharge, pain, discomfort and bleeding at sexual intercourse, and sometimes urinary retention.

MEDICAL MANAGEMENT

Treatment Initial treatment may be with antibiotics or anticandidal agents. If the individual is sexually active, he and his partner will both require treatment to prevent the infection being passed back and forth. Circumcision is the treatment of choice and may have to be performed as an emergency if urinary retention has occurred (see Box 8.5 and Case Histories 8.2 and 8.3).

CASE HISTORY 8.2

Mr A

Mr A, aged 20, presented to his GP with bleeding from the foreskin following sexual intercourse. He was concerned as this was the sixth occurrence.

On examination the foreskin was found to be very tight, and the GP advised circumcision. Referral was made to the local consultant urologist, and Mr A was put on the waiting list. After only a few weeks he was admitted as a day case for circumcision. Before discharge, he was given the following advice verbally and in written form by nursing staff:

- Take daily baths
- Do not go straight back to work. Avoid walking around for the next few days
- Change underwear daily. Do not wear anything tight until the wound has healed
- You must be able to pass urine before leaving hospital, and you should drink at least 3 L of fluids in 24 h to prevent urinary tract infection
- If you have pain, take a simple analgesic such as paracetamol every 4–6 h for the first 48 h
- At any sign of swelling, redness or fever, go and see your GP
- Sexual intercourse should be avoided until the skin is healed and feels normal
- Should any other problems arise, report to your GP or, if necessary, return to the hospital
- Change the dressing if it becomes wet with urine. Use a non-stick dressing.

CASE HISTORY 8.3

Mr C

Mr C, a 70-year-old widower, was referred by his GP to a urologist as an emergency, because he was in pain and having difficulty passing urine. On examination it was found that he had a tight foreskin and it was difficult to see the meatus. On abdominal examination he appeared to be retaining urine. Ultrasound confirmed that there was approximately 500 mL in his bladder.

Mr C was admitted to the ward with instructions that he would be operated on within the next 2 h for circumcision and urethral catheterisation. He was told that the catheter may need to stay in position for 24–48 h, depending on his general condition, and that his stay in hospital would be between 48 h and 1 week.

NURSING PRIORITIES AND MANAGEMENT: Phimosis

Prevention

Health education of the parents is important in the early years. It should be stressed that retraction of the foreskin for cleansing is unnecessary. Normal bathing or showering routines should suffice.

Promoting wound healing after circumcision

The nurse can promote wound healing by the following means:

- teaching good personal hygiene to the newly circumcised person
- washing the wound area daily with soap and water and applying a protective, non-adhesive dressing to prevent clothing disturbing wound healing
- providing more frequent washing and dressing changes should urine leakage occur onto the wound or dressing
- counselling the sexually active patient to refrain from sexual intercourse until the wound is well healed.

8.5 How would your discharge advice to Mr A in Case History 8.2 compare with that given to Mr C in Case History 8.3? Would you make any changes, omissions or additions in your advice to the older man? What assumptions would prompt such changes? Are all of these assumptions fair?

Paraphimosis

Paraphimosis is a condition in which a foreskin that has been retracted over the glans penis cannot be returned to its usual position. The swollen band of foreskin obstructs the circulation to the glans, which in turn becomes swollen and painful. It is classed as a medical emergency as delayed action may lead to gangrene of the glans (Downey 2000).

Cold compresses applied to the penis may help to relieve the swelling and pain. The doctor or nurse may be able to manipulate the glans back under the foreskin with or without anaesthesia. Because of extreme pain, patients may require a penile nerve block, topical analgesic or oral opioids. If manipulation is unsuccessful, a dorsal slit may be made in the foreskin. There remains a risk of recurrence of the paraphimosis and a circumcision may be advisable at a later date.

Congenital disorders of the urethra and penis

At birth, an infant is examined to confirm its sex and to make sure that expected bodily structures are present. In boys, the urethral meatus is normally seen at the anterior tip of the glans penis. Occasionally a malformation of the urethra is identified as a congenital defect.

Hypospadias

Hypospadias is a condition where the meatus of the urethra is found in a position on the undersurface of the glans penis. It is the commonest congenital penile abnormality (Brewster et al 2001, Underwood et al 2003). The condition is usually treated quite effectively by enlargement of the meatus by plastic surgery. In some cases the urethral orifice is positioned further back on the lower surface of the penis, and this will complicate treatment. Surgical reconstruction should take place before the age of 2 years, as this avoids cosmetic and fertility problems in later life. The position of the meatus, distal urethra and presence or absence of chordee (downward curvature of the penis) will influence the surgical approach adopted.

Epispadias

The condition of epispadias is one in which the urethra opens onto the upper surface, or dorsum, of the penis. The meatus of the urethra may be positioned anywhere along the length of the penile surface. Epispadias may coexist with other serious congenital abnormalities involving a poorly developed anterior section of the urinary bladder and abdominal wall. Surgical reconstruction is likely to be complex and may involve transplantation of ureters.

DISORDERS OF THE PROSTATE

Benign prostatic hyperplasia

The prostate gland increases in size with age, reaching about 20–25 g by the time the individual is 20 years old. In individuals over the age of 45, the smooth muscle segments atrophy and are replaced by collagen fibres. As ageing progresses, connective tissue accumulates, resulting in benign prostatic hyperplasia (BPH), the most common neoplastic growth in men. Fifty per cent of men over the age of 60 will have BPH, but not all will have symptoms (Thorpe & Neal 2003). Demographic trends suggest that as people age, symptoms will become more prevalent (Wilt 2002). The cause of BPH is unknown, but it is thought that it may be associated with reduced androgen secretions.

Bladder outflow obstruction can occur for a number of reasons (see Box 8.6), but the most common cause is benign prostate hyperplasia.

PATHOPHYSIOLOGY

Stasis of urine in the bladder and a build-up of pressure in the bladder and ureters predispose the individual to infection, the formation of stones and possible renal failure. The bladder becomes enlarged, forming bundles called trabeculae. Diverticula may also be noted. If left untreated, obstructive effects will develop (see Fig. 8.10).

Common presenting symptoms The enlargement of the gland may be asymptomatic, perhaps noted only on a routine rectal examination. However, as the hyperplasia increasingly distorts and compresses the urethra and even the bladder, an inability to void normally will become obvious. Many men tolerate symptoms indefinitely, seeing them as just 'old men's problems' that have to be accepted. Presenting symptoms include:

- Irritative symptoms
  - — frequency >7 times/day
  - — urgency
  - — nocturia

Box 8.6

Bladder outflow obstruction

Causes
- Benign prostatic hyperplasia
- Bladder calculi
- Bladder tumour
- Diuretics
- Neurological disturbances
- Phimosis
- Prostatic carcinoma
- Urethral strictures, stenosis, trauma

Common symptoms
- Double voiding
- Dribbling post-voiding
- Dysuria
- Diminished force of urine flow/stream
- Frequency
- Hesitancy
- Haematuria (occasional)
- Nocturia
- Incontinence
- Interrupted stream
- Urgency
- Urinary retention

Inadequate emptying of the bladder can result in a build-up of residual urine, increasing the risk of urinary tract infection and the incidence of bladder stone formation.

Diagnosis
Diagnosis of bladder flow obstruction may be assisted by:

- Blood screen of urea, electrolytes and creatinine
- Endoscopy — urethroscopy and cystoscopy
- History of symptoms
- Physical examination
- Ultrasound scan — residual urine volume and upper urinary tract
- Urinalysis
- Urine culture
- Urodynamic evaluation
- Voiding cystometrogram

- Voiding symptoms
  — hesitancy
  — poor stream
  — incomplete emptying
  — terminal dribbling
  — prolonged voiding times.

In addition, a history of recurrent urinary tract infections may be given. Increasing pressure due to obstruction, if untreated, can eventually result in renal impairment.

Acute urinary retention may be the single presenting feature, particularly if the prostate gland suddenly increases in size or if infection occurs. Some patients present with chronic urinary retention, sometimes associated with haematuria and urethral bleeding. Abnormal voiding patterns and disruption of daytime activities or sleep patterns can affect the individual's ability to work and interact normally with colleagues, partners and family. Bedwetting or urinary incontinence may cause embarrassment and distress. Embarrassment about such symptoms may also result in failure to seek professional help until the condition becomes unbearable.

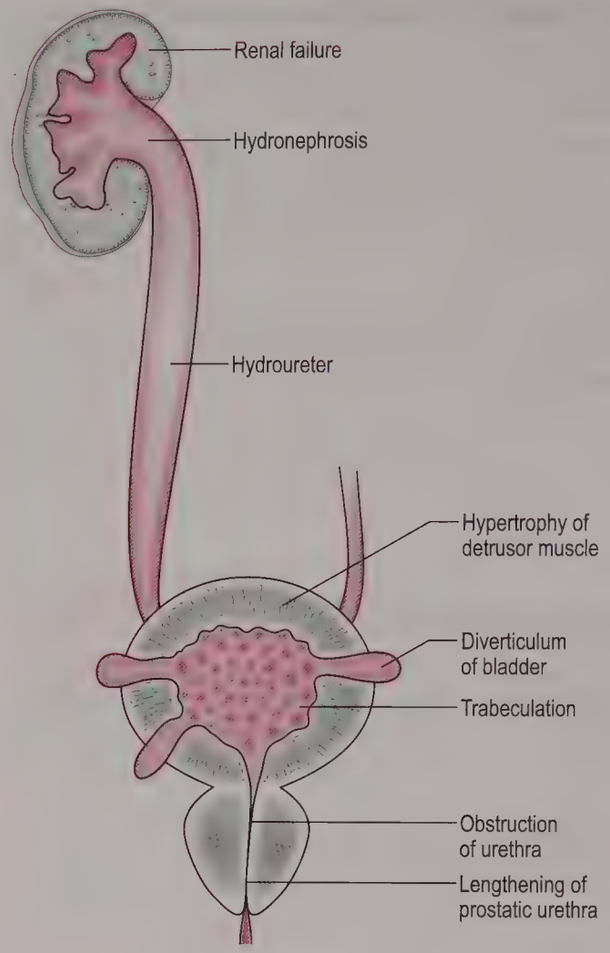

Fig. 8.10 Late sequelae of prostatic obstruction.

MEDICAL MANAGEMENT

Investigations Diagnosis can be made by rectal examination; the prostate gland will feel large, elastic and uniform. Investigations will include:

- ultrasound scan
- urinary flow rates
- renal function tests
- full blood count
- symptom score to quantify symptoms and measure how 'bothersome' they are, for example, International Prostatic Symptom Score (IPSS) (Haslett et al 2002)
- serum acid phosphatase or serum prostate-specific antigen (PSA) to eliminate diagnosis of carcinoma in selected patients
- MSU.

Treatment is dependent on individual wishes, severity of symptoms and degree of obstruction (Underwood et al 2003).

Treatment options include:

- watchful waiting
- surgery
- laser therapy
- transurethral ablation
- transurethral microwave therapy (Thorpe & Neal 2003).

For further information, see Downey (2000), Garden et al (2002) and Thorpe & Neal (2003).

Transurethral resection of the prostate gland (TURP) is the surgical operation of choice. Where the gland is too large to resect transurethrally, an open procedure is used, most commonly taking the retropubic or transvesical approach. Prior to commencing the resection, a cystoscope is passed to view the bladder (see Box 8.7). A resectoscope is then passed and small sections are chipped away from the prostatic lobes, removing the material that had been intruding into the urethra and bladder neck. Irrigation fluid of a non-electrolyte solution, glycine, constantly flushes out the bladder during the procedure; an electrolyte solution is contraindicated in the presence of diathermy as this does not transmit electrical current effectively. Most commonly, irrigation continues postoperatively, as the operative bed can give rise to considerable bleeding and clots could lead to obstruction.

Potential postoperative complications of TURP are:

- haemorrhage — evident as haematuria
- clot retention
- infection — urinary tract, epididymis or testis
- extravasation — escape of urine into surrounding tissue due to bladder or urethral damage
- deep vein thrombosis and pulmonary embolism.

Possible late complications are:

- urethral stricture
- incontinence
- impotence
- retrograde ejaculation
- bladder neck stenosis.

For further information, see Reilly (1997).

Box 8.7

Cystoscopy

This procedure allows the surgeon to visualise the interior of the bladder and to take biopsies where suspicious lesions are evident. It may be carried out either under general anaesthetic with a rigid cystoscope or under local anaesthetic with a flexible cystoscope. The method selected will depend on the condition of the patient.

Cystoscopy under general anaesthetic

The standard procedures for preparing a patient for general anaesthesia will apply. The lower bowel should be free of faeces so that insertion of the cystoscope is not impeded or the view restricted.

Once recovered from the anaesthetic, the patient should be encouraged to drink and should be able to pass urine within 6 h of the procedure. The nurse should collect the first specimen passed and record its colour and amount.

Upon discharge, the patient should be advised that he may experience some frequency of desire to pass urine. He should watch for blood in the urine and, should this appear, increase his fluid intake. If the frequency does not settle, or if any bleeding continues, the patient should contact his GP or the hospital.

Cystoscopy under local anaesthetic

There is no restriction on the taking of food or fluids prior to this procedure, but the lower bowel should be free of faeces. The local anaesthetic is placed directly into the urethra in the form of lidocaine (lignocaine) gel. In a male patient, a penile clamp is applied to the penis to allow the gel to move along the urethra. A period of 10–20 min should normally be allowed for the local anaesthetic to take effect.

Following the procedure, the patient will normally pass urine sooner than under general anaesthetic, as there will have been no restriction applied to fluid intake prior to the operation.

NURSING PRIORITIES AND MANAGEMENT: Benign prostatic hyperplasia

General considerations

Patients with acute retention

Most patients presenting with acute retention as a result of BPH will be discharged home with a catheter in situ and will return for planned surgery at a later date; this reduces perioperative inpatient stay (Pickard et al 1998). Once the obstruction is relieved there is no urgency to perform surgery, which allows the treatment of any associated medical conditions and, when appropriate, the patient can be placed on the operating list.

Patients with chronic retention

Chronic urinary retention is usually the result of a crescendo of symptoms of prostatism. These men do not always complain of symptoms of bladder outflow obstruction, but mainly of urge incontinence, dribbling urine or wet beds at night. They usually have no pain and, although they have a large amount of residual urine, their bladder distension is not always obvious to the eye or palpable on physical examination.

Because of the large amount of residual urine, these patients are at risk of developing upper urinary tract dilatation and impaired renal function. However, if there is no renal impairment, it is not essential that these individuals are catheterised. It is urgent to make a diagnosis and proceed to prostatectomy once rehydration and renal function have returned to normal.

Catheterisation will permit bladder drainage and allow renal function recovery (see Boxes 8.8 and 8.9). Once catheterised, the patient may have a huge diuresis. His thirst mechanism will not allow adequate fluid replacement, making parenteral fluid replacement necessary. Large fluid replacement volumes put the patient at risk of heart failure and it should be borne in mind that impaired renal function may have precipitated anaemia.

Once the patient has been catheterised, his renal function restored and any anaemia corrected, there is no urgency to proceed to surgery. The individual may in fact benefit from a period of recuperation and bladder rest with the catheter in place. Depending upon the general well-being of the individual and upon community resources, care may be given in hospital or in the patient's home.

A trial without the catheter should not be made, as this would again lead to chronic retention followed by renal failure.

Box 8.8

The use of catheters

Indications for catheterisation

- Acute or chronic retention of urine
- Diagnostic investigations of the bladder function
- Pre- and postoperative needs
- Following trauma, burns, road traffic accidents or any trauma to the lower urinary tract
- Therapeutic instillations of specifically prescribed medication
- Intractable incontinence where all other methods have failed
- Protracted loss of consciousness

Choice of catheter

Points to consider when choosing a catheter are:

- The purpose of the catheterisation
- The length of time the catheter must remain in situ
- Whether a self-retaining catheter is necessary
- The gender of the patient.

Features of the catheter

- The smallest catheter that will adequately drain the bladder should be used: size 12–16 Fg for adults with clear urine; size 18–22 Fg for adults with haematuria
- The lumen of the catheter will vary depending on the material used. A latex catheter is made up of several layers of material, often coated inside with silicone, and its lumen will be smaller than that of a silicone catheter, which is extruded from one piece of material (Pomfret 1996)
- Balloon size: the larger the balloon, the higher the drainage eye lies in the bladder. This can impair drainage and cause more irritation to the sensitive trigone of the bladder. The balloon should be just large enough to stop the catheter falling out or being pushed out if the patient bears down. The recommended balloon size for routine use is 5–10 mL. A 30 mL balloon should be used only following surgery on the prostate gland

Note that underinflation of a large-capacity balloon causes distortion of the tip of the catheter and occlusion of the drainage eye. Therefore a large balloon should be filled with at least 20 mL of water. A smaller-ballooned catheter, because the water must reach the balloon, should be filled with at least 10 mL.

- Catheters for short-term use are made of a latex material that can cause irritation of the urethra and build-up of crystals in the bladder. Therefore it is not recommended to use this type of catheter for longer than 2 or 3 weeks
- Catheters for long-term use are made of 100% silicone material; they are less irritating, softer, and cause less build-up of crystals

For those with milder symptoms, it is a matter of discussion between the patient and his doctor as to whether symptoms are interfering with the individual's lifestyle sufficiently to warrant an operation and whether he stands a good chance of improvement from surgery. In rare cases where there is poor life expectancy or the patient is too unfit for surgery, prostatectomy may not be offered and a permanent indwelling catheter may be considered the best management.

Specific considerations for the patient undergoing TURP

Informed consent

The patient must be given a clear explanation of the after-effects of TURP, so that he can give his informed consent prior to the procedure. Since many men have retrograde ejaculation after prostatectomy, it is essential that they are counselled adequately beforehand. Retrograde ejaculation does not cause impotence, but a patient who has not been given adequate reassurance on this point could suffer psychological upset resulting in impotence. Retrograde ejaculation will not render the patient sterile, but neither will it necessarily permit him to father children easily. It should not be presumed that all older men are not sexually active, and all patients are entitled to preoperative information (see Case History 8.4 and Box 8.10).

8.6 Identify and consider all the information that it will be necessary to give to Mr M in Case History 8.4. How could this information best be given to ensure he can really understand and remember the details?

Major patient problems

Patients who have undergone TURP may have the following problems and concerns postoperatively:

- Anxiety
  - — about the success of the surgery and the outlook for recovery
  - — about bleeding from the prostatic bed
  - — about the embarrassment of having a catheter in situ
- Pain
  - — from the raw area in the bladder
  - — from clots forming in the prostatic bed and blocking the catheter
  - — from the catheter itself
  - — from bladder extravasation
- Immobility
  - — due to inability to get out of bed because of the surgery
  - — because of irrigation
  - — due to fear of moving
  - — due to i.v. infusion

CASE HISTORY 8.4

Mr M

Mr M was admitted for a TURP. He was 73 years old and had been suffering from the miserable symptoms of an enlarged prostate gland for some time. He was glad to be in hospital but did not feel well. His joints and bones ached from long-standing osteoarthritis. His chest was not good and his feet and hands were always cold. He knew smoking did not help and he had been cutting down.

The surgeon and anaesthetist visited him and explained the surgery and that he would have an epidural anaesthetic. The physiotherapist visited him and discussed breathing techniques and encouraged him to stop smoking. Nursing staff were always at hand. They explained all the tests and procedures involved in preparation for surgery as well as how he could expect to feel after the procedure.

Box 8.9

Principles of catheter management

Performing catheterisation
The nurse performing catheterisation must introduce the catheter into the bladder using aseptic technique, without causing trauma and with minimum discomfort to the patient. The following considerations are essential:

- Adequate cleaning of the genital area
- Working under good light, especially when catheterising females
- Positioning the patient correctly
- Ensuring the patient's privacy
- Providing adequate anaesthetisation of the urethra for both male and female patients. An anaesthetic-containing antiseptic should be instilled and left to take effect for a minimum of 5 min.

Management of the indwelling catheter
The main priorities of catheter care are to prevent infection and to safeguard the dignity of the patient. To minimise the risk of infection the nurse should:

- Establish and maintain a closed system of drainage
- Promote good personal hygiene
- Carry out catheter hygiene once a day and after each bowel movement, using soap and water
- Encourage a fluid intake of 2–4 L daily, according to the individual's needs
- Encourage maximum mobility
- Change the catheter only when necessary, rather than routinely
- Avoid causing trauma to the urethra and bladder neck
- Give bladder washouts only when absolutely necessary, i.e. when the catheter is blocked or when washouts have been prescribed as a treatment (Getliffe & Dolman 2003). Bladder washouts should not be employed as a prophylactic treatment for urine infections.

Maintaining the dignity of the patient
The following measures will help to preserve the patient's dignity and self-esteem:

- Providing education and promoting self-care where possible in catheter toilet, the use of a bidet, emptying and changing bags
- Using a female length catheter for a female patient to allow her to wear skirts
- Encouraging the use of leg bags so the catheter is not in view
- Encouraging maximum mobility to promote confidence and give better drainage.

Problems and possible interventions
The nurse should be prepared for the following potential problems:

Bypassing
- Check to see if the catheter or drainage tube is blocked, kinked or looped
- Consider changing to a smaller catheter. It is a misconception that if the catheter bypasses, a larger catheter is required
- Check whether or not medication which can cause spasm has been prescribed
- Exclude constipation — relieve constipation immediately and emphasise the importance of a high-fibre diet
- Check with the doctor about the possibility of prescribing anticholinergic drugs if the bypassing still persists

Balloon not deflating
- Attach syringe to the valve in position without aspiration. It may self-deflate
- The balloon may be burst by injecting 2–5 mL of dilute ether via the balloon inflating channel
- A fine sterile wire may be passed up the inflating channel and the balloon burst
- Never cut off the end of the inflation channel of the catheter

Blockage
- This may be caused by medication, e.g. aperients causing phosphatic debris in the urine — change or stop the drug, encourage the patient to take a high-fibre diet and encourage more exercise
- Infection must be treated with the correct antibiotic. Check the amount of fluid intake and where possible try to increase this. Check the standard of personal hygiene
- If clots occur, carry out a bladder washout with normal saline

Urethral discharge
- Normal secretion of the urethral mucosa is increased with the presence of a foreign body, i.e. the catheter. To prevent this becoming troublesome to the patient, adequate meatal toilet should be instituted from the first day of catheterisation

- Difficulty eating and drinking
  — due to nausea
  — due to immobility
- Disturbed sleep
  — due to irrigation changes, checks on temperature, pulse, blood pressure
  — due to pain
  — due to noise in the ward.

Major nursing considerations

Risk of haemorrhage Since haemorrhage is a major risk after prostatectomy, preoperative care should involve determining baseline haematological values. Careful consideration must be given to those individuals receiving oral anticoagulants for any other disease, since the risk of haemorrhage is considerable. It may be necessary to discontinue oral therapy preoperatively and to use i.v. heparin postoperatively until the oral regimen can be recommenced and stabilised. This may take some weeks to achieve and will require the patient to make additional visits to the hospital or GP surgery.

Anaemia Preoperative anaemia should be corrected and blood transfusion given postoperatively if required to replace blood loss. Blood is not routinely cross-matched due to the availability of protein and plasma products.

Fluid and electrolyte balance Preoperative determination of urea and electrolyte levels will provide baseline measurements and permit correction before surgery if required. This may involve urethral catheterisation to enable adequate

Box 8.10

Information for patients undergoing prostatectomy

Your doctor has already explained to you that you require an operation on your prostate gland. The prostate is situated at the base of the bladder and it is quite common in older men for the prostate to enlarge, causing the symptoms which you have been experiencing. In order to relieve these symptoms it is necessary to remove that part of the prostate gland which is causing a blockage to the flow of the urine from the bladder.

The anaesthetic
The operation may be performed under a general anaesthetic, when you will be completely asleep, or a spinal anaesthetic, which involves an injection in your back and makes the lower half of your body completely numb. This decision is usually made by the anaesthetist.

The operation
There are two ways of removing the prostate gland. Generally it is possible to do the operation through a telescopic instrument which is passed up through the penis. This operation is known as a transurethral resection of the prostate (TURP). The prostate tissue is cut away in small pieces which are washed out of the bladder and any bleeding is stopped using a special electrocautery probe.

Alternatively, it is sometimes necessary to remove the prostate by an open operation through an incision in the lower part of the abdomen. The same amount of tissue is removed by both operations and the end result is the same. Your surgeon will naturally try to remove your prostate with the tele-endoscopic instrument but it may be necessary to perform the 'cutting' operation, especially if the prostate is unusually large.

After the operation you will have a tube (catheter) draining the urine from your bladder into a bag which will be emptied regularly by the nursing staff. Immediately after the operation the catheter will contain blood, so the bladder, prostate and catheter are washed continuously with fluid that runs through an extra tube attached to the catheter. This is disconnected when the urine is clear, usually the morning after the operation. After the operation you will also have an infusion into a vein for about 24 h to provide extra fluid or blood if necessary.

After the operation
As soon as possible after the operation we like you to start drinking large quantities of tea, squash, fruit juice or water, but fizzy drinks are not recommended. An occasional can of beer is permissible. This will speed up your recovery by producing more urine to wash away the blood in the catheter and prevent infection. The catheter will be removed when the urine is clear, usually in the evening or the next morning after the operation. This is not painful. After it has been removed you should continue to drink as much as possible and pass urine every 2–3 h. This may be uncomfortable to start with and you may have to hurry or experience some dribbling but these minor symptoms improve rapidly. Once you are satisfied that you are passing urine well and your surgeon is satisfied with your progress, you may return home, usually 1–2 days after removal of the catheter.

At home
When you get home you should continue to drink well and avoid constipation, strenuous exercise and heavy lifting. You should not drive a car for 2 weeks, or play golf or go jogging for at least 3 weeks. Sometimes you may see some blood in your urine 7–10 days after the operation. This is rarely serious and if you drink plenty of fluids and rest it should disappear. If bleeding persists you should contact your family doctor. Infection and other problems are unusual. The bladder may be 'irritable' for several weeks after a prostate operation with frequency and urgency, but any remaining symptoms should disappear within 12 weeks.

You will be seen again in the urology outpatient clinic 2–3 months after your operation. You can return to work at that time or even sooner, if you feel able to do so.

Sexual activity after prostatectomy
This operation will alter your sex life but it is unlikely that there will be any change in the quality of the erections or climax. Sexual intercourse can take place 5–6 weeks after the operation. During sexual climax, however, you will not emit any semen from your penis. The ejaculation (semen) may flow into the bladder instead of down the penis and the first time you pass urine after intercourse it will be cloudy. This is not harmful. You are unlikely to produce any children following this operation but this should not be relied on as safe contraception.

Reproduced with permission from the Department of Urology, The Freeman Hospital, Newcastle upon Tyne.

bladder drainage and the use of i.v. fluids to achieve hydration.

During TURP, the bladder is irrigated with fluid to provide a clear view for the surgeon. Some of this fluid is usually absorbed, and if there is an interruption in the venous system during the resection, the fluid absorbed can be excessive. The fluid used in irrigation is usually isotonic glycine, excessive absorption of which can cause the patient to become hyponatraemic. This can cause confusion, a restless mental state and, in some cases, unconsciousness. This imbalance can be corrected by restricting fluid intake and encouraging the patient to increase the amount of salt in his diet.

Water is not used for irrigation because it can be readily absorbed and cause haemolysis. Saline interferes with the use of diathermy, and so is also unsuitable for irrigation during surgery. It is, however, the solution of choice for postoperative bladder washouts.

Urinary infection Men who have an indwelling urethral catheter preoperatively are at a high risk of developing infective complications. The effectiveness of prophylactic antibiotics is uncertain, but it would seem that those who do not receive systemic therapy at the time of operation, followed by a postoperative course, will be likely to develop bacteraemia and become unwell.

Urinary infection is common after prostatectomy, even in those who had sterile urine preoperatively. About one-third of men who have bacteria in their urine postoperatively are asymptomatic but should receive the appropriate

oral therapy. This reduces the incidence of secondary haemorrhage caused by infection.

Management of irrigation

An irrigation set with a Y-connection will be used to allow two 3 L bags of normal saline to be erected at any one time, with one bag running at a time. The irrigation runs into the bladder via the irrigating channel of the catheter, diluting the urine, which then drains out through the outlet channel of the catheter into a drainage bag. Irrigation prevents blood clots forming and obstructing the catheter. The irrigation is regulated, via a clamp, to run at a speed sufficient to keep the bladder clear of blood clots. The bags are numbered and the amount of irrigation fluid recorded on a fluid chart. The patient's total output, i.e. urine and irrigation fluid, should be measured and recorded. The amount of irrigation fluid used should be subtracted from the measured output to give the urine output volume.

Specific assessment points are as follows:

- Observe and palpate the patient's lower abdomen. Abdominal distension may indicate clot retention or extravasation. Clot retention is a common complication in the first 12–24 h. Bladder washout or deflation and reinflation of the catheter balloon may be required.
- Note the colour of the irrigation fluid: a bright red colour may indicate fresh bleeding; a dark red colour would suggest old blood.
- In an uncircumcised male patient, check that the foreskin is over the glans penis to prevent paraphimosis.

The morning following surgery, the irrigation will be discontinued, provided the patient is able to drink large quantities of fluid to help flush the prostatic bed of any further bleeding or clots.

Pain relief should be adequate to allow the patient to rest and feel comfortable.

Catheter care (see also Boxes 8.8 and 8.9) A common problem while the catheter is in situ is the bypassing of urine around it. This is sometimes difficult to resolve, and the nurse should take the following preventive measures:

- Check that the catheter is not blocked by clots or debris and that it is in the bladder.
- Check the amount of water in the balloon. If it is 30 mL, then reduce it to approximately 20 mL or so, but not less than 15 mL.
- Give anticholinergic medication as prescribed, e.g. oxybutynin.
- Encourage the patient to continue to drink large quantities of fluid.

The catheter will stay in position for 2–3 days following surgery or until the urine output is clear. Before removing it, the nurse should ensure that the patient's bowels have moved, as straining following catheter removal can lead to further urethral bleeding. Following removal, the patient may experience urgency and frequency as before. He should be reassured that this is normal and that it may take up to 8 weeks for a normal voiding pattern to be established. The patient should be educated to tighten the sphincter muscle and to hold on as long as possible before passing urine.

Patients who had chronic retention before surgery often fail to void postoperatively. A long-term catheter will normally be inserted in such cases, and the patient allowed home for several weeks (usually 6). This time period allows the bladder to rest and regain its elasticity.

Patient involvement

The patient's dependence on nursing care will gradually decrease as blood loss and hence the need for irrigation lessens. Involvement of the patient in aspects of his own care is to be encouraged and may include:

- making entries in his own fluid chart; drinking at least 3 L in 24 h; emptying his own drainage bag; recording amount and colour (most patients will be happy to do this but may need guidance on colour and amount)
- attending to own personal hygiene; this would include cleaning the urethral catheter once or twice a day using soap and water (Pratt et al 2001)
- taking regular, if somewhat gentle, exercise (it should be remembered, however, that some patients feel embarrassed about carrying around a urinary drainage bag).

Discharge

Once the urine is clear, the catheter can normally be removed. This is usually done in the morning to allow the patient to establish a normal voiding pattern before retiring to bed. Provided the patient is able to pass urine without difficulty, he may be discharged from hospital the following day.

For further information, see Doherty & Winder (2000), Evans & Godfrey (2000), Pratt et al (2001), Pomfret (2001) and Robinson (2003).

Many patients feel, after the operation, that they have gained no relief from their problems. It must be understood that it will take about 6 weeks for the prostatic bed to heal, such that full urinary control is possible. During the early postoperative weeks, the patient should refrain from vigorous exercise. He should drink plenty of fluids and avoid becoming constipated. The community nurse will give advice and support should urinary problems occur.

It should be noted that at about 14 days postoperatively, when desiccated tissue has sloughed off the prostatic bed, haemorrhage can occur (secondary haemorrhage; see Ch. 26, p. 921).

Occasionally, urethral stricture occurs as the urethral mucosa in the prostatic region heals.

For further information, see Thorpe & Neal (2003).

Cancer of the prostate

Cancer of the prostate gland is the second most commonly diagnosed malignancy in men (Gray 2002). The incidence of prostatic cancer increases with age and postmortem studies have shown that approximately 30% of asymptomatic men over the age of 50, and 90% over the age of 90, have microscopic foci, evident only on histological examination. About 10% of men thought to have a benign prostate on examination are later found by histological examination to have prostatic cancer.

PATHOPHYSIOLOGY

The cause of prostatic cancer is not clear, but there is some evidence to show that hormonal activity plays a part in the transformation of certain normal cells into cancerous ones. Benign hyperplasia and carcinoma arise in different parts of the gland. Carcinoma occurs in the peripheral gland. Metastases often move to bone, where they are associated with severe pain. In cases of extreme bony destruction, pathological fractures may occur. It has been known for spinal destruction to cause paraplegia.

Common presenting symptoms Diagnosis of this disease is difficult because the patient is often asymptomatic. The GP is likely to see patients who present with advanced disease which is already beyond cure. Patients with locally advanced disease are likely to complain of bladder outflow obstruction, a sudden onset of urgency to void urine, and possibly haematuria.

Chronic urinary retention secondary to bladder outflow obstruction may cause renal damage by dilating the upper renal tracts. The patient may present with a palpable bladder or with renal failure; he is likely to be generally unwell and losing weight. Renal failure may also be caused by ureteric infiltration of tumour or by para-aortic lymph node obstruction causing ureteric obstruction. Those who feel unwell and are anaemic are likely to have suffered bone marrow infiltration and/or renal failure. A complaint of persistent backache may suggest bone metastases.

An irregular, enlarged, hard prostate gland does not prove diagnosis, although most advanced carcinomas will be felt as such on rectal examination. However, prostatitis or prostatic stone disease may feel similar on rectal examination. Moreover, if there is a tumour within the anterior part of the gland, rectal examination will reveal no abnormality.

MEDICAL MANAGEMENT

Investigations The only certain means of making a diagnosis is by histological examination. Fine-needle transrectal prostatic biopsy can be done without anaesthetic for this purpose. Specimens (prostatic chips) resected at the time of transurethral or open prostatectomy should be sent for histological examination. However, this may yield a false negative if the sample is not taken from the peripheral part of the gland. Prostatic cancer is graded histologically to assess malignant potential.

Additional investigations to provide evidence of local and metastatic spread include IVU, CT scanning, magnetic resonance imaging (MRI), ultrasound scanning, skeletal X-rays and lymphangiography.

Treatment The nature of the treatment offered and whether it is given on an outpatient or an inpatient basis will depend upon the extent of the disease and on how the patient presents symptomatically and clinically.

Surgery TURP is normally carried out to relieve urinary symptoms and retention. This does not, however, afford a cure.

Radical prostatectomy and clearance of any pelvic lymphatic involvement are performed in the hope of achieving a cure. This treatment is restricted to those with disease localised to the prostate, a life expectancy of greater than 10 years and no significant co-morbidity. The patient should be counselled preoperatively about his disease and the almost certain complication of urinary incontinence.

Radiotherapy This is given as either external beam or interstitial seed implantation (brachytherapy). For external beam radiotherapy, if the patient is generally fit, he will probably attend for daily treatment as an outpatient. Should the patient or medical team prefer, inpatient treatment may be given (see Ch. 31, p. 1044).

The side-effects of treatment vary from person to person. Liaison with the patient's relatives and with the community health care team will help to ensure that the patient is given optimum support in dealing with these (see Ch. 31, p. 1047). In some cases, the side-effects will necessitate hospitalisation, e.g. when nausea, vomiting and diarrhoea cause dehydration, or when urinary frequency or incontinence causes severe physical and psychological distress.

Treating advanced disease The aims of treatment in advanced disease are to provide symptomatic relief and to preserve an acceptable quality of life for the individual. The outlook for improvement will depend upon various factors; those with renal failure, anaemia or urinary retention and metastases have a poor prognosis.

Those who have metastatic disease and are symptomatic are normally offered hormonal treatment. Hormonal manipulation can be achieved by bilateral orchidectomy (excision of the testes) or by the administration of oestrogens or of luteinising hormone-releasing hormone agonists (LHRH), e.g. diethylstilbestrol, or non-steroidal anti-androgens. Of patients given hormonal treatment, 70% will experience symptomatic relief for a period, but will have recurrent symptoms in the long term.

The treatment of those with metastatic disease who are asymptomatic will usually be deferred until symptoms develop. Once hormonal treatment has been given and relapse occurs, the outlook is poor.

It would appear that chemotherapy is ineffective in treating advanced prostatic carcinoma. However, radiotherapy is sometimes beneficial in the relief of bony pain caused by metastases. Vertebral collapse caused by metastatic disease of the spinal column requires emergency radiotherapy or laminectomy and hormonal manipulation. If effective, these measures may prevent neurological symptoms and/or paraplegia from developing.

Pain control by means of opiate analgesics may cause constipation; this in turn can cause urinary retention. It may be more appropriate to administer non-steroidal anti-inflammatory medication to avoid this side-effect. Should analgesics be required, they should be given in doses which prevent pain occurring (see Ch. 19, p. 750). Sustained or slow-release medication is often very useful.

NURSING PRIORITIES AND MANAGEMENT: Carcinoma of the prostate

General considerations

The nursing management of the patient with prostatic cancer is very much influenced by the particular presentation of the disease in each individual. The nurse should take a problem-solving approach to care, and promote independence and self-care for as long as possible. The nurse

should bear in mind that constipation and urinary retention or urinary incontinence are commonly encountered and can be very distressing both for the individual and for his family. Ongoing liaison between hospital and community teams will help to ensure that care is effective and genuinely responsive to the individual's unique situation (see Ch. 33).

A range of medical interventions may be necessary at different stages in the disease process. Nursing involvement will then include assisting with procedures such as:

- correction of anaemia by blood transfusion
- TURP to relieve retention
- bilateral subcapsular orchidectomy to reduce the hormone level, help prevent the spread of metastases and reduce pain.

In many cases, medical intervention can offer only temporary improvement, and the emphasis of care will turn to palliation. Treatment of advanced disease is usually shared between hospital and home, and the patient and his family will need a great deal of moral and practical support in both settings. It is important to convey a sense of optimism so that life can continue to be enjoyed to the fullest degree possible. In the last stages of the illness, however, it should not be seen as a defeat or failure to help the patient to let go of life and face death with dignity (see Ch. 33).

For further information, see Donovan et al (2001).

Table 8.3 Presenting features of bladder cancer

Sign/symptom	Reason
Haematuria, urine retention	Tumour growth Tumour spread
Dysuria, urgency, hesitancy, frequency	Stimulation of reflex micturition arc Secondary infection
Urinary incontinence	Irritability of bladder
Chills and cystitis	Obstruction/infection
Backache, pain	Ureteric obstruction Dependent upon the stage: infiltration Symptoms of cystitis or burning
Lower limb oedema	Venous obstruction Lymphatic obstruction
Infection	Obstruction Tumour necrosis
Malaise, anaemia	Frequency causing lack of rest or sleep Bleeding
Suprapubic mass, abnormal mass on rectal examination	Tumour size Tumour spread

DISORDERS OF THE BLADDER

Cancer of the bladder

Tumours of the bladder, usually transitional cell carcinoma, occur more commonly in men than in women (M:F = 4:1). The peak incidence of bladder cancer in the UK occurs at around 65 years of age. Bladder tumours are histologically similar to tumours of the renal pelvis and ureter. About 95% are malignant, and benign tumours often recur after apparently successful treatment.

There are geographical variations in incidence — tumours are more common in industrialised regions than in underdeveloped regions. Possible causative agents or factors include:

- occupational exposure (industrial dyes, solvents)
- cigarette smoking
- calculi
- diverticulae
- chronic inflammation due to indwelling catheterisation.

Screening of those in high-risk groups may help to reduce incidence and to monitor factors associated with bladder cancer, but as many years may elapse between exposure to a carcinogen and the development of cancer, direct connections are difficult to establish.

8.7 What part can the occupational health nurse play in prevention?

Refer to Royal College of Nursing (2004).

PATHOPHYSIOLOGY

Tumour growth usually commences in the epithelial lining of the bladder, often as a papillary growth. (Papillae are minute nipple-shaped projections.) Benign growth will, without treatment, usually progress to malignancy and then, by stages, from superficial to deep muscle tissue involvement, eventually spreading locally into surrounding tissue and other parts of the urinary tract or organs.

Common presenting symptoms (see Table 8.3) Approximately 80% of people with bladder cancer will notice haematuria. This may be the only presenting feature of the disease. Dysuria, frequency, symptoms of obstruction and infection may also be noticed, but embarrassment may prevent the individual from visiting their GP. Symptoms may not persist following initial presentation, e.g. if associated infection is resolved by a course of antibiotics. Investigations should, however, be undertaken if the cause of haematuria is unclear.

8.8 A 35-year-old man notices blood in his urine each morning. He has no discomfort and is otherwise well. Unless the haematuria persists this man may decide not to visit his GP. How might you encourage him to report the haematuria? What anxieties might he have about reporting to his GP?

MEDICAL MANAGEMENT

Investigations Diagnosis may be aided by physical examination, a full blood count, urea and electrolyte estimation and other biochemical assays. Examination of an MSU specimen will exclude evidence of infection. If the patient has microscopic or macroscopic haematuria and an infection has been excluded, the patient's upper urinary tract and bladder must be investigated. Table 8.4 lists the principal diagnostic investigations; in many respects these will be similar to those used in diagnosing prostatic disorders.

Table 8.4 Principal diagnostic investigations for tumours of the bladder

Investigation	Reason
Intravenous urogram (IVU)	If presenting feature is haematuria, IVU may exclude renal pelvic carcinoma
Cystoscopy and biopsy	Suspicious lesions can be examined for abnormal cells
CT scan	If local spread of tumour is suspected
Chest X-ray	If metastatic spread is suspected
Bone scan	
Liver function tests	

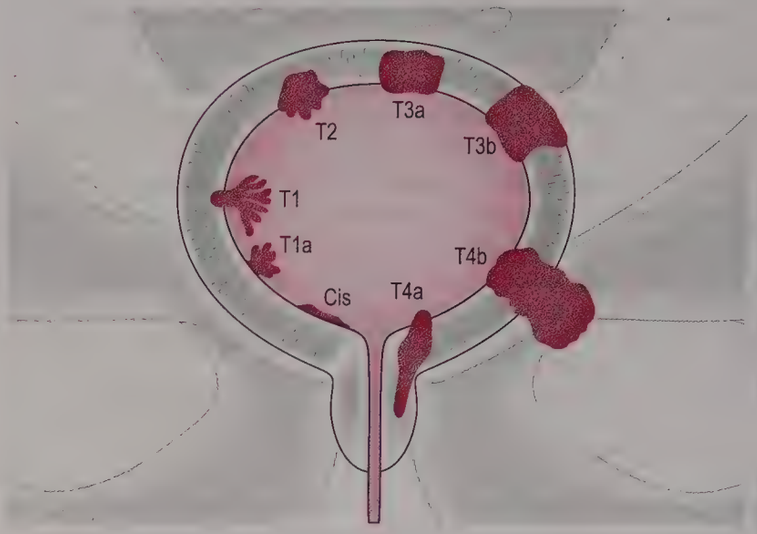

Fig. 8.11 Categories of bladder tumours. Cis, carcinoma in situ. (Garden et al 2002.)

Staging The staging of bladder tumours is illustrated in Figure 8.11 (see also Ch. 31). In addition to staging according to the actual tumour, the pathologist will grade transitional cell tumours according to the invasion differentiation of the lesion (National Institute of Clinical Excellence 2002).

Treatment The choice of treatment will depend on the type of tumour and the degree of invasion of local tissue, as determined by cystoscopy (see Table 8.5). Superficial lesions without muscle invasion can be treated by excision of the tumour through the urethra — transurethral resection of tumour (TURT) or cystodiathermy. Irrigation of the bladder may be used to keep the bladder clear of blood clots following transurethral resection (see p. 379).

For invasive bladder tumours, a combination of surgery (i.e. total cystectomy), radiotherapy and chemotherapy may be used.

Total cystectomy involves removing the lower ureters, bladder, prostate, urethra and lymphatics in men, and also, in women, the gynaecological organs. Urinary diversion is required and is most commonly ileal conduit and stoma formation (see Fig. 8.12). With this type of diversion, the ureters are anastomosed to an isolated section of the bowel (ileum with blood supply) and the loop brought to the abdominal surface as a stoma. This is a major procedure which will fundamentally affect the lifestyle of both the patient and family members.

Developments in reconstructive surgery have led to the use of bladder substitutes in place of urinary diversion, i.e. part of the intestine is anastomosed directly to the membranous urethra which provides a reservoir for urine; however, this technique is not appropriate for everyone as it requires major surgery.

For further information, see Downey (2000), Trotto (2000) and Pashos et al (2002).

Radiotherapy is normally given as an external treatment for bladder carcinoma over a 6-week period. It may be used as a palliative measure or in conjunction with surgery and/or chemotherapy, pre- or post-treatment. The age and general condition of the patient will determine whether treatment is given on an outpatient or inpatient basis. Sometimes the severity of the patient's symptoms leads to conversion from outpatient to inpatient care and a short period respite from the treatment plan to allow the patient to recuperate before progressing to the next treatment.

Chemotherapy Treatment of invasive bladder cancer with systemic chemotherapy is under investigation. Regimens of treatment vary. Some patients receive care on a

Table 8.5 Treatment choices in tumours of the bladder

Tumour	Treatment	Comment
Localised, well-differentiated tumour	Diathermy	Annual cystoscopy to check for recurrence
Histologically malignant tumours: — extensive superficial — locally invasive	Chemotherapy: intrarenal Radiotherapy Transurethral resection of tumour (TURT)	Annual cystoscopy to assess effect and check for recurrence
Failure to control tumour spread/severe symptoms	Cystectomy and ureter transplant to ileal conduit (urinary diversion)	Radiotherapy may be used to reduce size of tumour prior to surgery
Inoperable tumour	Analgesics Palliative radiotherapy	
Metastatic spread	Systemic chemotherapy	An option although success is limited

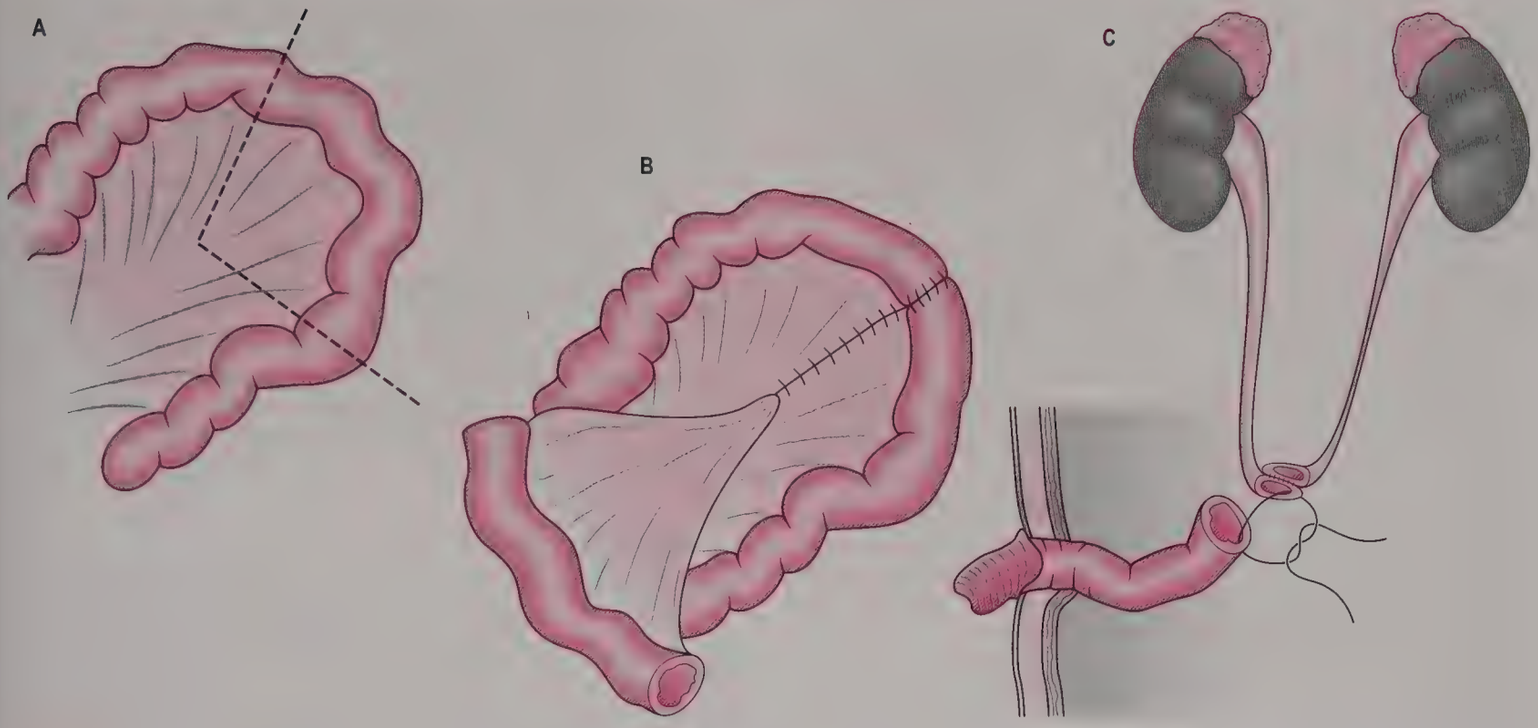

Fig. 8.12 Ileal conduit urinary diversion. A, B: Isolation of segment of terminal ileum. C: Fashioning of ureteroileal anastomosis. The stoma is made to protrude from the skin to minimise skin contact with urine and so reduce irritation.

day-care basis, receiving i.v. injections, while others attend for inpatient hospital care involving 2–3 days in hospital for each cycle of treatment. (For further details on systemic chemotherapy, refer to Ch. 31.)

Intravesical chemotherapy may be offered in some cases. The recurrence of superficial bladder tumours resected endoscopically is approximately 65%. Recurrent tumours are usually of the same type and stage as those previously resected. Further endoscopic resection may be the treatment of choice, but intravesical chemotherapy is also given. A urethral catheter is inserted and the chosen medication is instilled via the catheter. Treatment may be weekly, monthly or bimonthly, depending upon the type of tumour and the medication used.

Once the medication is instilled the catheter can be removed. The patient is asked to try to avoid passing urine for an hour and is asked to turn from back to front to sides every 15 min, in order to wash the medication around the bladder. The nurse administering the treatment should bear in mind that this patient may have difficulty in postponing the passing of urine for up to 1 h because of symptoms of frequency and bladder irritability. The patient should be reassured that an inability to comply with this request is not a sign of 'failure'.

The side-effects of the medications used in this treatment vary, but chemical cystitis leading to inflammation and bladder irritability, urgency and frequency is common. Sensitivity rashes are seen less commonly, as are more severe effects such as systemic toxicity and bone marrow suppression.

Since the medications used are toxic agents, precautions should be taken, such as wearing protective goggles, gloves and gowns when preparing and administering treatments and when discarding used equipment.

After the treatment has been completed, the patient should be advised that urine passed will contain chemical substances that will irritate the skin and that leakages or dribbles should be washed off immediately.

Effectiveness of treatment with intravesical chemotherapy varies considerably from individual to individual.

NURSING PRIORITIES AND MANAGEMENT: Total cystectomy and urinary diversion

Preoperative care

Psychological preparation (see Case History 8.5)
The patient admitted for cystectomy and urinary diversion may already know the nursing and medical staff on the ward from a previous admission. Staff should endeavour to build upon this rapport and provide information both verbally and in written form to prepare the patient for the physical effects of the operation, particularly the formation of a stoma. Considerable psychological adjustment may be required on the part of the patient to come to terms with the lifestyle changes that will be necessary and with the alteration in body image that may occur.

The patient is likely to have concerns relating to any pain that will be experienced, whether the operation will effect

CASE HISTORY 8.5
Mr L

Mr L, a 58-year-old married man employed as a bus driver, was diagnosed 5 years ago with cancer of the bladder. He was treated with regular cystoscopy and transurethral resection of tumour. Six months ago the tumour was found to be stage T2, and a course of chemotherapy was prescribed. Recent cystoscopy showed that this treatment had not been successful. Total cystectomy is now being considered for this patient.

a 'cure', how his family will cope in his absence and after his return home, and how he will appear to other people. The contribution of the named nurse and the stoma therapist in answering questions and allaying fears in the preoperative period is invaluable. It may be helpful to arrange for the patient and his family to meet with someone who has a stoma.

It should be noted that patients rarely ask about the effect surgery may have on sexual function. However, one of the side-effects for male patients of this life-saving procedure is impotence. This important matter must be discussed with male patients and their partners prior to the surgery in order to help them return to and lead a normal life (Black 2000).

The patient may gain confidence from the knowledge that his community nurse and GP as well as a stoma nurse are available to support him. He should be given a contact telephone number to use in the event of difficulty. He should be reassured that any problems and concerns, however small, can be discussed as he makes the challenging adjustment from hospital to home.

For further information, see Black (2000).

8.9 How can the nurse help Mr L in Case History 8.5 to come to terms with his disappointing news and the prospect of total cystectomy?

8.10 Mr L is provided with an indwelling catheter which will remain in situ until he can be admitted to hospital. What advice and support could you offer to Mr L and his wife to ensure that no catheter-related problems develop? What part can the community nurse play? Review Boxes 8.8 and 8.9.

Physical preparation

The stoma will be sited on the abdomen below the waist, normally on the right-hand side. Considerations in choosing the exact site include:

- the patient's build
- access for the surgeon
- previous surgery
- access for the patient following surgery
- type of clothing to be worn after the surgery.

The following procedures are carried out in preparation for surgery:

1. The patient is kept on a fluid only or low-residue diet at commencement of bowel preparation.
2. The bowel is cleared of faeces. This may be by means of an enema or a high colonic washout and is carried out 2 days prior to the operation. Bowel sterilisation with systemic and local antibiotics may be prescribed.
3. Prophylactic antibiotic therapy is commenced preoperatively (and continued postoperatively).
4. The skin is shaved from nipple to knee, or according to the surgeon's wishes (see Ch. 26).
5. The chosen site for the stoma is marked.

Postoperative care

Return from theatre (see Nursing Care Plan 8.2)

Following surgery and recovery from anaesthetic, the patient will return to the ward. A nasogastric (NG) tube will be in place for aspiration of gastric contents. Examination will reveal a midline incision, covered by a surgical dressing, and a wound drain. The stoma, in the pre-marked position, should have a moist, red appearance and be covered by a collection bag fitted with a drainage tap and autoreflux valve to prevent back-flow of urine when the patient is lying flat.

Infant feeding tubes which form temporary splints across the ureteroileal anastomosis may be seen protruding from the stoma. The splints, one for each ureter and inserted at surgery, pass through the ileal loop and along the ureters across the junction of the anastomosis. The support provided by the splints maintains patency and reduces the risk of urine leakage from the anastomosis before healing has taken place.

The recovery period

The NG tube will be in place for 24–48 h, or until bowel sounds have returned. Drains may be removed when discharge is less than 50 mL/24 h; this is usually at 4–5 days postoperatively. Removal of splints from the stoma can usually be done at 10–14 days, and removal of sutures at 10 days. Assessment by the dietitian and provision of a diet plan may aid wound healing and recovery by ensuring an adequate nutritional intake.

During this time, the stoma nurse will visit. Working with the named nurse, they will teach the patient how to clean the stoma and change the bag and flange on a daily basis. The patient should be shown how to cut the flange to shape and fit it in position with the bag.

Patients differ in the time it takes them to come to terms with management of their stoma. Some show no interest at first in looking after the stoma and need a lot of encouragement to do so. Planning a programme with the patient, identifying goals to be attained and involving close relatives/carers will help to ensure successful self-care. A second visit from an individual who has already made the adjustment to life with a stoma may also help.

Discharge

Provided no complications have arisen, by 10–14 days after the operation the patient and nurse should be planning for discharge home. The first follow-up appointment will usually be scheduled for 6–8 weeks after the operation. Thereafter, outpatient appointments will be arranged at longer intervals, but will continue for life. To ensure optimal function and prevent long-term complications (see Box 8.11), periodic i.v. urograms or loopograms may be performed. A loopogram is the radiological examination of the bowel segment used to form the urinary diversion; this investigation may reveal any disorder of filling or capacity.

RENAL DISORDERS

Glomerulonephritis

The term 'glomerulonephritis' refers to a group of disorders characterised by inflammation of the glomeruli of the kidney. The disease may be primary to the glomeruli or secondary to a systemic disorder. Box 8.12 lists primary and secondary causes of glomerulonephritis.

Nursing Care Plan 8.2 Nursing care in the first 24 h following total cystectomy and urinary diversion

Potential problem	Action	Desired outcome
1. **Cardiovascular instability and hypovolaemic shock due to haemorrhage and pain**	• Record vital signs and report any deviations from normal range • Monitor and mark extent of blood loss evident on wound dressing • Record blood loss in drains and report if in excess of 100 mL/h	Cardiovascular stability Minimal blood loss Minimal pain
2. **Pain**	• Observe patient for distress. Assess pain using an appropriate pain assessment tool (NB: generalised abdominal pain may indicate peritonitis caused by leakage from anastomosis) • Administer prescribed analgesics • Evaluate effect after 30 min by asking patient if pain has been relieved	Patient is pain-free
3. **Fluid and electrolyte imbalance**	• Measure and record hourly urine output (NB: output <30 mL could indicate obstruction or possible leakage from ureteroileal anastomosis leading to peritonitis) • Balance all fluid output against all fluid input in 24 h • Observe for evidence of dyspnoea and dehydration, e.g. dry skin and mouth • Observe for vomiting	Fluid and electrolytes maintained at satisfactory levels
4. **Paralytic ileus**	• Remain nil by mouth • Perform NG aspirations hourly/free drainage • Administer antiemetics as necessary	Comfort is maintained until return of bowel sounds
5. **Deep vein thrombosis (DVT) and/or pulmonary embolism (PE)**	• Supply anti-embolic stockings preoperatively • Encourage movement of lower limbs • Observe for evidence of DVT or PE	Circulatory integrity is maintained
6. **Chest infection**	• Encourage deep breathing and coughing • Refer to physiotherapist • Position patient as upright as possible	Chest is clear with no evidence of infection
7. **Wound infection**	• Observe wound for leakage, check drains hourly • Record temperature and report pyrexia • Leave dressings undisturbed for 48 h if dry	Wound heals without infection
8. **Development of pressure ulcers**	• Change patient's position regularly and observe for reddening • Use a risk assessment scale to assess patient's needs • Ensure skin is clean and dry • Use Spenco mattress if necessary	Skin integrity is maintained
9. **Inability to perform personal hygiene tasks**	• Provide bed bath and mouth care	Patient is clean and comfortable
10. **Anxiety**	• Ensure the nurse call system is close at hand at all times • Discuss any concerns with patient. Provide information, but take post-anaesthetic drowsiness into account • Evaluate patient's understanding of information given. Return next day and ask if there are further questions or concerns	Patient understands what is happening and feels secure in the care provided

Box 8.11

Complications following total cystectomy

Specific complications post-cystectomy
- Breakdown of anastomosis
- Breakdown of blood supply to stoma (necrosis)
- Pelvic abscess
- Poor wound healing post-radiotherapy
- Prolapse of stoma
- Renal failure
- Retraction of stoma
- Urinary infection

Later complications
- Depression
- Prolapse of stoma
- Recurrence of tumour
- Retraction of stoma
- Stenosis of stoma
- Stone formation
- Urinary infection
- Urinary reflux

Box 8.12

Causes of glomerulonephritis

Primary causes
- Minimal change glomerular disease
- Proliferative glomerulonephritis
  - — mesangial (mesangium is a cellular network in the glomerulus that supports the capillary loops)
  - — diffuse capillary
  - — focal
  - — IgA nephropathy
  - — mesangiocapillary
  - — crescentic (Goodpasture's syndrome)
  - — membranous glomerulonephritis
  - — focal segmental glomerulonephritis

Common secondary causes
- Systemic lupus erythematosus
- Polyarteritis
- Diabetes mellitus
- Amyloidosis
- Henoch–Schönlein purpura
- Malarial nephropathy

Proteinuria, haematuria, hypertension, nephrotic syndrome and renal impairment characterise this disease but the severity of these effects will vary between individuals. Presentation is usually described in terms of a range of clinical syndromes, but accurate diagnosis requires histological investigation.

PATHOPHYSIOLOGY

Histological examination of renal tissue will demonstrate inflammation in the majority of cases, but it is also possible to find minimal change and no evidence of an inflammatory process. The disease process results from a defect in the immune response, such as a hypersensitivity to an exogenous antigen. The antigen–antibody reaction results in the formation of insoluble immune complexes that circulate in the blood and, instead of being ingested by macrophages, reach the kidney, where they become 'trapped' and set up a damaging inflammatory reaction in the delicate filtration structure. As a result of this:

- protein and red blood cells pass through the filtration fenestration
- the osmotic pressure of the blood plasma falls, leading to oedema
- sodium and water are retained, as are waste products and potentially toxic substances.

It would seem that many cases of acute glomerulonephritis occur 1–3 weeks after an 'innocent' streptococcal infection such as tonsillitis or otitis media, most commonly in children or adolescents; however, only 5% of these infections lead to glomerulonephritis. In recent years, there has been a significant reduction in the incidence of post-streptococcal glomerulonephritis as a result of better hygiene and the use of antibiotics. The disease can range from a mild, transitory, asymptomatic condition to a very severe form that precipitates acute renal failure, cardiac failure and convulsions.

Common presenting symptoms are exemplified in Case History 8.6.

For further information, see O'Callaghan & Brenner (2000) and Thomas (2002).

MEDICAL MANAGEMENT

Tests and investigations A patient such as T (see Case History 8.6) would probably be admitted to hospital, where investigations would confirm the diagnosis. This would be especially likely if there were symptoms of breathlessness or a risk of convulsions, which would indicate cardiac or cerebral complications. Investigations would include:

- urinalysis
- MSU
- full blood count and urea and electrolyte estimation
- throat swab

CASE HISTORY 8.6

T

T was an active 15-year-old schoolgirl. In September she developed a sore throat which completely robbed her of her voice for several days. It didn't last long and she was used to such minor ailments. In early October she began to notice a feeling of weariness that was quite uncharacteristic. She found herself longing for her bed as the day progressed and declined evening invitations for the usual lively events. On waking one morning, she noticed that her face appeared rather puffy and, on close inspection, found she had puffy ankles. Her parents became concerned and T made an appointment to see her doctor. She now began to consider other problems. She had lost her appetite, often felt rather sick and had noticed that her urine had been rather smoky and darker in hue.

T's GP identified significant proteinuria and haematuria, an elevated blood pressure and marked oedema. A diagnosis of acute glomerulonephritis was made.

Box 8.13

Life-threatening complications of glomerulonephritis

Acute hypertensive encephalitis leading to convulsions (see Ch. 9)

Management
- Maintain airway
- Monitor level of consciousness (e.g. with Glasgow Coma Scale)
- Give anticonvulsant therapy, e.g. i.v. diazepam
- Give hypotensive agents

Pulmonary oedema/cardiac failure (see Chs 2 and 3)

Management
- Give oxygen therapy
- Monitor cardiovascular status
- Give diuretic therapy, e.g. i.v. furosemide
- Give opiate analgesics, e.g. i.v. morphine combined with an antiemetic

Acute renal failure

Management
- Dialysis

- chest X-ray
- ECG
- ultrasound scan
- biopsy.

Treatment The aim of treatment is to reduce renal workload, restore and maintain fluid and electrolyte status and prevent uraemia. Thus management aims to prevent serious complications from occurring (see Box 8.13).

NURSING PRIORITIES AND MANAGEMENT: Glomerulonephritis

Major nursing considerations

Promoting rest
Bed rest is a necessity, especially in the early period, to reduce the workload of both the kidneys and the heart. This can pose quite a challenge in the care of younger patients. Time needs to be spent with the patient, explaining why rest is so important.

Maintaining fluid and electrolyte balance
While renal function is impaired and fluid overload poses a very real problem, fluid and sodium intake must be restricted. Potassium levels in the blood must be closely monitored and, if necessary, dietary modification made or ion exchange resins given. If hypertension is marked, antihypertensive medication may be required.

Preventing uraemia
While the kidney is impaired, the waste products of metabolism will build up in the blood. To prevent this, a protein-restricted diet will be necessary. Calorie intake can be maintained with carbohydrates, and vitamin supplements can be given. This diet must also be low in salt and many patients find meals unpalatable. The dietitian can contribute greatly to the patient's well-being by ensuring that the restricted diet includes at least some of the patient's favourite foods.

Preventing infection
If a streptococcal link is confirmed, penicillin may be prescribed. All patients with renal impairment are prone to infection. All procedures necessary for the prevention of cross-infection must be adhered to (see Ch. 16, p. 664).

Promoting convalescence and the maintenance of health
Most patients make a full recovery, but convalescence may take as long as 2 years. The acute condition can resolve fairly rapidly, and the majority of people recover normal renal function within a couple of months. Such patients often feel better quite quickly and it can be hard to persuade them that restrictions are still needed. Proteinuria can persist and regular monitoring will be necessary. After discharge, support for the patient and family will ensure that necessary lifestyle adjustments are made for the initial months. Exercise should be gentle and energetic sports activities avoided. Any infection should be treated seriously and medical advice sought.

Incomplete resolution and permanent glomerular damage can result in chronic glomerulonephritis and all the associated symptoms of renal impairment. Failure of function may be such that dialysis is required (see p. 391).

Nephrotic syndrome (see Case History 8.7)

Nephrotic syndrome encompasses a group of symptoms including proteinuria, oedema and lipidaemia. It can be a manifestation of certain forms of glomerulonephritis but may also occur as a complication of diabetes mellitus or amyloid disease, whereby insoluble starch-like deposits occur in kidney tissue. Often no cause can be found.

PATHOPHYSIOLOGY
In the normal kidney, protein molecules passing across the glomerular membrane are reabsorbed in the kidney tubules. However, where increased glomerular permeability occurs, increased numbers of protein molecules enter the tubules. When the capacity of the tubule to reabsorb protein is exceeded, protein is lost in the urine. Further protein is lost following catabolism of protein reabsorbed in the tubule, resulting in hypoproteinaemia. Muscle wasting can result from the catabolism of muscle protein as the body tries to maintain normal plasma protein levels. A low plasma protein reduces plasma osmotic pressure and fluid leaks into the extracellular areas. The resultant oedema occurs in dependent areas and may give rise to ascites in severe cases. Intravascular volume is maintained in many cases. How this occurs is not fully understood, but activation of the renin–angiotensin–aldosterone mechanism is thought likely.

Clinical features This syndrome is characterised by heavy proteinuria and hypoproteinaemia and by oedema. These patients generally have a low urine output and low urine

CASE HISTORY 8.7
Mrs Y

Mrs Y, aged 29, presented to her GP with a 3-week history of anorexia and tiredness. Examination revealed no muscle wasting but did show a moderate degree of ankle and sacral oedema. Mrs Y said that her complexion was naturally pale but that her face seemed to have become puffy in the last week or so. Urine testing showed heavy proteinuria. Blood samples were taken for biochemical analysis.

A clinical diagnosis of nephrotic syndrome was made and she was prescribed 80 mg of furosemide daily and a diet with no added salt. Mrs Y was advised that a renal biopsy might be necessary. She resisted immediate admission to hospital and the GP and district nurse arranged to attend Mrs Y's home on alternate days.

Mrs Y wished to stay at home as she had a 3-year-old son and a 6-month-old daughter to care for. On weekday mornings she took her son to a nursery half a mile away and collected him at midday. The family were dependent financially on Mr Y, who worked 200 miles away and was able to return home only at weekends.

One of the major difficulties Mrs Y will face is dealing with the increased diuresis that results from diuretic therapy. A heavy diuresis will occur for about 4 h following each dose. This may make it virtually impossible for Mrs Y to leave the house. Taking her son to the nursery and shopping for household necessities may become difficult. Confined to the house with two small children and a husband 200 miles away, Mrs Y may become socially isolated. The 'no-added-salt diet' may also pose a problem for Mrs Y, particularly if she enjoys salty foods.

The symptoms that Mrs Y has experienced are uncomfortable and frightening. It has been suggested to her that she might need a renal biopsy to determine the cause of her symptoms. It is likely that she will be worried and may need time to voice her concerns and perhaps obtain information and reassurance about her physical condition. It is possible that she may feel unable to carry out all the care for her children and require assistance at some times during the day.

sodium. Derangement of lipoproteins is evident and loss of fibrinogen in the urine can occur. Infection and thrombosis are common complications.

MEDICAL MANAGEMENT

Treatment The main aim of treatment is to reduce oedema. Diuretic therapy can be adjusted according to the severity of the oedema and small maintenance doses can be administered when the oedema is under control. Severe oedema may also be treated by the administration of salt-poor albumin to temporarily increase plasma osmotic pressure. Patients are advised to adhere to a diet free from added salt.

Identification of the underlying disease process, possibly by renal biopsy and histological examination, will dictate the nature of ongoing treatment. In many patients, chronic renal failure will eventually develop.

8.11 Since Mrs Y in Case History 8.7 has young children, the health visitor will already know this family well. The effectiveness of intervention will depend on the quality of communication between members of the primary health care team. What are the essential features of teamwork that will contribute to the well-being of Mrs Y and her family? Draw from the following reference as you consider these issues in a discussion group.

For further information, see Thomas (2002).

Acute renal failure (ARF)

Acute renal failure, the sudden and severe reduction in previously normal renal function, may result from primary renal disease but is more frequently associated with other organ failure. Failure is often reversible, but should the kidneys fail to recover, permanent treatment will be required.

A mortality rate of up to 50% is associated with acute renal failure, the actual risk depending on the type of patient, the cause of failure and other organ involvement (Thomas 2002). Where death occurs, renal failure is often not the primary cause.

PATHOPHYSIOLOGY

Causes The causes of acute renal failure may be classified into three categories — pre-renal, renal and post-renal — each having a different physiological location.

Pre-renal causes are those in which a loss or decrease in renal perfusion results in renal ischaemia. They include:

- extracellular depletion, resulting from large GI loss such as vomiting, diarrhoea or NG aspiration; urinary loss due to polyuria or diuresis; loss from the skin, e.g. sweating or burns
- circulating volume loss, as in haemorrhage or hypoalbuminaemia
- reduced cardiac output, as in cardiac arrest, valvular disease, cardiac tamponade
- vascular disease, e.g. renal artery thrombosis or embolism.

Renal causes include conditions that impair renal function by damaging the structure of the kidney (tubules, interstitium, glomeruli or capillaries). If tubular damage occurs, this is termed acute tubular necrosis (ATN), although microscopically the tubules usually show dilatation rather than necrosis. ATN is often caused by prolonged pre- and post-renal events.

Nephrotoxic substances can also result in acute failure. These include:

- medications, e.g. cephalosporin antibiotics and non-steroidal anti-inflammatory drugs
- exogenous chemicals, e.g. heavy metals, phenols, carbon tetrachloride, chlorates, ethyl glycol
- bacterial toxins, particularly those released in Gram-negative septicaemia (see Ch. 18, p. 727).

Post-renal causes are mainly attributed to obstruction. The most common of these is bladder output obstruction which may be due to prostatic hypertrophy, tumours or calculi.

Clinical features Acute renal failure proceeds through four phases: onset, oliguric, diuretic and recovery. The onset phase is the time from the initial insult to the onset of oliguria. The oliguric phase is characterised by a urine output of less than 400 mL/24 h; however, some patients may be anuric. The oliguria is accompanied by abnormal

plasma levels of creatinine, urea and electrolytes. The effects of acute fluid overload and hyperkalaemia (K^+ >6 mmol/L) can result in sudden death.

The patient may complain of anorexia, nausea and vomiting. Increased respiration due to pulmonary oedema and acidosis can occur. Drowsiness, confusion and coma may follow.

MEDICAL MANAGEMENT

Tests and investigations will depend on the suspected cause and on the immediacy of the presentation but may include:

- full blood count and urea and electrolyte estimation
- urinalysis, MSU, 24-h collections of urine for creatinine clearance
- X-ray of kidneys, ureters and bladder
- ultrasound
- renal biopsy.

Treatment The goal is to restore biochemical balance and prevent ARF progressing. The onset of renal failure must be identified early to minimise damage and, if possible, prevent the necessity for dialysis. The priorities of treatment are as follows.

Treating the cause, e.g. correcting hypovolaemia and increasing renal perfusion; managing sepsis; relieving any urinary obstruction.

Reversing, restoring and maintaining fluid and electrolyte status:

- *Hyperkalaemia.* Immediate measures may be required to correct hyperkalaemia, which could cause lethal dysrhythmias. Cardiac monitoring is essential, in particular observing for any changes in cardiac rhythm. Hyperkalaemia can be corrected in the short term by i.v. insulin–glucose infusion or sodium bicarbonate, either of which will shift potassium into the cells. Other measures include the administration of ion exchange resins, which when administered orally or rectally remove potassium ions.
- *Hyponatraemia and hypernatraemia.* In the oliguric state there is a danger of hyponatraemia, due to the risk of fluid overload and to the failure of the damaged tubules to reabsorb sodium. However, hypernatraemia can also be a problem in pre-renal ARF, as mechanisms instituted retain sodium in order to restore blood volume. Fluid intake must be restricted to the equivalent of insensible loss plus the previous day's urinary output. Sodium intake must be monitored closely.
- *Uraemia.* The inability to excrete the waste products of metabolism is managed by dietary restrictions, but ensuring adequate calorie intake to prevent the patient becoming catabolic. Parenteral nutrition may be necessary and potassium intake will be restricted (see Ch. 21, p. 806).
- *Metabolic acidosis.* The loss of the kidneys' buffering function, the electrolyte imbalance and the increased anaerobic respiration by damaged renal cells all result in acidosis. In the short term, this is managed by i.v. sodium bicarbonate.

If acute renal failure is very severe, persists or worsens, dialysis will be necessary.

NURSING PRIORITIES AND MANAGEMENT: Acute renal failure

Major nursing considerations

The care of patients with ARF will involve a large multidisciplinary team and may be carried out either in an intensive care setting or on a ward, depending on the condition of the patient. Priorities of nursing intervention will be as follows:

- to reduce the patient's anxieties and recognise the risk of altered consciousness due to uraemia and electrolyte imbalance
- to control fluid and electrolyte balance by:
  - — monitoring cardiac status for signs of dysrhythmias
  - — monitoring pulse, respiration and blood pressure for signs of overload and hypertension
  - — restricting fluid intake and measuring and recording urine output and other losses; daily weighing may be required
  - — administering prescribed medication and carrying out urinary assays as required
- to maintain nutritional status within the necessary limitations by the oral, enteral or parenteral route and to monitor the nutritional status of the patient
- to prevent infection due to uraemia by strict asepsis with regard to infusion sites and catheter management and by close monitoring of temperature and the patient's reported symptoms
- to manage anaemia by the safe administration of blood transfusions, if required
- to promote comfort at all times.

8.12 Reconsider the care of T, who had acute glomerulonephritis (see Case History 8.6). Severe forms can result in acute tubular necrosis and acute renal failure. Draw up a care plan that would have met T's needs should ARF have developed.

The diuretic and recovery phases

The oliguric phase of renal failure may last 1–2 weeks and is followed by the diuretic phase, which indicates that renal function is returning. This is often a time of relief, but because the kidneys will not yet have regained their capacity for selective reabsorption, urine output can be as much as 4 L/day. This, in itself, could potentiate dehydration and electrolyte imbalances. Close monitoring must therefore continue. The recovery phase that follows can last several months and will require close medical follow-up of renal function. Convalescence in the form of rest, restricted activity, the avoidance of infections and alertness to any symptoms that might indicate renal problems may be a source of considerable stress to the patient, who may also be concerned about fulfilling family and work responsibilities.

For further information, see Albright (2001) and Thomas (2002).

8.13 What community support services might help to alleviate such stress?

Chronic renal failure

Chronic renal failure is the gradual and progressive reduction in renal function. Failure may occur over weeks, months or even years. Each year, acceptance rates for renal replacement therapies are increasing, at a rate that exceeds death rates, and this is predicted to continue for the next 10 years (DH 2004). The available treatments are dialysis, haemodialysis, peritoneal dialysis or transplantation, which may be from cadaveric or living related donors (Thomas 2002).

PATHOPHYSIOLOGY

Any disorder which damages kidney function can result in renal failure (see Box 8.14).

Clinical features In the initial stages of failure the patient may be asymptomatic. Proteinuria, hypertension, anaemia or an elevated blood urea are, however, common presenting features.

As renal failure progresses, the patient may complain of fatigue, lethargy, pruritus, nausea, vomiting and indigestion. Breathlessness on exertion, headaches, visual disturbances, pallor and loss of libido may also be noted. A reduced immune response occurs, making the patient prone to infection, particularly of the urinary tract (see Ch. 16).

Metabolic bone disease, generalised myopathy, neuropathy and metabolic acidosis can be seen in advanced stages of renal impairment. Atherosclerosis due to altered lipid and carbohydrate metabolism and hypertension may also occur. Vascular calcification and pericarditis may also be identified.

Box 8.14

Aetiology of chronic renal failure

Congenital and inherited diseases
- Polycystic kidney disease (infantile or adult)
- Alport's syndrome
- Fabry's disease

Vascular disease
- Arteriosclerosis
- Vasculitis (polyarteritis nodosa [PAN], systemic lupus erythematosus [SLE], scleroderma)

Glomerular disease
- Proliferative GN
- Crescentic GN
- Membranous GN
- Mesangiocapillary GN
- Glomerulosclerosis
- Secondary GN (PAN, SLE, amyloidosis, diabetic glomerulosclerosis)

Interstitial disease
- Chronic infective interstitial nephritis (chronic pyelonephritis)
- Vesicoureteric reflux
- Tuberculosis
- Analgesic nephropathy
- Nephrocalcinosis
- Schistosomiasis
- Unknown origin

Obstructive uropathy
- Calculus
- Retroperitoneal fibrosis
- Prostatic hypertrophy
- Pelvic tumours
- Other causes

Reproduced with permission from Haslett et al (2002).

MEDICAL MANAGEMENT

Treatment aims to identify the cause, extent and complications of the renal failure and to preserve useful renal function for as long as possible.

Where hypertension is evident, antihypertensive drugs may be used to reduce and control blood pressure gradually. Lifestyle advice should also be given to assist with reducing blood pressure, e.g. stopping smoking and losing weight.

Fluid restriction may be required if the glomerular filtration rate is less than 5 mL/min as fluid overload can exacerbate problems with hypertension. Poor urine concentration can, however, result in a urine output of more than 2.5 L/24 h, in which case an intake of about 3 L/day is required.

Dietary measures are likely to include potassium and phosphate restrictions. Sodium restriction is not indicated unless there is evidence of oedema, hypertension or cardiac failure. In the case of salt-losing conditions, sodium supplements may be required. A diet with no added salt may be appropriate in some cases.

Regular monitoring of biochemistry and assessment of symptoms allow treatment to be readjusted and progression of the disease to be assessed.

Dialysis in the form of haemodialysis or peritoneal dialysis are the treatments available to replace the excretory functions of the kidneys (see Box 8.15). At present, transplantation is restricted by a lack of available cadaver donor kidneys. However, for some patients, it may be possible to consider a close family member as a live donor.

NURSING PRIORITIES AND MANAGEMENT: Chronic renal failure

General considerations

Nursing management requires a strategy to help the patient and family come to terms with an illness for which there is no cure and in which sudden death can occur. Nursing intervention should aim to help the patient maintain a good quality of life by developing ways to cope with the constraints of the treatments and the possibility of complications occurring.

Adherence with treatment

Patient beliefs about the value and benefit of a treatment may differ markedly when compared with the priority given to the same treatment by the nurse. Failure to adhere to diet and fluid restrictions may indicate that the patient has an underlying problem, or is not coping with some aspect of the treatment; alternatively, there may be a lack of understanding of the importance of the treatment regimen.

Box 8.15

Dialysis

Principles

Dialysis requires a semi-permeable membrane to combine three principles — diffusion, osmosis and filtration — in order to permit the removal of metabolic wastes, excess electrolytes and fluids from patients with renal failure.

Diffusion

Diffusion is the movement of molecules from an area of high concentration, across a semi-permeable membrane, to an area of low concentration. This process continues until the concentrations in each compartment are the same.

Osmosis

Osmosis is the movement of a fluid or solvent from a lower concentration to a higher one.

Filtration

Filtration is the movement of both solvent and solute across a semi-permeable membrane under pressure.

Types

Haemodialysis

Haemodialysis requires a means of vascular access, e.g.:

- *Percutaneous access*, including subclavian, femoral and jugular lines which are either temporary or permanent.
- *Arteriovenous fistula and arteriovenous grafts (synthetic).* A fistula involves the anastomosis of an artery and a vein. The increased blood flow causes increased pressure on the vein walls which leads to thickening and dilatation (arterialised); this allows the repeated insertion of needles for dialysis. This developmental stage takes about 12 weeks. The fistula can be seen as well as felt.

The blood is pumped from the patient to an artificial kidney (the dialyser) and back to the patient, having now been cleansed by the dialysate. The artificial kidney is normally a disposable hollow fibre or flat plate dialyser; different dialysers consist of different membranes. The type of membrane used is important as part of the patient's individualised dialysis prescription. Issues to consider are desired clearance, fluid removal and biocompatibility.

Peritoneal dialysis

The peritoneal membrane serves as the semi-permeable membrane for dialysis. A temporary or permanent Tenckhoff catheter is placed into the abdomen. The dialysate is instilled into the abdomen (usually 2 L at each session). A set time elapses and the dialysate is drained out.

Continuing ambulatory peritoneal dialysis (CAPD)

Two litres of dialysate are instilled into the peritoneal cavity and left in place, usually for 6 h, when it is exchanged. Once patients have been instructed in this method, they can be independent, visiting the hospital only for clinic appointments or when any problems arise; the main potential problems are peritonitis, dehydration and constipation.

Other methods

Other methods of renal replacement therapy are often used in intensive care, including:

- continuous arteriovenous haemofiltration (CAVH)
- continuous arteriovenous haemodiafiltration (CAVHD)
- continuous venovenous haemofiltration (CVVH)
- continuous venovenous haemodiafiltration (CVVHD).

Knowing the patient and having an understanding of the patient's social and cultural background can give insight into behaviour with regard to a particular treatment.

Major patient problems

Fatigue and lethargy characteristic of chronic renal failure can reduce both ability and performance at work. Absence from work due to sickness or attendance at hospital may result in unemployment or reduction of income. Feelings of helplessness, hopelessness and depression are often expressed by patients with a chronic illness (Thomas 2002). Loss of control over many aspects of life and low self-esteem are likely to influence family relationships. Transplantation is acknowledged as the treatment of choice for a person with end-stage renal disease. A successful transplant offers the patient freedom and independence as well as an enhanced quality of life (see Ch. 32).

For further information, see Thomas (2002).

Living with peritoneal dialysis

Peritoneal dialysis (PD) is performed either as continuous ambulatory peritoneal dialysis (CAPD) or automated peritoneal dialysis (APD). CAPD is a continuous treatment, generally performed four times a day; APD is achieved by machine, generally overnight in the patient's own home. PD offers patients a greater degree of control over their treatment and lifestyle. While the number of fluid exchanges per day will be prescribed by the doctor, the timing of each exchange can be decided by the patient, to fit in with family life or work commitments. In addition, freedom to be away from home for visits or holidays is possible. For holidays abroad, the dialysate manufacturer may be able to deliver fluid requirements to the holiday destination.

The need for regular fluid exchanges and aseptic technique can be limiting for some patients. Performing the exchange in a designated area at home can give confidence and reassure patients that they have done all they can to reduce the risk of peritonitis. There may be a reluctance to perform exchanges in the homes of friends and relatives, particularly if the patient's illness is poorly understood and a source of embarrassment.

8.14 How might you help a patient to gain confidence in dealing with the treatment in order to take advantage of the relative freedom that PD offers?

The insertion of a tube and presence of fluid in the abdomen can alter body image and sexuality, thus discouraging those who are conscious of their appearance. A further disadvantage of CAPD is that it presents a constant reminder to the patient of their illness.

For further information, see Levy et al (2001) and Thomas (2002).

Living with intermittent haemodialysis

For some patients, haemodialysis may be the preferred option. This is generally hospital based, or in some areas satellite treatment centres are available. In some cases the patient may opt for home haemodialysis. A patient opting for home haemodialysis will undergo a training programme with their partner/carer before commencing the treatment.

Hospital or satellite haemodialysis is performed on an outpatient basis, two or three times a week.

Dialysis as a treatment does have a number of drawbacks, including the following:

- the need for transport to and from hospital
- the need to be away from home and dependants two or three times a week
- the difficulty of fitting in dialysis sessions with work and family commitments
- the increased fluid load prior to dialysis
- the need to restrict the diet
- the financial implications of lost work time
- the side-effects of dialysis and the continuing feeling of not being fully fit
- living with the uncertain hope of a kidney transplant
- the stress and strain on the family of dealing with the lifestyle constraints imposed by treatment.

8.15 Consider the problems listed above and, for each, suggest ways in which the health care team can help.

Nursing support during dialysis

Assessments to be performed before haemodialysis are:

- Record patient's weight — compare with weight after last dialysis and the patient's recognised dry weight, i.e. the weight at which there is no clinical evidence of oedema, increased jugular venous pressure, shortness of breath or hyper/hypotension.
- Record temperature, pulse and blood pressure — compare these with values after the last dialysis. Any temperature increase could indicate an infected dialysis site. Raised blood pressure may indicate fluid overloading.
- Enquire how the patient has been feeling, i.e. well or unwell.
- Assess any known specific medical problem, e.g. blood sugar level in patients with diabetes mellitus.
- Once a month, take blood for urea and electrolyte levels pre- and post-dialysis; a full blood count should be checked every month.

During dialysis, the nurse should record the pulse and blood pressure. A drop in blood pressure may mean that the patient needs extra fluid. If necessary, the nurse should check the patient's weight halfway through the session.

At the end of dialysis, the patient's temperature, pulse, blood pressure and weight should be recorded in order to assess the effectiveness of the treatment. Any prescribed medications should be administered and the patient should be given the opportunity to raise any further concerns.

CONCLUSION

This is a challenging and rapidly developing area of practice in which to work, one in which the role of the nurse is constantly developing.

Caring for patients who have problems within the urinary system is complex and demanding. Conditions that affect the urinary tract can be either acute or chronic and it is important that the nurse recognises that the patient's needs are often multifactorial.

In order to provide high quality nursing care, when caring for these patients the nurse must demonstrate not only a good understanding of anatomy and physiology, the disease process and the potential complications but also good interpersonal skills and sensitivity in the experience of illness.

INTRODUCTION

Many nurses may have only brief contact with patients suffering from neurological disorders, either while they are waiting to be transferred to a specialist neurological unit or following their return from such a unit. Community nursing staff, however, are increasingly involved with patients recovering at home, either from acute neurosurgical interventions or long-term neurological disorders, where the disorder cannot be cured. Recent years have also witnessed a growth in the number of specialised liaison or support nurses for patients with disorders such as epilepsy and multiple sclerosis.

This chapter considers the more common neurological and neurosurgical disorders and, where appropriate, makes reference to the less common disorders. The specialised neuroscience textbooks listed at the end of the chapter provide more detailed information. It is hoped that the information contained here will raise awareness of this specialised field of nursing, and stimulate further discussion on how best to meet the needs of the patient with a neurological condition and of their family and/or significant others.

ANATOMY AND PHYSIOLOGY

The nervous system is a complex, interrelated body system responsible for many functions including communication, coordination, behaviour and intelligence. It constantly receives data from the external and internal environments, interprets these, and then responds by adapting appropriately to demands.

The nervous system can be considered in two distinct parts, namely the central nervous system (CNS), comprising the brain and spinal cord, and the peripheral nervous system (PNS), consisting of the cranial and spinal nerves. The peripheral nervous system has two functional parts, the sensory division and the motor division (see p. 406).

Basic tissue structure

Nervous tissue consists of neuroglia (or 'glial cells') and neurones (or 'nerve cells'). The neuroglia markedly outnumber the neurones and form a supportive and protective network for the nervous system, e.g. by attaching neurones to their blood vessels and protecting the nervous system through phagocytic action, as the white cells do elsewhere in the body. In the peripheral nervous system, supporting cells, called 'Schwann cells', form the myelin sheath as well as having a phagocytic role.

Myelin protects and electrically insulates nerve fibres from one another, and potentiates, i.e. speeds up, nerve impulse transmission. Myelinated nerve impulses are transmitted by saltatory conduction, whereby the impulse jumps from one node of Ranvier to the next (see Fig. 9.1). Impulses in myelinated nerves are therefore transmitted very much faster than in unmyelinated nerves and require very much less energy. The importance of myelin in nerve impulse transmission is painfully clear to those suffering from demyelinating diseases such as multiple sclerosis. In this condition, the myelin sheath is destroyed, impulse conduction ceases and the affected individual loses the ability to control voluntary muscle movement (p. 430).

Neurones

Although fewer in number, neurones form the basis of the structural and functional unit of the nervous system. They are capable of conducting impulses throughout the nervous system and to other excitable tissues, including the muscles and glands. The structure of a typical multipolar neurone is shown in Figure 9.1.

The axons of sensory and motor neurones constitute the nerve fibres. They are bundled together in the peripheral nervous system by connective tissue to form the peripheral nerves (see Fig. 9.2). In the CNS, the axons of connector neurones are held in distinct tracts by the glial cells.

Classification of neurones Neurones are classified according to their structure and function. The functional classification is determined by the direction in which the impulse travels and the structural classification is based on the number of poles on the cell body.

Sensory or afferent neurones transmit impulses from receptors in the skin, sense organs and viscera to the brain and spinal cord. Structurally, these are unipolar, i.e. cells with processes projecting from one pole, or bipolar, where processes project from two poles at opposite ends of the cell. Bipolar neurones are found only in special sense organs, e.g. the retina of the eye.

Motor or efferent neurones transmit impulses in the opposite direction, from the brain and spinal cord to muscles and glands in the body (the effectors). Typically, these are multipolar, i.e. cells with processes projecting from many points all over the cell body (see Fig. 9.1).

Connector neurones or interneurones convey impulses within the CNS. Typically, these are also multipolar.

The nerve impulse

A nerve impulse can be initiated by a stimulus such as a change in temperature, pressure or the chemical environment, or impulses can be generated spontaneously by pacemaker cells. The impulse is described as a self-propagating wave of electrical charge along the membrane of the neurone, effecting changes crucial to the conduction of the impulse.

At rest, the nerve cell has an unequal distribution of ions on either side of the plasma membrane. These comprise potassium and sodium and are necessary to maintain the chemical difference which produces an electrical difference: the inside of the cell is negatively charged in relation to the outside. This has been measured at –70 mV and is termed the resting membrane potential. The cell is maintained in this condition by a system whereby ions are exchanged between the intracellular and extracellular fluids. A property of all nerve cells is their ability to respond to stimuli by producing an impulse when the stimulus is sufficient to initiate certain electrical and chemical changes within the cell membrane. These positive–negative changes occur in rapid succession, spreading to the end of the axon.

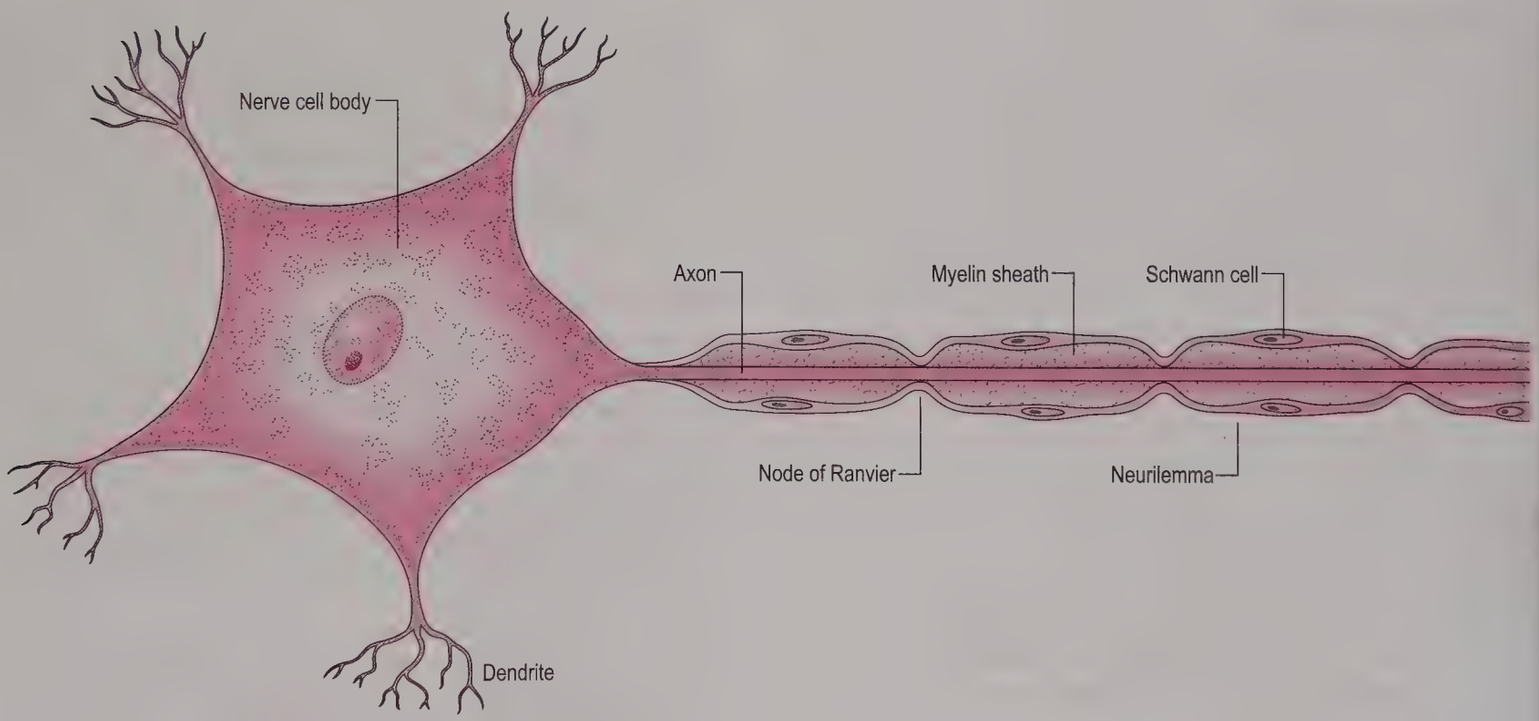

Fig. 9.1 Structure of a multipolar neurone. It consists of three parts: (1) The nerve cell body, which is grey in colour. Each cell body is enclosed in a selectively permeable membrane, which also extends along the cell processes. The cell body contains a nucleus surrounded by cytoplasm which also contains other structures called organelles. (2) The dendrites are thread-like extensions of the cell body which increase the surface area available to receive signals from other neurones. (3) The axon is a single long process that conducts impulses away from the cell body. In many large peripheral axons, the axolemma is surrounded by another covering called the myelin sheath. This is a multiple-layered covering of fatty material which is white in colour. Its function is to insulate the neurone electrically and thus speed up the conduction of the nerve impulse, by segmentation. Each interruption of the sheath is known as a node of Ranvier and the speed of the impulse is increased by its 'jumping' from node to node. The axon and its collaterals branch into axon terminals, the ends of which form a bulb-like structure. These help to transmit an impulse from one neurone to another across the gap (synapse) between them or at the junctions with effector cells.

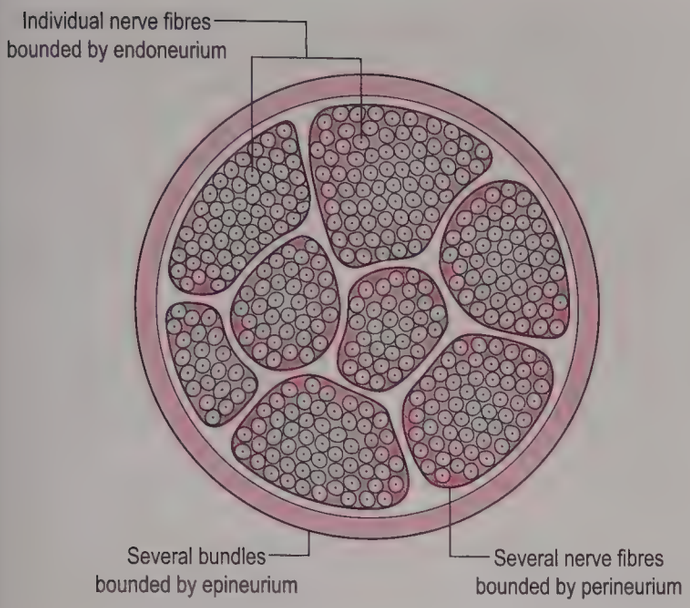

Fig. 9.2 Transverse section, peripheral nerve. The nerve fibres are surrounded by a fine connective tissue covering called the endoneurium. Several nerve fibres are bound together by another connective tissue covering called the perineurium and a number of these bundles may be surrounded by another covering called the epineurium.

Other more subtle and complex changes also occur.

For further information, see Marieb (2004) and Tortora & Derrickson (2006).

Generally, the larger the diameter of the axon, the quicker the nerve impulse travels, but the alternative device of saltatory conduction is found in myelinated neurones, as shown in Figure 9.3.

Neurotransmitters

The junctions between one neurone and another, and between neurones and muscles or glands, are known as synapses. Nerve impulses are transmitted across the gap at these synapses by chemical transmitters (neurotransmitters). The chemical is stored in vesicles in the expanded end of the axon and is released when the nerve impulse reaches this point. Several chemical transmitters have been identified, the most common ones being acetylcholine and noradrenaline. Many of these neurotransmitters are excitatory, resulting in the nerve impulse being transmitted to the receiving tissue and thus producing an effect such as contraction of muscle cells. Some, however, have an inhibiting effect and prevent the onward transmission of impulses, allowing, for example, muscle cells to relax. The effect of the neurotransmitter is terminated when it is destroyed by enzymes or reabsorbed into the neurone.

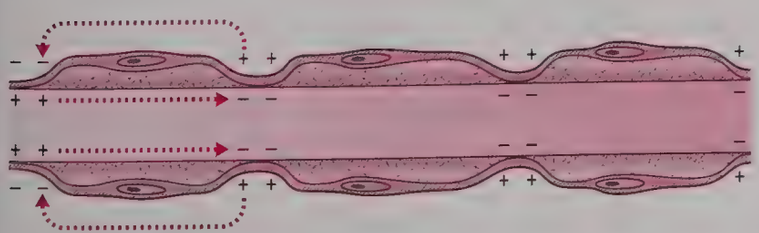

Fig. 9.3 Saltatory conduction in a myelinated nerve.

The central nervous system

The central nervous system consists of the brain and spinal cord.

The brain

The cerebrum, the largest constituent of the nervous system, forms the bulk of the brain. The outer surface, the cortex, is of grey matter and consists of nerve cell bodies. The surface area of the cerebral cortex is increased by a series of grooves (sulci) and ridges (gyri). The deeper grooves are termed fissures and some form landmarks, e.g. the longitudinal fissure which almost splits the brain into two hemispheres (see Fig. 9.4).

Each hemisphere is subdivided into four lobes, and each lobe is named according to the skull bones it underlies:

- frontal
- temporal
- parietal
- occipital.

The cerebral cortex is responsible for three main functions:

- receiving and interpreting a mass of sensory information from various sources in the internal and external environments
- initiating and controlling voluntary movement in response to the sensory information received
- integrating crucial functions such as memory and consciousness.

Certain areas of the cerebral cortex have been identified as being responsible for these functions, and these areas form a map, as illustrated in Figure 9.5.

Relative size The lips, thumbs and face use many more receptors than the trunk and legs: similarly, the thumbs, fingers, lips, tongue and vocal cords are more sensitive than the trunk, due to the greater number of receptors found in them. The homunculus (see Fig. 9.6) illustrates how the various parts of the body are represented in the corresponding motor and sensory areas of the cerebral hemispheres,

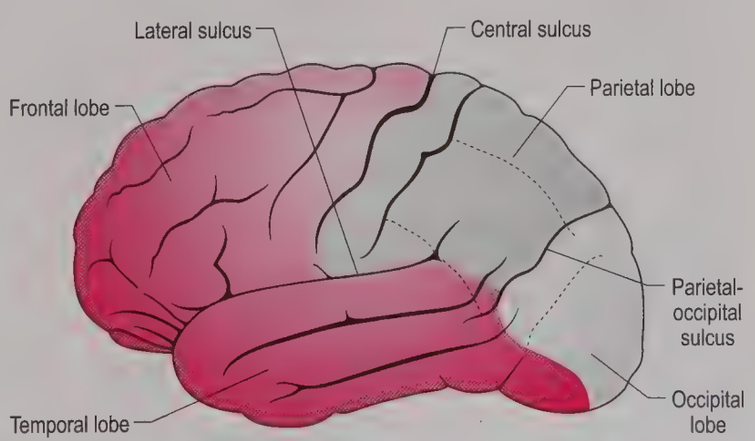

Fig. 9.4 The lobes and sulci of the cerebrum. Each of the lobes is bounded by 'landmark' fissures: the frontal lobe is separated from the parietal lobe by the central sulcus; the temporal lobe is separated from the frontal and parietal lobes by the lateral sulcus; and the occipital lobe is separated from the temporal and parietal lobes by the parietal–occipital sulcus.

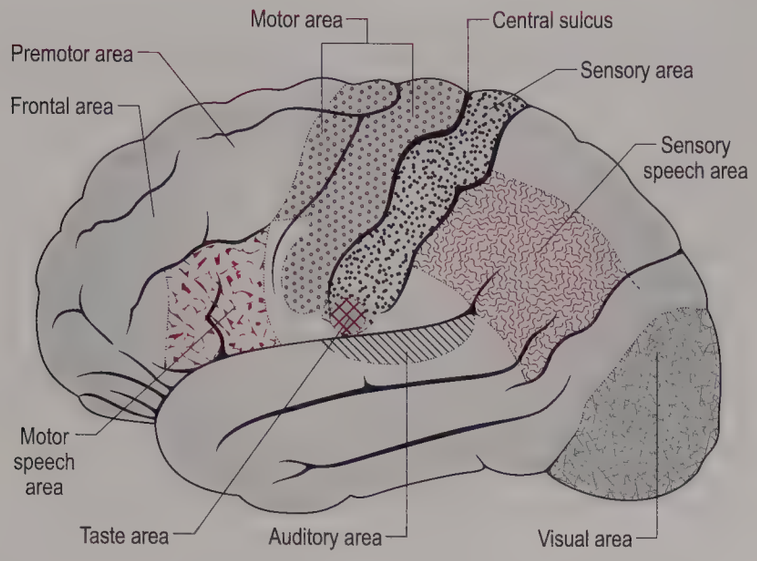

Fig. 9.5 The cerebrum showing the functional areas.

i.e. representation is proportional not to the relative size of the body parts, but to each part's complexity of movement or the extent of its sensory innervation.

For further information, see Waugh & Grant (2001).

9.1 Discuss with your lecturer or mentor how this strange-looking representation might impact on the perceptions and experiences of a patient, for example, following limb amputation or where there has been stroke damage.

The concept of dominance The functions of speech and motor control are usually more highly developed in one cerebral hemisphere than in the other. This is referred to as dominance. Approximately 95% of the population are dominant in the left hemisphere and, as most of the spinal pathways cross over in the medulla (see p. 399), they are right-handed. However, if the dominant hemisphere is damaged, the opposite hemisphere is capable of taking over and assuming a dominant role.

Association areas Some areas of the brain remain unmapped (see Fig. 9.5). These are called 'association areas' and are thought to be responsible for complex functions such as integration of the senses, memory, learning, thought processes, behaviour and emotion.

Connecting pathways Below the outer cortical layer can be found areas of white matter (myelinated nerve fibres) that form connections between the cerebral cortex and other areas of grey matter in the CNS. Three types of connecting pathways (see Fig. 9.7) have been identified:

- association fibres — these connect between gyri in the same hemisphere
- commissural fibres — these connect between gyri in different hemispheres; one important group of commissural fibres is the corpus callosum
- projection fibres — these provide connections between the brain and spinal cord in ascending and descending pathways; one example is the internal capsule.

For further details on these interconnecting pathways, see Montague et al (2005).

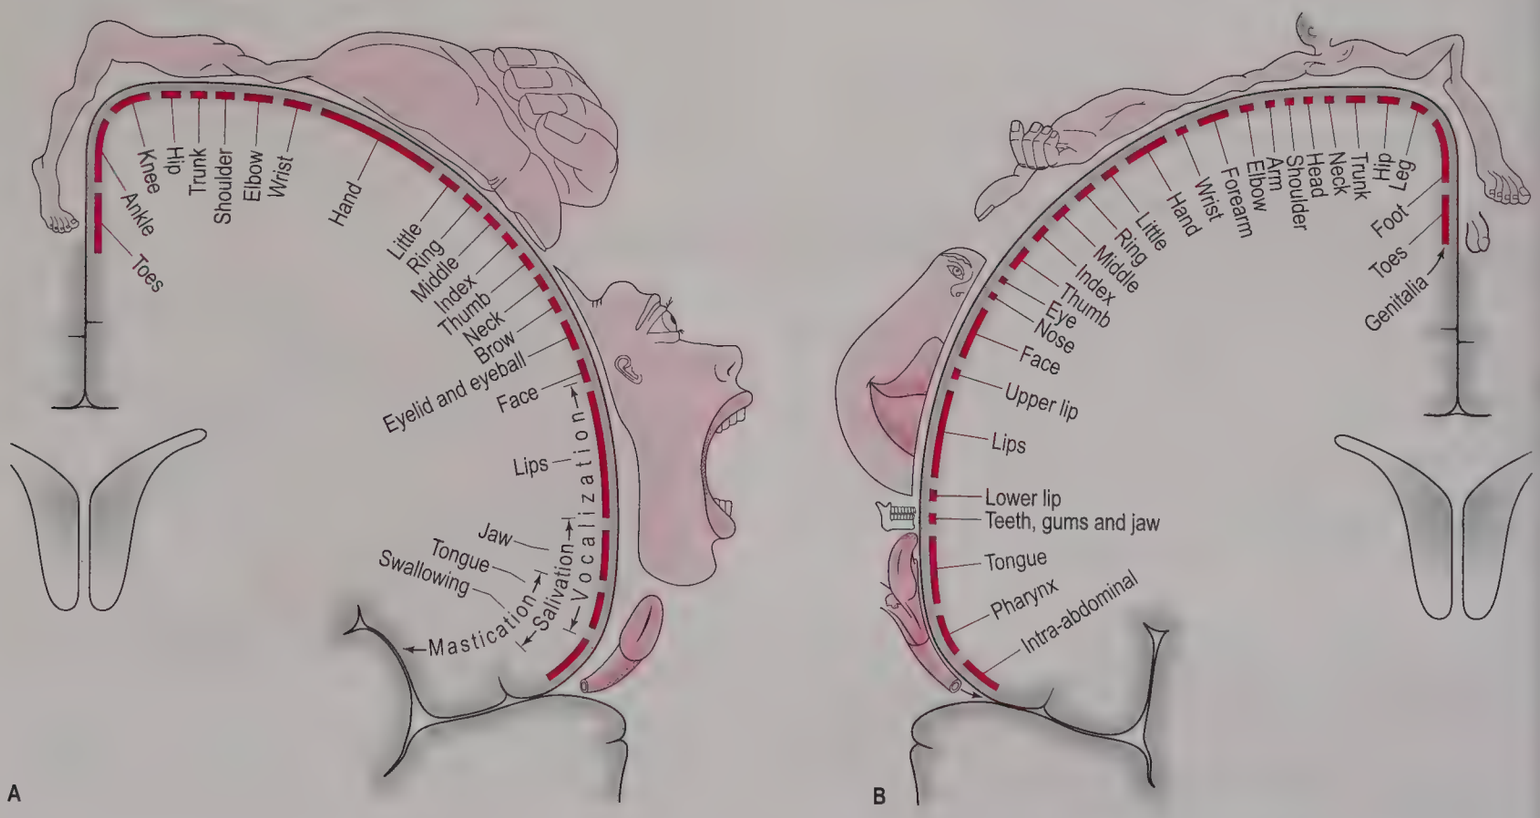

Fig. 9.6 A: The motor homunculus showing how the body is represented in the motor area of the cerebrum. B: The sensory homunculus showing how the body is represented in the sensory area of the cerebrum.

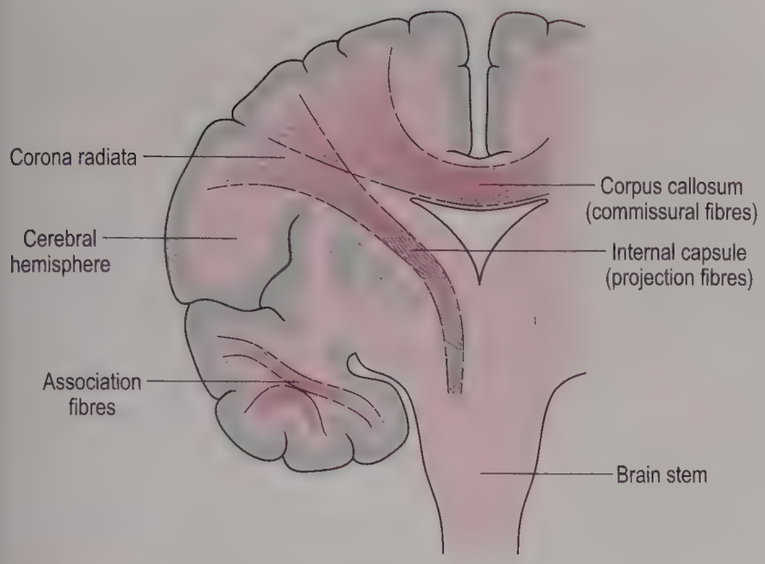

Fig. 9.7 White matter of the cerebrum.

Basal nuclei (ganglia) Within the white matter of the cerebrum are paired islands of grey matter called the 'basal nuclei'. They control large subconscious movements, such as swinging the arms while walking and regulating muscle tone for specific body movements, a function that is lost in Parkinson's disease.

Other structures closely associated with the cerebrum are the cerebellum and the pituitary gland.

The cerebellum is located below the posterior part of the cerebrum and is separated from it by a fold of dura mater. It consists of two hemispheres separated by a narrow strip called the 'vermis'. The cortex of the cerebellum consists of grey matter which has many folds to increase its surface area. The interior comprises white matter presented in a branching configuration termed the arbor vitae or 'tree of life'. There are three connections, called the 'cerebellar peduncles', which link the cerebellum to the rest of the brain and spinal cord. These allow the cerebellum to receive sensory information and thereby to maintain equilibrium and modify voluntary movement, making it smooth and coordinated.

The pituitary gland The pituitary gland is situated at the base of the brain in a depression in the sphenoid bone called the 'sella turcica' (Turkish saddle). It is attached to the brain via a stalk which is continuous with the hypothalamus, and communication is by means of nerve fibres and blood vessels. It has three lobes, an anterior, a middle and a posterior lobe, which secrete hormones that exert an influence on other parts of the body (see Ch. 5, Part 1, for details of the actions of pituitary hormones).

Diencephalon Three bilaterally symmetrical structures comprise the diencephalon:

- the thalamus
- the hypothalamus
- the epithalamus.

Collectively, these three structures enclose and form the boundaries of the third ventricle.

The thalamus consists of two oval-shaped masses (thalami), mainly consisting of grey matter with some white matter, and is situated within the cerebral hemispheres just below the corpus callosum. Sensory impulses associated with pain, temperature, pressure and touch are conveyed to the thalamus, which acts as a 'gateway'. Chaos would reign if all the sensory information flooding into the nervous system were allowed to reach the sensory cortex.

The hypothalamus is situated below the thalamus and forms the walls and floor of the third ventricle. It controls the output of the hormones from the pituitary gland and is located directly above it. Other functions include the regulation of hunger, thirst and body temperature (see Ch. 22). The last function is significant for patients with a hypothalamic disturbance following head injury.

The epithalamus is the most dorsal part of the diencephalon and forms the roof of the third ventricle. Extending from its posterior border is the pineal gland, thought to be concerned with growth and development (Hickey 2002).

The brain stem This is the collective name given to three structures: the medulla, the pons and the midbrain. Inferiorly, the medulla is continuous with the upper spinal cord and connects with the pons above. The pons is continuous with the midbrain, which connects with the lower portion of the diencephalon.

The medulla All the spinal pathways pass through the medulla, constituting its white matter. Some of these cross to the opposite side in triangular-shaped structures called the 'pyramids', a process known as 'decussation'. The purpose of this has never been established.

- It contains the reticular formation, a diffuse area of grey and white matter that has connections with the rest of the brain stem and cerebral cortex, within which is a structure known as the reticular activating system, responsible for consciousness and arousal.
- It accommodates three reflex centres, which control vital functions; these include:
  - — the cardiac centre, which regulates heartbeat and force of contraction
  - — the medullary rhythmicity area, which adjusts the basic rhythm of breathing
  - — the vasomotor centre, which regulates the diameter of blood vessels (important in control of blood pressure).

  Other non-vital centres include those responsible for coordinating swallowing, vomiting, coughing, sneezing and hiccupping.
- It also contains the nuclei of cranial nerves VIII to XII (see Table 9.1).

The pons The pons acts as a bridge between the medulla and the midbrain. It comprises fibres and nuclei. The fibres run in two directions: the transverse fibres connect with the cerebellum and the longitudinal fibres maintain the vital link between the spinal cord and the brain. The nuclei are the origins of cranial nerves V–VIII inclusive (see Table 9.1). Other important nuclei also exert an influence on respiration.

The midbrain The third component of the brain stem is the midbrain, which contains the central centres for visual, auditory and postural reflexes. It is located above the pons

Table 9.1 Cranial nerves

Number	Nerve	Origin	Termination	Functions	
I	Olfactory	Olfactory mucosa	Olfactory cortex	Sensory:	Smell
II	Optic	Retina	Visual cortex	Sensory:	Vision
III	Oculomotor	Midbrain	Upper eyelid muscle Extrinsic eye muscles Ciliary muscles Sphincter muscle of the iris	Motor:	Eyelid movement Eyeball movement Accommodation of lens Pupillary constriction
		Proprioceptors in extrinsic eye muscles	Midbrain	Sensory:	Proprioception
IV	Trochlear	Midbrain Proprioceptors in extrinsic eye muscle (superior oblique)	Extrinsic eye muscle superior oblique Midbrain	Motor: Sensory:	Eyeball movement Proprioception
V	Trigeminal	Pons Ophthalmic branch takes sensory fibres from skin of upper eyelid, eyeball, lacrimal glands, nasal cavity, side of nose, forehead and anterior half of scalp Maxillary branch takes sensory fibres from mucosa of nose, palate, parts of pharynx, upper teeth, upper lip, cheek and lower eyelid Mandibular branch takes sensory fibres from anterior two-thirds of tongue, lower teeth, skin over mandible and side of head in front of ear	Muscles of mastication Midbrain, pons and medulla	Motor: Sensory:	Chewing Touch, pain, temperature, proprioception
VI	Abducens	Pons Proprioceptors in lateral rectus	Extrinsic eye muscle (lateral rectus) Pons	Motor: Sensory:	Eyeball movement Proprioception
VII	Facial	Pons	Facial, scalp and neck muscles Lacrimal and salivary glands	Motor:	Facial expression Salivation Lacrimation
		Taste buds on anterior two-thirds of tongue Proprioceptors in muscles of face and scalp	Gustatory cortex	Sensory:	Taste Proprioception
VIII	Vestibulocochlear	Cochlear and vestibular portions of the ear	Cochlear nuclei in pons Vestibular nuclei in the medulla	Sensory:	Hearing Equilibrium
IX	Glossopharyngeal	Medulla	Swallowing muscles in the pharynx Parotid gland	Motor:	Swallowing Salivation
		Taste buds on posterior one-third of tongue Carotid sinus Proprioceptors in muscles of face and scalp	Gustatory cortex	Sensory:	Taste Regulation of blood pressure Proprioception
X	Vagus	Medulla	Visceral muscles (muscles of pharynx, larynx, respiratory tract, oesophagus, heart, stomach, small intestine, proximal half of large intestine, gall bladder, liver, pancreas)	Motor:	Swallowing, digestive movements and secretions
		Receptors in the same structures that the motor portion innervates	Medulla and pons	Sensory:	Range of sensory inputs from organs supplied and proprioception from muscle

Table 9.1 Cranial nerves *(Continued)*

Number	Nerve	Origin	Termination	Functions
XI	Accessory	Bulbar portion: medulla	Muscles of pharynx, larynx, soft palate	Motor: Swallowing
		Spinal portion: cervical spinal cord	Sternocleidomastoid and trapezius muscles	Head movements
		Proprioceptors in muscles supplied by motor fibres	Medulla	Sensory: Proprioception
XII	Hypoglossal	Medulla	Muscles of tongue	Motor: Tongue movements
		Proprioceptors in tongue	Medulla	Sensory: Proprioception

For further information, see Tortora & Derrickson (2006).

and is the origin of the nuclei of cranial nerves III and IV (see Table 9.1). Cranial nerves I and II originate in the cerebrum.

The meninges

The brain and spinal cord are surrounded and protected by three meninges:

- the innermost layer, the pia mater
- the middle layer, the arachnoid mater
- the outer layer, the dura mater.

The pia mater is of the same structure as the arachnoid mater (see below), except that it has its own blood supply. The pia closely follows and adheres to the contours of the brain and spinal cord.

The arachnoid mater consists of collagenous and elastic fibres, covered by squamous epithelium. Fine strands of connective tissue connect the arachnoid with the pia below. The arachnoid mater projects into the sinuses as arachnoid villi, which are the structures responsible for the absorption of cerebrospinal fluid, and at certain points it joins the linings of the ventricles to form the choroid plexus, where cerebrospinal fluid is produced.

The dura mater is a double layer of dense fibrous tissue. The outer, periosteal layer adheres closely to the underside of the cranial bones, whilst the inner, meningeal layer is much thinner. The spinal dura mater has only one layer, which corresponds to the meningeal layer of the cranium. The two layers of the dura mater separate at several locations and these spaces contain the venous sinuses, e.g. the falx cerebri and the tentorium cerebelli. The former forms an incomplete division dipping down between the two cerebral hemispheres and is attached to the ethmoid bone at the front and the occipital protuberance at the back (see Fig. 9.8).

The tentorium cerebelli forms a division between the occipital lobes of the cerebrum and the cerebellum. It is attached along the midline to the falx cerebri, which draws it upwards to produce a tent-like appearance.

The ventricular system

The ventricular system consists of four fluid-filled irregular cavities (ventricles) interconnected by narrow pathways (see Fig. 9.9) and is connected with the central canal of the spinal cord and the cranial subarachnoid space. There are two lateral ventricles, one in each cerebral hemisphere, one

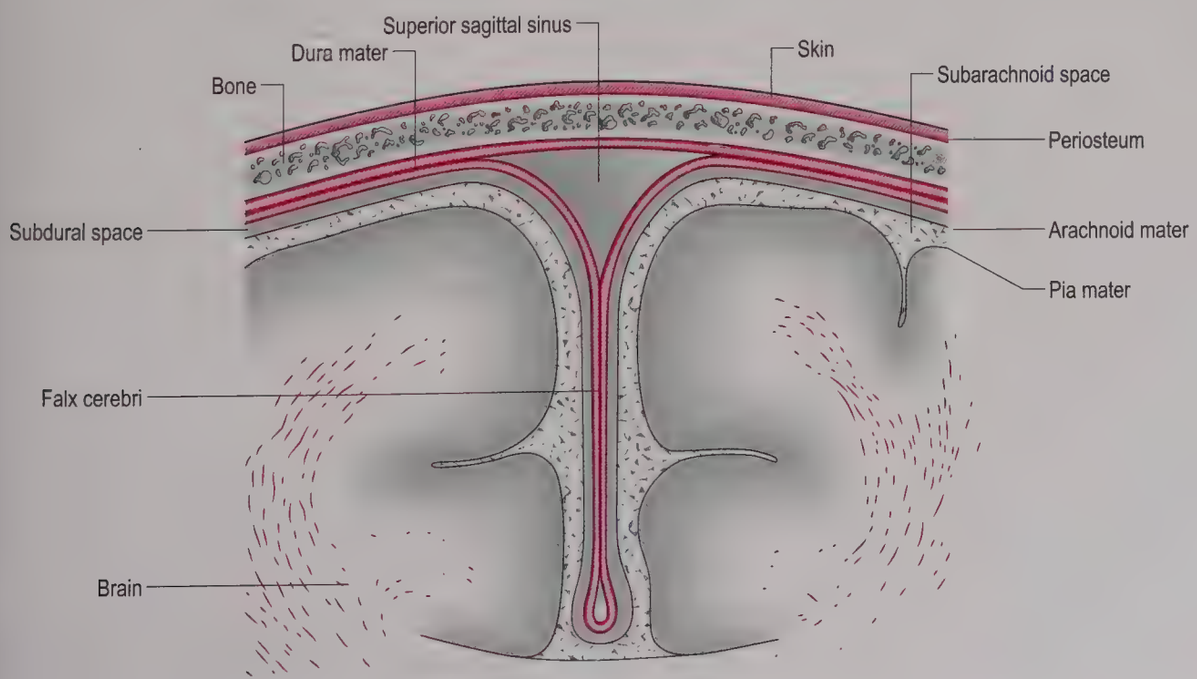

Fig. 9.8 Meninges of the brain.

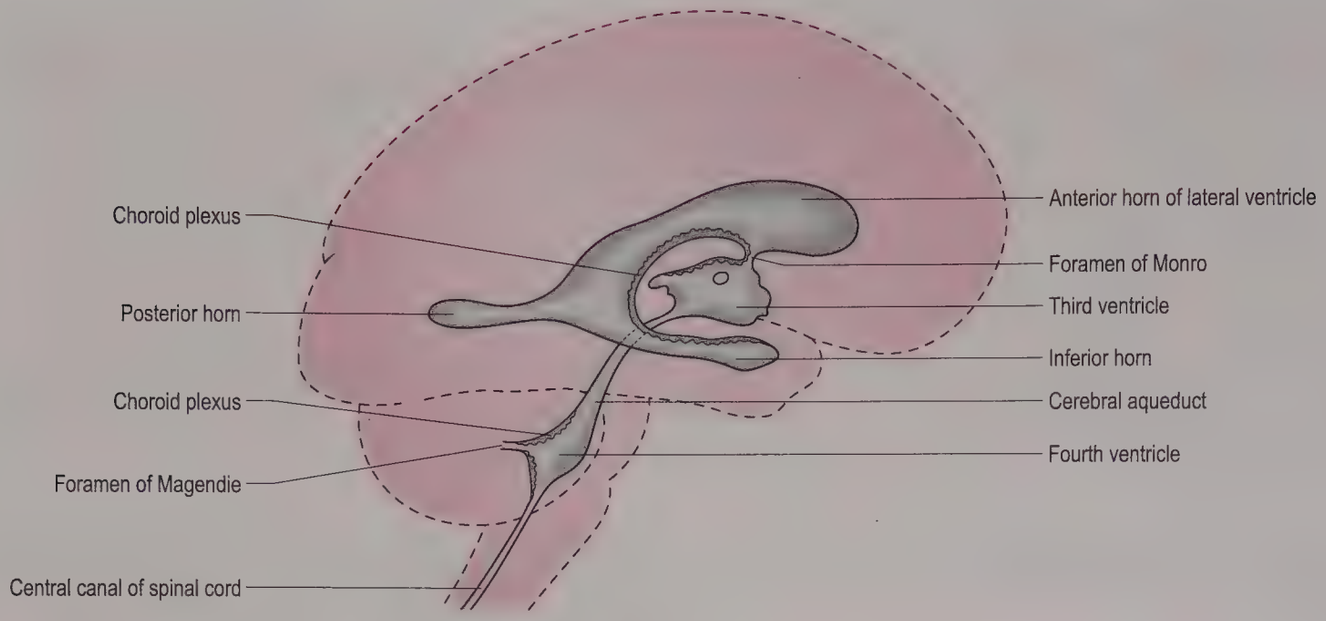

Fig. 9.9 Ventricular system.

Box 9.1

Normal features of cerebrospinal fluid

Colour: crystal clear
Pressure: 80–160 mmH_2O
Volume: 120–150 mL
Cells:
- red blood — none
- white blood
  - — polymorphonuclear leucocytes — none
  - — lymphocytes 0–5/mm^3

Protein: 0.2–0.4 g/L
Gamma globulin (IgG): less than 13% of total protein
Sugar: 3.6–5.0 mmol
Wassermann reaction: negative

ventricle (the third) located in the diencephalic region and another located in the medulla, called the fourth ventricle.

Cerebrospinal fluid (CSF) circulates within the closed ventricular system. Healthy cerebrospinal fluid is clear and colourless. Its normal features are as outlined in Box 9.1.

The CSF production–absorption cycle is continuous, and a fairly constant volume of 120–150 mL is maintained. When this process is interrupted and the volume is increased beyond normal limits, hydrocephalus occurs.

The main source of production of CSF is the choroid plexus, a collection of specialised capillaries located within the internal lining of the ventricles, the largest amount being produced in the lateral ventricles. From here, the CSF passes through two interventricular foramina (foramen of Monro) to the third ventricle, then via the single cerebral aqueduct (aqueduct of Sylvius) to the fourth ventricle. Some CSF passes down into the central canal of the spinal cord but most passes up through the two lateral and one medial foramina in the roof of the fourth ventricle, to circulate round the brain and spinal cord in the subarachnoid space before being reabsorbed into the blood via the arachnoid villi.

The functions of CSF are:

- protection and cushioning of the brain and spinal cord
- provision of nourishment
- maintenance of a uniform intracranial pressure
- removal of waste products.

Blood supply and drainage

The supply of blood to the head arises from the left and right common carotid arteries, which subdivide to form the internal and external carotid arteries. These supply blood to the anterior part of the brain, and the vertebral arteries supply the posterior part.

The greater part of the brain is supplied with blood by the circle of Willis, an unusual configuration of anastomosed blood vessels located in the base of the brain (see Fig. 9.10).

Venous drainage is by small veins in the brain stem and cerebellum, and external and internal veins draining the cerebrum. Some of the external and internal veins empty into one large vein called the vein of Galen (great cerebral vein). Unlike other parts of the body, these veins do not correspond with their arterial supply. All these veins empty directly into a system of venous sinuses, which is shown in Figure 9.11.

The principal sinuses are the superior and inferior sagittal, the straight, transverse, sigmoid and cavernous sinuses.

For more detailed information on the areas of the brain supplied by the cerebral circulation, see Montague et al (2005).

The limbic system

The limbic system comprises an interconnected complex of structures, including the hypothalamus. These are thought to be responsible for special types of behaviour associated with emotions, subconscious motor and sensory drives and the intrinsic feelings of pain and pleasure.

The blood–brain barrier The capillaries supplying the brain consist of endothelial cells with very tight junctions,

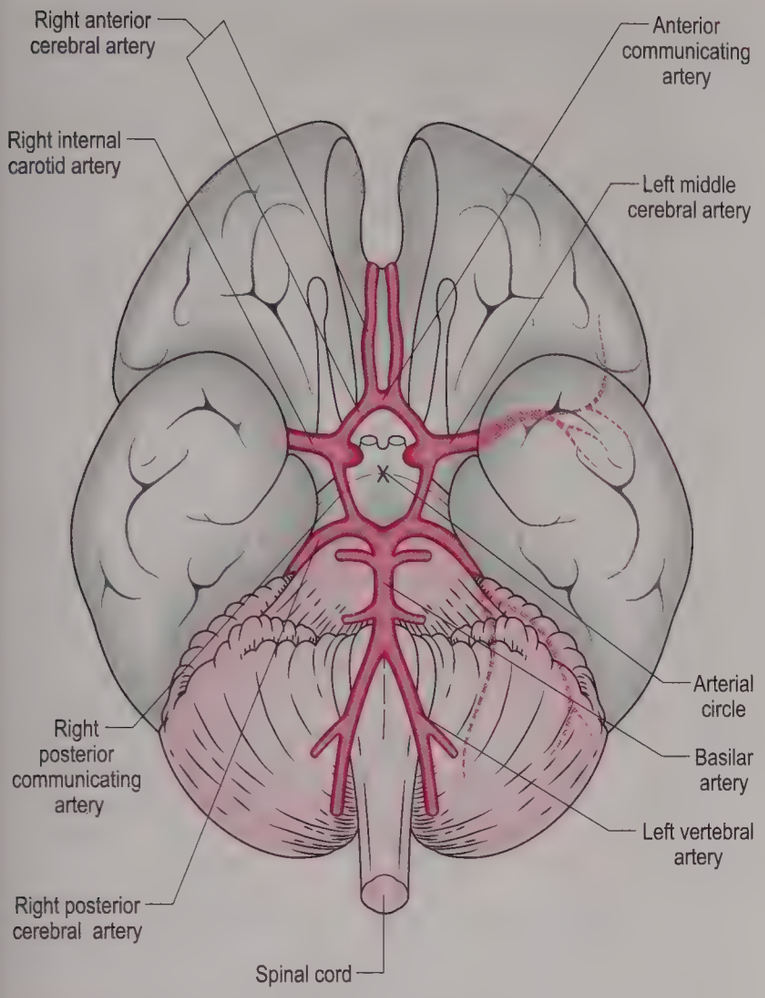

Fig. 9.10 Blood supply to the brain.

which make their permeability relatively low. This means that, as a protective mechanism, some substances are prevented or hindered from gaining access to the brain; this is termed the 'blood–brain barrier'.

For further information, seen Tortora & Derrickson (2006).

The spinal cord

The spinal cord is an oval cylinder that lies within the spinal cavity of the vertebral column. In adults, it is approximately 45 cm in length and extends from the medulla above to the first or second lumbar vertebrae at its lower end. Beyond this, the spinal nerves from the lumbar and sacral segments of the cord form the cauda equina, or 'horse's tail'. The cord is surrounded by the three meninges and CSF circulates in the subarachnoid space. The lower part of the cord is attached to the coccyx by the filum terminale and is tapered in shape (see Fig. 9.12).

The cord is segmented into five parts or regions, each corresponding to a specific number of vertebrae (in brackets):

- cervical (7)
- thoracic (12)
- lumbar (5)
- sacral (5)
- coccyx (1).

A shorthand labelling system has evolved to identify different levels within the spinal cord and vertebrae. For example, the third cervical vertebra becomes C3 and the fourth lumbar vertebra becomes L4 and so on.

Two enlargements of the spinal cord can be noted. The first is in the cervical region, extending between C4 and T1 and containing the nerve supply for the upper limbs. The second enlargement is lower in the lumbar region and is called the 'lumbosacral enlargement'. It extends from L2 to S3 and supplies innervation to the lower limbs. The spinal nerves, which are considered to be part of the peripheral nervous system, are attached by two short roots to the cord. There is a pair of spinal nerves equivalent to each of the vertebrae outlined above and these are labelled and numbered in a similar way. More detail on the spinal nerves can be found in the section on the peripheral nervous system (see p. 406).

The structure of the spinal cord is illustrated in cross-section in Figure 9.13.

The spinal pathways are described as:

- sensory — these ascend from the periphery of the body, e.g. cutaneous receptors in the hand, and are conveyed to the sensory cortex for interpretation

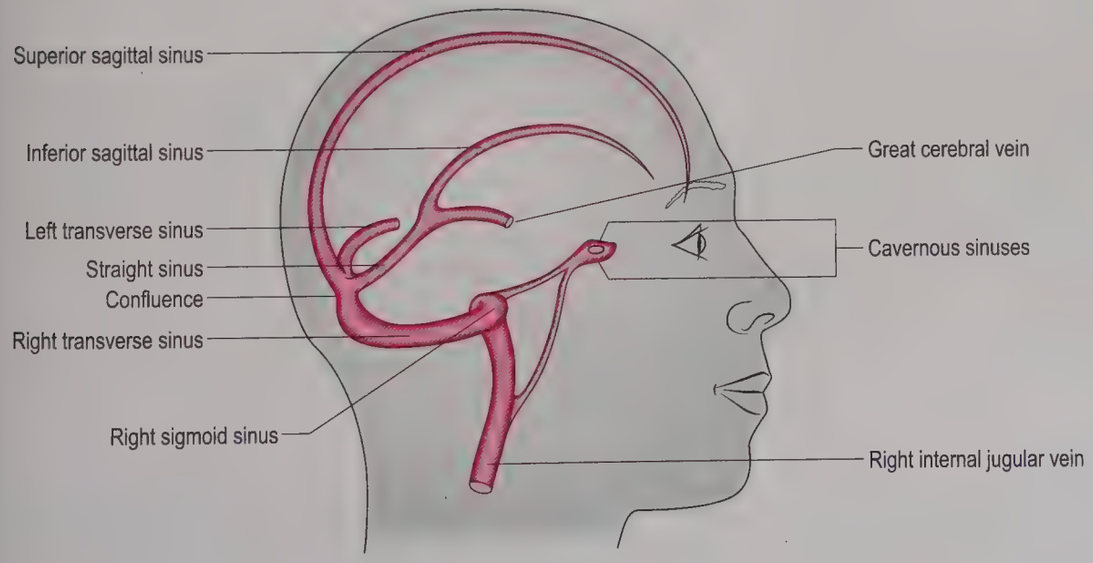

Fig. 9.11 Venous drainage of the brain.

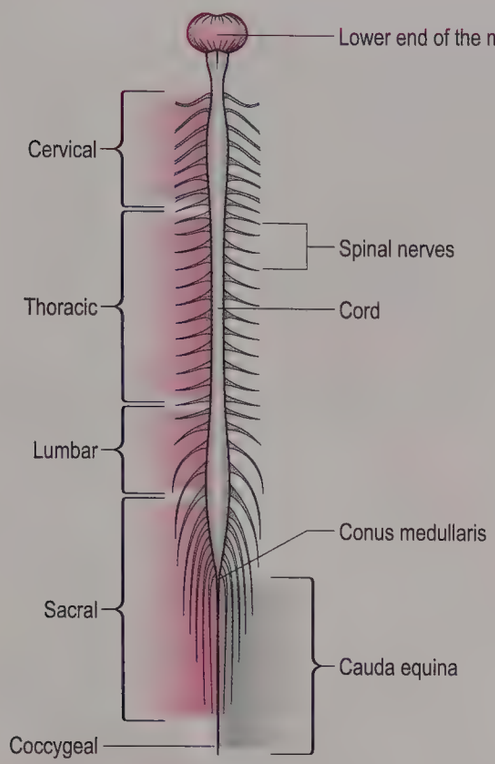

Fig. 9.12 Spinal cord.

- motor — these descend from the brain down to the periphery of the body, e.g. to skeletal muscles, where they initiate a motor response.

Each pathway has a name, derived from the white column in which it travels, the origin of the cell bodies and the termination of the axon. For example, the medial spinothalamic tract is located in the anterior white column, originates in the spinal cord and terminates in the thalamus.

The sensory pathways consist of:

- the posterior column pathway
- the spinothalamic pathway
- the cerebellar pathway.

The posterior column pathway Each pathway consists of a chain of three neurones, which transmit information such as discriminative touch and vibration sense from the appropriate receptors to the sensory cortex (see Fig. 9.14).

The spinothalamic pathways are:

- the lateral spinothalamic tract
- the medial spinothalamic tract.

The first order neurone in both pathways connects the receptor with the spinal cord where it synapses with the second order neurone in the posterior grey horn. The pathway crosses over to the opposite side of the cord and ascends in either the lateral or anterior spinothalamic tract to the thalamus. The second order neurone synapses with the third order neurone, which then continues, terminating in the sensory cortex. The lateral tract is responsible for conveying information about pain and temperature, and the medial tract conveys light touch and pressure (further information on pain can be found in Ch. 19).

The cerebellar tracts are:

- the posterior spinocerebellar tract
- the anterior spinocerebellar tract.

Both tracts are concerned with conveying impulses about subconscious muscle sense. Proprioceptors in the muscles and joints convey information via the spinal pathways, terminating in the cerebellum instead of the cerebral cortex.

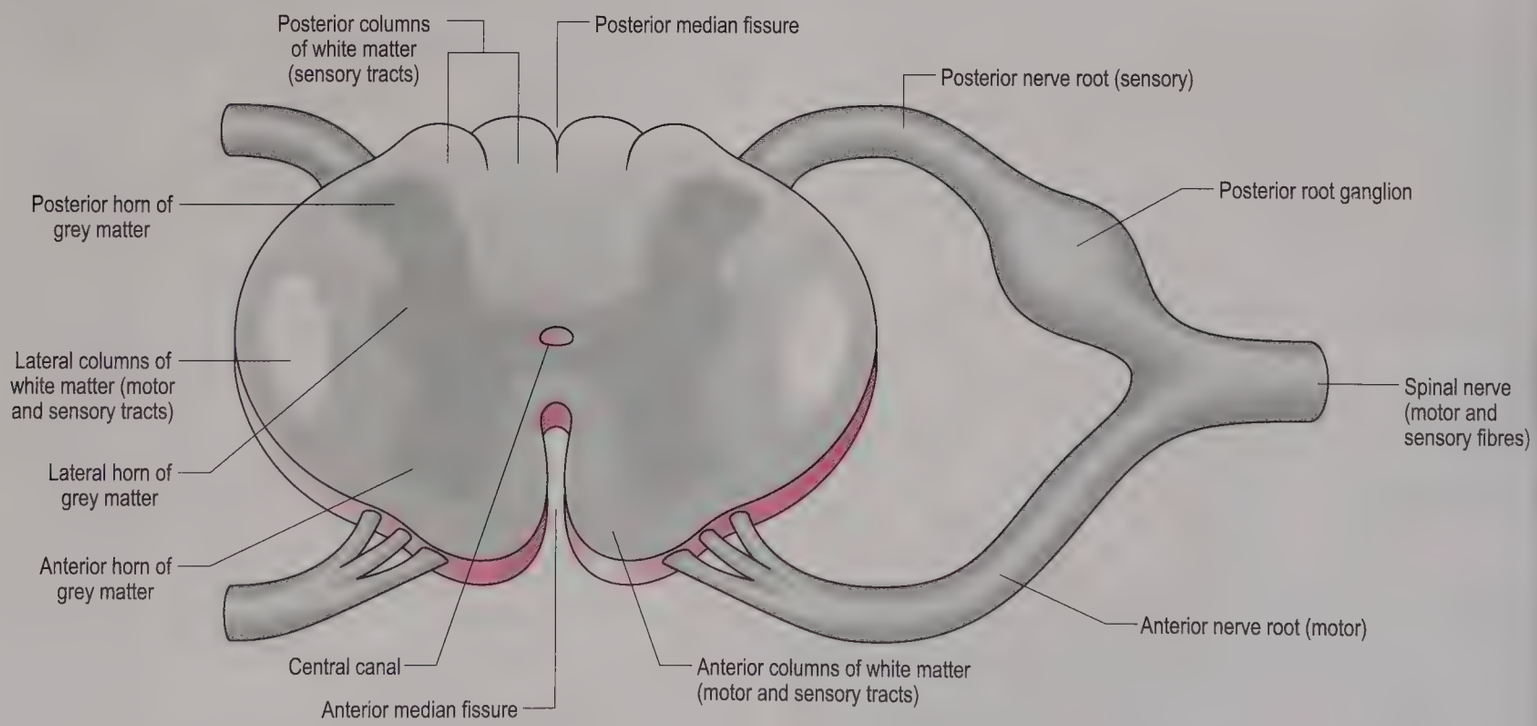

Fig. 9.13 Cross-section of spinal cord. It can be seen that the cord is incompletely divided into right and left halves by the posterior and anterior median fissures. In the centre is the central canal which contains cerebrospinal fluid originating from the fourth ventricle. Extending the entire length of the cord, this is located within an H-shaped area of grey matter with posterior and anterior and, at some levels, lateral horns. The remainder of the cord is made up of white matter organised in columns in the posterior, lateral and anterior segments.

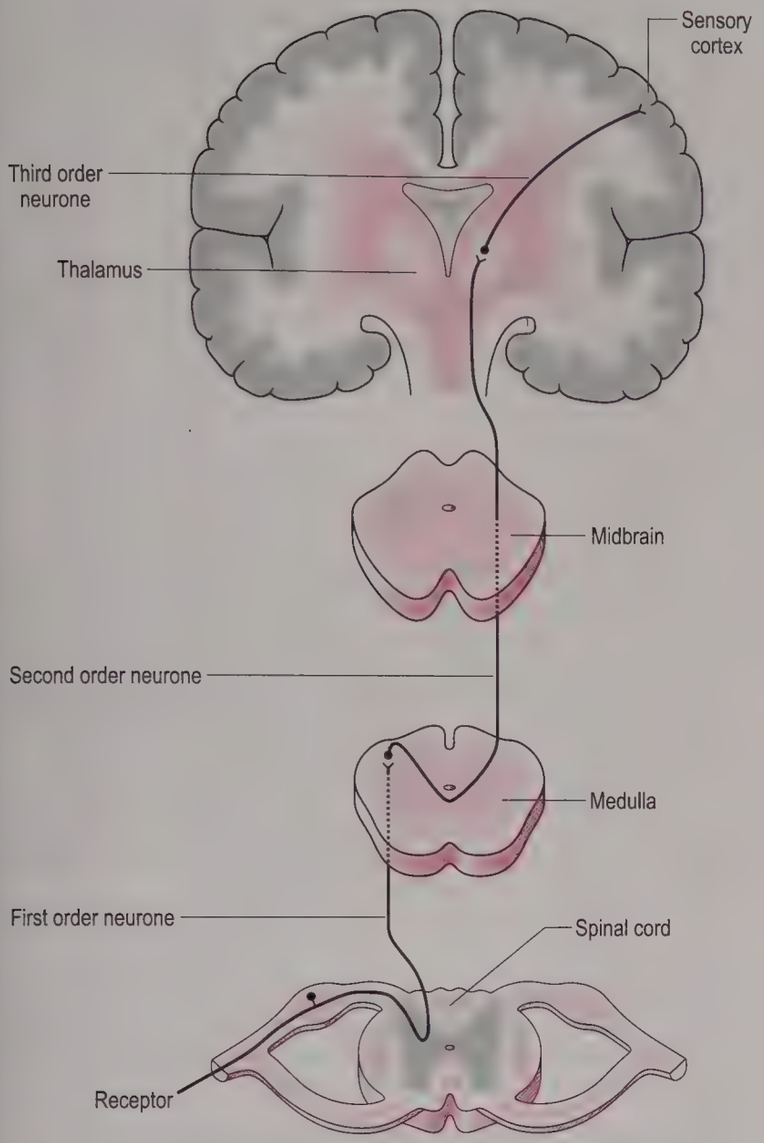

Fig. 9.14 The posterior column pathway. The first order neurone connects the receptor with the spinal cord and medulla on the same side of the body. In the medulla, the first order neurone synapses with the second order neurone, which decussates and then passes upwards to the thalamus where it synapses with a third order neurone which completes the sensory pathway, terminating in the sensory cortex.

This time there are only two neurones involved, synapsing in the posterior grey horn (see Fig. 9.15).

The sensory pathways are responsible for conveying a mass of information into the central nervous system. This information forms part of a large pool and decisions are made regarding the response to a given situation. The response is manifested by the motor system via its own set of pathways; this is described as 'integration' (Hickey 2002).

Motor pathways Once the motor process is initiated within the motor area of the cortex, the impulses descend via two main motor pathways, classified as the:

- pyramidal tracts — this indicates that the pathway passes through the internal capsule and forms the main pathway for impulses to the voluntary muscle
- extrapyramidal tracts — these are complex tracts which provide separate pathways between the cerebral

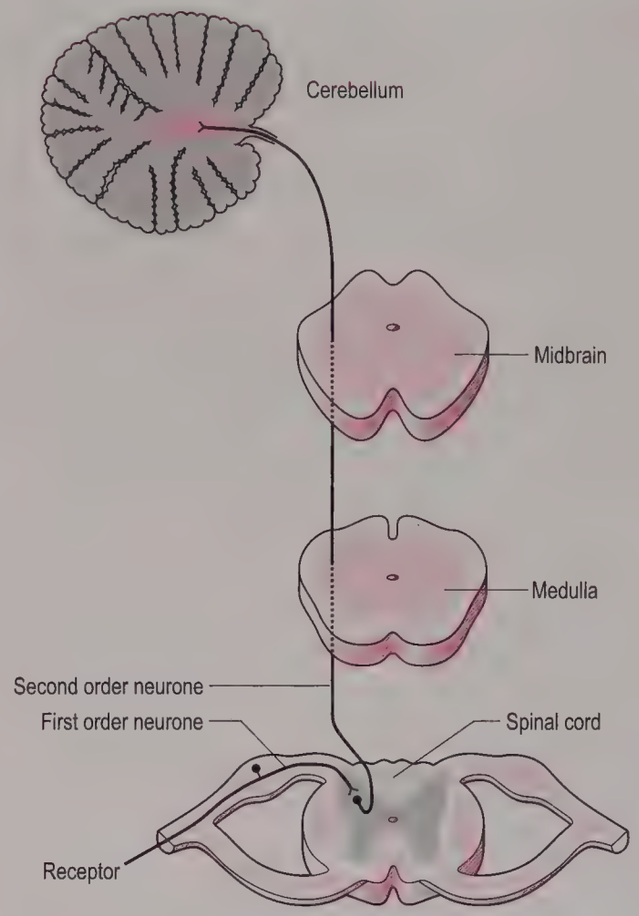

Fig. 9.15 The spinocerebellar tracts.

hemispheres, the basal nuclei, the brain stem and the spinal cord. These tracts include all descending motor tracts, other than those corticospinal tracts which pass through the medulla (the pyramidal tracts). Extrapyramidal tracts collectively assist in maintaining muscle tone and gross automatic skeletal muscle movements.

It is important to clarify the terms upper and lower motor neurones. These are the functional units of the motor system and they convey motor impulses. Damage to one or the other will result in very different functional impairment. An example of lower motor neurone disease is poliomyelitis.

The upper motor neurones extend from the motor cortex of the brain and pass down the pathways to end at the cranial nerve nuclei in the brain stem and the anterior horn of the spinal cord. This means that the upper motor neurone is contained entirely within the central nervous system (Tortora & Derrickson 2006). These are described in Box 9.2.

9.2 Can you find some examples of upper motor neurone disease?

The lower motor neurones start at the anterior horn of the spinal cord and pass via the anterior nerve roots of the spinal nerves and the motor end-plate of muscles. Some start in the brain stem and are contained in the cranial nerves.

Box 9.2

The motor pathways

Pyramidal tracts
The pyramidal pathway comprises three main tracts:

- lateral corticospinal
- anterior corticospinal
- corticobulbar.

The lateral corticospinal tract
This is the actual pyramidal tract. It originates in the motor cortex and descends to the medulla where 85% of the fibres decussate. They continue downwards in the lateral white column of the corticospinal tract. Most synapse in the anterior grey horn with the lower motor neurone, which then exits the spinal cord via the spinal nerves to terminate on the appropriate skeletal muscle.

The anterior corticospinal pathway
These fibres follow a similar pathway to the lateral, except that they travel in the anterior white column and most of the fibres do not decussate.

The corticobulbar tracts
These are important in that they terminate in the nuclei of the cranial nerves in the medulla. They follow the same pathway as the corticospinal pathway.

Extrapyramidal tracts
These consist of all the descending motor pathways that do not pass through the pyramids. They are concerned with functions of tone and posture such as control of head movement and maintaining balance.

There are three of these pathways:

- *The rubrospinal tract*, which originates in the midbrain, decussates and descends in the lateral white column. It is concerned with tone and posture.
- *The tectospinal tract* also originates in the midbrain, decussates and descends in the anterior white column and enters the anterior grey horns of the cervical cord.
- *The vestibulospinal tract* originates in the vestibular nucleus of the medulla and descends on the same side in the anterior white column and terminates in the anterior grey horn at the cervical and lumbosacral levels of the cord. It is concerned with regulating muscle tone in response to movements of the head and therefore has an important part to play in maintaining equilibrium.

Peripheral nervous system

The peripheral nervous system has two functional parts:

- the motor division — this is further divided into:
  - — the somatic nervous system, which conducts impulses from the CNS to skeletal muscles
  - — the autonomic nervous system, which conducts impulses from the CNS to smooth muscle, cardiac muscle and glands
- the sensory division.

The cranial nerves

The cranial nerves pass from their origin, principally from the brain stem, out via small openings in the skull to innervate the appropriate structures. Each pair of nerves is named according to its distribution or function and is also numbered I–XII (see Table 9.1). Cranial nerves were formerly described as either motor or sensory, or a mixture of both; however, most motor nerves are now considered to be mixed, but with a dominance of motor fibres (Tortora & Derrickson 2006).

Spinal nerves

There are 31 pairs of spinal nerves, named and grouped according to the vertebrae with which they are associated (number of nerves in brackets):

- cervical (8)
- thoracic (12)
- lumbar (5)
- sacral (5)
- coccygeal (1).

It should be noted that there is one more cervical spinal nerve than there are vertebrae. This is because the first pair leave the vertebral canal between the occipital bone and the atlas, and the eighth pair leave below the last cervical vertebra. Thereafter, the spinal nerves are named and numbered according to the vertebra immediately above.

As can be seen from Figure 9.13, each spinal nerve has an anterior and a posterior root. The anterior root consists of motor nerve fibres, whereas the posterior roots are sensory. The posterior root can be distinguished by its root ganglion, a cluster of nerve cell bodies.

Shortly after leaving the intervertebral foramina, both roots join together to form a mixed nerve. From here the spinal nerves continue to form a complex network all over the body, carrying motor signals to effectors such as the skeletal muscles and conveying sensory information such as touch to the CNS for interpretation.

Further details of this complex network can be found in Tortora & Derrickson (2006).

The autonomic nervous system

The autonomic nervous system is outwith voluntary control and is the most complex and perhaps least understood part of the nervous system. Its involvement in, and effect upon, everyday activities is vague until its delicate mechanisms are upset. The effects are then readily felt by the individual.

The autonomic nervous system consists only of the nerves carrying motor impulses to the internal organs; thus it is exclusively peripheral and motor. Its activity is influenced by many factors, including sensory information from the internal organs, numerous peptides and hormones, and signals from higher control centres such as the hypothalamus. It is described as having two divisions, the sympathetic and parasympathetic, each imposing different effects (see Figs 9.16 and 9.17).

HEAD INJURY AND RAISED INTRACRANIAL PRESSURE

In 2000/2001, statistics demonstrated that almost 113 000 people were admitted to hospital in England as a result of head injury; 72% of these were males and 30% were under the age of 15 (DH 2000/2001). Of all people with a head injury, 90% will present with a mild injury, whilst the

remaining 10% are classified as moderate or severe, but it is these 10% who are more likely to develop subsequent complications (Swann & Teasdale 1999).
