General paresis, a chronic meningoencephalitis that severely disturbs cerebrocortical function and results in gross atrophy of the frontal and temporal lobes, is characterized by granulations in the ventricles, hydrocephalus, and widened cerebral sulci. Depending on the damaged area, the symptoms may be psychiatric, neurologic, or, more commonly, both. [21] Untreated, the course of this process spirals downward towards death. In the Oslo study, general paresis developed in 2.5 percent of men and 1.4 percent of women. The disease begins about 15 to 20 years after infection. The onset may be sudden but is more commonly insidious, with changes in personality and behavior. Irritability, forgetfulness, inability to concentrate, and headaches are followed by impaired judgment, emotional lability, and inappropriate social or moral behavior. [21] Delusions of grandeur with marked euphoria occur in 20 percent of the cases. It has been said that everyone in contact with the paretic suffers but the patient. Paranoia, tantrums, and alcohol abuse may appear. Full-blown psychosis is followed by a period of neurologic deterioration. Tremors of the hands, lips, or tongue; seizures of any type; and incontinence of urine and feces are common. At this point, a paralytic facies devoid of facial expression is typical. Mental and neurologic deterioration progresses to death in an average of 2 to 12 years from pneumonia, infected pressure ulcers, or septicemia. The clinical spectrum is summarized in the clever Holmes mnemonic, *paresis*: *p*ersonality disorder, *a*ffect (flat), *r*eflexes (hyperactive), *e*ye changes (unequal pupils that react poorly to light), *s*ensorium (delusions), *i*ntellect impairment, and *s*peech dysarthria. Serum and CSF serologic tests are reactive in almost all cases. Adequate antibiotic treatment halts progression of the disease in 80 percent of patients.

Optic atrophy may occur as an isolated finding. The visual loss begins in one eye, but soon involves the other. Optic atrophy also results from syphilitic optic neuritis. In both conditions, the CSF is usually abnormal. Penicillin does not restore vision but prevents further loss.

Focal (gummatous) cerebral meningeal syphilis is caused by compression and invasion of the brain by a gumma, which usually arises from the pia mater. Because serologic tests can be unreactive in the serum and the CSF, a biopsy may be required for diagnosis. The symptoms produced by spinal gummas are caused by compression. Cerebral gummas respond poorly to antibiotics, so surgical resection may be necessary. [23]

In clinical practice, an unusual combination of signs and symptoms may be present, resulting in a puzzling neurologic picture. Perhaps as a result of the liberal use of antibiotics, which may partially treat CNS infection, the classic forms of

neurosyphilis are becoming less common and the presentations more atypical. There are reports of patients with blurring of vision accompanied by Argyll-Robertson pupils or with isolated bilateral oculomotor nerve paresis or with tinnitus accompanied by variable auditory deficits. The presentation may be ophthalmic symptoms, confusion, personality changes, the Guillain-Barré syndrome, or persistent dizziness. The diagnosis of neurosyphilis should be strongly considered in a young adult with a stroke, new seizure disorder, confusional syndrome, or dementia. Detection relies on a combination of clinical manifestations, serum serologic tests, CSF examination, and radiographic scans.

CONGENITAL SYPHILIS

As early as 1529, Paracelsus recognized that syphilis could infect the fetus, although “genetically from father to son” rather than transplacentally. At that time, because of another popular misconception, wet nurses were publicly paraded and flogged (with the approval of medical practitioners) for supposedly transmitting the disease to their previously healthy charges. In time, the mode of transmission became clear, but not until the nineteenth century was the disease studied systematically. In 1854, Paul Diday described the syphilitic newborn as “a little wrinkled potbellied old man with a cold in his head” (see Fig. 228-28). The definition of congenital syphilis was recently updated (Table 228-4); however, because most infants have no clinical or serologic evidence of syphilis at birth and develop abnormalities months to years later, all potentially infected infants should be treated with penicillin. [24] Despite the popularity of the term *congenital syphilis,* prenatal syphilis better indicates that the signs and symptoms may develop before or after delivery rather than always being present at birth, and are not hereditary, as congenital implies. Mothers usually transmit the infection to the fetus transplacentally and possibly during delivery through contact with an infectious genital lesion. Syphilis is not transmitted through breast-feeding unless an infectious lesion is present on the breast. [25]

FIGURE 228-28 Early prenatal syphilis in a newborn. The skin is dry and wrinkled with a yellowish-brownish hue. There is hemorrhagic rhinitis. This is what Diday described as “a little wrinkled potbellied (not seen here) old man with a cold in his head.” Note also the aged appearance of the fingers in this newborn.

Type	Definition
Confirmed	An infant in whom *T. pallidum* is identified in lesions, placenta, umbilical cord, or autopsy tissue
Presumptive	Any infant whose mother was untreated or treated with antibiotics other than penicillin before delivery, regardless of findings in the infant or Any infant or child with a reactive treponemal test for syphilis and any one of the following: Evidence of congenital syphilis on physical examination or X-ray of long bones Presence in the CSF of lymphocytosis and elevated protein (without other cause) Reactive CSF VDRL or Infant RPR fourfold higher than mother (both drawn at birth) or Reactive IgM-treponemal antibody test in serum
Syphilitic stillbirth	A fetal death in which the mother had untreated or inadequately treated syphilis at delivery of a fetus after a 20-week gestation or of a fetus weighing >500 g

*Congenital syphilis includes cases of prenatally acquired syphilis in infants and children, as well as syphilitic stillbirths.
NOTE: RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratory

TABLE 228-4 **Definition of Congenital Syphilis***

In a recent study, 66 percent of fetuses of women diagnosed with infectious syphilis had hepatomegaly, and some also had abnormal transaminases, thrombocytopenia, and anemia. [26]

Approximately 25 percent of infants from mothers with untreated primary or secondary syphilis die in utero. Of those infants born, almost half develop the disease, another quarter are seropositive without clinical manifestations, and one-quarter are not infected. About 40 percent of infants born to mothers with early latent syphilis are infected, and an additional 20 percent are premature, 10 percent stillborn, and 4 percent die perinatally. In late latent syphilis, 10 percent develop congenital syphilis and another 10 percent are stillborn or premature. [25] One-quarter of newborns with signs and symptoms of congenital syphilis die shortly after birth unless treated. Syphilis is the most common cause of nonimmune hydrops fetalis, resulting in pallor, edema, and a bloated abdomen.

Spirochetes have been detected in fetuses as young as 9 weeks, but before the fifth month of gestation the fetus seems to escape harm, probably as a result of an inability to mount an inflammatory response. Even at birth, the inflammation

affects the placenta more than the infant. A fibrosed, large, thick, and pale placenta and a diseased umbilical cord with alternating streaks of red, pale blue, and chalky white may be the only clue to the diagnosis of congenital syphilis. Some infants may develop the disease after birth from colonization of *T. pallidum* in the nasopharynx and gastrointestinal system.

Clinical Manifestations

Prenatal syphilis is divided into early (first 2 years) and late (after 2 years) stages. In 80 percent of cases, the diagnosis is missed during the first year of life, and in one study, the average age at diagnosis was 30 years. Most infants are asymptomatic, and even when manifestations develop, these are often subtle and nonspecific.

EARLY PRENATAL SYPHILIS Clinical manifestations develop within the first 2 years of life. This stage is comparable to the secondary stage of acquired syphilis because treponemes disseminate throughout the fetus. Without treatment, almost half of symptomatic infants die. However, with improved perinatal care and treatment, the prognosis is now good. Infants tend to be small for dates or they are premature, irritable, and cry feebly. In descending order of frequency, the manifestations found are low birth weight, hepatosplenomegaly, anemia, jaundice, thrombocytopenia, skin lesions, respiratory distress, rhinitis, and pseudoparalysis. [26] Rhinitis ("snuffles") has been reported in 73 percent of infants. It usually develops in the second to third week of life and may be the earliest clinical sign. Initially thin, a mucoid nasal discharge, teeming with spirochetes, can become purulent or bloody (Fig. 228-28). The nasal septum may become perforated. If untreated, flattening of the nasal bridge results in the characteristic saddle or *fleur de lis* nose. [27] The skin of the syphilitic neonate is often dry and wrinkled and, in newborns with fair skin, has a café au lait hue (see Fig. 228-28). Mucocutaneous manifestations occur in about half of patients younger than 6 months of age and, like secondary syphilis lesions, usually consist of an eruption of copper- to red-colored macules and papules, with or without scale, predominantly on the palms, soles, and diaper area. Condylomata lata and mucous patches may also be present. Annular or corymbiform eruptions may also occur. [25] Rare, but characteristic for the disease, are bullae between 1 and 5 cm in diameter. They are highly infectious and may be generalized or, more often, limited to the extremities including the palms and soles (Fig. 228-29). Commonly known as syphilitic pemphigus, the blisters are invariably a sign of severe disease. Pustules may appear on the fingers, toes, and at the angles of the mouth. Ulcerations around the mouth, nose, or anus may heal with rhagades (Parrot's lines), depressed linear scars that persist to adulthood and radiate from the orifice like the spokes of a wheel (Fig. 228-30).

FIGURE 228-29 Bullous eruptions on the soles of a newborn with early prenatal syphilis. Bullae have ruptured and now present as erosions ("syphilitic pemphigus").

FIGURE 228-30 Perioral rhagades are linear scars that result from ulcerations that appear during early congenital syphilis and persist to adulthood.

Lymphadenopathy occurs in half the cases but may not be prominent. The presence of firm, movable, nontender epitrochlear nodes is especially characteristic for prenatal syphilis. Bone disease, although usually asymptomatic, is the most common early manifestation, having been reported in 97 percent of autopsied infants younger than 6 months of age. The most frequently observed osseous lesion, osteochondritis, is diagnosed by its characteristic radiographic *sawtooth* appearance in the metaphysis. In the medial aspect of the proximal tibial metaphysis, this defect occurs in one-fifth of early cases and has been called the *Wimberger* or *cat-bite sign*. Longitudinal lines of rarefaction like "celery sticks" may expand into the diaphysis. Pain from osteochondritis of the long bones, or epiphysitis, is exacerbated by movement, so the child keeps the affected limb still, a sign known as *pseudoparalysis of Parrot*. Painful periostitis, commonly observed in the latter half of the first year, may lead to blunting of the scapular spines and anterior tibial margins in later life. The resulting multiple layers of new bone produce the radiographic "onion-peel periosteum" sign. Osteitis of the fingers is uncommon but may produce dactylitis during the first 2 years of life. Neurosyphilis occurs in 40 to 60 percent of all syphilitic infants. However, only 10 percent of these infants develop symptomatic neurosyphilis, which does not usually become clinically evident until the third to sixth month of life. It is essentially meningovascular and can present as various neurologic syndromes.

LATE PRENATAL SYPHILIS Manifestations appear after the age of 2 years, but rarely past the age of 30, and can be divided into two groups: malformations (stigmata) and active pathologic processes (Table 228-5). Most manifestations are not specific, with the exception of the Mulberry molars and the characteristic interstitial keratitis. Late congenital syphilis is not infectious. The order of frequency of late syphilis signs varies in different reports.

Stigmata	Active Disease
Ophthalmic	Retinitis
Corneal clouding	Interstitial keratitis
Oral	
Hutchinson's teeth	Gummas in nose or palate
Mulberry molars	
High-arched palate	
Ears, nose, throat	
Saddle nose	
Orthopedic	
Frontal bossing	Periostitis
Short maxilla	Dactylitis
Protuberant mandible	Clutton's joints
Saber shins	
Scaphoid scapula	
Thickened medial clavicle	
Neurologic	Eighth nerve deafness
	Neurosyphilis
Mucocutaneous	Gummas
Gastrointestinal	Hepatomegaly
	Splenomegaly

TABLE 228-5 **Clinical Manifestations in Late Prenatal Syphilis**

Interstitial keratitis occurs in 8.8 percent of cases, and the average age of onset is 13.5 years for men and 27.1 years for women. The course eventuates in corneal clouding (syphilitic nebulae) (Fig. 228-31A) or glaucoma. Iritis and iridocyclitis may also be found, but usually earlier. Corneal transplantation often restores vision.

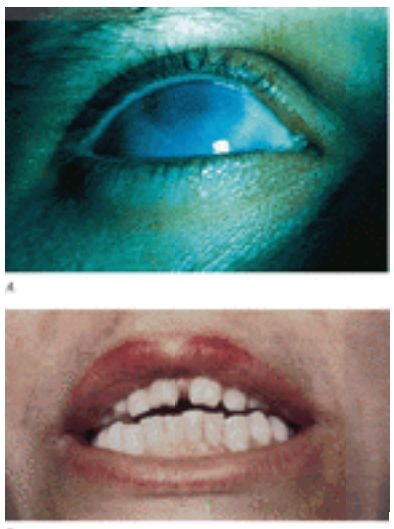

FIGURE 228-31 *A*. Interstitial keratitis with corneal clouding in late prenatal syphilis. *B*. The presence of small, notched, peg-shaped upper incisors (Hutchinson's teeth) is also part of the late congenital syphilis triad.

Asymptomatic neurosyphilis occurs in 30 to 50 percent of patients and is diagnosed only through abnormal CSF findings. Symptomatic neurosyphilis is rare and usually delayed until puberty. Juvenile paresis, the most common pattern, affects 1 to 5 percent of all patients with congenital syphilis. The presentation often involves personality and behavior changes such as deteriorating school performance and inappropriate emotional responses. Within a year, any combination of ataxia, dysarthria, tremors, and seizures develop. Other CNS complications include mental retardation and cranial nerve palsies. Bilateral eighth-nerve disease with vertigo, tinnitus, and deafness has been reported in 3 to 38 percent of patients, usually adolescents. The deafness progresses despite antibiotics, but the response to systemic glucocorticoids has been encouraging. Skin manifestations consist of granulomatous lesions and gummas, just as in late benign syphilis. Bone manifestations, such as arthritic perisynovitis, chondroosteoarthritis, epiphysitis, and periostitis, may also occur in late prenatal infection. A thickened, prominent forehead produced by localized periostitis of the frontal and parietal bones (*frontal bossing of Parrot*) is present in approximately 87 percent of patients. A short maxilla, with a shallow dish configuration, results from impaired development caused by syphilitic rhinitis and is present in up to 83 percent of patients. The *Higoumenakis sign,* which is a rather nonspecific finding, is a unilateral, irregular enlargement of the sternoclavicular portion of the clavicle resulting from previous periostitis. Anterior bowing and thickening from periostitis of the midportion of the tibia (*saber shins*) occur in 4 percent of patients. *Scaphoid scapulae,* a concavity of the vertebral border of the scapulae, is observed in 0.7 percent of patients. Mandibular protuberance, *or bulldog jaw,* was found in 25.8 percent of patients. The size is normal but appears proportionally larger in comparison to the size of the maxilla. *Clutton joints* are symmetric, nontender swellings of the knees, which often follow trauma and produce bilateral hydrarthrosis. Deformities such as painless perforation of the nasal septum or soft palate and deep ulcers of the pharynx and tongue can result from damage by gummas. Dental abnormalities are caused by treponemal invasion of the tooth buds. The pathognomonic *Hutchinson's teeth* refer to widely spaced, small permanent incisors that are screwdriver or peg-shaped, wider at the gingival margin, and notched at the biting edge because of defective enamel production (Fig. 228-31B). *Mulberry* or *Moon's molars,* found in 65 percent of cases, are dome-shaped and have numerous diminutive cusps arrayed in a tight circle at the top of the dome. The first lower molars most commonly show these changes. As a consequence of defective enamel, these teeth are predisposed to caries and rarely persist beyond adolescence. Dental abnormalities can be prevented if treatment is initiated before the third month of age. Congenital syphilis can be a difficult diagnosis in the absence of physical signs and symptoms. Maternal IgG antibodies can cross the placenta, but nontreponemal tests become nonreactive within 3 to 6 months and treponemal tests within 6 to 12 months after birth. There is an interval of 2 to 3 months between the onset of the infection and fetal production of IgM antibodies, so serologic reactivity at birth depends on when the fetus became infected. The presence of reactive IgM tests in the serum of newborns is considered to prove the diagnosis of congenital syphilis, but the FTA-ABS IgM may be falsely negative in 35 percent of infants. The umbilical cord should be sent for pathologic examination with special stains for treponemes. Nasal secretions and mucocutaneous lesions should be examined by dark-field microscopy. Radiographs showing periostitis of the tibia suggest the diagnosis.

SYPHILIS AND HIV INFECTION

Infection with syphilis imparts a greater risk for acquiring HIV infection, at least in part because the genital ulceration provides an easier entry to the virus into the systemic circulation. Numerous studies demonstrate that syphilis is more common in HIV-infected than in HIV-seronegative persons.

Surprisingly, HIV infection does not significantly influence the clinical course, serologic response, or treatment outcome of most patients with early syphilis. [28], [29] The appearance of primary chancres is typical, but patients with primary syphilis

present more frequently with multiple ulcers and chancres may persist up to the secondary stage. The course of secondary syphilis is usually unchanged, although rarely, rapidly progressive disease, and unusual manifestations have been reported. [30] Nodular and noduloulcerative lesions (Fig. 228-32) are more common, but most of these cases have no constitutional symptoms associated with malignant syphilis. [31] Perforation of the palate has been rarely reported. There are several reports of eye involvement, but syphilis is an uncommon cause of uveitis in HIV infection (0.6 percent). [32]

FIGURE 228-32 Ulcerated papules in an HIV-infected man. This was the initial presentation of HIV infection.

Although most cases of early syphilis in HIV-positive patients respond to conventional doses of penicillin, serologically defined treatment failures are more common, and for this reason closer evaluation after therapy is mandatory. In one study, 18 percent of patients treated with intramuscular penicillin had serologically defined treatment failures at 6 months and 14 percent at 12 months, but this rate was similar to the HIV-seronegative control group. [33] Clinical relapses occurred in 1 percent of patients in a prospective study, and more frequently in retrospective studies. Rarely, patients experience multiple relapses.

Neurosyphilis may be the first clinical manifestation of HIV infection. In one study, investigators recovered *T. pallidum* from the CSF of 26 percent of HIV-infected patients with early syphilis before treatment and 20 percent after treatment. [33] These percentages are similar to those of HIV-seronegative patients. [33] In a prospective, multicenter, randomized, controlled trial that compared HIV-seropositive and HIV-uninfected persons with syphilis, no differences in neurologic status were apparent. [34] The presence of *T. pallidum* in the CSF in early syphilis does not differ according to HIV status and is not predictive of treatment failure. Most cases of neurosyphilis comprise asymptomatic or meningovascular neurosyphilis, but focal gummas and other types of neurosyphilis have also been reported. Manifestations include cranial nerve palsies, optic neuritis or neuroretinitis, polyradiculopathy, transient ischemic episodes, and strokes. A rare fulminant form (necrotizing neurosyphilis) is reported more frequently in AIDS patients.

Not only is the prevalence of neurosyphilis higher in patients coinfected with both syphilis and HIV, but the progression to symptomatic forms of neurosyphilis is accelerated, even after conventional therapy. [34] In a small but significant study, which included 15 HIV-infected and 25 HIV-seronegative patients with primary or secondary syphilis, *T. pallidum* was isolated from the CSF by rabbit inoculation in a similar proportion from both groups. [35] Only CSF leukocytosis was more common (67 versus 25 percent) in the HIV-seropositive group. Notably, one injection of benzathine penicillin failed to eradicate the CNS infection in three of the four HIV-infected cases with positive treponeme cultures. Since then, several unsettling reports have alluded to the unexpected frequency of neurorelapse after benzathine penicillin therapy in HIV-infected patients. Serologic response and CSF abnormalities usually resolve successfully in HIV-infected patients with neurosyphilis, but 8 percent may fail therapy even by the recommended high doses of intravenous penicillin the first time, and 23 percent have persistent pleocytoses. [35] Patients with CSF abnormalities should be cautiously diagnosed as having asymptomatic neurosyphilis, because CSF leukocytosis or elevated protein is present in up to 60 percent of nonsyphilitic HIV-infected patients who are not taking effective antiretroviral therapy.

Dysregulation of the humoral immune response may result in uncontrolled production of antibodies with extremely elevated titers. In a study, the median rapid plasma reagin (RPR) titers (see below) were four times higher (1:128 versus 1:32) in HIV-infected patients than in HIV-uninfected patients with their first episodes of early syphilis. [36] Furthermore, B cell activation occasionally results in a higher rate of biologic false-positive, nontreponemal serologic tests. Conversely, an occasional patient may have a nonreactive nontreponemal test during early syphilis, and the sensitivity of treponemal tests appears to be lower in patients treated for past syphilis if they are HIV infected (80 versus 97 percent). [37]

In view of the occasional unreliability of serologic testing, the threshold to biopsy skin lesions should be lower. The classic pathologic findings of secondary syphilis are usually present, although some cases with lymphoid infiltrate resembling cutaneous T cell lymphoma have been reported.

DIAGNOSTIC TESTS

The definitive test in early syphilis is demonstration of spirochetes in lesional exudate or tissue either by dark-field microscopy or by direct immunofluorescence. Unless the diagnosis is unequivocal as a result of these examinations or from clinical evaluation of typical lesions coupled with reactive serologic results, skin biopsy is recommended in primary, secondary, and certainly in tertiary syphilis lesions.

Histopathologic Examination

The epidermis of a chancre is acanthotic at the margins and becomes thinner and more edematous towards the eroded center. A dermal infiltrate, composed predominantly of lymphocytes, plasma cells, some histiocytes, and a few neutrophils, is dense in the central portion and perivascular in the periphery of the chancre. In untreated cases, the spirochetes stain gray with an impregnated silver stain such as the Warthin-Starry stain. In contrast to immunofluorescence with fluorescein-labeled syphilitic rabbit serum, which requires fresh tissue, immunoperoxidase testing can be done on paraffin-embedded tissue. The spirochetes are more easily found in the epidermis and around dermal capillaries. Under electron microscopy, *T. pallidum* is predominantly found extracellularly. Less commonly, it is found intracellularly within the endothelial cells of capillaries and inside the vacuoles and phagolysosomes of plasma cells, macrophages, and neutrophils; and, occasionally, within fibroblasts and nerve fibers. Syphilitic buboes show follicular hyperplasia, endothelial proliferation, and a chronic inflammatory infiltrate with plasma cells and many spirochetes. Occasionally, noncaseating sarcoidal granulomas are present at the end of the primary stage.

Characteristically, secondary syphilis lesions show dilatation and thickening of blood vessels with a proliferation of endothelial cells and a superficial and deep perivascular dermal infiltrate containing numerous plasma cells. The infiltrate often becomes lichenoid, may obscure the dermal epidermal interface, and, in a third of cases, surrounds adnexal structures and nerves. Other changes depend on the biopsied lesion. Macules show mild or no epidermal changes.

Papulosquamous plaques show psoriasiform epidermal hyperplasia, parakeratosis and, often, focal spongiosis, basal vacuolar changes, and microabscesses with neutrophils. Other common epidermal changes are epidermal pallor, keratinocyte necrosis, extravasated red blood cells, and exocytosis of mononuclear cells. The dermal vessels show endothelial proliferation and swelling. There is a deep and superficial perivascular infiltrate arranged in a coat-sleeve pattern and composed of lymphocytes, histiocytes, and many plasma cells. The infiltrate assumes a lichenoid pattern that may involve the superficial and deep dermis and, in one-third of the cases, surrounds adnexal, vascular, and neural structures. The infiltrate may also be T-shaped or perivascular. Small epithelioid granulomas, which may have Langhans or foreign-body–type giant cells, may be present, even in young lesions. In lesions of pustular syphilis, neutrophils within the subcorneal pustules may infiltrate the hair follicles. In ulcerating lesions, there is infarction necrosis of the epidermis and dermis because of occlusion of blood vessels by fibrinoid material. The epidermis may be absent from the specimen.

In nodular tertiary syphilis, there is a dermal lymphohistiocytic and plasma cell infiltrate with small granulomas and islands of epithelioid cells intermingled with some multinucleated giant cells. A mild degree of caseation necrosis may be present. In gummas, the infiltrate contains numerous epithelioid and multinucleated giant cells and extends throughout dermis to the subcutaneous tissues. Extensive caseation necrosis surrounded by epithelioid and giant cells is present in the center of the lesion. Nodular tertiary syphilis may be difficult to differentiate from lupus vulgaris, and gummatous syphilis from scrofuloderma and erythema induratum.

Dark-Field Microscopy

Dark-field examination is the diagnostic test of choice in chancres and moist lesions of secondary syphilis, especially condylomata lata and mucous patches. The test is invalid in oral membranes because saprophytic treponemes, which cannot be differentiated from *T. pallidum,* are common in the mouth. Here, a lymph node aspirate can be examined by dark-field microscopy.

The surface of the lesion should be cleaned and gently abraded with a sterile gauze soaked in 0.9 percent sterile saline, carefully avoiding bleeding as blood cells obscure detection of the treponemes. After squeezing the base of the lesion with two gloved fingers, a serous exudate accumulates on the surface and can be scraped off with a scalpel or drawn off with a pipette. The exudate is mixed with one or two drops of saline on a glass slide and covered with a plastic slip. The slide is examined under a dark-field microscope for the presence of treponemes.

Direct Fluorescence Antibody Test

The lesion exudate on the glass slide is stained with fluorescein-labeled anti- *T. pallidum* immunoglobulin. In contrast to dark-field microscopic examination, the smear can be held for later evaluation and oral or anal lesions can be examined because only *T. pallidum* is stained. The sensitivity of the test is greater than 90 percent. [38]

Serology

Serologic tests for syphilis are divided into two types. The simpler cardiolipin-based nontreponemal tests are used for screening and to follow therapeutic response. The more elaborate *T. pallidum*-based treponemal tests are used for diagnostic confirmation and to improve diagnosis of early, congenital, and neurosyphilis. [39]

A presumptive diagnosis of syphilis is made by a reactive nontreponemal test, such as the *RPR test* or the *Venereal Disease Research Laboratory* (VDRL) test, confirmed by a treponemal test, such as *the microhemagglutination assay with T. pallidum antigen* (MHA-TP) or the *fluorescent treponemal antibody-absorption test* (FTA-ABS) (Table 228-6). [40] Although treponemal tests have higher specificity and sensitivity, because of their higher cost they are not used for screening but rather to corroborate the accuracy of reactive nontreponemal tests.

RPR	MHA-TP	Capia (IgM) EIA	
–	–	–	No syphilis or incubating syphilis
–	–	+	Early primary syphilis
+	+	+	Primary or secondary syphilis
+	–	+	Early infection
+	+	–	Late secondary or latent syphilis
+	–	–	Biologic false-positive, late syphilis
–	+	–	Late infection, treated syphilis, or false-positive treponemal test
↑	+	↑	Reinfection, relapse

Note: ↑, rising titers; EIA, enzyme immunoassay; MHA-TP, microhemagglutination assay with *T. pallidum* antigen; RPR, rapid plasma reagin.

TABLE 228-6 **Interpretation of Serologic Tests**

Reaginic Tests

These tests are inexpensive and are widely used for screening. The antigen (reagent) is a combination of cardiolipin, cholesterol, and lecithin. The VDRL and RPR become reactive 4 to 5 weeks after infection and revert to negative in 25 to 30 percent of cases during late latency. Results are reported qualitatively as reactive, weakly reactive, or nonreactive or quantitatively as a titer of the sample diluted with saline in a geometric progression by a factor of 2 (1:2, 1:4, 1:8, and so on). The highest dilution that gives a positive result is reported as the titer. Titers may differ slightly between laboratories. A high titer (=1:32) usually indicates active disease, while low titers (=1:8) may remain unchanged for years following therapy of late disease. Titers decline more slowly in patients with previous episodes of syphilis. After treatment, the titers should decline fourfold (a titer of 1:32 decreases to 1:4 or lower) within 6 months in primary or secondary syphilis, and within 24 months in latent syphilis. In patients treated for primary syphilis, the tests become nonreactive in 60 percent by 4 months and in nearly all patients by 12 months. In secondary syphilis, the tests usually become nonreactive in 12 to 24 months after treatment. If therapy is administered in the early latent stage, low titers may remain for up to 5 years or longer. In one study, 18 percent of patients treated for secondary syphilis had reactive tests at low titers after 30 to 35 years, and 44 percent of patients treated during the late latent stage had reactive tests after 35 years. In tertiary syphilis, the tests may revert to nonreactive in 20 to 30 percent of cases, even without treatment. A titer that neither decreases nor increases fourfold after treatment is referred to as serofast. If an initially high titer (=1:32) fails to decrease after treatment, the patient should be evaluated for neurosyphilis and retreated appropriately. A fourfold titer increase indicates reinfection or treatment failure. Weakly reactive qualitative tests should be repeated, because up to a third will be eventually positive.

False-negative results occur during very early infection or in latent and late syphilis. In 1 percent of secondary syphilis cases, results are falsely reported as nonreactive as a result of the prozone phenomenon, because, unless the serum is diluted, the high levels of antibody prevent flocculation.

Biologic false-positive results constitute 1 to 2 percent of reactive tests, depending on the population studied. In 90 percent of patients, the titers are less than 1:8. Biologic false-positive results may be transient and acute (6 months) or longer lasting and chronic (6 months) (Table 228-7). In narcotic addicts, false-positive reactions may persist even after 14 months of drug abstinence. [37]

	Acute	Chronic
Physiologic	Pregnancy	Advanced age
Spirochete infection	Leptospirosis	Endemic syphilis
	Lyme disease	Pinta
	Rat-bite fever	Yaws
	Relapsing fever	
Viral infection	Cytomegalovirus	Human T cell leukemia/lymphoma virus I
	Infectious mononucleosis	HIV infection
	Hepatitis	
	Herpes simplex	
	Herpes zoster-varicella infection	
	Measles	
	Mumps	
	Mycoplasma pneumonia	
	Toxoplasmosis	
	Viral sepsis

Autoimmune disease		Autoimmune hemolytic syndrome
		Autoimmune thyroiditis
		Idiopathic thrombocytopenic purpura
		Mixed connective-tissue disease
		Polyarteritis nodosa
		Primary biliary cirrhosis
		Rheumatoid arthritis
		Sjögren's syndrome
		Systemic lupus erythematosus
Other		Drug abuse
		Dysproteinemias
		Hepatic cirrhosis
		Malnutrition
		Malignancy
		Lymphoproliferative disorders

TABLE 228-7 **Causes of Biologic False-Positive Nontreponemal Tests**

Specific Treponemal Tests

These tests use whole or fragments of *T. pallidum* as antigen. Compared to nontreponemal tests, they are more cumbersome to perform but have greater sensitivity in the primary and late stages and slightly higher specificity (Table 228-8). They are widely used to confirm reactive, nontreponemal test results. [39]

	Sensitivity, %				
	Primary	Secondary	Latent	Tertiary	Specificity, %
VDRL	80 (74–87)	100	80 (75–100)	71 (55–86)	98
RPR	86 (81–100)	100	80 (75–100)	73 (55–86)	98
FTA-ABS	98 (93–100)	100	99	97 (95–100)	99
MHA-TP	82 (50–95)	100	99	96 (90–99)	99
Capia (IgM) EIA	82	60	53	34	100

Note: For explanation of serologic tests, see text.

TABLE 228-8 **Sensitivity and Specificity of Serologic Tests**

The FTA-ABS test is the most sensitive serologic test in primary syphilis, and reactivity begins during the third week of infection, but the MHA-TP, which is less expensive and cumbersome to perform, is more popular. The tests rarely

become nonreactive in untreated patients, and reactivity usually continues even after treatment. Although 15 to 25 percent of patients become unreactive after treatment of primary syphilis, long-term reactivity persists in many after appropriate treatment of secondary syphilis.

The specificity and sensitivity of both tests range between 94 and 100 percent during the secondary and the late phases of the disease (Table 228-8). Their high sensitivity permits detection of very small amounts of antibodies, so the tests are not useful to assess the efficacy of treatment. False-negative results are very rare. False-positive FTA-ABS results are usually caused by autoantibodies (rheumatoid factor) or antibodies to spirochetal infections (Table 228-9).

Infectious mononucleosis
Lepromatous leprosy
Leptospirosis
Lyme disease
Malaria
Relapsing fever
Systemic lupus erythematosus

TABLE 228-9 **Common Causes of False-Positive Treponemal Tests**

Treponemal-based *enzyme immunoassays* (EIA) are more specific (99.5 percent) than the RPR when used for screening, and more sensitive than the FTA-ABS in patients with past infection. [41]

IgM tests, such as the *Captia syphilis (IgM) EIA,* are the serologic test of choice in primary infection, assessment of reinfection, and congenital syphilis. IgM antibodies can be detected in the serum toward the end of the second week of infection. The test is the first to become positive and has a 93 percent sensitivity in primary infection. However, because memory cells do not synthesize IgM antibodies, the sensitivity is only 85 percent in secondary infection and 64 percent in early latent infection. Reactivity ceases within 3 to 9 months after therapy of early syphilis, but may persist for 12 to 18 months after treatment of late infection. In untreated persons, a reactive result indicates almost with certainty the need for therapy, but a nonreactive result does not exclude infection. Persistence of reactivity after therapy indicates treatment failure or false-positive results because of autoantibodies of the IgM class.

Because IgM antibodies cannot pass through the placenta or the intact blood–CSF barrier, IgM reactivity in the serum of a newborn confirms prenatal infection, and detection of antitreponemal IgM in the CSF indicates neurosyphilis. The sensitivity of the Captia (IgM) EIA is very high in congenital syphilis (100 percent), but less so in primary (82 percent), neurosyphilis (34 percent), and treated syphilis (11 percent). [40] The test is highly specific because there appears to be no interference by rheumatoid factors or competitive inhibition by antitreponemal IgG. Values below 0.9 are nonreactive, between 0.9 and 1.0 are equivocal, and above 1.0 are reactive.

Immunoblots have a very high sensitivity and near-perfect specificity. Although laborious, they are the tests of choice to confirm a false-positive test, and are promising as a replacement of other confirmatory treponemal tests. [39]

PCR assays have achieved a sensitivity and specificity of over 95 percent in identifying *T. pallidum* in genital ulcers. [42] They have also become essential investigational tools.

CSF Examination

Examination of the CSF by lumbar puncture to exclude asymptomatic neurosyphilis offers marginal benefits as the risk of developing neurosyphilis in HIV-seronegative patients after standard parenteral penicillin treatment is very small. However, lumbar puncture should be performed if there is clinical evidence of neurologic involvement. Because no clinical presentation is specific for neurosyphilis, reliable criteria by laboratory examinations are particularly important (Table 228-10). Elevated white blood cell count (5 cells per µL) and total protein (>400 mg/L) indicate inflammation and presumed infection. Of course, these findings are found in other types of aseptic meningitis. However, both may be normal or slightly elevated in asymptomatic disease as well as in tabes dorsalis.

Strongly indicative
Reactive VDRL (or RPR)
Reactive MHA-TP (or FTA)
Reactive western blot, PCR, or IgM tests
TPHA index >500
Strongly suggestive (in absence of other CNS disease)
Cell count >5 cells per µl
Protein >40 mg/100 mL
IgG index >0.7
Practically excluded
Nonreactive MHA-TP (or FTA)
TPHA index <70

TABLE 228-10 **Diagnosis of Neurosyphilis through CSF Testing**

A reactive CSF VDRL result indicates neurosyphilis. Blood contamination may increase titers but this only occurs when CSF is visibly bloody. Unfortunately, the CSF VDRL is not reactive in up to 70 percent of patients with neurosyphilis, particularly in asymptomatic cases and in tabes dorsalis. [43] The CSF FTA-ABS is unreliable because of false-positive results; however, a nonreactive test virtually excludes CNS involvement. [44] In certain cases, the diagnosis of neurosyphilis is particularly challenging. A patient with adequately treated syphilis and no neurosyphilis may have abnormal CSF serology, cell counts, and protein as a result of nonsyphilitic CNS infection (HIV, malaria) or a neoplasm.

TREATMENT

Parenteral penicillin is the treatment of choice for all stages of syphilis. Treatment failures are rare and regularly respond

to a second course of penicillin at the same or higher doses. The concentration of penicillin in the CSF is less than 10 percent of the serum level. However, even a single injection of benzathine penicillin produces effective levels in the perivascular areas where treponemes are found in the CSF. [45] Parenteral penicillin is the only treatment with documented efficacy in neurosyphilis, HIV infection, and pregnancy.

A concentration of penicillin above 0.018 mg/L is considered treponemicidal. However, the maximally effective in vitro level of concentration (0.36 mg/L), is recommended for a minimum duration of 7 to 10 days in early syphilis, and longer in late syphilis. [46]

Recommended doses of long-acting benzathine penicillin provide treponemicidal levels for 3 to 4 weeks. Oral penicillins can produce adequate serum and tissue levels, but is not recommended because of reduced efficacy because of lack of compliance. [47]

Tetracyclines, erythromycin, and third-generation cephalosporins have strong antitreponemal activity in experimental and clinical trials. Clinically, however, their efficacies are less than penicillin, and numerous treatment failures have been reported. Although less investigated and more expensive than tetracycline, doxycycline is preferred because of better compliance and absorption, which is less affected by food. [47] Erythromycin is slightly less effective than tetracycline. However, therapeutic results with another macrolide, azithromycin, administered in a single 2 g dose, are encouraging, and this antibiotic may eventually replace erythromycin, and even doxycycline, as the alternative treatment of choice. [48] Ceftriaxone at a dose of 500 mg daily for 10 days has also been studied. [48] 1 g intramuscularly or intravenously daily for 8 to 10 days appears to be effective in primary, secondary, and early latent syphilis, although experience with this treatment is limited. [49] Additionally, although not recommended, the drug can be safely administered during pregnancy. [46] HIV serology is recommended for all patients with syphilis, and should be repeated in 6 months in patients living in areas with high HIV prevalence. [47]

Primary and Secondary Syphilis (without Neurologic, Ophthalmologic, or Auditory Involvement) [47]

A single dose of benzathine penicillin G, 2.4 million units intramuscularly, is the preferred treatment.

PENICILLIN ALLERGY Patients with uncomplicated syphilis may be treated with doxycycline, 100 mg orally twice daily for 2 weeks. Compliance is better than with tetracycline, 500 mg orally four times daily, or erythromycin, 500 mg orally four times daily. Ceftriaxone, 250 mg daily or 1 g every other day intravenously for 10 days, is an alternative.
PREGNANCY Pregnant women should be treated with penicillin as discussed below. If there is allergy to penicillin the patient should be desensitized.
HIV INFECTION Three doses of weekly injections of benzathine penicillin G are preferred by some experts because of higher prevalence of neurosyphilis in these patients (although there is no evidence that this is more effective). Enhanced therapy with ampicillin and probenecid after treatment with benzathine penicillin injections does not improve responses. [33]
CHILDREN Children should be evaluated for congenital syphilis through examination and review of maternal and prenatal records. If CNS is abnormal, treat for neurosyphilis. If infection was acquired postnatally, consult with a child protection agency after treating with a single intramuscular injection of benzathine penicillin G, 50,000 units/kg up to 2.4 million units.
CSF EXAMINATION If there are signs or symptoms of CNS, eye, or hearing involvement, examine the CSF. Do a slit lamp examination if there is ophthalmologic disease. If CSF findings suggest neurosyphilis, treat accordingly.
FOLLOW-UP Patients should be reexamined clinically and serologically at 6 and 12 months (if HIV-seropositive, then at 3, 6, 9, 12, and 24 months).
TREATMENT FAILURES Patients should be retreated if there is a fourfold (or greater) increase in RPR or VDRL titer within 6 months. HIV serology should be repeated. Unless reinfection is definite, CNS examination is indicated. If CSF abnormalities indicate neurosyphilis, treat with intravenous penicillin. If neurosyphilis is excluded, treat with benzathine penicillin G, 2.4 million units intramuscularly for three doses 1 week apart. The management of patients who remain serofast, with RPR titers that do not decline by a fourfold factor in 6 months, is unclear. At the very minimum, clinical evaluation and HIV testing are indicated. If the patient is HIV seropositive, do a spinal tap and treat accordingly. If HIV seronegative but compliance cannot be assured, retreatment (preferably with three injections of benzathine penicillin G 1 week apart) is recommended.

Early Latent Syphilis [47]

A single dose of benzathine penicillin G, 2.4 million units intramuscularly, is the recommended treatment.

PENICILLIN ALLERGY If the patient is neither pregnant nor HIV-infected, treat with doxycycline, 100 mg orally twice daily for 4 weeks.
PREGNANCY Treat with penicillin. If there is allergy to penicillin, desensitize.
CHILDREN The treatment is the same as for primary syphilis.
FOLLOW-UP As in ate latent syphilis, below.

Indeterminate or Late Latent Syphilis

Benzathine penicillin G, 2.4 million units intramuscularly 1 week apart for three doses, is the treatment of choice. If the patient misses a dose, the treatment may be resumed as long as the interval between injections has not exceeded 2 weeks.

PENICILLIN ALLERGY Doxycycline, 100 mg orally twice daily, or tetracycline, 500 mg orally four times daily for 28 days, may be prescribed.
PREGNANCY Treat with penicillin as discussed below.

HIV INFECTION Treat with penicillin.
CHILDREN After appropriate evaluation to exclude congenital syphilis and sexual abuse, treat with weekly injections of benzathine penicillin G, 50,000 units/kg (up to 2.4 million units) intramuscularly for three doses.
CSF EXAMINATION In asymptomatic individuals, the yield of positive findings in lumbar punctures is low, but CSF examination is clearly indicated in certain cases:

- Cardiovascular, neurologic, eye, or auditory symptoms or in late benign syphilis
- HIV infection
- RPR titer =1:32
- Treatment failure
- Treatment other than penicillin

If the CSF examination demonstrates abnormal, unexplainable findings, patients should be treated for neurosyphilis. The outcome of treatment has not been conclusively studied, but in 469 treated patients with uncomplicated late latent syphilis who were followed for up to 12 years, the CSF remained normal and no cases of cardiovascular syphilis were reported.
TREATMENT FAILURES Patients with a normal CSF examination should be retreated for latent syphilis if signs or symptoms of syphilis develop, if a high titer (>1:32) fails to decline fourfold within 12 to 24 months, or if titers increase fourfold or higher.
FOLLOW-UP Quantitative nontreponemal serologic tests should be repeated at 6, 12, and 24 months (6, 12, 18, and 24 months if the patient is HIV infected). After treatment, the patient should be reevaluated for neurosyphilis and retreated accordingly if (1) titers increase fourfold, (2) an initially high titer (=32) fails to decrease fourfold within 12 to 24 months, or (3) the patient develops signs or symptoms attributable to tertiary syphilis.

Tertiary Syphilis (Cardiovascular, Late Benign Syphilis) [47]

Benzathine penicillin G, 2.4 million units 1 week apart for three doses, is the recommended treatment.

PENICILLIN ALLERGY If the patient is not HIV infected and the CSF is negative, treat with doxycycline, 100 mg orally twice daily for 2 weeks.
CSF EXAMINATION All patients should have spinal taps, and if abnormalities are found, treat for neurosyphilis.
PROGNOSIS After treatment of late benign syphilis, gummas heal slowly over several months, depending on the extent of tissue destruction. Gummas of the brain or spinal cord may need surgical excision. Because advanced symptomatic disease in cardiovascular syphilis is associated with poor prognosis even with recommended doses of benzathine penicillin, some experts prefer to treat cardiovascular disease with high-dose intravenous penicillin. The evidence suggests that penicillin has a beneficial effect in the majority of patients, although efficacy is difficult to evaluate as most symptomatic patients receive therapy to improve cardiac function. In studies, 63 percent of patients with aortic insufficiency, aneurysms, or both experienced symptomatic improvement from 6 to 12 months after penicillin treatment. The disease progressed in 4 percent of asymptomatic and 4.5 percent of symptomatic patients.

Neurosyphilis [47]

Aqueous crystalline penicillin G, 18 to 24 million units administered daily as 3.5 to 4 million units intravenously every 4 h for 10 to 14 days, is the treatment of choice. [47]

Alternatively, treatment with a single injection of procaine penicillin G, 2.4 million units intramuscularly daily; and probenecid, 500 mg orally every 6 h for 10 to 14 days, can be instituted in patients whose compliance can be assured. Treatment of neurosyphilis with ceftriaxone (1 g intravenously daily for 14 days) is not as effective as penicillin.

PENICILLIN ALLERGY Desensitize and treat with penicillin.
FOLLOW-UP Reexamine the CSF every 6 months until normal. Cell counts should decrease by 6 months, and CSF VDRL and protein levels by 2 years. If not, retreat with intravenous penicillin.
PROGNOSIS In one study, penicillin cured, improved, or stabilized the disease in 91 percent of patients with asymptomatic neurosyphilis, 81 percent with meningovascular disease or meningitis (78 percent cured), 75 percent with general paresis (48 percent cured), 72 percent with tabes dorsalis (47 percent cured), and 88 percent with miscellaneous neurologic abnormalities. If symptoms worsen during treatment, the dose may need to be increased. Optic atrophy, alone or in conjunction with tabes dorsalis, and eighth-nerve-related deafness are notoriously more resistant to treatment. No case of blindness because of optic atrophy is reversible with penicillin, although lack of progression or improvement occurs in up to 60 percent of cases. Eighth-nerve-related deafness benefits from the combination of long-term penicillin and prednisone.
RELAPSE Neurosyphilis relapses usually respond to additional courses of intravenous penicillin at equal or higher doses.

Treatment in Pregnancy [47]

The penicillin regimen appropriate for the stage of the infection should be used. In primary, secondary, and early latent syphilis, a second benzathine penicillin injection 1 week later is recommended by some experts.

PENICILLIN ALLERGY Desensitize and treat with penicillin. Erythromycin's ability to cross the placenta is fair to poor. Infants born to mothers who any of received erythromycin for syphilis during pregnancy should be thoroughly evaluated for active disease, treated with penicillin, and closely followed. Tetracycline is avoided because of dental staining as a result of deposition in enamel.
EVALUATION Perform fetal ultrasound, and if signs (hydrops, hepatomegaly) of fetal syphilis are present, consult with an experienced obstetrician.
SCREENING Pregnant women should be screened at their initial prenatal visit, and those with seropositive results should

be considered infected unless treatment can be verified and sequential serologic antibody titers convincingly demonstrate an appropriate response. In case of doubt, retreatment is warranted as the potential benefits outweigh the possible risks. Screening should be repeated in the third trimester and again at delivery.
FOLLOW-UP Repeat serologic titers monthly if there is risk of reinfection; otherwise, repeat in the third trimester and at delivery.
COMPLICATIONS A potential adverse effect of penicillin treatment is the Jarisch-Herxheimer reaction, which may precipitate labor (placental shock). However, the association of spontaneous abortion with this phenomenon is debatable and should not delay treatment.
PROGNOSIS In 414 pregnant women with early syphilis who were treated with variable doses of penicillin, only 5 percent of their newborns had syphilis, and an expected rate of stillbirths was reported. The failures were observed in women reinfected or treated late in pregnancy. In another study, the success of therapy in preventing congenital syphilis was as follows: primary syphilis, 27 of 27; secondary syphilis, 71 of 75; early latent syphilis, 100 of 102; and late latent syphilis, 136 of 136. [50]

Prenatal Syphilis [47]

Neonatal period: Aqueous penicillin G, 50,000 units/kg intravenously every 12 h for the first 7 days of life and every 8 h for the next 3 days, or procaine penicillin G, 50,000 units/kg intramuscularly daily for 10 to 14 days.

Postneonatal period: Benzathine penicillin G, 50,000 units/kg (up to 2.4 million units) intramuscularly if CSF examination is negative. If neurosyphilis, aqueous penicillin G, 50,000 units/kg every 4 to 6 h intravenously for 10 to 14 days.

ADDENDUM Infants should be treated for presumed congenital syphilis regardless of evaluation if born to mothers with any of the following:

- Untreated syphilis at delivery
- Treatment other than with penicillin
- History of treatment before becoming pregnant but no documentation of a fourfold decrease in titers
- Treatment for syphilis within 1 month of delivery
- Inadequate documentation of appropriate treatment
- Serologic evidence of relapse or reinfection after treatment
- No fourfold decrease in RPR titers after treatment during pregnancy

If the infant has signs of congenital syphilis on physical examination or serologic evidence of syphilis (infant's RPR titer is two dilutions greater than mother's), the evaluation should include complete blood count with differential and platelets and CSF examination for cell count, protein, and RPR. Other tests that can be ordered as clinically indicated include long-bone radiographs, chest radiograph, cranial ultrasound, ophthalmologic examination, auditory–brainstem response, and liver function tests. If the infant's clinical, CSF, serologic, and blood evaluation are normal and compliance is indisputable, the infant may be treated with a single intramuscular injection of benzathine penicillin G, 50,000 units/kg. If the mother was adequately treated and had an appropriate serologic decline in titers, evaluation of an infant with a nontreponemal titer equal to or less than the mother's titer is not necessary, but a single dose of benzathine penicillin is recommended. If the infant's titer is not reactive, no treatment is necessary.
FOLLOW-UP Seropositive infants (or infants born to mothers who were seroreactive at delivery) must be reexamined clinically and serologically every 2 to 3 months until the test becomes nonreactive or the titer has decreased fourfold. If the reactive test result was caused by passive transplacental transfer, nontreponemal antibody titers should decrease by 3 months and disappear by 6 months of age. If the child was infected and treated, the serologic decline may be slower. If the titers are stable or increasing after 8 to 12 months of age, the child should be reevaluated (including CSF analysis) and retreated with a 10-day course of intramuscular penicillin G. Treponemal tests may remain positive for 15 months if the disease was acquired transplacentally, but if the tests are reactive after 18 months, they indicate congenital syphilis. Close neurologic follow-up is indicated for infants with initially abnormal CSF examinations. If CSF pleocytosis was present, spinal taps should be done every 6 months until the cell count is normal. If the cell count remains abnormal after 2 years, or if a downward trend is not present at each examination, the infant should be retreated. The CSF VDRL should also be checked at 6 months, and retreatment administered if still reactive.

Persons Exposed to Syphilis (Epidemiologic Treatment)

If compliance cannot be assured, examine the patient, do a serologic test, and treat the patient prophylactically for primary syphilis. If the patient is reliable, examine and do RPR monthly for 3 months from the last exposure.

Syphilis in HIV-Infected Patients

A penicillin regimen should be instituted according to the stage of the disease.

PENICILLIN ALLERGY Desensitize and treat.
CSF EXAMINATION Spinal fluid analysis should be performed on patients with indeterminate or late latent disease or with early disease with neurologic symptoms. Some experts recommend CSF examination before treatment of early syphilis as well as 6 months after treatment, but there is no evidence of improved outcomes.
FOLLOW-UP A closer follow-up with clinical and serologic tests is needed for these patients. CSF examination is indicated if there is serologic evidence of treatment failure at any time, or if the serofast response continues after 12 months.
NEUROSYPHILIS Treat according to recommended regimens for neurosyphilis. Neurorelapse is more common in these patients, even after adequate treatment.

Complications of Treatment

The Jarisch-Herxheimer reaction is a clinical syndrome consisting of fever, headache, flare of mucocutaneous lesions, tender lymphadenopathy, pharyngitis, malaise, myalgias, and leukocytosis. It occurs within 12 h of therapy. The fever peaks in 6 to 8 h usually around 39°C (102.2°F), but it can be as high as 42°C (107.6°F). Patients should be warned about the possibility of developing this reaction prior to receiving treatment. Symptoms are controlled with nonsteroidal antiinflammatory agents or aspirin. The pathogenesis of the Jarisch-Herxheimer reaction is unknown. It has been proposed that destruction of spirochetes is followed by massive phagocytosis with release of pyrogenic cytokines. Systemic glucocorticoids modify the febrile reaction without affecting the skin lesions or the leukocytosis; if administered 12 h prior to or at the time of treatment, they suppress or mitigate the reaction.

Patients with neurosyphilis not uncommonly become febrile after treatment with penicillin. Febrile reactions are more common when the CSF contains high numbers of cells and protein. Convulsions, dementia, psychosis, and meningismus have been reported to occur in up to 2 percent of neurosyphilis patients treated with penicillin. Death is rare. About 50 percent of infants with early and 39 percent of those with late disease develop febrile reactions. Rare cases of elevated liver function tests and the nephrotic syndrome have been reported.

Therapeutic paradox, or deterioration of tertiary syphilis after therapy, results from rapid decomposition of gummatous tissue. Worsening of the aortic insufficiency murmur has been reported from this complication.

Hoigné syndrome (pseudoanaphylactic reaction) is a complication associated with intramuscular procaine penicillin treatment and is seen in approximately 1 case per 1000 treated patients. The reaction occurs immediately after the injection and is characterized by tachycardia, elevated blood pressure, fear of imminent death, violent combativeness, unusual taste sensation, auditory or visual disturbances, neuromuscular twitching, occasional seizures, and even loss of consciousness. It rarely lasts longer than 30 min. Treatment consists of observation and sedatives or anticonvulsants. Inadvertent intracapillary infusion of procaine or, less likely, penicillin during intramuscular injection resulting in microembolization has been proposed as the mechanism.

Anaphylaxis from administration of penicillin injection is a life-threatening emergency that is managed by intramuscular injection of epinephrine and diphenhydramine with hydrocortisone intravenously. [46]

VACCINES

A protective vaccine against syphilis will require considerably more investigation. In one promising study, repeated immunization of rabbits with purified antiendoflagellar antigen over 32 weeks did not prevent reinfection, but the lesions occurred earlier, had a flatter, softer appearance, and resolved more rapidly. [51] Twelve surface proteins that may be suitable components for designing a vaccine were identified after mapping of the genome. [52]

CONCLUSION

The preceding discussion leaves no doubt that syphilis is a disease with an exceptional diversity of possible organ involvement. However, the skin is affected in most cases with active disease. The study and treatment of syphilis had a pivotal influence in the development of dermatology as a specialty. Even today, a number of dermatology departments from around the world have retained the word syphilology in their names. No practitioner is more capable than a dermatologist of evaluating, diagnosing, or treating syphilis and preventing its daunting complications. The occasional need for consultation with other specialties does not detract from the dermatologist's expertise. In fact, it is appropriate and essential for dermatologists to contribute their experience and skills whenever syphilis is considered as a potential diagnosis by other primary care providers and specialists. The physician who understands syphilis is a more astute and competent clinician. This conclusion was reached long ago by the renowned physician William Osler who wrote, “Know syphilis in all its manifestations and relations, and all other things clinical will be added unto you.” With the mapping of the *T. pallidum* genome a new era dawned for understanding syphilis, developing new tests and treatments, and designing a vaccine to prevent infection.

TREATMENT
CONCLUSION
REFERENCES

The nonvenereal treponematoses (pinta, yaws, and endemic syphilis) constitute a group of three distinct spirochetal infections that have remained confined to endemic foci in indigent, remote, rural regions of tropical and subtropical countries. [1] The causative spirochetes cannot be distinguished morphologically or serologically from *Treponema pallidum* and, like syphilis, the diseases progress through successive clinical stages separated by periods of latency. However, in contrast to syphilis, transmission occurs from skin-to-skin contact rather than sexually. Infants contract the infections from their mothers during breast feeding, and children contract them from direct contact with mucocutaneous lesions of infected family members and playmates.

Without treatment, patients remain infectious indefinitely, although the skin lesions may become mild or subclinical. They do not develop lifelong immune resistance. Cross-immunity is absent in the early stages of syphilis, yaws, and pinta, but is variable in late stages. Patients with late pinta are resistant to syphilis but those with yaws or syphilis at any stage are susceptible to pinta.

The nonvenereal treponematoses are not fatal but are disfiguring and disabling, and patients suffer the effects of social ostracism.

PINTA (CARATE, MAL DE PINTA, AZUL)

Pinta, which means *colored spot* in Spanish, is caused by *Treponema carateum*, named after the Colombian name for the disease (*carate*).

The disease predominantly affects poor, undernourished infants, children, and adolescents who live in small, remote, crowded villages in hot, semiarid coastal areas. Twenty years ago, approximately 750,000 cases were estimated, but now only a few hundred new cases are reported each year, mainly from southern Mexico, Brazil, Colombia, Venezuela, Peru, and Ecuador. [1]

Transmission occurs from repeated, direct contact of the exposed skin of a healthy person with a cutaneous or mucous membrane lesion from an infected person.

Pinta is the only treponematosis with clinical manifestations confined to the skin, [1] although cardiovascular disease formerly was considered to be a complication of late pinta. As in syphilis, there are three distinct clinical stages, but in contrast to syphilis, lesions from different stages may be present in a single patient. Because cell-mediated immunity is not completely effective, the infection persists indefinitely, and people of all ages are infected. However, 40 to 60 percent of all patients are younger than 15 years of age.

Primary Stage

Between 3 and 60 days (average, 1 to 3 weeks) after contact with an infected lesion, one or more small, erythematous papules develop at the site(s) of inoculation. These primary lesions may be pruritic, become slightly scaly and enlarge, or coalesce with other lesions to achieve a size of 1 to 3 cm within 3 months. The resulting plaques are irregular, hyperkeratotic, lichenified and up to 20 cm in diameter (Fig. 229-1). [2] Primary lesions usually develop in exposed areas, especially the hands, feet, arms, legs, face, and neck. They can persist for years, and eventually heal spontaneously with residual hypopigmentation.

FIGURE 229-1 Lichenified patch in primary pinta with dyschromic changes.

Secondary Stage

Secondary lesions (*pintids*) usually appear 1 to 12 months, but sometimes years, after the appearance of the primary lesions. They may encircle the sites of the primary lesions, or erupt generally on the body. Pintids may appear on the palms, soles, and groin. [1] Secondary lesions may be indistinguishable from primary lesions, but are smaller and usually not pruritic. Some lesions may be circinate or annular with raised borders where the number of treponemes is highest. Over time, the lesions turn brown or copper-colored and eventually slate blue, gray, or black. More than one color may be present within a plaque. Lesions can recur up to 10 years after the initial infection. [2]

Tertiary Stage

Late lesions develop between 3 months and 10 years after the appearance of the secondary stage. Typically, patients have dyschromic patches that are hyperchromic, hypochromic, and achromic, imparting a mottled pattern with a variegated palate of white, brown, blue, red, and violet. [3] The lesions have irregular borders and vary in size. The more commonly involved areas are the wrists, palms, ankles, and elbows as well as the skin around and within old lesions (Fig. 229-2). In such areas, the lesions appear scarred and atrophic (cicatricial lesions of pinta). [3] Lymphadenopathy may develop during any stage of pinta. Patients with only late-stage lesions may appear to have vitiligo (vitiligo of pinta).

FIGURE 229-2 Depigmented and hyperpigmented, mottled patches in late pinta.

YAWS (FRAMBOESIA TROPICA, PIAN, BUBA, PARU, PARANGI)

Yaws is caused by *T. pallidum* (ssp. *pertenue*). Approximately 75 percent of new cases arise in children younger than 15 years of age. [4] /SUP>, [5] Yaws is contracted from direct contact with abraded, bitten, or excoriated skin with oozing lesions. Some experts contend with scant evidence that the disease can be transmitted by flies or through domestic utensils. [6]

The infection occurs in countries along the tropical belt in lowlands adjacent to forests characterized by heavy rainfall, high humidity, and hot temperatures that do not fall below 27°C (80.6°F). [5] Owing to mass treatment campaigns and improved living conditions, the disease has been eradicated in many areas, and greatly reduced in others. [4] However, sizeable foci were recently reported in several tropical regions of West and Central Africa (Ghana, Togo, Benin, and Central African Republic), and residual foci remain in South America (Colombia, Peru, Ecuador, and Brazil), Indonesia, Papua New Guinea, the Solomon Islands, Haiti, and Dominica. [6] Currently, at least 100 million children are estimated to be at risk of becoming infected. [1]

Primary Stage

After an incubation period of 9 to 90 days (average, 3 weeks), the primary lesion or mother yaw (*buba madre*) appears at the site of inoculation, which is usually an exposed body part, such as the face, neck, buttock, leg, foot, arm, or hand. [7] Characteristically, the lesion is a nontender, occasionally pruritic, infiltrated, erythematous small nodule that grows horizontally to a size of 1 to 5 cm. Its surface frequently becomes papillomatous and crusted. The primary lesion is usually single, but satellite papules may be present, becoming confluent into a plaque. The lesion eventually becomes an ulcer (chancre of yaws) with a raspberry-like (frambesial) base that may be covered by yellow crust (Fig. 229-3). Regional buboes are common. [1] The “mother yaw” heals spontaneously in 2 to 6 months leaving atrophic scarring and central hypopigmentation. Constitutional symptoms are rare.

FIGURE 229-3 Ulcerated primary-stage nodule (“mother yaw”). The genital location is unusual.

Secondary Stage

Resolution of the primary stage is typically followed by a period of latency, lasting weeks to months, which is then interrupted by an eruption of disseminated skin lesions with generalized lymphadenopathy. Constitutional symptoms, such as malaise, fever, and anorexia, are often present. The lesions (*daughter yaws* or *pianomas*) are soft, warty or vegetating, nonpruritic, scaly, yellow-red papules and plaques not unlike the mother yaws (frambesiomas) but smaller (up to 2 cm) (Fig. 229-4A). As the lesions grow, they become eroded and covered by a highly infectious fibrinous exudate, which dries into a crust (Fig. 229-4B and *C*). The exudate attracts flies that torture the afflicted persons. [7] *Pianic onychia* (paronychia) may develop.

FIGURE 229-4 *A*. Early secondary lesions of yaws (“daughter yaws”) showing eroded and crusted papules and plaques. *B*. Warty secondary-stage papillomas (“daughter yaws”). *C*. Eroded papillomas covered by fibrinous exudate. (*B and C Courtesy of HJH Engelkens, MD, J. van der Stek, MD, and E. Stolz, MD.*)

Pianomas may appear in any body area. In addition, dry, papulosquamous patches and plaques *(pianides)*, which resemble the lesions of secondary syphilis, may be present on any part of the body. [7] In body folds, they resemble condylomata lata; in mucous membranes, they resemble hypertrophic mucous patches. Thick, hyperkeratotic plaques of the palms and soles become fissured and ulcerated (worm-eaten soles). This painful involvement of the soles is also called *crab yaws* (Fig. 229-5) because patients walk with a deliberate slow, crustacean gait. Some lesions may be annular or circinate (*tinea yaws*). Lesions on the face are often seborrheic or psoriasiform. [7] Painful osteoperiostitis is common in early yaws. [6] The appearance of turnip-like, fusiform soft-tissue swelling of the proximal, but not the distal, phalanges because of periostitis is classic (ghoul hands). The metatarsal, metacarpal, and tibial bones are also commonly involved. [7] Infected persons then enter a latent period with serologic reactivity but no signs or symptoms of the disease. All lesions resolve without scarring, but relapses may develop during the initial 5 years of infection. In relapsing yaws, lesions tend to be confined to the perioral, perianal, and periaxillary areas.

FIGURE 229-5 Fissured hyperkeratotic plantar keratoderma in secondary yaws (“crab yaws”).

A less-contagious form of yaws with one or few dry, gray, transient patches predominantly in the axillae and perianal areas has been described. [1]

Tertiary Stage

In approximately 10 percent of cases, latency is interrupted after 5 to 10 years by a late stage with skin and skeletal lesions, and possibly with ophthalmologic and neurologic involvement. Cutaneous and subcutaneous gummatous nodules (*gumma framboesiodes*) necrose centrally and ulcerate, causing deep, mutilating damage. [6] Coalescence of the ulcers may result in the formation of circinate, serpiginous tracts that heal with deforming scars and contractures. [5] Palmoplantar hyperkeratosis may lead to keratoderma. Juxtaarticular nodes may form on the elbows and knees.

Late skeletal changes include hypertrophic periostitis, hydrarthrosis, gummatous osteitis and periostitis, and osteomyelitis. Considerable bone hypertrophy as a result of chronic osteitis may result in curvature of the tibia (saber shins). Bilateral hypertrophic osteitis of the nasal process of the maxillae with persistent swelling of the nasal bridge (*goundou*) slowly progresses over 5 to 20 years. The most dreaded consequence of yaws is rhinopharyngitis mutilans (*gangosa*), which leads to extensive destruction of the nose, maxillae, upper lip, and central face with eventual perforation of the nose and palate. It occurs in approximately 1 percent of untreated, infected persons.

Although eye, neurologic, and cardiovascular disease is not usually associated with yaws, there are rare reports of optic disk atrophy, myeloneuropathy, and aneurysms. [1]

ENDEMIC SYPHILIS (BEJEL, FIRJAL, BELESH, NJOVERA)

This nonvenereal infection caused by *T. pallidum* (ssp. *endemicum*) favors arid climates in rural areas bordering deserts. It has been reported to be a common health problem in children from Burkina Faso and in the Bedouin tribes of Saudi Arabia, Iraq, and Syria. Foci also remain in Saharan Africa (Sudan, southern Zimbabwe, and South Africa), in Southeast Asia, Turkey, and the Western Pacific. [2] Approximately 80 percent of cases occur in children and adolescents younger than 15 years of age. [8] Transmission occurs during skin or mucous membranes contact with infected skin lesions or saliva, or by drinking from contaminated flasks or from sharing pipes. [1] Anecdotal reports that the common fly, *Musca domestica*, is a disease vector have not been substantiated. The mucocutaneous lesions resemble those of venereal syphilis.

Primary Stage

The incubation period is 10 to 90 days. The primary lesion is a slimy patch that becomes eroded. It is frequently missed probably because the chancre is often present in the oropharyngeal mucosa. Because of the small inoculum, regional lymphadenopathy is rare. A primary chancre may develop in the nipple of a mother nursing an infected child. Primary lesions heal in 1 to 6 weeks. [2]

Secondary Stage

Usually a few nontender, oval or round, macerated, eroded, mucous patches erupt on the lips, tongue, and tonsils. Vegetating or hypertrophic condylomata lata appear on the anogenital area and the axillae. [4] Split papules are fissured mucous patches in the labial commissures. Occasionally, macular, papular, annular, and circinate eruptions, similar to those seen in secondary syphilis, develop. Nontender, generalized lymphadenopathy is common. Nocturnal lower extremity pain is caused by periostitis of the long bones.

The secondary stage persists for 6 to 9 months and is followed by a latency period, which may continue for only a few months but usually lasts 5 to 15 years. At this point, a tertiary stage with cutaneous skeletal and systemic manifestations develops. [9]

Tertiary Stage

Late lesions consist of gummas of the skin, bone, nasopharynx, and larynx. [6] The gummas develop destructive ulcerations, but the lesions are not as mutilating as those of yaws (Fig. 229-6). The ulcerations eventually heal, leaving atrophic, depigmented scars bordered by hyperpigmentation. Saddle-nose deformity, palate perforation, or gangosa are disfiguring complications. [2]

FIGURE 229-6 Cutaneous gummas in late endemic syphilis. Note the involvement of the elbow.

Skeletal involvement is common, but most patients are not significantly bothered by pain. Clinically apparent tibial bowing or tenderness are exceptions. However, bone defects may be radiologically present, most commonly on the tibia and fibula, and sometimes in the ulna and radius. Systemic involvement is rare. Uveitis, chorioretinitis, and optic atrophy have been observed. Aortitis and saccular aneurysms of the aortic arch have infrequently been reported. [2]

An attenuated form of endemic syphilis with fewer, more-rapidly healing cutaneous lesions but more frequent periostitis has been reported.

DIAGNOSIS OF THE NONVENEREAL TREPONEMATOSES

The diagnosis of these diseases is made through clinical evaluation of the lesions (Table 229-1) in inhabitants or former residents of endemic areas, and confirmed by detection of treponemes under dark-field microscopic examination of lesional exudate. In the absence of a positive dark-field examination, histologic or serologic confirmation is required. In yaws and endemic syphilis, nontreponemal tests become reactive in 2 to 3 weeks after the onset of the primary lesion. In pinta, these tests become reactive in 80 percent of cases within 3 months after the appearance of primary lesions and are reactive in all patients with the late stage of the disease. Other treponemal tests, including enzyme immunoassays (EIA), have not shown greater specificity than the fluorescence treponemal antibody absorption (FTA-ABS) test. [10] A finger-prick indirect hemagglutination test is advantageous for screening children. [11]

	Pinta	Yaws	Endemic Syphilis
Causative organism	T. carateum	T. pertenue	T. pallidum
Transmission	Skin-to-skin contact	Skin-to-skin contact	Skin or mucosal contact with infected skin or saliva, drinking vessels
Peak ages	1–15 years	1–15 years	Months–15 years
Incubation	3–60 (average, 1–2 weeks)	9–90 days (average, 2 weeks)	10–90 days
Primary lesions	Erythematous papules becoming psoriasiform plaques	Vegetating, soft, ulcerating papule (mother yaws), with satellites	Small eroded papule (often absent)
Secondary lesions	Erythematous scaly and psoriasiform plaques; primitiv develop; increased and decreased pigmentation	Warty or hyperkeratotic nodules, papulovegetanous plaques, palmoplantar "crab claws"	Mucous patches, condylomata lata, syphilis-like eruptions
Tertiary lesions	Dyschromic, hyperchromic, achromic, and polychromic patches	Cutaneous, pinkish dyschromia, juxtaarticular nodes, gangrena, gonoides, keratoderma	Serpiginous gummas, juxtaarticular nodes on elbows only
Reactive serology	2–3 months after primary lesion	2–3 weeks after primary lesion	2–3 weeks after primary lesion
Treatment	Penicillin	Penicillin	Penicillin

TABLE 229-1 **Nonvenereal Trepanomatoses—Clinical Manifestations**

HISTOPATHOLOGY

In a primary lesion of pinta, epidermal changes consist of mild acanthosis, epidermal edema, exocytosis of lymphocytes, liquefaction degeneration of the basal cell layer, and loss of melanin. In the upper dermis there is a dense infiltrate of plasma cells, lymphoid cells, some neutrophils and histiocytes, and many melanophages. In contrast to syphilitic chancres, endothelial swelling is minimal or absent.

Histologically, secondary lesions are indistinguishable from primary lesions. In the hyperpigmented patches of tertiary pinta, the epidermis is atrophic and the basal cell layer shows no melanin, but in the upper dermis there is an infiltrate of many melanophages and some lymphoid cells. As the lesions become increasingly depigmented, the infiltrate is milder and treponemes become scarcer to the point that neither is present. Treponemes are found in silver impregnation between epidermal cells in primary, secondary, and late-stage hyperpigmented lesions, but not in late hypopigmented patches.

The epidermal changes in a primary lesion of yaws are acanthosis, papillomatosis, edema, and neutrophilic microabscesses. In the dermis, there is a dense mixed-cell infiltrate of neutrophils, lymphocytes, histiocytes, fibroblasts, a few eosinophils, and many plasma cells. No endothelial proliferation is seen in the vessels. Secondary yaws lesions have a similar appearance to the primary lesions. In late yaws, the lesions are very similar to late benign syphilitic lesions. In the first two stages, treponemes are easily detected on silver-stained tissue, almost exclusively between epidermal cells. [12]

The lesions of endemic syphilis are histopathologically identical to those of venereal syphilis.

TREATMENT

The recommended treatment for pinta, yaws, and endemic syphilis is a single intramuscular injection of 1.2 million units of benzathine penicillin in adults or children older than 10 years of age and 0.6 million units in younger children. [6] Patients become noninfectious within 24 h. Children older than 8 years of age who are allergic to penicillin may be treated for 15 days with tetracycline 250 mg four times daily, or, if younger, with erythromycin 8 mg/kg four times daily. [8] Penicillin-allergic adults are treated for 15 days with tetracycline 500 mg four times daily, doxyclycline 100 mg twice daily. Erythromycin 500 mg four times daily and other macrolide antibiotics are also probably effective, despite a dearth of in vivo experience. In pinta, primary and secondary lesions disappear after treatment, but achromic patches persist for life. The effect of HIV infection on nonvenereal treponematosis is not known, but based on the experience with venereal syphilis, it appears prudent to screen those persons at risk with HIV serology and to consider closer follow-up. Recommendations for epidemiologic treatment depend on the number of seropositive children younger than 6 years of age (Table 229-2).

Area (Percentage of Seropositive Children)	Recommendation
Hyperendemic (>50%)	Treat the entire population
Mesoendemic (10–50%)	Treat all active cases, their contacts, and all children 15 years of age or younger
Hypoendemic (<10%)	Treat all active cases, their household members, and other obvious contacts

TABLE 229-2 **Epidemiologic Treatment**

CONCLUSION

The means to eradicate the nonvenereal treponematoses is available. However, history has shown that mass treatment campaigns alone are insufficient. [13] In some areas where the diseases had been thought to be eradicated, new cases are being reported at a surprising rate. [14] In 1997, the World Health Organization estimated the number of new cases of endemic treponematosis at 460,000 annually. [4] Treatment of those infected and those at risk must be followed by such sound public health measures as prolonged serosurveillance and periodic screenings. [15] Resurveys should begin 6 months after initial treatment and continued at least every 2 years. City dwellers are not at risk and the diseases are practically unknown in the West, where a single case usually stimulates a published case report. The western medical establishment regards these diseases as curiosities that are extinct or almost extinct.

DEFINITION

Chancroid is a sexually transmitted, acute ulcerative disease, usually localized at the anogenital area and often associated with inguinal adenitis or bubo. The disease is caused by infection with *Haemophilus ducreyi,* a gram-negative, facultative anaerobic bacillus that requires hemin (X factor) for growth.

HISTORICAL ASPECTS

Chancroid, or soft chancre (*ulcus molle*) was first distinguished from syphilis by Basserau in France in 1842. The causative bacillus was discovered and described by Ducrey, a bacteriologist at the University of Naples, in 1889. Unna described the histology of the chancroidal ulcer and found the chains of gram-negative rods in the lesion. It is still unclear who was the first to culture *H. ducreyi*. In his review, Albritton [1] credited Himmel (1901) with the first convincing isolation of *H. ducreyi,* but other authors in the same period also claimed priority.

EPIDEMIOLOGY

Chancroid is most common in many of the world's poorest regions with the weakest public health infrastructure, such as areas of Africa, Asia, and the Caribbean. More recently, chancroid prevalence has declined markedly in countries such as the Philippines, Senegal, and Thailand. [2] Outbreaks have been reported in a number of cities in industrialized countries during the last two decades, predominantly in the United States. [3] After an epidemic in California in 1981, the number of cases increased, peaking in 1987 at 5035 cases. In 2000, only 78 cases of chancroid were reported to the Centers for Disease Control and Prevention (CDC). [4] Chancroid occurred 10 times less frequently than syphilis. In a 10-city study, chancroid was confirmed in 12 percent of genital ulcers in Chicago, and in 20 percent of genital ulcers in Memphis. [5] Interpreting chancroid surveillance data is difficult because confirmatory culture media are not commercially available and the true incidence is probably vastly underreported.

The prevalence of chancroid is higher in lower socioeconomic groups. Recent epidemics in the industrialized countries usually were associated with prostitution, the use of crack cocaine, syphilis, and an increased risk of HIV infection. [6], [7] Lower-class prostitutes appear to be a reservoir in all reported outbreaks of this disease. Men have a markedly higher incidence of chancroid than do women. [3] Data from Africa and Thailand show that chancroid-ulcer is an important risk factor for the heterosexual spread of HIV-1. [2] Until now epidemiology of chancroid has been poorly documented because of little interest and lack of accurate and simple diagnostic tools (phenotypic markers for strain-typing). It is still not clear whether there is an asymptomatic reservoir of *H. ducreyi* and what the risks of transmission are. [8]

ETIOLOGY

Taxonomy

H. ducreyi is a gram-negative, facultative anaerobic bacillus that requires hemin (X factor) for growth. The organism is small, nonmotile, and non–spore-forming, and shows typically streptobacillary chaining, especially in cultures. The exact taxonomy is still controversial. The current classifications list *H. ducreyi* as a true Haemophilus species. Some biochemical properties, however, put this organism close to the Pasteurellaceae. [1]

Biochemistry

H. ducreyi has few distinguishing biochemical features. Nitrate reduction is a characteristic of the genus. All reported strains are oxidase-positive and catalase-negative and have a broad range of phosphatase activity. The alkaline

phosphatase reaction is used in its identification. [1] Differentiation from other hemin-requiring strains of *Haemophilus* is made by the lack of requirement for nicotinamide adenine dinucleotide (NAD, V factor) and its failure to produce hydrogen sulfide, catalase, or indole. [1], [9]

Growth Requirements

H. ducreyi is a fastidious bacillus. To get optimal rates of positive cultures, Nszane et al. [10] recommend the use of two media simultaneously: gonococcal agar supplemented with bovine hemoglobin and Mueller-Hinton agar supplemented with chocolate horse blood, each with 5% fetal calf serum. Growth is best at 30°C to 33°C (86°F to 91.4°F) in a water-saturated atmosphere.

Genetics and Virulence

The strains of *H. ducreyi* appear to be serologically and biochemically homogenous. *H. ducreyi* shares a significant gene pool with members of the Pasteurellaceae and the Enterobacteriaceae. The core plasmid conferring ampicillin resistance in *H. ducreyi* is found in other species of *Haemophilus* and *Neisseria*. [1] A number of plasmids mediating beta-lactamase production have been described and the reassortment of the different plasmids in various isolates can be used as a partial typing system. Isogenic mutants of *H. ducreyi* now can be constructed and the virulence properties of specific mutants can be determined. Recently, an isogenic hemoglobin receptor-deficient mutant of *H. ducreyi* was reported that showed an attenuated infection in a human model. [11]

PATHOGENESIS

Three major problems seem to be important in the pathogenesis of *H. ducreyi* infection: the adherence to the epithelial surface, the rate of exotoxins, and the resistance of the host defense mechanism. Many questions about pathogenesis are still unclear. In the absence of appropriate experimental model systems, attachment factors are not well understood. [12]

CLINICAL MANIFESTATIONS

The incubation period is between 3 and 7 days; rarely more than 10 days. No prodromal symptoms are known. The chancre begins as a soft papule surrounded by erythema. After 24 to 48 h it becomes pustular, eroded, and ulcerated; vesicles are not seen. The edges of the ulcers are often ragged and undermined. The ulcer is usually covered by a necrotic, yellowish-gray exudate and its base is composed of granulation tissue that bleeds readily on manipulation. In contrast to syphilis, chancroid ulcers are usually tender and quite painful. Half of the males present with a single ulcer. The diameter varies from 1 mm to 2 cm. Most lesions in males are found on the external or internal surface of the prepuce, on the frenulum, and on the glans (Fig. 230-1). The urethral meatus, shaft of the penis, and the anal orifice are involved less frequently. Edema of the prepuce is often seen. Rarely, if the chancre is localized in the urethra, *H. ducreyi* causes purulent urethritis.

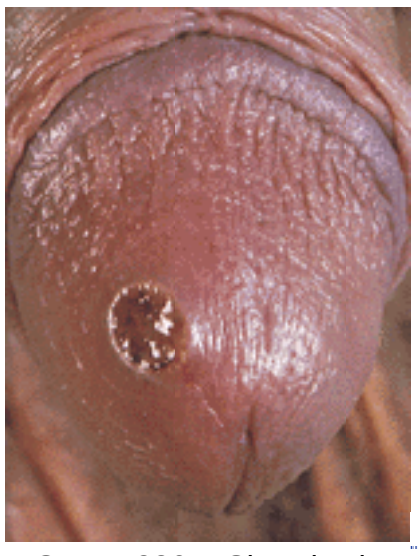

FIGURE 230-1 Sharply circumscribed ulcer on the glans.

In females, the lesions are mostly localized on the vulva, especially on the fourchette, the labia minora, and the vestibule. Vaginal, cervical, and perianal ulcers have also been described. Extragenital lesions of chancroid have been reported on the breasts, fingers, thighs, and inside of the mouth. Trauma and abrasion may be important for such extragenital manifestations.

Painful inguinal adenitis (bubo) occurs in up to 50 percent of patients within a few days to 2 weeks (average, 1 week) after onset of the primary lesion (Fig. 230-2). The adenitis is unilateral in most patients, and erythema of the overlying skin is typical. Buboes can become fluctuant and may rupture spontaneously. The pus of the bubo is usually thick and creamy. Lymphadenitis and buboes are less common in female patients.

FIGURE 230-2 Small chancroid ulcer on the internal surface of the prepuce with inguinal adenitis.

Clinical Variants of Soft Ulcer

Besides the common types of chancroid described above, a number of clinical variants have been reported:

- Giant chancroid: a single lesion extends peripherally and shows extensive ulceration.
- Large serpiginous ulcer: a lesion that becomes confluent, spreading by extension and autoinoculation. The groin or thigh may be involved (ulcus molle serpiginosum).
- Phagedenic chancroid: a variant caused by superinfection with fusospirochetes. Rapid and profound destruction of tissue can occur (ulcus molle gangrenosum).
- Transient chancroid: small ulcer that resolves spontaneously in a few days. It may be followed 2 to 3 weeks later by acute regional lymphadenitis (French: *chancre mou volant*).
- Follicular chancroid: multiple small ulcers in a follicular distribution.
- Papular chancroid: a granulomatous ulcerated papule that might resemble donovanosis or condylomata lata (ulcus molle elevatum).

Mild systemic symptoms rarely accompany chancroid, but systemic infection by *H. ducreyi* has never been observed.

LABORATORY AND SPECIAL EXAMINATION

Bacterial culture of *H. ducreyi* currently remains the main tool for the diagnosis of chancroid in the clinical setting. However, the advent of more-sensitive DNA amplification techniques has demonstrated that the sensitivity of culture of *H. ducreyi* reaches only 75 percent at best. [13] The bacillus will survive only 2 to 4 h on a swab unless refrigerated. Swabs from the purulent ulcer base should be examined directly or inoculated to appropriate culture medium because no satisfactory transport system is available. Cotton or calcium-alginate swabs are recommended for specimen collection.

The simultaneous use of two primary isolation media supplemented with hemoglobin and serum are recommended for high culture sensitivity [10] (see Etiology, above). Small, nonmucoid, yellow-gray, translucent colonies appear 2 to 4 days after inoculation. Typically, these colonies remain intact when they are pushed across the agar surface. The identification of *H. ducreyi* is performed following the recommendations of Lubwama: [14] demonstration of hemin requirement, oxidase and catalase test, beta-lactamase test, hydrogen sulfide (H_2S) and indole activity. Testing of antibiotic susceptibility is recommended because clinically significant antimicrobial resistance of *H. ducreyi* has become common.

Direct examination of clinical material by Gram or Giemsa stain may be helpful, but reported sensitivity and specificity values are low, being 10 to 63 percent and 51 to 99 percent, respectively. [15] The bacilli are usually found in small clusters or parallel chains of two or three organisms streaming along strands of mucus. This pattern has been described as a “school of fish” or “railroad-track” appearance (Fig. 230-3). This arrangement, said to be characteristic of *H. ducreyi,* is nevertheless not pathognomonic, because most genital ulcers have a polymicrobial flora. Some authors do not recommend direct microscopy in the routine diagnosis of chancroid. [1]

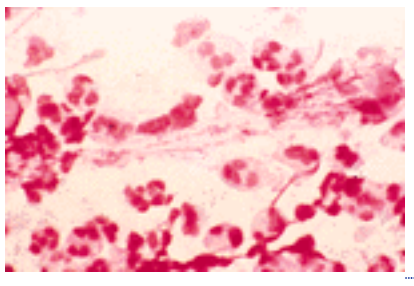

FIGURE 230-3 Smear from chancroid ulcer (Giemsa stain).

Characteristic histologic features with three vertically arranged zones (superficial necrotic zone, beneath a zone of new blood vessel formation, and a deep zone consisting of dense lymphocytic and plasma cell infiltrate) have been described in chancroid, [16] although tissue biopsy is not a recommended diagnostic method.

Histologic examination is useful as a means to exclude malignancy in nonhealing or atypical ulcers. [15]

Many attempts have been made to develop serologic tests for chancroid. Because of limited sensitivities for detection of circulating antibodies to *H. ducreyi,* serology has limited usefulness in the routine diagnosis of chancroid infection, but may be useful in population-based epidemiologic research as a screening method for past infection. [15], [17] Polymerase chain reaction (PCR) procedures with different primers showed superior sensitivity for the diagnosis of chancroid when compared to bacterial culture. [15] A multiplex PCR (M-PCR) assay has been developed for the simultaneous amplification

of DNA targets from *H. ducreyi, T. pallidum,* and herpes simplex types 1 and 2, [18] which seems to be a particularly attractive diagnostic tool in the investigation of patients presenting with genital ulcers. None of these PCR-based methods are commercially available yet, but their use for routine diagnostic purposes would be clearly advantageous.

In resource-poor settings where diagnostic facilities are not readily available, the World Health Organization advocates the use of a syndromic management approach for patients with genital ulcer disease. [19]

DIFFERENTIAL DIAGNOSIS

The three classic etiologic agents for anogenital ulceration are *H. ducreyi, Treponema pallidum,* and herpes simplex. The clinical appearance of the diseases caused by these three organisms can be extremely variable in both men and women and, therefore, clinical diagnosis of genital ulcer disease can be made with reasonable certainty only for a minority of patients. [20] The etiology of genital ulcers also differs considerable by geographic region. In a high percentage of genital ulcers, no pathogen can be isolated.

Clinical diagnosis alone is inadequate and the majority of authors consider even direct microscopic examination of smears from genital ulcers insufficient for diagnosis of chancroid. [1] Isolation of *H. ducreyi* on appropriate media and subsequent biochemical identification is necessary.

Syphilis may be eliminated by dark-field examination and repeated serologic testing for antibodies. Herpes simplex virus (HSV) infection can be diagnosed by culture, HSV DNA detection by PCR, or HSV antigen detection. Lymphogranuloma venereum (LGV) can be eliminated by a negative LGV complement-fixation test (titer less than 1:16) and by failure to demonstrate a significant rise in the titer on repeated testing after 3 weeks.

Donovanosis, superinfected traumatic lesions, and noninfectious causes of genital ulcerations, such as Crohn's disease or Behçet's syndrome must be considered in the differential diagnosis.

Mixed infections (chancroid and syphilis, chancroid and herpes simplex) are possible.

TREATMENT

Since the 1970s, beta-lactamase–producing strains of *H. ducreyi* emerged and treatment failures were common. Subsequently, further plasmid-mediated resistance to tetracycline, sulfonamides, chloramphenicol, and aminoglycosides has been reported. [21] Little is known about chromosomally mediated resistance in *H. ducreyi,* but decreased susceptibilities to various antibiotics in absence of identifiable resistance plasmids suggests evolution of such mechanisms. [21] Since the 1993 treatment guidelines for sexually transmitted diseases were published by the CDC, experience has indicated that the regimens recommended remain largely effective. [22] Based on in vitro susceptibility, the most active drugs against *H. ducreyi* are azithromycin, ceftriaxone, ciprofloxacin, and erythromycin. The in vitro findings of resistance to amoxicillin/clavulanate suggest that it may be less effective than when it was recommended as a second-line drug in 1993, and therefore it can no longer be recommended for the treatment of chancroid. [22] Newer quinolones show promise as effective agents. Table 230-1 lists the regimens recommended by the CDC. [23]

TABLE 230-1 **CDC Recommended Regimens for the Treatment of Chancroid**

Local treatment consists of antiseptic dressings (i.e., povidone-iodine). Suppurative nodes should not be incised; if necessary, they can be punctured to prevent spontaneous rupture and sinus tract formation. A large syringe should be used and the fluctuant buboes entered laterally through normal skin. In patients with phimosis, a circumcision may be necessary when all active lesions have healed.

Even after correct treatment, relapses occur in approximately 5 percent of patients. Retreatment with the original regimen is recommended. If a sexual partner was not treated, reinfection is probably the cause of relapse. HIV infection and lack of circumcision appear to be associated with an increased likelihood of treatment failure.

RELATIONSHIP BETWEEN HIV-INFECTION AND CHANCROID

Over the past decade, renewed interest in chancroid has led to evidence that genital ulcers promote the heterosexual transmission and acquisition of HIV-1. [24] Effective treatment of genital ulcers can reduce the incidence of HIV-1, and this strategy has become a cornerstone of HIV prevention programs in many parts of the world. [25] Furthermore, it was shown that concomitant HIV-infection has clinically significant effects on the course of the chancroid disease, and failure of single-dose or short-course therapy for chancroid in men is associated with HIV-1 seropositivity. [24] A wide variation in the clinical picture of chancroid has been observed in HIV-infected patients. [24] Epidemiologic control of chancroid may be a very important strategy to interrupt the heterosexual spread of HIV in some parts of the world. Accordingly, patients with chancroid should also be tested for HIV-antibodies. HIV-seropositive patients with culture-proven chancroid should be monitored closely and treated with a multiple-day regimen.

PREVENTION

The augmentation of the HIV epidemic by *H. ducreyi* has made chancroid control an urgent priority. Patients should be advised to abstain from sexual activity until all clinical lesions have cleared. Sexual contacts of the patient should be examined and treated regardless of whether symptoms of the disease are present, because asymptomatic carriage of *H. ducreyi* is possible. [9] Chancroid survives in populations in which many men are having sex with a few women. As a result, programs to trace and treat contacts are essential. Eradication of chancroid is considered to be a feasible public health objective. [2]

COURSE AND PROGNOSIS

The disease is self-limited and systemic spread does not occur. Occasionally, without treatment, genital ulcer and inguinal abscess have been reported to persist for years. Local pain is the most frequent complaint. If no clinical improvement is evident 1 week after the start of therapy, incorrect diagnosis, coinfection with another sexually transmitted disease, concomitant HIV infection, poor compliance, or a resistant strain of *H. ducreyi* must be considered. Infections do not confer immunity and reinfections are possible. To avoid reinfections, patients must be instructed to use condoms properly.

DIFFERENTIAL DIAGNOSIS
TREATMENT

REFERENCES

Lymphogranuloma venereum (LGV) is a sexually transmitted disease of chlamydial etiology with protean clinical manifestations involving the lymphatic system. It should be considered in the differential diagnosis of benign and malignant lymphadenopathy, genital lesions, proctocolitis, and rectal stricture. LGV, along with other causes of genital ulcer disease, is increasingly important as a potential facilitator of human immunodeficiency virus (HIV) transmission. [1]

HISTORY

The disease has a colorful nosologic history including such designations as tropical or climatic bubo; third, fourth, fifth, or sixth venereal disease; lymphopathia venerea; and Nicolas-Favre disease, but the current name is now universally accepted. The first major clinical description appeared in 1913, and inclusion bodies in material from lesions were demonstrated 10 years later. In 1930, the disease was produced experimentally by intracerebral inoculation of monkeys with pus from a bubo of LGV. [2] In 1940, Rake [3] grew the organism, then thought to be a filterable virus, in the yolk sac of embryonated eggs. In the 1960s and 1970s the organism was successfully grown in tissue culture by using cycloheximide-treated McCoy cells, [4] and microimmunofluorescence techniques were developed for speciation and recognition of serovariants. [5] During the 1980s and 1990s, the study of chlamydial infection benefited from the considerable advances in the techniques of microbial genetics and diagnostic methods with the development of polymerase chain reaction and ligase chain reaction techniques for genus identification. No commercial products are yet available for LGV identification, however.

EPIDEMIOLOGY

LGV probably occurs all over the world, with endemic foci in tropical and subtropical countries, but few, if any, systematic data describe incidence or prevalence. Most surveys are actually reports of proportional morbidity in clinic series, and the results are highly variable: Singapore, <1 percent; [6] Australia, rare with a recommendation to intensify surveillance; Durban, South Africa, 6 percent; [7] Madagascar, 24 percent in 1994 [8] and 14 percent in 1999; [9] Rwanda, 10 percent; [10] Paris, 0 percent; [11] Kuala Lumpur, 0 percent; [12] and Jamaica, about 4 percent over the decade of the 1980s [13] with a decrease to 3 percent by 1999 [14]. Several studies from Africa found very few cases, [15] but a substantial proportional morbidity (8 percent) was noted in Nigeria during the period 1993 to 1997. [16] In the United States, the number of cases reported yearly declined from a peak in 1944 of 2858 cases to a stable level of 200 to 300 during the 1980s, and a subsequent decline to 69 reported cases in 1999 (Fig. 231-1). [17] The chief foci of activity have been the District of Columbia and the southeastern United States, affecting predominantly African Americans of low socioeconomic status. Age-specific attack rates are highest in the 20- to 40-year-old group. The disease is spread by direct inoculation from genital fluids, but transmission efficiency is not known. Women may be asymptomatic and culture positive, and may serve as a reservoir for infection, as they do for gonorrhea and other genital chlamydial infections.

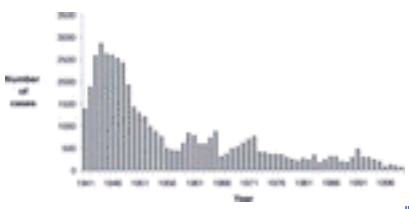

FIGURE 231-1 Cases of lymphogranuloma venereum, United States, 1941 to 1999.

ETIOLOGY

The disease is caused by members of the genus *Chlamydia* (previously known as *Bedsonia*) whose structure, metabolism, DNA and RNA content, and method of reproduction make them similar to *Rickettsia*. [18] The genus is composed of three species: *psittaci, pneumoniae,* and *trachomatis*. The species *Chlamydia trachomatis* has two major biologic varieties (biovars): trachoma or TRIC organisms, and LGV organisms. The latter, in turn, are characterized by three major serologic varieties (or serovars)-L1, L2, L3, and the more recently recognized L2'. [19] The LGV serovars are distinguished by their preferential infectivity for lymph nodes, intracerebral lethality for mice, and different behavior in cell culture. Experimentally, the LGV serovars produce severe hemorrhagic proctitis in monkeys, while TRIC serovars do not. [20] The two biovars, however, share a major cross-reacting antigen which complicates serologic distinction between them.

Distinction among types is now actively pursued with modern biochemical and molecular biologic methods, including exploration of mechanisms for immune-mediate lysis, [21] use of restriction fragment length polymorphism, [22] response to heparin sulfate lysis, [23], [24] use of pooled antibody to distinguish between genital and nongenital infection, [15] and structural genetic differences. [25]

CLINICAL MANIFESTATIONS

LGV is contracted by direct contact with infectious secretions, almost exclusively through sexual activity. The portal of entry and the initial symptoms are determined by the nature of the sex act; inoculation is usually genital, but it may be rectal or pharyngeal. The incubation period varies from 3 to 30 days if primary lesions occur, but it may be longer if adenopathy is the only manifestation. The period of infectiousness and transmission rates are not clearly defined.

Acute and chronic manifestations characterize both the genital (or inguinal) and rectal syndromes. The primary lesion is a 5- to 8-mm soft, erythematous, painless erosion (Fig. 231-2) that heals spontaneously in a few days. Occasionally, a button-like papule may appear that is also transient. Such lesions are reported by a fourth to a third of patients. Secondary inguinal adenopathy begins 1 to 2 weeks after the primary lesion as discrete, movable, tender nodes that later coalesce to form a firm, fist-sized, elongated, immovable mass. These may occur above and below Poupart's ligament, giving rise to the “groove” sign (Fig. 231-3). Nodes are bilateral in one-third of cases. Rupture of fluctuant nodes may lead to chronic sinus formation. Initially, the overlying skin is often slightly reddened and edematous, but it later may become thickened and develop a characteristic purplish hue. Generalized systemic symptoms such as fever, chills, and malaise may be prominent. Meningoencephalitis, hepatosplenomegaly, arthralgia, stiff neck, and headache may also occur. A strong association of LGV and other chlamydial infections has been established, [26] but the relationship of chlamydial treatment to improvement of arthritis is more tenuous. [27] Conjunctivitis with marginal corneal ulceration has been reported. [28] In untreated cases, the lymphadenopathy usually subsides spontaneously in 8 to 12 weeks.

FIGURE 231-2 Lymphogranuloma venereum. Soft painless erosion on the prepuce.

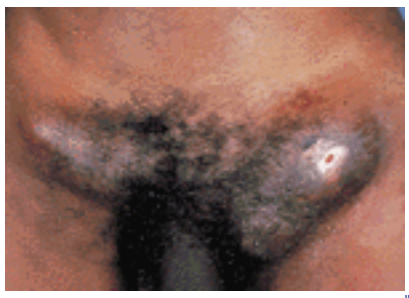

FIGURE 231-3 Lymphogranuloma venereum. Bilateral, firm, immovable masses above Poupart's ligament.

Late complications of the male inguinal syndrome are rare. Elephantiasis of the penis and scrotum characterized by infiltrative, ulcerative, and fistular lesions occur in approximately 4 percent of cases. [29] LGV may mimic cervical lymphoma, as reported in a homosexual male practicing fellatio and a heterosexual male engaging in cunnilingus. [31] In another report, clinical presentation and computerized tomography of intrapelvic nodes suggested cervical cancer in a 24-year-old woman with LGV, [32] and LGV has also been associated with tonsillar infection. [33] In keeping with the diagnostic confusion associated with lymphoproliferative syndromes, LGV has also been mistaken for cat-scratch fever.

The acute rectal syndrome occurs more frequently in women than men. In men, direct inoculation of the anal canal is believed to be the mode of entry, whereas the internal lymphatic drainage of the proximal two-thirds of the vagina has been invoked as the source for women. In both sexes, acute manifestations include rectal pain, tenesmus, and mucosanguineous rectal discharge, with typical findings of proctocolitis on sigmoidoscopy. It is important to distinguish LGV from other forms of inflammatory bowel disease, particularly in homosexual men. [34] The major late manifestation is rectal stricture. [35] In women, late scarring, fistulas, ulceration, and elephantiasis of the perineum, called esthiomene, may require radical surgical intervention. [36]

Various dermatologic conditions have been reported in association with acute manifestations, including erythema nodosum, erythema multiforme, scarlatiniform exanthem, and urticaria. [2] In addition, photosensitivity has been reported in

as many as 35 percent of patients, occasionally associated with conjunctivitis, joint involvement, and erythema nodosum. [2] Sonck [37] observed a photosensitivity reaction in 140 of 400 LGV cases studied. This reaction was manifest 1 to 2 months after the onset of bubo formation and occurred in 60 percent of the chronic and about 20 percent of subacute cases. Punctiform, red papules appeared on the skin 30 min to 3 h after exposure to sunlight. Accompanying this photosensitivity reaction was conjunctivitis in 19 percent, joint involvement in 33 percent, and erythema nodosum in 16 percent of patients. The possible allergic or autoimmune nature of these phenomena is supported by the frequent appearance of biologic false-positive tests for syphilis (estimated at 20 percent of cases), the high incidence of cryoprecipitins and rheumatoid factor, and the high serum levels of IgA and IgG in both acute and chronic syndromes. [38]

As noted, as a cause of genital ulceration LGV may play a role in facilitating transmission of HIV. Because of its lymphatic manifestations and potential effects on the immune system, it may also play a role in the differential diagnosis of acquired immunodeficiency syndrome (AIDS). [39] In one reported case, for example, disseminated Kaposi's sarcoma mimicked LGV in its initial presentation. [40] The syndrome of angioimmunoblastic lymphadenopathy has been reported in association with LGV, [41] and may, as occurred in one case, lead to progressive immunologic deterioration and rapidly fatal immunoblastic lymphoma.

PATHOLOGY

In general, histopathologic changes of LGV are nonspecific. Primary ulcers are characterized by an exudate of fibrin, polymorphonuclear leukocytes, and cellular debris. [42] Skin test sites or rectal lesions may contain epithelioid nodules, plasma cells, and occasional giant cells, but these changes are not diagnostic. Stellate triangular abscesses may be observed in biopsy specimens of lymph nodes and are characteristic, but not pathognomonic, of LGV. [43] The pathology of LGV-induced proctocolitis is characterized by crypt distortion, submucosal fibrosis, neuromatous hypertrophy, follicular inflammation, and occasional granuloma formation. It may be difficult to distinguish these changes from those associated with Crohn's disease, although localization of lesions is of considerable help (proximal in Crohn's disease, distal in LGV). [44] It is likely that LGV is not etiologically associated with Crohn's disease.

DIAGNOSIS

One of the earliest diagnostic techniques, the Frei test, used an intradermal inoculation of killed LGV organisms and was important to diagnosis for many years. Its sensitivity and specificity are in serious doubt, however, [45] and the test is now of historical interest only, because the antigen is no longer commercially available. The diagnostic accuracy of the clinical diagnosis is variable. In one study from South Africa, diagnostic accuracy (defined as true positives divided by true positives plus false positives plus false negatives) was found to be 66 percent in men and 40 percent in women, but these figures are based on a small number of cases. [7] In another attempt from South Africa, the diagnostic accuracy was 20 percent overall. [46] Although algorithmic approaches to genital ulcer disease is important in many clinical settings, clinical diagnosis alone may not be dependable.

Definitive diagnosis is possible through isolation of the organism from tissue or body fluids, and distinction among the four serovars can be made by using microimmunofluorescence techniques. [47] Because tissue culture may not be readily available, the clinician must often rely on serologic methods. First developed in the 1930s, the complement fixation test has long been the mainstay of diagnosis of LGV. It suffers from lack of specificity: virtually all members of the genus *Chlamydia* share the target antigen. [48] Although less than 3 percent of the general population has a titer as high as 1:16, [45] 40 to 50 percent of women with uncomplicated TRIC-agent cervical infection had titers of 1:16 to 1:32; similar titers occurred in 15 to 20 percent of men with TRIC-associated urethritis. A titer of 1:64 or greater is, however, highly suggestive of LGV. Coupled with a fourfold change in titer (which is not uniformly detected), a high titer greatly increases diagnostic assurance. The microimmunofluorescence test, originally developed as a guide to identification of organisms, has been successfully adapted as a serologic test. It responds, similar to the complement fixation test, to the broadly reactive range of antibodies produced by patients with LGV. Again, very-high titers of IgG antibody are usual in patients with acute infection. Other tests, including enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay methods, are also available but appear to offer little advantage over the microimmunofluorescence test. [49]

DIFFERENTIAL DIAGNOSIS

In view of the nonspecific nature of signs and symptoms, acute LGV should be considered in the differential diagnosis of syphilis, herpes progenitalis, granuloma inguinale, and chancroid, as well as in bacterial, fungal, or tuberculous skin infection. Adenopathy may require consideration of benign and malignant lymphoproliferative disorders (e.g., infectious mononucleosis, Hodgkin's disease), particularly in the presence of oral and cervical infection. Late manifestations must be distinguished from neoplastic skin disease, filariasis, rectal cancer, inflammatory bowel disease, and hidradenitis suppurativa.

TREATMENT

Antibiotics are effective in the acute illness but may have little or no effect on late lymphatic pathology. Standard recommended treatment is doxycycline 100 mg orally twice a day for 21 days. An alternative regimen is erythromycin base 500 mg orally four times a day for 21 days. [50] To avoid formation of fistulous tracts, buboes should be aspirated rather than incised and drained. With treatment, prognosis for avoidance of late complications is excellent.

Granuloma Inguinale

HISTORY
EPIDEMIOLOGY
ETIOLOGY AND PATHOGENESIS
CLINICAL MANIFESTATIONS
PATHOLOGY
DIAGNOSIS
TREATMENT

REFERENCES

Granuloma inguinale is an indolent, progressive, ulcerative, and granulomatous skin disease caused by *Calymmatobacterium granulomatis*. It is probably spread by both homosexual and heterosexual venereal contact, as well as by nonvenereal means. [1] Untreated it exhibits no tendency to go into spontaneous remission, and in later stages, it may be severely debilitating.

HISTORY

The first description is credited to McLeod in 1882, who termed the illness *serpiginous ulcer*. [2] Many other names have been suggested, but aside from granuloma inguinale, only the term *donovanosis* persists. Donovan, in 1905, first described the bipolar-staining, intracellular inclusions in macrophages from lesion exudate (termed *Donovan bodies*). These organisms were grown in embryonated eggs in 1943; [3] requirements for growth on artificial media were established in 1959. [4]

EPIDEMIOLOGY

Small numbers of sporadic cases of granuloma inguinale have been reported from developed countries. Since 1970, fewer than 100 cases per year have been reported in the United States; in 1989, there were only 7; in 1995, no cases were reported; and in 1999, 19 cases were reported. [5] Endemic foci are usually seen only in tropical and subtropical environments such as New Guinea, Brazil, central Australia, the Caribbean, and parts of India. [6], [7] Recently, a focus was recognized in South Africa, after an apparent eclipse of 50 years. [8] Investigators in Durban, South Africa, noted a peak in case reports in the late 1980s, [9] and recognized that, by 1995, granuloma inguinale accounted for almost 10 percent of cases of genital ulcer disease seen at one clinic in that city. [10] Several large case series [11], [12] and [13] confirmed a strong association with syphilis and HIV infection, but the influence of the latter infection on the course of granuloma inguinale remains controversial. No special effect has been noted on the course of pregnancy, [12] but a case control study in India of patients with and without HIV infection observed 40 percent faster healing of similarly treated lesions in those patients without HIV. [14]

Certain ethnic predispositions have been noted—higher incidence in African Americans than in whites in the United States; in natives than in Europeans in Papua, New Guinea; in Hindus than in Moslems in India—but there is no evidence for specific ethnic susceptibility. Rather, socioeconomic status and living conditions are a major risk factor.

The venereal nature of transmission has been debated for many years and is supported by the genital site of early lesions, the prominence of perirectal disease in male homosexuals, and the predominant occurrence of infection in the sexually active group. [7] The possibility of nonvenereal transmission is suggested by the occurrence of disease in sexually inactive children, the infrequency of infection in partners repeatedly exposed to open lesions, and the infrequency of infection in sexually active people (e.g. prostitutes) in some endemic areas. [1], [7], [15] It seems clear, however, that granuloma inguinale is one of a class of diseases that causes genital ulceration that may predispose persons to the transmission of HIV. [16] One investigator suggests that a global program to eradicate granuloma inguinale could retard the spread of HIV. [17]

ETIOLOGY AND PATHOGENESIS

The causative agent (formerly termed *Donovania granulomatis*) is a gram-negative rod that in early studies was purported to be found in fecal flora, [4] supporting the hypothesis that disease transmission may occur through fecal contamination in environments with lower levels of hygiene. This may also explain the occurrence of disease in males practicing rectal intercourse. Recently, it was shown to have a close phylogenetic relationship to the *Klebsiella* group, with which it has 95 percent homology. Its reclassification as *Klebsiella granulomatis* [18] has been proposed, based on a similarities demonstrated using polymerase chain reaction (PCR) diagnostics. [19] Long resistant to in vitro cultivation, the organism has now been propagated in a monocyte coculture system, [20], [21] and in Hep-2 cell culture. [22] A colorimetric test, linked to the PCR that has been developed, [19] promises to provide simple field methods for testing. [23]

Antibody against the organism may be detected by a complement-fixation test, although the test has little diagnostic value. Circulating antibody, which does not affect the relentless course of untreated disease, has raised the possibility that a defect in cell-mediated immunity may predispose the patient to clinical illness, as is the case in the other diseases

caused by intracellular organisms (e.g., leprosy and tuberculosis). [24]

CLINICAL MANIFESTATIONS

The primary lesion may be a button-like papule, a subcutaneous nodule, or an ulcer. The incubation period is poorly defined and may range from 2 weeks to 3 months. Experimental human inoculation has produced lesions after latency of 21 days. [25] Papules or nodules are quickly denuded and ulcerate within several days. The subcutaneous nodules, if large enough, may be mistaken for lymph nodes, giving rise to the term *pseudobubo*. True adenopathy is rare. In men, the penis, scrotum, and glans are the most common sites of primary lesions; in females, the labia minora, mons veneris, and fourchette are the most common sites. Lesions of the cervix may occur in as many as 10 percent of infected women, and the disease may also involve the uterus and adnexa. Typically, the disease spreads, either by direct extension or autoinoculation, to the inguinal and perineal skin.

Four major clinical varieties are described: [7], [26] the *nodular* variety is characterized by soft, red nodules that eventually ulcerate and present a bright-red granulating surface (Fig. 232-1); the *ulcerovegetative* variety (most common) (Fig. 232-2) develops from the nodular type and consists of large, spreading, exuberant ulcers; the *hypertropic* form (relatively rare) exhibits a proliferative reaction and formation of large vegetating masses; and the *cicatricial* type produces spreading scar tissue formation that is a direct consequence of disease spread per se, rather than of healing. Superinfection with fusospirochetal organisms may give rise to necrotic lesions with massive tissue destruction, similar to the situation in so-called *phagedenic* chancroid. The disease may rarely progress to destroy genital and inguinal tissue. Elephantiasis of the penis, scrotum, or vulva is a mutilating potential sequela.

FIGURE 232-2 Granuloma inguinale: large ulcerovegetative type.

Extragenital lesions are infrequently reported, with occasional systemic involvement, notably of bone, [27] but involving nongenital skin as well, for example, the orbit, [28] the foot, [29] the chin, [30] the thigh, [31] and the axilla. [32] Chronic ulcerating oral mucosa lesions may occur with or without associated genital lesions [33] and may resemble actinomycosis. [34] Granuloma inguinale may affect cervical lymph nodes both in adults (resembling tuberculous lymphadenitis), [35] and in infants. [36], [37] Rarely, systemic abscesses have been reported, manifested as otitis media with mastoiditis [38] and as a psoas abscess. [39] The disease shows no tendency toward spontaneous healing, although lesions may be stable for long periods of time. There is believed to be an increased incidence of squamous cell carcinoma of the genital skin in granuloma inguinale, [40] although the relative rarity of the infection renders this observation difficult to document.

PATHOLOGY

Histologically, the skin exhibits a massive cellular reaction, predominantly polymorphonuclear, with plasma cells, foamy histiocytes, and, rarely, lymphocytes. [41], [42] The marginal epithelium demonstrates acanthosis, elongation of rete pegs, and pseudoepitheliomatous hyperplasia. [43] These latter changes can be suggestive of early malignancy and squamous cell carcinoma. Hypertropic and cicatricial forms demonstrate an increase in fibrous tissue. Typically, large mononuclear cells containing numerous cytoplasmic inclusions (the Donovan bodies) are scattered throughout the lesions. These are considered to be diagnostic of granuloma inguinale and are often best demonstrated with special stains, such as Giemsa's stain, Delafield's hematoxylin, Dieterle's silver stain, and the Warthin-Starry stain. [41]

Although the histopathology of granuloma inguinale is well recognized, the pathophysiology is not understood. Some investigators suggest the transepithelial elimination (TEE) of irritative dermal substances through intact epidermis, [44] citing the finding of pseudoepitheliomatous hyperplasia and other markers found in processes classically associated with

TEE. The investigators recognize, however, that the sequence of events remains unelucidated.

DIAGNOSIS

The clinical diagnosis of granuloma inguinal, based on history and appearance, may be fairly accurate in endemic areas. In one study from South Africa, the diagnostic accuracy was 63 percent and the positive predictive value between 71 percent and 83 percent. [45] Despite the cited advances in microbiology, laboratory diagnosis usually requires a crush or touch preparation stained with Wright's or Giemsa's stain from a punch biopsy specimen. [46] Superficial curettings can be inadequate because of bacterial contamination. The diagnostic Donovan bodies are seen as deeply staining, bipolar, safety pin-shaped rods in the cytoplasm of macrophages (Fig. 232-3). Diagnosis may require multiple specimens because clinical varieties differ in the quantity of organisms present. Rapid-staining techniques [such as the RapiDiff stain (Clinical Science Diagnostics Ltd.)] are available and suitable for use under a variety of field conditions. [47] As noted, serologic tests, such as the use of complement fixation, have evoked some research interest, but have little practical application.

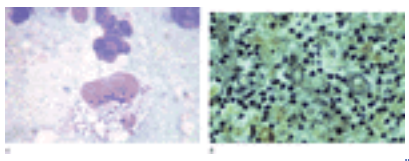

FIGURE 232-3 Granuloma inguinale: tissue smear showing Donavan bodies, which are gram-negative (*A*) and readily stained with Giemsa stain (*B*).

In its typical form, granuloma inguinale is easily differentiated from other ulcerative and granulomatous skin diseases, but atypical forms may be difficult to distinguish from syphilis, chancroid, lymphogranuloma venereum, tuberculosis of skin, cutaneous amebiasis, and filariasis. Squamous cell carcinoma with metastases may be closely mimicked by granuloma inguinale.

TREATMENT

Numerous drugs have been used to treat granuloma inguinale, including streptomycin, chloramphenicol, tetracycline, ampicillin, and gentamicin. Case series, usually assembled over a decade or more, offer a variety of regimens, as do numerous case reports, but few controlled trials are available. The US Public Health Service recommends either trimethoprim-sulfa, one double-strength tablet orally twice a day for 3 weeks minimum or doxycycline, 100 mg orally twice per day for 3 weeks minimum. Erythromycin, 500 mg four times a day orally for 3 weeks minimum and ciprofloxacin 750 mg twice a day orally for 3 weeks minimum are offered as alternatives. [48] Considerable recent interest in azithromycin has developed, and one pilot-controlled trial has been performed. [49] The Australian Antibiotic Guidelines now recommend azithromycin, 1 g orally per week or 500 mg orally daily for 3 weeks minimum. [50] Response may be monitored by clinical appearance and serial biopsy specimens examined for persistent presence of Donovan bodies. In early cases, prognosis for complete healing is good. In late cases, irreparable tissue destruction may have supervened, and radical surgery may be required.

Gonorrhea is a bacterial infection caused by *Neisseria gonorrhoeae,* a gram-negative diplococcus whose only natural reservoir is humans. The infection is almost always contracted during sexual activity.

The usual presentation in males is acute urethritis; in females, it is cervicitis, which may be asymptomatic. Other parts of the genitourinary apparatus, as well as the rectum, pharynx, and eye, may be infected. Occasionally bacteremia occurs, which is regularly associated with arthralgia and skin lesions; metastatic infection in joints or other foci may ensue. Although good treatment is available, the disease remains an important public health problem, causing a large percentage of female sterility and considerable morbidity in both sexes.

HISTORY

The name *gonorrhea* is attributed to Galen, who thought the urethritis represented abnormal flow of semen, hence the combination of *gonos* (seed) and *rhoea* (flow). The slang name for gonorrhea, *clap,* likely derives from a French word for brothel, *clapoir*.

Early confusion among the venereal diseases was augmented by the unfortunate experiment of John Hunter in 1767. He inoculated himself with a presumed gonococcal urethral exudate, only to develop syphilis. With isolation of the causative organism of gonorrhea by Neisser in 1879, positive identification of the disease became possible.

Treatment for gonorrhea has progressed from sandalwood oil to urethral irrigations with potassium permanganate to sulfonamides in the 1930s. Resistance to sulfonamides developed rapidly, but, fortunately, in the 1940s, the exquisite sensitivity of gonococcal strains to penicillin was discovered. The emerging problem of the organism's resistance to penicillin and other antibiotics is discussed below.

EPIDEMIOLOGY

The incidence of gonorrhea in the United States increased dramatically in the 1960s and early 1970s to more than 1 million reported cases annually. It is estimated that fewer than one-third of the new cases are reported. In the 1980s, there was a slow decline in reported cases to about 700,000 per year. This gradual decline has continued with fewer than 400,000 cases of gonorrhea reported in 2000. [1] The downward trend in infections slowed, but continued through 1997. Why has this two-phase trend occurred? [2] The epidemic was intensified, first, by behavioral factors, including increased sexual activity, changes in birth control methods, high population mobility, and an increase in repeated infections, and, second, by increased reporting when the federal gonorrhea screening effort was introduced in 1972. The subsequent decrease in incidence in the United States resulted from the Herculean efforts of the US Public Health Service through the national control program to detect and treat asymptomatic gonococcal infections. The practice of safer sex in the era of acquired immunodeficiency syndrome (AIDS) had additional impact on decreasing the incidence of all sexually transmitted diseases. In 1998, the number of reported cases rose slightly from 327,000 to 360,000, where it remained through 2000. Increased screening and sensitivity of tests are partially responsible for this increase, but true increases in certain populations appear to have occurred. [3]

The disease is spread almost exclusively by sexual activity, although newborns may be infected by exposure during parturition. Although all age groups are susceptible, infection is more prevalent in the 15- to 35-year-old age group. Among women in 2000, 15- to 19-year-olds had the highest incidence (715.6 per 100,000), while among men, 20- to 24-year-olds had the highest rate (589.7 per 100,000). [3] The disease is concentrated in high-density population centers, with a core group of active transmitters. [4] However, the mobility of individuals results in the occurrence of gonorrhea everywhere.

A signal event that has affected the epidemiology of gonorrhea is the dramatic increase in resistance of *N. gonorrhoeae* to antibiotics. Since the availability of sulfonamides and penicillin in the 1940s, antimicrobial resistance in *N. gonorrhoeae* has been evolving. The appearance of penicillinase-producing strains of *N. gonorrhoeae* in the United States in 1975 accelerated the trend toward greater antibiotic resistance. Penicillinase (beta-lactamase) synthesis in these organisms depends on the presence of plasmids, extrachromosomal packets of DNA, which can be transferred among organisms. At least five beta-lactamase plasmids of *N. gonorrhoeae* have been reported. Chromosomal

resistance to penicillin and tetracycline is also occasionally at levels sufficient to result in treatment failure. [5] For all practical purposes, in most areas penicillin is no longer the treatment of choice for gonorrhea.

In 1987, the Gonococcal Isolate Surveillance Project (GISP) was established by the Centers for Disease Control (CDC) to periodically monitor national trends in *N. gonorrhoeae* antibiotic resistance. [6] Of all isolates collected by GISP in 2000, 24.7 percent were resistant to penicillin, tetracycline, or both. Ciprofloxacin resistance was first identified in 1991 and is fairly widespread in Asia; the rate of resistance in the United States, however, has remained low (0.4 percent of isolates in 1999 and 2000) and largely restricted to specific geographic areas. Of note, ciprofloxacin resistance in Hawaii was 14.3 percent of GISP isolates in 2000, and the CDC has recommended that fluoroquinolones not be used to treat gonorrhea in that state. The proportion of isolates with elevated minimum inhibitory concentrations (MICs) to azithromycin also has risen. In 1992, 0.9 percent of isolates had azithromycin MIC >0.5, compared with 2.4 percent in 2000. In contrast, no cephalosporin resistance has been identified by GISP. In 2000 all isolates were sensitive to ceftriaxone and cefixime. [7]

ETIOLOGIC AGENT AND PATHOGENESIS

N. gonorrhoeae is a gram-negative diplococcus with distinctive morphology; the cocci are flattened and the long axes of the bean-shaped organisms are parallel. Gonococci tolerate oxygen but usually require 2 to 10 percent CO_2 in the growth atmosphere. The organisms have narrow temperature [35°C to 37°C (95°F to 98.6°F)] and pH (7.2 to 7.6), optimal for growth. Although fragile, they have relatively simple growth requirements. Defined media are now available on which the organisms will grow readily. Different strains have somewhat different growth requirements. Careful study of these requirements has led to a system of typing gonococcal isolates called auxotyping. [8], [9] Auxotyping was an important advance, because the ability to distinguish one *N. gonorrhoeae* isolate from another made epidemiologic studies feasible. Several other systems for typing gonococci were developed subsequently, including sensitivity to bacteriocins, the presence of specific lipopolysaccharide antigens, the use of monoclonal antibodies, and identification of specific opa genes. [10]

Kellogg and coworkers recognized four colony types of *N. gonorrhoeae*. [11] Only types 1 and 2 were pathogenic for humans. These types were also found to possess surface hairlike structures termed *pili*. The nature of pili as virulence factors has not been clarified; pili may foster adherence of gonococci to mucosal surfaces or resistance to phagocytosis. Other virulence factors are being identified, and might include capsular production in vivo, resistance to the immune bactericidal action of serum, and the ability of gonococci to survive in the presence of various competing commensal organisms. Griffiss and Artenstein [12] point out that all *Neisseria* are adapted to moist mucous membranes. Of them, the meningococcus and the gonococcus are the ones capable of escaping from host restraints, proliferating rapidly, and even invading the bloodstream. The reason why certain organisms occupy particular ecologic niches and the factors conferring virulence are only beginning to be understood.

CLINICAL MANIFESTATIONS

Signs, symptoms, complications, and the natural history of gonorrhea differ dramatically between males and females. However, careful studies have exposed the myth that males with gonorrhea are symptomatic and females asymptomatic.

Males

After a single exposure to an infected contact, approximately 25 percent of males will develop gonorrhea. It is estimated that 85 percent of men with gonococcal urethritis develop an acute process, with discomfort, dysuria, and purulent discharge usually ensuing from 2 to 10 days after exposure. Figure 233-1 shows a typical purulent discharge. Fifteen percent of urethritis in the male is minimally symptomatic or asymptomatic. Because these patients may not receive treatment, they tend to accumulate in the population. The resultant point prevalence of minimally symptomatic or asymptomatic male gonorrhea may be as high as 40 percent. [13] Clearly these men are capable of spreading disease. Untreated symptomatic urethritis subsides over several days to weeks, but occasionally local complications such as epididymitis, seminal vesiculitis, and prostatitis occur. Anorectal [14] and pharyngeal [15] gonococcal colonizations are uncommon. The incidence of positive cultures correlates with the practices of passive rectal intercourse and fellatio, respectively. Because symptoms of proctitis and pharyngitis correlate poorly with positive cultures, colonization of these areas rather than overt infection is likely to be what occurs.

FIGURE 233-1 Purulent urethral discharge.

Females

When an uninfected woman is exposed to an infected man, gonorrhea ensues over half the time. Once infected, the specific symptoms and signs of acute salpingitis may occur (20 to 40 percent) or the less-specific symptoms of dysuria,

increased discharge, or abnormal bleeding (20 to 30 percent) may be seen within a few days to a few weeks. Thirty to 60 percent of infected women will be minimally affected or asymptomatic, yet remain long-term carriers capable of transferring the infection. [16], [17] As described for men, these cases will accumulate, because symptomatic gonorrhea is treated preferentially. Because none of the symptoms or signs is diagnostic of gonorrhea, cultures of endocervix, urethra, rectum, and pharynx should be carried out if the disease is suspected or the patient is reported as a contact of gonorrhea.

Pelvic inflammatory disease (PID) is the most important complication of gonococcal infection. PID is the result of ascending infection from the endocervix, causing endometritis and/or salpingitis and/or pelvic peritonitis. Clinical findings can vary from crampy abdominal pain with minimal tenderness in mild cases to fever, severe abdominal pain, and exquisite tenderness with adnexal masses in florid cases. Prompt diagnosis and aggressive treatment are mandatory because infertility, ectopic pregnancy, and chronic pelvic pain are frequent complications. Several organisms other than *N. gonorrhoeae* may cause PID. The etiologic diagnosis, which is discussed below, may be difficult. Tragically, the role of silent or asymptomatic PID in causing adverse reproductive sequelae is becoming increasingly appreciated.

DISSEMINATED GONOCOCCAL INFECTION

Spread of *N. gonorrhoeae* to the bloodstream is estimated to occur in 1 to 3 percent of patients with gonorrhea, [18] with the majority of cases in females. Although endocarditis and meningitis have been reported, they are rare complications. Arthritis and skin lesions, on the other hand, are regularly associated with disseminated gonococcal infection (DGI). The syndrome is so characteristic that a presumptive diagnosis can usually be made on clinical grounds alone; the syndrome has been labeled the arthritis–dermatitis syndrome. The onset of gonococcal bacteremia usually occurs with menstruation or pregnancy in females. In males, DGI is most often seen in association with asymptomatic infection. Fever, chills, polyarthralgias, arthritis, and tenosynovitis are common. In the early stages of the disease, skin manifestations occur that are quite characteristic (Fig. 233-2). The skin lesions typically are few in number (often fewer than a dozen) and concentrated on the extremities, usually acral, and often around the joints. The lesions may be petechial or papular; however, they usually evolve into vesicles or pustules on an erythematous base, which may become hemorrhagic. Sometimes they present as hemorrhagic bullae. Prompt diagnosis and therapy are mandatory, because delay may result in frank pyogenic arthritis with potential for joint destruction.

FIGURE 233-2 Disseminated gonococcal infection. Lesions on the fingers and palm consisting of pustules and hemorrhagic, necrotic pustules, which are slightly tender.

It has been recognized that organisms causing DGI often differ from those causing urethritis. Most strains of gonococci are susceptible to the complement-mediated bactericidal action of normal serum; the strains causing DGI are resistant. [18] This important observation may explain why some gonococci are capable of causing bacteremia while others are restricted to mucous membranes. In support of the necessity for serum resistance in strains causing DGI are the reports that patients deficient in the late complement components, which are required for serum killing, are peculiarly susceptible to recurrent neisserial sepsis. [19]

The pathogenesis of the arthritis–dermatitis syndrome is unclear. Bacteremia regularly occurs early in the course of DGI, but it has been suggested that most signs and symptoms of DGI are manifestations of immune-complex formation (see also Chap. 197).

MISCELLANEOUS CLINICAL MANIFESTATIONS

In rare cases, an ulcer or abscess may appear on the raphe of the penis. Gonococcal perihepatitis is a complication of gonococcal peritonitis with hepatic capsular fibrosis and adhesions (Fitz-Hugh-Curtis syndrome). [20] Adhesions such as those between the hepatic capsule and the anterior abdominal wall can cause discomfort, which may be persistent and difficult to diagnose.

Gonococcal ophthalmia neonatorum is neonatal purulent conjunctivitis contracted by the newborn in passage through an infected birth canal. Reappearance of this problem in greater numbers in the 1970s was probably a reflection of the higher incidence of gonorrhea combined with a more casual use of silver nitrate prophylaxis in newborns. [21]

Cornified squamous epithelium is quite resistant to infection with *N. gonorrhoeae,* hence vulvovaginitis is infrequent in adult women. However, in children, the vagina is lined with columnar epithelium; acute vulvovaginitis is the usual manifestation of genital gonococcal infection in the prepubescent female.

PATHOLOGY

The picture of active gonococcal infection is usually that of an acute or subacute inflammatory response with

polymorphonuclear leukocytes predominating. The histopathology of the vesiculopustular lesions of DGI consists of infiltrates of neutrophils admixed with some mononuclear cells and red blood cells. Fibrinoid necrosis of vessel walls may be seen. The bullae are subepidermal in location. [22] Bacteria are rarely seen in or grown from the skin lesions.

DIAGNOSIS

Definitive diagnosis of gonorrhea depends upon identification of the organisms by Gram stain and/or culture. A positive Gram stain consists of characteristic gram-negative diplococci in the cytoplasm of neutrophils (Fig. 233-3). Such a Gram stain from the male urethra is considered diagnostic. Gram stain of endocervical discharge is not usually done because even a positive smear is not considered diagnostic; culture confirmation is required. In women, endocervical cultures give a higher yield of positives than vaginal cultures. In males without exudate, swabs for culture should be inserted several centimeters into the urethra. In women with gonorrhea, endocervical cultures as well as rectal, urethral, and pharyngeal cultures should be obtained. In DGI, blood, skin lesions, and joint effusions should be cultured. Skin lesions are regularly negative; joint fluid is usually negative until acute purulent arthritis occurs. Blood cultures are positive only early in the disease. Thus, the diagnosis of DGI must frequently be made on clinical grounds only. This rarely presents a problem, because the clinical picture, especially the skin lesions and the tenosynovitis, is quite characteristic.

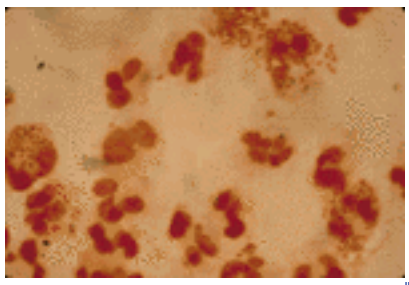

FIGURE 233-3 Diagnostic Gram-stained smear of urethral exudate of a man with gonococcal urethritis.

When culturing an area in which a mixed bacterial flora is unusual, for example, synovial fluid or male urethra, chocolate agar may be used for isolation. When culturing an area that has an exuberant flora, such as the throat, rectum, or endocervix, one should use selective media containing antimicrobials that inhibit organisms other than *Neisseria*. Modified Thayer-Martin medium is usually employed. Transgrow is a similar medium, but it also contains CO_2 and is a good transport medium for gonococci.

In addition to *N. gonorrhoeae,* several other organisms cause PID, including *Chlamydia trachomatis,* endogenous anaerobic and aerobic bacteria, and, probably, genital mycoplasmas. It is clearly advantageous for proper therapy to know the causative organism. Endocervical cultures are the only practical way to distinguish between gonococcal and nongonococcal PID; patients in whom gonococci are grown from the cervix are assumed to have gonococcal PID. [23] A DNA probe assay (Gen-Probe) has been tested as an alternative to culture for diagnosis of gonorrhea. [24], [25] The DNA probe does not require viable organisms; this is a major advantage that obviates the need for rapid and careful transport of the specimen to the laboratory. Another important advantage of the probe versus culture is that simultaneous testing for *C. trachomatis* on the same specimen is possible. In many institutions, the DNA probe assay has replaced culture as the routine screening and diagnostic test for gonorrhea.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of genitourinary gonococcal disease in the female includes the following:

- *Trichomonas vaginalis* infection. This usually presents as a profuse, frothy, foul vaginal exudate, at times with urethritis. A positive saline preparation for the protozoa is diagnostic.
- *Candida albicans* infection. Often this presents as a pruritic infection with creamy or curdy exudate, and diagnosis depends on identification of the organism by smear and/or culture.
- *Gardnerella vaginalis* or bacterial vaginosis. There is still dispute about the role of various organisms in bacterial vaginosis. However, the syndrome is well defined, with a malodorous, gray, acidic discharge that shows clue cells on smear and yields a fishy, amine odor on alkalinization with potassium hydroxide. All patients with vaginal discharge should be cultured for gonococci. Even though inflammatory vaginitis is rarely seen with gonorrhea alone, mixed infections do occur rather commonly.

In men, urethritis can also be caused by multiple organisms. *T. vaginalis* and *C. albicans* can infect the male and be asymptomatic or cause urethritis or balanitis. Some urethritis has been attributed to *Herpesvirus hominis*. However, even more common than gonorrhea as a cause of urethritis in many populations is so-called nongonococcal or nonspecific or postgonococcal urethritis.

Urethritis with an identified pathogen (except gonococci) is referred to as a *nongonococcal urethritis* (NGU). The term *nonspecific urethritis* describes a urethritis caused by an unidentified organism. NGU may be the most common sexually transmitted disease in humans in most industrialized countries, although reporting is not required in the United States. It is characterized by dysuria, often by urethral discharge or urinary frequency, and by the absence of *N. gonorrhoeae*. In contrast to classic gonococcal urethritis, NGU usually has a longer incubation period, a less-acute onset, and scanty urethral discharge; at times, no discharge is evident, only urethral discomfort or tenderness. Occasionally, coinfection with *N. gonorrhoeae* occurs, and urethritis remains following effective antibiotic therapy for gonorrhea; this has been labeled *postgonococcal urethritis*.

Until the mid-1970s, causative agents of NGU were not identified; however, it was clear that symptoms usually yielded to

therapy with tetracyclines. Now there is good evidence that at least two organisms are responsible for NGU. *C. trachomatis* has been demonstrated convincingly to cause most of the cases of NGU. *Ureaplasma urealyticum* and possibly a few other organisms may be responsible for some of the remaining cases of NGU. Because NGU has been the subject of such intensive study recently and is so common, it is also discussed separately in Chap. 234.

TREATMENT AND CONTROL

Ideal therapy for gonococcal urethritis has the following attributes in addition to curing urethritis: it should be given as a single dose; it should abort coincubating syphilis; and it should cure coexisting chlamydial infections. No single-drug regimen achieves these ideals. Previously recommended penicillin or tetracycline regimens are no longer indicated because of widespread resistance of *N. gonorrhoeae* to these antibiotics.

Multiple regimens have merit: (1) ceftriaxone 125 mg IM in a single dose; (2) cefixime 400 mg PO in a single dose; (3) azithromycin 1 g PO in a single dose; (4) ciprofloxacin 500 mg PO in a single dose; and (5) ofloxacin 400 mg PO in a single dose. [26]

When using a cephalosporin regimen for gonorrhea, additional treatment for coexisting chlamydial infection should be given, often doxycycline 100 mg bid for 7 days. Although the cephalosporins have been used widely to treat gonorrhea, no significant resistance has yet developed. Azithromycin as a single dose effectively treats gonococcal and chlamydial infections. The drawbacks of this regimen are high cost, lack of FDA approval for gonorrhea treatment, and concern regarding increased MICs to azithromycin in strains with chromosomal resistance to penicillin or tetracycline. [7] The single-dose fluoroquinolone regimens for gonorrhea treatment may not be adequate for treatment of chlamydial infections. Gonococcal strains with decreased susceptibility to ciprofloxacin have emerged, causing concern about the future efficacy of these agents. [7] The GISP of the Centers for Disease Control and Prevention periodically monitors antimicrobial susceptibility of *N. gonorrhoeae*. [7] These surveillance data are valuable for predicting the efficacy of the various antibiotic regimens for gonorrhea treatment.

Control of the gonorrhea epidemic probably depends more on other factors than on the details of therapy of acute disease. It is essential to educate the public about venereal disease, including signs and symptoms, methods of prevention, and resources available. Medical personnel must also be made aware of the most effective case-finding techniques, including screening of at-risk populations and aggressive search for contacts of patients with gonorrhea. More controlled sexual activity in the wake of the AIDS epidemic, including widespread use of condoms, will probably help ameliorate the epidemic of gonorrhea.

GENITAL CHLAMYDIA INFECTIONS

Fifteen different serovars of *Chlamydia trachomatis* are presently known: A, B, Ba, and C are considered to be the causative agents of trachoma; D, E, F, G, H, I, J, and K are associated with genital tract infections, conjunctivitis, and childhood pneumonia; and serovars L_1, L_2, and L_3 cause lymphogranuloma venereum (LGV) (see Chap. 231). Although serotypes E, F, and D account for 60 to 70 percent of urogenital *C. trachomatis* infections, there is no evidence that specific genital syndromes are serotype specific. [1]

Epidemiology

In 1997, more than 500,000 *C. trachomatis* infections (~200/100,000 population) were reported to the CDC. This is obviously a considerable underestimate of the actual number of cases (estimated at 3 to 4 million) in the United States each year. The World Health Organization (WHO) currently estimates that there are approximately 90 million infections annually worldwide attributable to *C. trachomatis.* [2]

Etiology and Pathogenesis

Chlamydiae have a cell wall and cell membrane and contain DNA and RNA in their cytoplasm; they are bacteria endowed with a characteristic metabolism. However, they are energy-requiring parasites that can multiply only within other cells, where they form inclusions in the cytoplasm. Reproduction occurs by binary fission and in cell culture, and the cycle of development takes 48 to 72 h. [3] Chlamydial infection leads to an immune response in the form of circulating antibodies and cellular immunity. The major chlamydial antigens are the major outer-membrane proteins (MOMP), the lipopolysaccharides, and the heat-shock proteins (HSP). [4]

Clinical Manifestations

INFECTIONS OF THE FEMALE GENITAL TRACT Urogenital infection in women is symptomatic in approximately 30 percent of the cases. The most important manifestations include mucopurulent cervicitis, purulent vaginal discharge, lower abdominal pain, postcoital or intermenstrual bleeding, dysuria, and pelvic inflammatory disease (PID). Sequelae include extrauterine pregnancy, tubal infertility, and cervical cellular atypia.
Cervicitis *Chlamydia trachomatis* attacks the cylindrical epithelium of the cervix, where the cervicitis cannot be distinguished clinically from other inflammatory cervical processes. Approximately 30 to 50 percent of women with proven chlamydial cervicitis show no clinical symptoms. In women who do, the principal symptom is mucopurulent discharge, followed by hypertrophic ectopia, postcoital bleeding, and spotting. Simple objective criteria for the presumptive diagnosis of mucopurulent cervicitis include an increased number (>10 per high-power field) of polymorphonuclear leukocytes in cervical smears, a positive swab test, erythema, edema, and induced mucosal bleeding in the area of ectopy and the transformation zone. [1] Epidemiologic studies suggest that *C. trachomatis* serotype G infections are associated with subsequent development of cervical squamous cell carcinoma. [5]
Pelvic inflammatory disease PID is the most severe complication of infection of the lower genital tract. The clinical spectrum of chlamydial PID has a wide range: subclinical endometritis, salpingitis, pelvic peritonitis, periappendicitis, and perihepatitis. Consequently, the traditional clinical and laboratory criteria for diagnosis of PID are inaccurate. Laparoscopy, endometrial biopsy, transvaginal ultrasonography, or magnetic resonance imaging are recommended to improve the accuracy of the diagnosis. Laparoscopy is generally accepted as the gold standard for diagnosis of PID. [1] Concern about silent PID and its sequelae has led to a change in the recommendations for clinical diagnosis of PID. The minimal criteria for clinical diagnosis of PID are:

- Lower abdominal tenderness

- Bilateral adnexal tenderness
- Cervical motion tenderness
- No evidence of a competing diagnosis (e.g., positive pregnancy test, acute appendicitis)

When a proper diagnosis of chlamydial PID is uncertain or delayed, adequate antibiotic treatments should be started if the above mentioned criteria are observed. [1]

Perihepatitis (Fitz-Hugh-Curtis syndrome) Chlamydia can pass from the cervix via the endometrium and the uterine tubes to reach the region of the right diaphragm. There it causes a perihepatitis, which does not involve the liver parenchyma. Clinically, it is characterized by piercing pain below the right costal margin. Symptoms are reminiscent of those seen in acute cholecystitis or pleuritis. Perihepatitis appears to be more common in chlamydial infections than in gonorrhea. [6]

INFECTIONS IN MEN Urogenital infection in men is symptomatic in approximately 75 percent of the cases. The most frequent symptoms are urethral discharge, dysuria, signs of epididymitis, and prostatitis. The genital manifestations of chlamydial infection are very similar to those of gonococcal infection, but the symptoms start later and are milder. Mucous membranes are infected first; later, more-invasive infection occurs. Infection by the serotypes D through K can result in the following diseases in men: nongonococcal urethritis (NGU), postgonococcal urethritis, prostatitis, vas deferentitis, epididymitis, and proctitis. In 30 to 50 percent of the patients with NGU, *Chlamydia* can be found. The incubation period ranges from 7 to 21 days. Urethritis caused by *Chlamydia* is more often asymptomatic than urethritis caused by *Neisseria gonorrhoeae*. Coinfection with *Chlamydia* in men is found in about 15 to 35 percent of patients with gonorrhea. *Chlamydia* causes postgonococcal urethritis in 70 to 80 percent of patients, [6] and is the cause of acute vas deferentitis and epididymitis in men younger than 35 years of age in more than 50 percent of cases. Untreated vas deferentitis/epididymitis produces an obliteration of the vas deferens; sterility can result if both sides are affected. Identification of the causative pathogen in an aspirate and increased levels of IgG and IgM antibodies in the serum provide verification of the diagnosis. [7] The role of *Chlamydia* in prostatitis is still controversial. Chlamydial proctitis is frequently seen in homosexual men, caused by the serotypes D through K. Approximately 50 percent of the men with proctitis present clinical symptoms, including anorectal pain and bleeding, mucous discharge, and diarrhea. Crohn's disease must be excluded in these patients. [6] *Chlamydia* is present in approximately 80 percent of patients with the genitourinary form of Reiter's syndrome, [8] where it is considered to have a trigger function.

INFECTIONS IN NEWBORN CHILDREN These infections are a direct consequence of a genital chlamydial infection of the mother.

Chlamydial pneumonia in the newborn Patients with chlamydial pneumonia are often afebrile with a pertussis-like cough and mucous sputum. X-ray reveals symmetric interstitial infiltrates. Laboratory findings include marked eosinophilia, hypergammaglobulinemia, and IgM antibodies to *Chlamydia*. Tracheal aspirates and lung biopsy specimens should be tested if available. [9]

Inclusion-particle conjunctivitis *Chlamydia* can be isolated from 15 to 20 percent of all children with postnatal blennorrhea. The conjunctivitis appears between days 5 to 15 and is often unilateral. The eyelids are edematous and inflamed and a suppurative secretion is observed. For confirmation of the diagnosis, material is taken from the conjunctiva of the lower eyelid. [9]

Laboratory Examinations

Laboratory diagnosis for *Chlamydia* has rapidly developed during the last few years. [9], [10] and [11]

The following techniques are used to detect *C. trachomatis:* [12]

- Cell culture
- Direct fluorescent antibody assays (DFA) (Fig. 234-1)

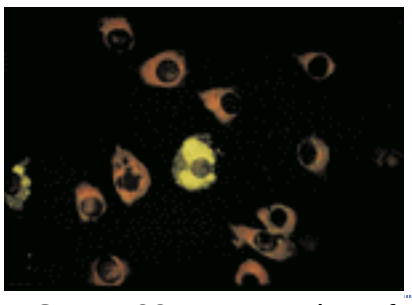

FIGURE 234-1 Detection of *Chlamydia trachomatis* by direct immunofluorescence with monoclonal antibodies.

- Enzyme immunoassays (EIA)
- RNA-DNA hybridization [polymerase chain reaction (PCR) and ligase chain reaction (LCR)]

The nucleic acid amplification tests (PCR, LCR) have a sensitivity of at least 90 percent and a high specificity (97 to 99 percent). A further advantage is that noninvasive samples (urine and vulvovaginal) can be used. Sensitivity seems to be highest from cervical samples. [13]

SEROLOGY All organisms of the genus *Chlamydia* possess a common group-specific antigen that stimulates the formation of IgM, IgA, and IgG antibodies in infected patients. The antibodies can be detected using a microimmunofluorescence (MIF) test or the enzyme-linked immunosorbent assay (ELISA) technique in the case of invasive forms of the infection. Serologic methods are without significance in localized chlamydial infections. The MIF is very useful for epidemiologic studies. [10], [12]

Diagnosis

The definitive diagnosis results from the direct identification of the causative pathogen by one or more of the tests

mentioned above. For invasive forms of chlamydia infection an additional serologic investigation can be helpful.

Treatment

Tetracyclines and the macrolides are the antibiotics of choice for uncomplicated genital chlamydial infections. A single dose of azithromycin (1 g) is effective in treating *Chlamydia* but at a much greater cost than a 7-day course of doxycycline. [14] In patients for whom compliance is in question, azithromycin may be cost effective. Sexual partners and the mothers of infected newborns must be examined and treated. For chlamydial PID and perihepatitis, more extensive treatment regimens are necessary. [15]

Prevention

Effective prevention consists of the careful examination and treatment of all sexual partners. If techniques for appropriate diagnosis are not available, it is recommended that patients with NGU and nongonococcal mucopurulent cervicitis undergo tetracycline or azithromycin therapy, just as is used for proven chlamydial infections. Patients at risk during pregnancy must be examined and treated prophylactically when indicated with erythromycin (500 mg orally four times daily for 7 days) or amoxicillin (500 mg orally three times daily for 7 days).

GENITAL MYCOPLASMAS

Mycoplasmas are the smallest self-replicating microorganisms. In the genital region, three species, *Mycoplasma hominis, Ureaplasma urealyticum,* and *M. genitalium,* have been detected and correlated with genital disease. Whether these mycoplasmas have definite pathogenic properties is still a matter of controversy. Mycoplasmas are found relatively frequently on the genital mucosa in sexually active people without giving rise to any manifest disease. The frequency of the colonization of the genital mucosa increases with sexual experience and the number of partners. [16]

Pathogenesis

It has still not been definitely determined whether *M. hominis* and *U. urealyticum* cause NGU. Newer investigations indicate that *Ureaplasma* is not a cause of NGU and vaginitis. [17], [18] *M. genitalium* is strongly associated with acute NGU in men, and there is good evidence that it is a cause. The involvement of *M. genitalium* in genital tract disease of women needs further investigation. [19]

Detection and Treatment

Mycoplasmas can be detected by culture from swabs. Until now, seven serotypes of *M. hominis* and 14 serotypes of *U. urealyticum* are known. Whether a relationship exists between individual serotypes and particular diseases is unknown. In addition to NGU, mycoplasmas have been considered as possible etiologic agents in other diseases: adnexitis, puerperal fever, fever after abortion, natural miscarriage, prostatitis, and bartholinitis. [20] Mycoplasmas are sensitive to tetracyclines and macrolides. Dosage and duration of treatment are the same as those used against chlamydial infections.

TRICHOMONAS VAGINALIS

Since the reporting of sexually transmitted diseases (STDs) is not obligatory in most countries, reliable figures for incidence are hard to find. In most western countries, however, trichomonal infections seem to be declining. [21] Transmission results from sexual contact. Perinatal infection is the most frequent nonvenereal form of transmission. The causative pathogen can survive for several hours on moist objects and in body fluids.

Clinical Manifestations

The most common clinical symptoms in women are a yellow vaginal discharge, abnormal vaginal odor, pruritus, reddening and swelling of the vulva, and punctate petechiae of the cervix (“strawberry cervix”) (Fig. 234-2). More than half of all infected women show symptoms. [22] The majority of infected men are asymptomatic. In males, the most common symptoms are milky discharge and dysuria. Serious complications are unknown.

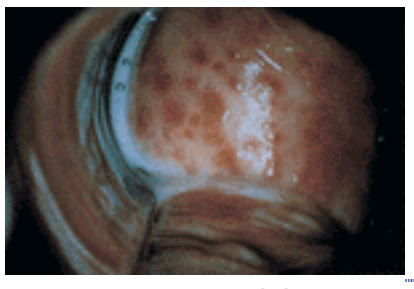

FIGURE 234-2 *Trichomonas vaginalis* infection: “strawberry” appearance of cervix with punctate bleeding erosions. (*Courtesy of U. Lauper, MD.*)

Diagnosis

The 10- to 20-µm protozoan with four to five flagellae can be directly detected on a wet mount. Phase-contrast or dark-field microscopy is helpful (Fig. 234-3). In women, the specimen must be taken from the vagina, because the

causative pathogen attacks only multilayered squamous epithelia. Attempts to demonstrate the causative organism in men are not always successful, but *Trichomonas vaginalis* can be detected in the urinary sediment. Various culture media are available from industrial sources. Culture is the current “gold-standard” for diagnosis. The PCR-based detection of *T. vaginalis* needs further investigation. [23]

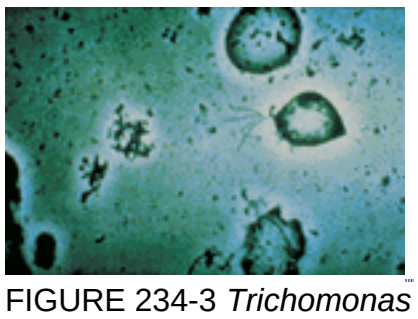

FIGURE 234-3 *Trichomonas vaginalis,* phase-contrast microscopy. (*Courtesy of U. Lauper, MD.*)

Therapy

The therapy of choice is a nitroimidazole such as metronidazole. This can be given orally as a single 2 g dose or as 250 mg three times daily for 7 days. In some individuals, metronidazole has a disulfiram-like effect. Thus, it can produce symptoms such as nausea and flushing.

BACTERIAL VAGINOSIS

Bacterial vaginosis (BV) is characterized microbiologically by a shift in the vagina away from a lactobacillus-predominant flora and toward a predominantly anaerobic milieu. The cause of BV is unknown, but the epidemiology of the syndrome suggests an association with sexual activity. BV is the most frequent vaginal infection in sexually active women. The prevalence ranges from 5 percent (in women during a routine gynecologic checkup) to 40 percent (in women visiting an STD clinic). [24] BV can be diagnosed by four clinical criteria:

- Thin, homogeneous vaginal discharge
- Vaginal pH >4.5
- Release of a fishy odor from vaginal discharge after alkalinization with 10% potassium hydroxide
- Clue cells (see below) on wet mount (Fig. 234-4)

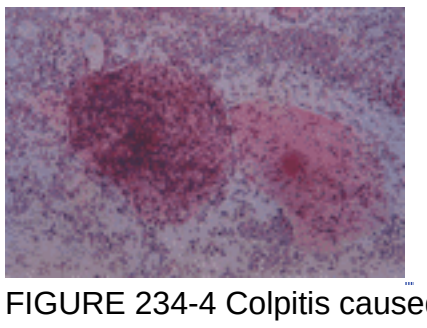

FIGURE 234-4 Colpitis caused by *Haemophilus vaginalis*. Clue cells, Gram-staining. (*Courtesy of U. Lauper, MD.*)

Gram stain gives excellent results with regard to sensitivity and specificity. Routine vaginal microbiologic cultures in women with suspected BV are of no diagnostic value. [25]

Clue cells are epithelial cells coated with bacteria (predominantly *Gardnerella vaginalis*). *G. vaginalis* is found in high concentrations in the vaginal fluid of more than 90 percent of women with BV. Patients with BV have only few or no lactobacilli in the vaginal flora. [25] BV in nonpregnant women is treated successfully with metronidazole orally or locally. A single oral dose of 2 g metronidazole is as successful as a 5- to 7-day course of 1 g daily. Intravaginal clindamycin cream (2%) for 5 to 7 days is the drug of choice in pregnancy. [26] Routine treatment of male partners is not recommended as no study has shown that treatment of the male partner decreases the risk of recurrence.

Protozoa are ubiquitous, unicellular, nonphotosynthetic, eukaryotic organisms that are microscopic or near microscopic in size. Although most are free-living, some have adapted to a parasitic existence; it is this group that is of major medical importance.

The basic structure of protozoa consists of a cell membrane surrounding cytoplasm in which one or more nuclei are embedded. Each of the major classes of protozoa has evolved distinctive organelles to mediate locomotion and provide for metabolic activity.

The taxonomy of the protozoa subkingdom is complex. Table 235-1 lists a simplified classification of those protozoan species that cause diseases of dermatologic interest.

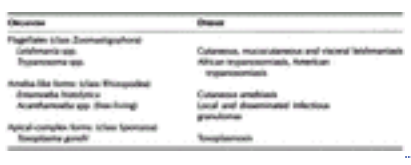

TABLE 235-1 **Protozoa Causing Dermatologic Disease**

LEISHMANIASIS

Leishmaniasis is the result of infection with intracellular protozoan parasites belonging to the genus *Leishmania*. The infections cause a wide spectrum of clinical changes that divide leishmaniasis into four broad divisions based on the extent and severity of involvement in the human host: cutaneous leishmaniasis (CL), diffuse cutaneous leishmaniasis (DCL), mucocutaneous leishmaniasis (MCL), and visceral leishmaniasis (VL).

The prevalence of all forms of leishmaniasis worldwide is in excess of 18 million cases. Movement of new immigrants into endemic areas, an increase in tourism to “exotic” areas of the globe, a decrease in the use of insecticides, and improvement in diagnostic methods have all contributed to raising the incidence of cutaneous leishmaniasis, which the World Health Organization estimates will soon exceed 1.5 million new cases annually. The more serious forms of the disease, such as MCL and VL, cause the death of more than 80,000 persons annually.

Characterization of *Leishmania* Parasites

The parasites that cause leishmaniasis are members of the order Kinetoplastida, family Trypanosomatidae. They are found in two morphologic forms during their life cycle. In humans and other mammalian hosts, they exist within

macrophages as round to oval nonflagellated amastigotes, 2 to 3 µm in diameter. In the arthropod vectors (sandflies belonging to the genus *Phlebotomus* or *Lutzomyia*), the parasites exist as elongated flagellated promastigotes, 10 to 15 µm in length and 2 to 3 µm in width. Both forms of the parasites have a nucleus and a smaller DNA-containing kinetoplast. Although promastigotes of different *Leishmania* species vary slightly in the width-to-length ratio, amastigotes show no significant differences, and it is not possible to distinguish species of *Leishmania* by their morphology in tissue smears.

Until the 1980s, different species of *Leishmania* were identified largely by the pattern of their clinical involvement. The Old World forms of CL were thought to be caused by *L. tropica*, New World MCL was attributed to *L. braziliensis*, New World CL to *L. mexicana*, and VL to *L. donovani*. Recently, more precise techniques for identifying *Leishmania* species have been developed, such as monoclonal antibodies, isoenzyme characterization, DNA hybridization, and the polymerase chain reaction (PCR). Based on findings using these techniques, the older clinical categories have been subdivided and now include recently identified species. Table 235-2 provides a practical, somewhat simplified classification scheme.

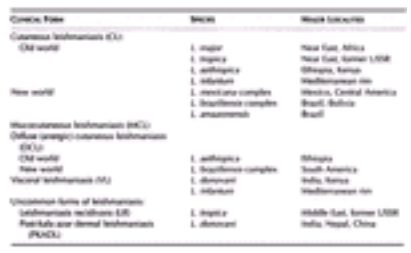

TABLE 235-2 **Classification of Leishmaniasis**

VECTORS *Leishmania* parasites are transmitted by phlebotomine sandflies of the genus *Phlebotomus* in the Old World and *Lutzomyia* in the new world. Sandflies are small mosquito-like insects, 1.5 to 4 mm in length. Their small size enables them to pass through ordinary mesh screens and mosquito netting. Sandflies are widely distributed throughout the tropics and subtropics in a variety of habitats, including deserts, rain forests, and highlands. Only the females are hematophagous (blood sucking).
LIFE CYCLE Parasites, in the form of amastigotes from infected tissue or blood, are taken up from the mammalian host during feeding by female sandflies. Within the midgut of the sandflies, the parasites undergo a change to the promastigote form and multiply. Once the promastigotes are fully developed, they migrate from the gut to the pharynx and proboscis, where they remain until they are injected into a new mammalian host during a subsequent blood meal. Between 10 and 200 promastigotes enter the dermis during each feeding by an infected sandfly. Many of the “free” promastigotes are thought to be destroyed by polymorphonuclear leukocytes and serum complement. The exact details of the early stages of infection are still unknown. Some of the promastigotes become attached to receptors on the surface of dermal macrophages and are phagocytosed. It has been shown that sandfly saliva, injected with the parasites, enhances parasite virulence, mainly because of its impressive vasodilatory properties. Studies in animals suggest that the saliva also has an immunomodulatory effect, delaying a protective cell-mediated response. [1] Within the macrophage, the promastigotes transform into amastigotes (also called Leishman-Donovan bodies) and are incorporated into the cells' phagolysosomes (parasitophorous vacuoles). Within the phagolysosome, the parasites are able to resist destruction and multiply readily by binary fission. When a macrophage becomes filled with amastigotes, the macrophage is disrupted. The amastigotes reenter the extracellular space and are taken up again by other macrophages. The duration of the extracellular stage is unknown. Dissemination of the parasites from the inoculation site depends in large measure on the species of the parasite. Some species, such as *L. donovani* and *L. infantum*, can spread to macrophages elsewhere in the reticuloendothelial system early in the course of the illness. Other species, such as members of the *L. braziliensis* complex, travel to specific locations in the host, including the mucosal surfaces of the nose, pharynx, and upper respiratory tract. Amastigotes of dermatotropic species, such as *L. major* and *L. tropica*, generally remain confined to the skin and probably to the draining lymph nodes. The cycle of infection continues when an infected mammal is again bitten, and amastigotes are taken up by a female sandfly.
RESERVOIRS Each species of *Leishmania* favors one or more animal reservoirs, except *L. donovani*, which is thought to be largely anthroponotic. *L. tropica* is probably not anthroponotic, but in many countries the specific animal reservoir has not yet been identified. Identification and control of the reservoir may have a profound influence on the epidemiology of the disease. For example, in southern France and Spain, where dogs serve as the main reservoir for VL (caused by *L. infantum*), destruction of infected animals has led to a marked decrease in the frequency of the disease in humans. In an area of Turkmenistan, as a result of a zoonotic control program, CL was practically eliminated.

Immunobiology

Leishmaniasis can be pictured as an immunologic spectrum that in many aspects parallels leprosy. At one end lies CL, in which the host usually develops a protective immune response; at the other is VL, in which the host shows little evidence of resistance and may show signs of immunosuppression. In the middle are MCL, which provokes an intense inflammatory reaction, and DCL, in which there is extensive and widespread proliferation of the organisms of the skin, but without much inflammation or tendency for visceralization. Unlike leprosy, the extent and pattern of leishmaniasis that develop are strongly influenced by the specific species of *Leishmania* involved.

Additional factors that affect the clinical picture include the number of parasites inoculated, the site of inoculation, the nutritional status of the host, and even the nature of the last nonblood meal of the vector. In some cases, the sandfly vector is heavily infected, and a large load of parasites may partially block the insect's pharynx, often requiring the sandfly to make multiple probes to obtain an adequate blood meal. [2] This may result in a localized cluster of cutaneous lesions in the host. Rather broad differences in the disease pattern may develop from apparently similar or identical strains of *Leishmania*. Some patients infected by *L. major* develop inapparent infections, whereas others infected by identical *Leishmania* species show deep or widespread lesions that involve subcutaneous tissue and lymph nodes. Although CL caused by *L. aethiopica* results in spontaneous cure in 80 percent of patients, widespread diffuse cutaneous

lesions develop in the remaining 20 percent.

Immunologic Response

Cell-mediated immunoregulation plays a central role in the outcome of leishmanial infection. On the one hand, the clinical expression of the disease is a result of immunologic processes rather than the number of parasites in the lesions; on the other hand, cell-mediated immunity is crucial for healing and development of long-lasting immunity. Although antileishmanial antibodies are produced during infection, their presence does not correlate with resolution of the disease. In experimental animals, disease progression is associated with T_H2 lymphocytes, which produce interleukin (IL)-4, IL-5, IL-10, and transforming growth factor (TGF)-ß; control and resolution of infection are mediated by T_H1 lymphocytes, which produce interferon (IFN)-? and IL-2. Experiments using transgenic mice and selective gene disruption have shown that both cytokines and chemokines are major regulators of the immune response. For example, IL-12 has been found to play a central role in both the induction and maintenance of long-term protection to infection by *L. major*. [3] And natural killer (NK)-cell–activating chemokines have been shown to induce NK cells to promote parasite containment and stimulate a T_H1 protective immune response. [4]

Parasites are eliminated by an effector mechanism which involves IFN-?–mediated activation of infected macrophages. Recent evidence suggests that parasite killing within macrophages is mediated largely through the upregulation of nitric oxide synthetase (NOS) and the generation of nitric oxide (NO). The expression of inducible NOS is upregulated by T_H1 cytokines and suppressed by T_H2 cytokines. [5], [6] In general, the murine leishmania model has served as a model for diseases exhibiting the T_H1/T_H2 dichotomy, such as leprosy.

Although it is suggested that similar mechanisms may be operative in human CL, the picture that emerges from human studies is less clear. Several researchers have measured cytokine production in CL lesions, and mostly a mixture of T_H1 and T_H2 cytokines has been found, without a clear correlation with healing. [7] Other studies show that patients with active CL have circulating lymphocytes that produce IFN-? in response to leishmanial antigen, thus supporting a role for T_H1 lymphocytes in healing. It is not known how parasites are killed in humans. Although it has been shown that human macrophages in vitro can kill parasites by the generation of NO, it is unclear if this represents the operative mechanism during the disease process.

In general, infection and recovery are followed by lifelong immunity to reinfection by the same species of *Leishmania*. In some cases, interspecies immunity has also been reported. An effective vaccine for the prevention of leishmaniasis is still unavailable. Leishmanization, the injection of viable infective parasites in a controlled manner, has been used in some parts of the world as a means of preventing infection upon reexposure under field conditions.

Clinical Patterns

OLD WORLD

CL caused by L. major CL is found in widely scattered parts of Asia, Africa, and Europe, largely in tropical and subtropical zones, and in much of the Middle East, especially Iran, Iraq, eastern Saudi Arabia, the Jordan Valley (of Israel and Jordan), and the Sinai Peninsula. The disease begins as a small erythematous papule, which may appear immediately after the bite of the sandfly, but usually appears 2 to 4 weeks later. The papule slowly enlarges in size (to 2 cm or more) over a period of several weeks and assumes a more dusky violaceous hue (Fig. 235-1). Eventually the lesion becomes crusted in the center. When the crust is removed, a shallow ulcer is found, often with a raised and somewhat indurated border. In some cases, the central part of the nodule becomes hyperkeratotic, and a firmly adherent horn develops over the lesion. Small satellite papules (Fig. 235-2) may also be found at the periphery of the lesion, and occasionally subcutaneous nodules develop along the course of the proximal lymphatics. Rarely, lesions become locally invasive and extend to subcutaneous tissue and even muscle. This latter occurrence may be related to specific deficiencies in the host's immune response.

FIGURE 235-1 Cutaneous leishmaniasis. Large moist plaque on the cheek caused by *L. major*.

FIGURE 235-2 Cutaneous leishmaniasis, late plaque-stage. Central plaque with peripheral satellite papules (*L. major*) is

seen near the ankle.

After the lesion has been present for 2 months or more, peripheral spread stops and the ulcerated nodule remains approximately the same size for another 3 to 6 months, or even longer (Fig. 235-3). The lesion then heals, usually leaving a slightly depressed scar. In some cases, CL has been found to remain “active,” that is, with positive smears, for 24 months or even longer. Such cases have been designated *nonhealing chronic cutaneous leishmaniasis*.

FIGURE 235-3 Cutaneous leishmaniasis, Old World. A deep ulcerated lesion on the leg, caused by *L. major*, in a man with specific deficit in cell-mediated response to the parasite.

The number of lesions that develop in *L. major* CL depends largely on the circumstances of exposure and the extent of the infection within the sandfly vector. Infection with *L. major* may result in multiple lesions (Fig. 235-4); up to 100 or more have been reported in a single individual. The reservoir for *L. major* is desert rodents, and the incidence of the disease is highest in areas close to the burrows of the infected animals.

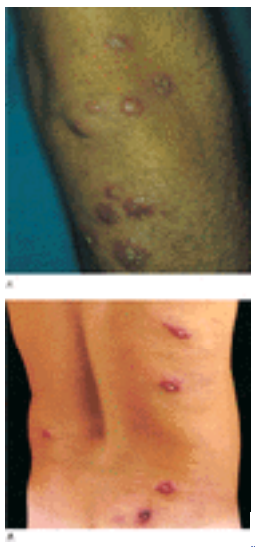

FIGURE 235-4 Cutaneous leishmaniasis, multiple lesions. *A*. Multiple nodules on the arm caused by *L. major. B*. Multiple, nodular, ulcerated lesions on the trunk at the sites of sandfly bites. Note that the ulcerated nodules look like volcanoes seen from above (“volcano sign”).

CL caused by L. tropica CL caused by *L. tropica* is found in parts of southern Europe, Iran, Iraq, the Middle East, and the southern republics of the former USSR. The disease is more common in urban areas than is CL from *L. major*. *L. tropica* is largely a disease of humans although recent evidence suggests that hyrax and rats may serve as reservoirs. The clinical pattern of *L. tropica* infection is similar to that of *L. major*, although lesions are more apt to be solitary and tend to be somewhat more inflammatory. They last longer and are usually more difficult to treat.
CL caused by L. infantum CL caused by *L. infantum* is found in countries bordering the Mediterranean, including southern Europe and northern Africa. The skin lesions are similar to those in the *L. major* form of the disease, but their duration is usually shorter. Wild canines and dogs serve as the reservoir. Reports from endemic areas in Spain have shown that up to 20 percent of dogs tested for the presence of *L. infantum* were harboring parasites in the skin and in internal organs.
CL caused by L. aethiopica This is found in Kenya, the Sudan, and Ethiopia. The common form of the disease seen in these areas is similar to CL caused by *L. major*. However, in a significant number of patients, widespread skin involvement develops (DCL) that resembles lepromatous leprosy (see below).
NEW WORLD CL
CL caused by L. mexicana complex In the New World form, the skin lesions of CL are caused by parasites of the *L. mexicana* complex. The disease is found in Mexico, Central America, as far north as Texas, and as far south as Brazil. The vectors for this form of CL are *Lutzomyia* sandflies. The lesions develop in a similar fashion to those caused by *L. major* in the Old World form. A small erythematous papule develops at the site of the bite of an infected sandfly and gradually develops into an ulcerated nodule. Eventually, the lesion heals, leaving a depressed scar. Although lesions can develop on any part of the body, in Mexico and Central America sores characteristically involve the pinna of the ears (chiclero ulcers).
CL caused by L. braziliensis Most cases are caused by transmission from forest rodent to sandfly to human, with the latter serving as a sporadic host when entering into the habitat of the forest rodent reservoirs. The clinical symptoms of the cutaneous lesions are similar to those caused by the Old World species of *Leishmania*, except that some of the strains of the *L. braziliensis* complex can invade the mucous membranes of the mouth, nose, pharynx, and larynx, giving rise to MCL (see below).

Histopathology

In acute CL, the epidermal changes are highly variable and can range from atrophy or ulceration to hyperplasia, which may be pseudoepitheliomatous. The most constant feature is a diffuse dermal inflammatory cell infiltrate composed of varying proportions of histiocytes, lymphocytes, plasma cells, and neutrophils. Specific diagnosis requires the identification of amastigotes within the cytoplasm of dermal macrophages. In general, the number of parasites present is

inversely proportional to the duration of the lesion. The amastigotes measure from 2 to 4 µm and are a dull blue-gray color with hematoxylin and eosin (H&E) staining. Infected macrophages are usually present in clusters. Although the parasites are more apparent with Giemsa stain, in the authors' experiences, it is rare to find them with Giemsa stain if they are not visible with H&E. An immunoperoxidase, monoclonal antibody stain can be performed on paraffin sections and is sometimes more helpful than either H&E or Giemsa staining in locating amastigotes.

In chronic CL, the dermal infiltrate is nodular and is characterized by tuberculoid-type histiocytic granulomas with lymphocytes and plasma cells surrounding them. Amastigotes are usually not detectable. Necrosis rarely occurs. This histology generates a differential diagnosis that includes other causes of tuberculoid type granulomas such as lupus vulgaris, tuberculoid leprosy, and granulomatous rosacea. A specific diagnosis at this stage requires clinicopathologic correlation.

Diagnosis

PARASITOLOGIC DIAGNOSIS [8] The diagnosis of CL rests on finding parasites in the skin. The most effective method for detecting parasites is a tissue smear from a lesion. Tissue smears are obtained by making a shallow slit in the skin with a scalpel blade at the edge of the lesion. After staining with Giemsa, the amastigotes are seen as pale-blue oval bodies with a dark-blue nucleus and a small point-shaped kinetoplast within the cytoplasm of tissue macrophages (Fig. 235-5). Occasionally, abundant organisms are located in an extracellular location. These extracellular amastigotes are generally somewhat larger than the intracellular forms and often have an elongated profile.

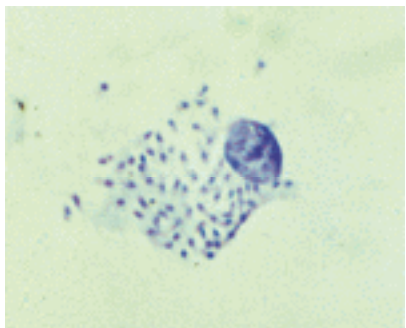

FIGURE 235-5 Amastigotes within a macrophage in a Giemsa-stained smear of a CL lesion.

Parasites can also be cultured from tissue fluid obtained from a lesion. The material is cultured in a biphasic medium, such as Novy-MacNeal-Nicolle (NNN), or a liquid medium, such as Schneider's insect culture medium, in the presence of fetal calf serum. Promastigote forms appear after several days and can be detected in the culture medium. Cultures should not be discarded as negative before 4 weeks. Strains that do not grow in culture media may be inoculated into susceptible animals, but this method is not very practical for routine diagnosis. In regions of the world where more than one species of *Leishmania* is found, emphasis should be on species identification, because characterization of the parasite may influence treatment. PCR has proven useful for this purpose, and primers have been developed than can detect different parasite species, using very small amounts of tissue material. [9]

IMMUNOLOGIC DIAGNOSIS Although both circulating and cellular responses can be demonstrated during the course of the illness, animal studies show that protective immunologic reaction is based solely on cell-mediated immunity. Generally, tests of immune function are of more value in following the course of the disease than they are for diagnosis. Enzyme-linked immunosorbent assays (ELISA) for circulating antibodies that use purified leishmanial products as the test antigen are available. Antibody levels are often elevated in the early stages of CL, but they are not considered a useful diagnostic sign. The cell-mediated immune response can be measured by the leishmanin (Montenegro) skin test, in which phenol-killed preparations of promastigotes are injected into the dermis; the extent of the inflammatory response is measured at the end of 48 and 72 h. Biopsy of a positive Montenegro test at 72 h shows a diffuse cellular infiltrate in the upper dermis, with occasional histiocytes and eosinophils. An in vitro lymphocyte proliferation assay for cell-mediated immunity is also available. In this test, the proliferation of peripheral blood lymphocytes in response to a crude extract of promastigotes is measured after 6 days of incubation. Like the Montenegro test, this assay reflects both present and past infection. [10] The assay is useful in the diagnosis of CL in infants, where it is easier to obtain a drop of blood from a finger prick than a biopsy, especially when the face is involved.

Other Types of Leishmaniasis

DIFFUSE CUTANEOUS LEISHMANIASIS In both the Old and New Worlds, a form of CL is found in which large areas of the dermis are invaded by leishmania-containing macrophages, without a tendency toward visceralization. In the Old World, the disease is caused by *L. aethiopica*; DCL is found in 20 percent of leishmaniasis patients in Ethiopia and the Sudan. In South America, DCL is attributed to a poorly characterized member of the *L. braziliensis* complex. DCL usually presents as a single nodule, which then spreads locally, often through extension from satellite lesions, and eventually by metastasis. In time, the process becomes widespread, with nonulcerating nodules appearing diffusely over the face and trunk; these lesions show a close clinical resemblance to lepromatous leprosy (Fig. 235-6). DCL usually runs a protracted course but does not visceralize. It responds poorly to treatment. Parasites are abundant in skin smears and skin biopsies from DCL and circulating antibodies are present, but tests for cell-mediated immune response, such as the Montenegro skin test and lymphocyte proliferation assay, are negative. There is still some question about the pathogenesis of this form of leishmaniasis, but most workers attribute it to deficiencies in the host's immune response, rather than to an especially virulent strain of leishmania.

FIGURE 235-6 Disseminated anergic cutaneous leishmaniasis. Confluent nodules on the foot resembling lepromatous leprosy; there was generalized cutaneous involvement as well. (*Courtesy of David Wyler, MD.*)

MUCOCUTANEOUS LEISHMANIASIS MCL is characterized by involvement of both skin and the upper respiratory tract. The disease is caused by parasites of the *L. braziliensis* complex in South America and by *L. aethiopica* in Africa. In the form of the disease caused by *L. braziliensis*, mucosal lesions develop from cutaneous lesions in more than 75 percent of those infected. However, in infections caused by less virulent species in the complex, such as *L. braziliensis guyanensis*, nasal involvement develops in only 5 percent of infected cases. In the Old World, MCL can be found infrequently in patients infected by *L. aethiopica*. MCL begins with a cutaneous lesion that is identical to that of CL; a small red papule develops at the site of a sandfly bite and gradually enlarges, ulcerates, and finally heals. However, rather than showing eventual resolution, as in CL, the infection extends to the mucosa of the mouth, nose and pharynx and eventually to the cartilages of the upper respiratory tract, especially the nose and the larynx (Fig. 235-7). Edema and inflammatory changes occur that lead to epistaxis and coryzal symptoms. Eventually there is destruction of the cartilaginous structures in the area, including the nasal septum, and there is also destruction of the floor of the mouth, and the tonsilar areas. Bony structures are usually spared. The disease leads to marked disfigurement, known as espundia in South America (Fig. 235-7). If this form of the disease is not arrested, death usually results from superimposed bacterial infection or pharyngeal obstruction leading to acute respiratory failure or malnutrition.

FIGURE 235-7 Mucocutaneous leishmaniasis, South American. Painful, mutilating ulceration with destruction of portions of the nose. (*Courtesy of Eric Kraus, MD.*)

The diagnosis of MCL rests largely on clinical grounds. The parasites are often difficult to demonstrate or isolate from the mucosa of the respiratory tract.

VISCERAL LEISHMANIASIS In VL, also called kala azar, the parasite establishes itself mainly in the bone marrow, spleen, and liver. The disease, if untreated, is often fatal, but in some areas, many subclinical cases have been reported. It is a disease of all age groups. The disease is present in China, India, the former USSR, the Middle East, from east Africa through the Sudan to west Africa, and across South America. The main *Leishmania* species involved are *L. donovani* in India and Africa, *L. chagasi* in South America, and *L. infantum* in the Mediterranean countries. In India, the disease is transmitted directly from person to person by sandflies; post-kala azar dermal leishmaniasis (PKDL; see below) may represent the human reservoir of the parasite. In other types of VL, foxes, jackals, and dogs are naturally infected, and humans are regarded as accidental hosts. The disease in this case is not believed to be transmitted directly from person to person. In India, VL is mostly an urban disease; elsewhere, it is mostly rural. As in CL, the incubation period may last from weeks to months; there is often a febrile onset that may be so severe as to be fatal, or so slight that it may be little remarked upon. The next symptom to appear is usually splenomegaly, then pancytopenia, fever, wasting, and serious imbalance of serum proteins. There is a high death rate among untreated cases. Definite diagnosis of VL requires the demonstration of parasites; they can be detected in smears or cultures prepared from bone marrow biopsies or spleen aspirates, or in histologic sections from the spleen. Specific serologic tests are often positive in the acute stage of the disease, but cell-mediated immunity, is suppressed. This suppression is reversed after treatment and cure. In a small number of Gulf War veterans who developed a systemic illness characterized by fever, fatigue, malaise, cough, and intermittent diarrhea, but without either lesions of CL or the typical features of VL, *L. tropica* was isolated from bone marrow or lymph nodes; this form of VL has been termed *viscerotropic leishmaniasis*. [11]

LESS-COMMON FORMS OF LEISHMANIASIS

Leishmaniasis recidivans Leishmaniasis recidivans (LR) is a distinctive form of chronic cutaneous leishmaniasis that is a complication of an *L. tropica* infection. Lesions are characterized by dusky-red plaques, with active, spreading borders and healing centers, giving rise to gyrate and annular forms. LR most commonly affects the face and can cause tissue destruction and severe deformity. Generally, the smear and culture are negative, but the patients have a strongly positive leishmanin test, and tests for cell-mediated immunity are positive. Reactivation of *Leishmania* parasites in the scars of cutaneous lesions long thought to be clinically cured may account for LR. Persistence of *Leishmania* has been found by PCR in scars of patients with healed CL up to 11 years after treatment. [12]

Post-kala azar dermal leishmaniasis PKDL is a sequel to VL that has apparently been cured spontaneously or following adequate treatment. The skin lesions usually appear within a year after a course of therapy and consist of macular, papular, and nodular lesions on the face, trunk, and extremities. Many of the lesions take the form of

hypopigmented macules and plaques. The nodules rarely ulcerate. When the lesions are numerous, the clinical picture resembles lepromatous leprosy. *L. donovani* can be recovered from the skin lesions by culture, and smears are usually positive. PKDL has been reported to develop in almost 20 percent of Indian patients treated for VL, and in more than 50 percent of patients in the Sudan. [13] Because there is no known animal reservoir for VL in India, it is thought that patients with PKDL serve as an important human reservoir for this disease.

Treatment

The treatment of leishmaniasis depends on the clinical form of the disease. [14] CL in the Old World is usually self-limited and in most cases does not require specific treatment. Treatment in this form of the disease should be given for extensive lesions, especially involving the face, or for those lesions that invade deeper tissues. The most successful therapy consists of intralesional injections of pentavalent antimonials (Pentostam), usually administered at weekly intervals. Up to 1 mg/kg body weight of the drug may be injected in the borders of the lesions. For very extensive lesions, Pentostam is administered intravenously. Other measures that have been advocated for the treatment of CL include freezing, local heat, oral ketoconazole, and topical amphotericin B. A topically applied aminoglycoside antibiotic, paromomycin, is sometimes effective for the treatment of CL. Trials using these modalities have not been widespread, however, and their efficacy is unconfirmed. Treatment of DCL and VL usually requires parenteral Pentostam.

AFRICAN TRYPANOSOMIASIS

Trypanosomiasis, also known as sleeping sickness, is a potentially fatal protozoan infection of the central nervous system that occurs in sub-Saharan Africa, in a band between N15° and S20°. Although approximately 45,000 cases were reported in 1999, the World Health Organization estimated that the real number of people affected was ten times greater.

The disease exists in two rather distinct forms: Gambian trypanosomiasis (West African sleeping sickness), caused by the subspecies *Trypanosoma brucei gambiense*, is found mainly in the lowland rain forests of West and Central Africa, and is characterized by a relatively slow progression of systemic involvement, leading to mental deterioration, somnolence, and progressive emaciation over a period of months or years. Rhodesian trypanosomiasis, caused by *T. b. rhodesiense* is endemic in the eastern regions of Africa and generally follows a more rapid course, with signs of an acute infection (fever, chills, arthralgias, and anemia) overlapping with a diffuse encephalopathy that generally ends fatally within a few months.

The parasites of both forms of trypanosomiasis are transmitted by the bite of male and female tsetse flies (*Glossina* spp.) These insects are vigorous fliers. They are active mainly during daylight hours and are attracted by dark clothing and moving objects.

In the western regions endemic for *T. gambiense*, humans are the natural hosts. East African trypanosomiasis is a zoonosis, and reservoirs for this form of the disease include wild and domestic animals (such as antelope and cattle) as well as infected humans. [15]

Pathogenesis

Parasites that enter the skin following the bite of an infected fly remain within the local area for about 10 days, and then enter the bloodstream as trypomastigotes. In the blood, the two subspecies of *T. brucei* are morphologically identical; they have an elongated body, 10 to 30 µm long, with a large central nucleus, a kinetoplast, and an undulating membrane that extends the length of the organism. A single flagellum emerges from the anterior end of the body. Some of the signs and symptoms of sleeping sickness are the direct result of the parasites, while other effects are related to circulating immune complexes.

Researchers have shown that the inability of an infected patient to mount a successful immune response stems from the parasites' abilities to express distinct surface antigens (variant surface glycoproteins). Once the parasites enter the host's bloodstream, antibodies are produced that result in the clearing of the majority of trypanosomes. However, the surviving parasites undergo a series of antigenic variations, resulting in subsequent waves of parasitemia. Thus, the host is induced to manufacture antibodies that have little protective value, and the parasites are able to escape total immune elimination.

Clinical Features

GAMBIAN TRYPANOSOMIASIS Three stages of the infection are recognized, although not all those infected demonstrate the complete range of symptoms. During the early stage, usually within a week after the bite of an infected fly, about one-third or fewer of patients will develop an inflammatory skin lesion at the site of inoculation. The lesion, known as a *trypanosome chancre*, is a local response to the proliferation of parasites in the dermis. It consists of a red or violaceous, indurated nodule surrounded by a pinkish halo. It is tender and accompanied by regional adenopathy. Occasionally, an eschar develops in the center of the lesion. The chancre persists for a few weeks and then disappears spontaneously. During the second stage of the disease—6 to 8 weeks later— transient erythematous macules or urticarial lesions develop, often showing an annular or irregular pattern, most commonly on the trunk. [15] During this stage the patient begins to show evidence of systemic involvement, including fever, headache, arthralgias, malaise, and dizziness. Facial or peripheral edema may also be present. Winterbottom's sign (enlargement of lymph nodes along the posterior cervical chain) is a characteristic finding. The third and final stage of the disease evolves slowly over a period of 2 to 3 years, with signs of central nervous system involvement, including lassitude, weakness, personality change, and apathy, that eventually progress to somnolence, coma, and death.
RHODESIAN TRYPANOSOMIASIS Trypanosomiasis caused by *T. b. rhodesiense* follows a similar but more fulminant course. Skin involvement, in the early stages of the disease, occurs more commonly and tends to be more severe (Fig. 235-8).

FIGURE 235-8 East African trypanosomiasis. The trypanosome chancre is a lighly inflammatory, erythematous lesion with bulla formation and a necrotic center. This patient was treated with Suramin and survived (From Case Records of the Massachusetts General Hospital, Case 20-2002, *N Engl J Med* 346:2069, 2002, with permission of the Massachusetts Medical Society.)

A trypanosome chancre is found in more than half of those infected and is often more pronounced than in the Gambian form of the disease. Winterbottom's sign, however, is commonly absent. A transient macular eruption may occur in the second stage of the illness, along with fever, malaise, and headache. There may also be edema of the hands and feet. Disseminated intravascular coagulation may complicate the clinical picture. The major feature characterizing East African sleeping sickness is the rapidity with which the systemic changes develop; trypanosomes enter the circulation within 2 or 3 weeks, and symptoms of central nervous system involvement, such as changes in behavioral and sleep patterns, may appear within 6 to 8 weeks. This form of trypanosomiasis may be fatal within months, even before marked changes of the central nervous system develop. Mild cases of both forms of trypanosomiasis have been reported among indigenous inhabitants, but generally the course of the disease is progressive and the ultimate prognosis is poor. Without treatment trypanosomiasis is regularly fatal.

Diagnosis

During the early stages the diagnosis depends on the identification of parasites in blood, bone marrow, or spinal fluid or in material aspirated from the skin lesion at the site of inoculation or from an enlarged lymph node. Parasites are identified in thick or thin blood films, in tissue aspirates stained with Giemsa, or in unstained wet preparations, by using high-power microscopy. Serologic tests, which may provide additional evidence of infection, are available, but are not diagnostic.

The early skin lesion of trypanosomiasis should be distinguished from the skin lesions of other infectious disorders seen in Africa, including tick-borne relapsing fever, cutaneous diphtheria, anthrax, and African spotted fever. [16]

Treatment

Suramin (naphthylamine sulfonic acid) or pentamidine are useful in the early stages of infection. Once central nervous system involvement has been confirmed, specific therapy consists either of Melarsoprol B (a trivalent organic arsenical) or eflornithine (an ornithine decarboxylase inhibitor), given by intravenous injection, in slowly increasing doses.

Prior to a lumbar puncture, Suramin is given intravenously to clear peripheral parasitemia.

AMERICAN TRYPANOSOMIASIS (CHAGAS DISEASE)

This is a systemic disease caused by the pleomorphic trypanosome *Trypanosoma cruzi*. The disease is endemic in rural areas of Central and South America and affects 16 to 18 million people. Chagas disease is characterized by an acute phase with fever, tissue edema, lymphadenopathy, and diffuse acute myocarditis, and by a chronic phase with cardiomyopathy and megacolon. Skin lesions with characteristic features may develop during the early stage of the illness.

Epidemiology

The disease is usually spread when parasites, in the feces of infected reduviid bugs, are deposited on the skin at the time of biting, and penetrate through the puncture wound or excoriations. The insect vectors (*Reduviidae* spp.) are 3 to 4 cm long and are recognized by their elongated “snout” (“cone-nosed” bugs). They inhabit cracks found along the walls and floors of mud or wooden houses in rural areas and come out at night to feed. Transmission can also occur directly from person to person by transfusion of infected blood.

A Chagas disease control program, now in effect in the southernmost countries of South America, has achieved remarkable success. The program, which consists of insecticide spraying of thatched and adobe houses, has reduced the incidence of the disease in Argentina by 85 percent and in Chile and Uruguay by 99 percent. The goal of the control program is the elimination of Chagas disease by 2010. [17]

Pathogenesis

Trypanosomes exist in the epimastigote form in the gut of the insect vector, as free-living trypomastigotes in the

bloodstream of a vertebrate host, and as amastigotes within tissue cells. The organisms are taken up by reduviid bugs during a blood meal and proliferate in the insects' hindguts. When the bugs feed again, epimastigotes are excreted on the skin surface in the insects' feces. From the skin surface, the epimastigotes invade the skin (or conjunctiva) through the bite wound or through an abrasion and are taken up by macrophages and other cells. They differentiate into trypomastigotes and are spread by way of the bloodstream to other organs and are found in macrophages of the spleen and the Kupffer cells of the liver. Organisms may persist for years in the heart and walls of the gastrointestinal tract, inducing both inflammatory and immunologic disturbances. [18]

Clinical Features

The cutaneous lesion that may develop early in the course of the illness at the site of inoculation consists of a small and often painful erythematous nodule, 1 to 3 cm in diameter, surrounded by a halo of edema, and associated with local adenopathy. Occasionally, necrosis develops in the skin overlying the lesion, a presentation known as a chagoma. If inoculation occurs through the conjunctiva, or nearby on the face (a favorite location for the reduviid bug's blood meal), the resulting conjunctivitis and edema of the orbital area is known as Romaña's sign.

Signs of systemic involvement appear about a week after inoculation (between 4 and 12 days) and consist of fever, headache, generalized adenopathy, arthralgias, and malaise. During this stage a widespread and transient morbilliform eruption may also be seen, along with hepatosplenomegaly. Acute cardiac involvement (giving rise to hypotension and electrocardiographic changes) or acute meningoencephalitis may also be present.

The chronic phase of Chagas disease may last 20 years or more. During this phase, involvement of the heart and gastrointestinal tract is found, eventually leading to congestive failure and/or achalasia of the esophageal sphincter, megaesophagus, and megacolon.

Diagnosis

The diagnosis of American trypanosomiasis is suggested by the appearance of the characteristic chagoma or by Romaña's sign in patients living in endemic areas. The diagnosis is confirmed by finding parasites in thick or thin blood smears, in material from a lymph node biopsy or aspirate, or in blood cultures. Skin biopsy from an involved area may also reveal amastigotes within macrophages.

Serologic tests for the presence of IgM anti- *T. cruzi* antibodies are positive early in the course of the disease. Complement fixation and hemagglutination tests are also available, but they are more useful in identifying cases during the chronic phase.

Treatment

Treatment during the acute phase consists of either benznidazole (a nitroimidazole) or nifurtimox (a nitrofuran). Both drugs may cause significant side effects. The management of patients with chronic infection is based on individual circumstances. [19]

CUTANEOUS AMEBIASIS

Amebae are unicellular protozoa that belong to the subphylum Sarcodina; they are characterized by pseudopod-dependent motility and by reproduction by binary fission. *Entamoeba histolytica*, the causative agent of intestinal amebiasis, occasionally invades the skin, causing cutaneous amebiasis.

It is estimated that as many as 48 million people worldwide (about 1 percent of the world's population) develop intestinal amebiasis each year, although not all cases are symptomatic. The death toll from amebiasis is estimated to be between 50,000 and 70,000 persons annually, mainly infants and children. Amebiasis is found in all regions of the globe, but its prevalence is higher in the tropics and in rural areas, especially in areas where sanitary conditions are poor. Skin involvement occurs infrequently, more commonly among malnourished individuals. [20]

Pathogenesis

Intestinal amebiasis is contracted by the ingestion of food or water contaminated with cyst forms of *E. histolytica*. In the bowel, the cysts transform into trophozoites (ameba forms) and invade the intestinal wall, where they cause little or no irritation or may become invasive, penetrating through the mucosa into the muscular layers. In the cecum, appendix, or ascending colon, the organisms may cause ulcers and eventually perforations into the peritoneal cavity. *E. histolytica* amebae can also penetrate venules and lymphatics and be carried to the liver by the portal circulation to give rise to hepatic amebic abscesses.

If local conditions become unfavorable to the amebae, they encyst, giving them the capability of survival for long periods. Cysts usually do not induce clinical signs of disease, but they are important in the transmission of the disease by apparently healthy individuals.

Clinical Features

Cutaneous lesions in amebiasis are usually the result of direct invasion of the parasites into the skin from an underlying amebic abscess. Typical sites of involvement include the perianal area (as direct extension of rectal involvement) (Fig. 235-9) or the abdominal wall (at the outlet of a sinus draining an abscess in the colon or liver). The penis or vulva may become involved through direct transfer of parasites during intercourse. Amebic skin lesions have also been reported at sites of surgical incisions that were contaminated with amebae during a procedure to remove an abdominal or hepatic

amebic abscess. Rarely, cutaneous lesions have been reported in more remote sites, such as the face, spread by autoinoculation.

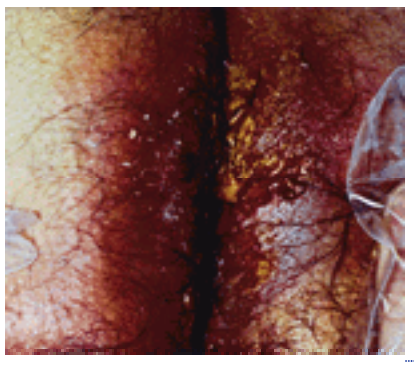

FIGURE 235-9 Cutaneous amebiasis. A painful, ragged, foul-smelling ulcer with an erythematous halo in the perianal region.

The skin lesion usually begins as an indurated pustule or as a localized area of redness that quickly becomes purulent, breaks down, and develops into a painful ragged ulcer with an erythematous halo (see Fig. 235-9). The lesions are often foul-smelling and covered by a layer of pus or necrotic tissue. The borders of the cutaneous lesions are raised and undermined, and regional lymphadenopathy is common. The ulcers tend to expand rapidly and can be especially destructive in children and in poorly nourished adults. The course of the cutaneous lesions tends to be progressive, and large areas of tissue may be destroyed. Without treatment the disease usually ends fatally.

Diagnosis

The appearance of a rapidly enlarging, painful, and foul-smelling ulcer in a patient with a history of dysentery is suggestive of cutaneous amebiasis, and a careful search for trophozoites (ameba forms) within the border of the skin lesion should be carried out.

The diagnosis is made by finding typical trophozoites in tissue scrapings or biopsy material from the border of an ulcer. The tissue is suspended in saline and examined under a microscope for the presence of amebae. The organisms measure 20 to 40 µm and show active movement of pseudopodia in fresh preparations. In biopsy specimens stained with H&E, the organisms are identified by their large size and finely granular pink cytoplasm. *E. histolytica* can be distinguished from nonpathogenic amebae by the presence of ingested erythrocytes within their cytoplasm.

Serologic tests for amebiasis are available, but they may not be positive until several weeks after tissue invasion. The presence of intestinal amebiasis should be confirmed by stool examinations.

Because the clinical features of cutaneous amebiasis are not specific, other causes of ragged-looking skin ulcers must be considered, including other infectious granulomas (such as syphilis, chancroid, and cutaneous tuberculosis) and malignancies. [21]

Treatment

In the past, the standard treatment for cutaneous amebiasis consisted of intramuscular injections of emetine (1 mg/kg daily, not to exceed 60 mg/day), but today newer “mixed” antiamebic agents (effective both in tissues and in the intestinal lumen) are replacing emetine. The most effective of these mixed amebicides are metronidazole and tinidazole, a nitroimidazole derivative. [22]

CUTANEOUS ACANTHAMEBIASIS

Accidental inoculation by free-living amebae (*Acanthamoeba* spp.) may cause granulomatous skin lesions. These parasites are usually introduced at a site of trauma from a contaminated environmental source, including streams, ponds, and swimming pools. Widespread cutaneous involvement may also occur in patients who are immunocompromised and present with a disseminated form of the disease. [23], [24]

Skin lesions initially appear as indurated red or violaceous deep nodules or large pustules, which soon ulcerate. The histologic picture at the border of the ulcer is one of a granulomatous inflammation. Cysts or trophozoites (ameba forms) are formed in scrapings or in biopsy specimens. In wet preparations, the trophozoites of *Acanthamoeba* are actively motile, and show slender, pointed projections (acanthopodia) that continuously form and disappear.

CUTANEOUS TOXOPLASMOSIS

Toxoplasmosis, in its systemic form, is widespread throughout the world. The causative organism, *Toxoplasma gondii,* is an obligate intracellular parasite that infects many animal species. Human infection is usually contracted from contact with infected house cats (*Felix domestica*) or other large cats. Cats acquire the infection by eating rodents, which serve as intermediate hosts of the parasite.

Cutaneous involvement occurs in only a small proportion of individuals with the systemic form of the disease. In neonates, toxoplasmosis is acquired during pregnancy, usually when the mother comes in contact with cat feces or soil containing oocysts of the parasite. In children and adults, the disease may be acquired by eating raw or undercooked

meats from infected animals.

Skin manifestations of toxoplasmosis are rare. A variety of skin lesions have been described in the acquired form of the disease, including roseola and erythema multiforme-like eruptions, prurigo-like nodules, urticaria, and maculopapular lesions. In neonates toxoplasmosis may present as punctate macules, ecchymoses, or “blueberry muffin” lesions.

The diagnosis of cutaneous toxoplasmosis rests upon the demonstration of *T. gondii* in the skin. The form of the parasite seen in the skin, the tachyzoite, is about 6 µm long and 2 µm wide, bow-shaped, with a large nucleus about one-third the size of the body. The organism may be found in all levels of the epidermis. In formalin-fixed paraffin embedded tissue stained with Giemsa, the cytoplasm of the parasite appears blue and the nucleus appears red. Tachyzoites also may be identified by electron microscopy. [25]

In confirmed cases of congenital or acquired disease, or in recurrent infections in immunosuppressed patients, pyrimethamine and sulfadiazine or clindamycin are the drugs of choice. In immunocompetent individuals, the duration of treatment is generally 4 to 6 weeks. Curtailing the ingestion of undercooked or raw meats has been suggested as one measure to lower the incidence of toxoplasmosis. In addition, pregnant women should avoid handling cat litter boxes.

Although many helminthic diseases occur sporadically in the United States, helminthic diseases are a common cause of morbidity and mortality worldwide, particularly in tropical and developing countries. Common helminthic infections include ascariasis, cysticercosis (the most common helminthic infection of the central nervous system), enterobiasis, hookworm disease, lymphatic filariasis, onchocerciasis, and schistosomiasis. Because of the increase in global migration of populations—including immigration of persons from tropical countries to the United States, travel, and prolonged visits of people from industrialized to tropical regions—the dermatologist must be familiar with skin manifestations of helminthic diseases (Table 236-1).

TABLE 236-1 **Summary of Helminths Included in This Chapter**

For many helminthic infections, skin lesions may provide important diagnostic clues (Table 236-2, Table 236-3, Table 236-4 and Table 236-5). A thorough history and physical examination are essential. The patient history should include exact geographic location(s) and durations of stay; means of transportation; occupation; lifestyle; housing; dietary habits (food and water); clothing and shoes worn; exposures (beach, fresh or salt water, insects, plants, animals); personal contacts; history of similar signs and symptoms in other family members, fellow travelers, or persons who have visited same areas; use of preventive measures (insect repellent, mosquito netting); and any known recent outbreaks or diseases endemic to geographic areas previously lived in or visited. The history should also include a thorough review of medications and other preparations (including herbal and local treatments) that the patient may have used. The dermatologic history should include any alterations in skin integrity and underlying skin diseases prior to presentation, description of initial presentation and progression of lesions, time of onset relative to potential exposures, duration of lesions, anatomic distribution, and any associated local and systemic signs and symptoms.

TABLE 236-2 **Helminthic Causes of Dermatologic Nodules and Cysts**

Disease	Helminth(s)	Comments

TABLE 236-5 **Helminthic Causes of Pruritic Lesions***

The laboratory and diagnostic evaluation of a patient with a suspected helminthic infection is based on the history and clinical findings. Many helminthic infections are associated with a peripheral eosinophilia; however, the peripheral eosinophilia may be low-grade or absent (Table 236-6). Other laboratory evaluations (including serologic tests and biopsy of skin lesions for identification of the parasite) and radiologic studies may be warranted, depending on the suspected parasite. [1], [2], [3], [4], [5], [6], [7], [8] and [9] The treatment of these diseases is summarized in Table 236-7.

TABLE 236-7 **Treatment for Parasitic Infections Discussed in This Chapter**

ASCARIASIS [10], [11]

Synonyms

Roundworm infection, ascaridiasis

Etiology

Ascariasis is caused by *Ascaris lumbricoides* and occasionally by *Ascaris suum,* the pig roundworm. *Ascaris lumbricoides* is the largest intestinal nematode. The female measures 20 to 35 cm in length and 3 to 6 mm in thickness, and the male measures 11 to 22 cm in length.

Pathogenesis

Humans are the only host of *A. lumbricoides*. After a human ingests the eggs, larvae emerge from the eggs in the duodenum and penetrate the intestinal wall via the mesenteric lymphatics and venules. Five to 14 days after ingestion, the larvae reach the heart, lungs, trachea, and pharynx. Swallowed larvae reach the intestines (primarily jejunum) and, within 60 to 75 days, mature into adults capable of producing eggs that are passed in the feces. Under the appropriate environmental conditions (temperature, humidity), these eggs embryonate over the course of 2 to 4 weeks. If the infective eggs are ingested by another human, the cycle repeats.

Geographic Distribution

Ascariasis is found worldwide. The number of persons infected may be as high as 1.3 billion. The highest rates of infection are in children, in hot and humid climates, and in areas with crowding and poor sanitation. Clay soils are especially suited for the survival of *Ascaris* species.

Epidemiology

ACQUISITION Infection with *A. lumbricoides* follows the ingestion of infective eggs in soil contaminated with human feces. Such soil may contaminate fruits, vegetables, water, and hands. Infection may also occur through the inhalation of eggs in dust, on footwear, and on dog fur. In some areas, prevalence of infection exceeds 90 percent.
INCUBATION PERIOD AND TIME FRAME Pulmonary symptoms and eosinophilia may begin 10 to 14 days after ingestion of *A. lumbricoides* eggs. Gastrointestinal symptoms may precede the shedding of eggs in feces, which begins 50 to 75 days after ingestion of infective eggs. Initial symptoms may be noted weeks or months after onset of infection. Most adult worms survive 8 to 12 months; occasionally, as long as 24 months.

Clinical Features

The dermatologic manifestation of ascariasis is urticaria, although the majority of infections are asymptomatic or mild. The rare fatalities occur primarily in children with heavy worm burdens. Patients may have a cough, wheezing, fever, and vague gastrointestinal symptoms. Complications arise from intestinal obstruction by worms, usually in the terminal ileum. In its migration, the adult worm can perforate the bowel wall, obstruct biliary or pancreatic ducts, or be associated with acute appendicitis. Cases involving the migration of a worm to the eye, brain, and heart have been reported. General anesthesia and fever may precipitate the migration of adult worms.

Partial immunity follows infection, but reinfection is common.

Laboratory Findings

A peripheral eosinophilia may accompany the stage of pulmonary migration in ascariasis.

Diagnosis

Finding eggs in the feces usually leads to the diagnosis of ascariasis. The diagnosis can also follow identification of the adult worm in stool, pharynx, or an operative specimen. Rarely, larvae appear in sputum or on gastric lavage. Transient bilateral infiltrates on chest x-ray films are seen early in infection. Gastrointestinal contrast study will reveal a filling defect.

Differential Diagnosis

The causes of acute and chronic urticaria are among the differential diagnosis of the skin findings.

Treatment

For ascariasis, treatment options include albendazole, mebendazole, or pyrantel pamoate.

Prevention

Proper waste disposal and avoidance of ingestion of fecally contaminated soil can prevent ascariasis. The embryonated eggs of *A. lumbricoides* can remain viable in soil for years.

CERCARIAL DERMATITIS [12], [13]

Synonyms

Clam digger's dermatitis, schistosome dermatitis, sedge pool itch, swimmer's itch

Etiology

Cercarial dermatitis (Fig. 236-1) results from the infestation of the skin by cercariae (larvae) of nonhuman schistosomes, whose usual hosts are birds and small mammals. Many nonhuman schistosomes have been implicated, including *Trichobilharzia, Gigantobilharzia, Ornithobilharzia, Microbilharzia* and *Schistosomatium*. (Also, see the discussion of Schistosomiasis.)

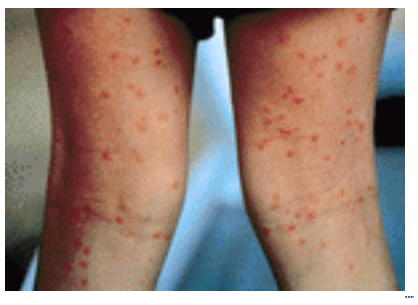

FIGURE 236-1 Cercarial dermatitis. (*Courtesy of Jay S. Keystone, MD, FRCPC.*)

Life Cycle

The adult schistosome inhabits a primary host (e.g., finch, marshbird, mouse, muskrat, vole, waterfowl). Eggs produced by adult schistosomes living in animals are shed with animal feces into the environment. On reaching water, the schistosome eggs hatch, releasing miracidia (fully developed larvae). If the miracidia reach appropriate snail hosts (e.g., *Lymnaeidae* and *Physidae*) before dying, they penetrate the snail and mature in its digestive gland as sporocysts. After 4 to 6 weeks of maturation, they emerge from the snail as fork-tailed cercariae, which must penetrate the skin of a vertebrate host to continue development. Humans cannot support the development of these schistosomes and, hence, are incidental, dead-end hosts.

Pathogenesis

The free-swimming, fork-tailed stage of the parasite, the cercariae, penetrate intact human skin and die without invading other tissues. The schistosomes elicit an inflammatory response. Schistosomes capable of causing invasive disease in humans (e.g., *Schistosoma mansoni, S. haematobium,* and *S. japonicum*) may cause a similar skin eruption shortly after penetration, as well as late visceral complications.

Geographic Distribution

Cercarial dermatitis occurs worldwide. It involves both fresh and salt water that is inhabited by the appropriate molluscan hosts. Sporadic reports come from all continents.

Epidemiology

ACQUISITION Cercarial dermatitis is acquired by skin exposure to fresh or salt water infested with cercariae. It occurs in swimmers and in people whose occupations lead to water exposures (e.g., aquarists, clam diggers, paddy workers, rice farmers).
INCUBATION PERIOD AND TIME FRAME Typically, pruritus and skin changes begin within hours of exposure to the schistosomes. In persons with previous exposures to cercariae, the rash may begin sooner and may be more severe. The eruption peaks in 2 to 3 days and usually resolves over 1 to 2 weeks. Occasionally, lesions first appear days after the exposure.

Clinical Features

A prickling sensation begins during or within minutes of exposure to the cercariae. Approximately 1 hour later, a pruritic, erythematous macular eruption develops that persists for several hours. Ten to fifteen hours after exposure, papular, papulovesicular, and urticarial lesions develop, with marked pruritus. Purpura may develop as well. The distribution of the eruption includes skin surfaces that were exposed to the water and typically spares parts of the body that were covered

by clothing. The severity of the eruption increases with repeat exposures. Secondary bacterial infection can complicate the dermatitis.

Laboratory Findings

In most instances, laboratory studies are not performed because the process is self-limited. Biopsy of skin lesions will show an inflammatory infiltrate with eosinophils.

Diagnosis

The basis for the diagnosis of cercarial dermatitis is usually the characteristic clinical findings and appropriate epidemiologic exposures. Documenting the presence of schistosomal cercariae in epidemiologically incriminated water provides supportive evidence.

Differential Diagnosis

Clinicians should consider seabather's eruption; contact dermatitis due to marine plants, hydroids, and corals; insect bites; and causes of urticaria in the differential diagnosis.

Treatment

Cercarial dermatitis resolves without specific antiparasitic therapy. The systemic use of antihistamines and the topical use of steroids may reduce the symptoms. The systemic administration of steroids has been helpful in severe cases.

Prevention

Avoidance of contaminated water prevents cercarial dermatitis. If contact does occur, vigorous towel drying as soon as the swimmer leaves the water may reduce the penetration of the cercariae.

COENUROSIS [14], [15]

Synonyms

Disease in sheep is named gid and staggers.

Etiology

Coenurosis is caused by the larval stages of several species of *Multiceps,* a cestode (tapeworm). Some authors consider these parasites to belong to the genus *Taenia*. The species that cause human disease most often are *M.(Taenia) multiceps, M.(Taenia) serialis,* and *M.(Taenia) brauni*.

Life Cycle

Definitive hosts of multiceps are the dog, fox, and wolf. Eggs shed in the feces by the infected definitive host are ingested by the intermediate host—herbivorous mammals such as sheep (most commonly), antelope, cattle, gazelle, goat, horse, monkey, and rarely, humans. In the intermediate host, the parasite develops into the larvae in various tissues that the definitive hosts eat, thus completing the cycle.

Pathogenesis

In humans, oncospheres hatch from ingested eggs in the intestine, penetrate the intestinal wall, and may reach many parts of the body, including the central nervous system, subcutaneous muscle tissue, and eye. In these tissues, the larval stage (coenurus) develops. Degenerating or dying larvae provoke an inflammatory reaction and fibrosis.

Geographic Distribution

Reported human cases of coenurosis are sporadic and rare, with the majority from Africa. Infections have occurred in Asia, Europe, and North America, particularly in areas where sheep are common. In tropical Africa, infections are more commonly located in subcutaneous or muscle tissue, or the eye and orbit (particularly in children). In nontropical Africa, infections occur primarily in the central nervous system of adults.

Epidemiology

ACQUISITION Humans acquire coenurosis by ingesting eggs in water or food or on contaminated fingers.
INCUBATION PERIOD AND TIME FRAME The incubation period is months. The disease may be present for years before the infection is recognized. Limited information suggests that the pathogen may survive in the human for at least 15 years.

Clinical Features

Soft tissue coenurosis typically presents as a subcutaneous or intramuscular nodule that is a solitary unilocular cyst. Size varies from 2 to 6 cm in diameter. The lesion is often painless. The most common anatomic locations are the trunk, intercostal region, and anterior abdominal wall, although cysts do occur on the head, neck, and limbs. The parasite has a

tropism for the eye and central nervous system. In these sites, signs and symptoms reflect the presence of a mass lesion. Systemic signs and symptoms are usually absent.

Laboratory Findings

There is usually no peripheral eosinophilia.

Diagnosis

CT or MRI may be useful to determine the exact location of the mass lesion. Definitive diagnosis requires histologic examination of tissues and identification of the parasite. Currently, specific serologic tests are not available.

Differential Diagnosis

Included in the differential diagnosis of coenurosis are cysticercosis, echinococcosis, epidermal inclusion cyst, lipoma, ganglion, and neurofibroma. In the central nervous system, the differential diagnosis includes space-occupying lesions, including neurocysticercosis and cerebral echinococcosis.

Treatment

Complete surgical excision is curative. Follow-up physical examinations for further cysts is important. The prognosis depends on the location and extent of the cysts.

Prevention

Avoiding close contact with infected animals and food contaminated with their feces prevents coenurosis. Limited studies suggest praziquantel may be effective in treating infected sheep.

CUTANEOUS LARVA MIGRANS [16], [17] and [18]

Synonyms

Creeping eruption, creeping verminous dermatitis, sandworm eruption, plumber's itch, duckhunter's itch. Term describes a clinical finding caused by several different parasites.

Etiology

Most often, the larvae of hookworms (nematodes) of dogs, cats, and other mammals cause cutaneous larva migrans (Fig. 236-2). *Ancylostoma braziliense* is the most common cause. Other skin-penetrating nematode larvae that produce cutaneous larva migrans include *A. caninum, Uncinaria stenocephala* (hookworm of European dogs), and *Bunostomum phlebotomum* (hookworm of cattle). Filariform larvae of *Strongyloides stercoralis* can penetrate the skin (usually on the buttocks) and cause similar lesions, larva currens. Cutaneous larva migrans usually refers to lesions produced by nonhuman hookworms, but other parasites, including *Gnathostoma spinigerum, Strongyloides procyonis, Dirofilaria repens, Fasciola hepatica,* and some forms of myiasis can cause migratory skin lesions.

FIGURE 236-2 Cutaneous larva migrans. (*Courtesy of Jay S. Keystone, MD, FRCPC.*)

Life Cycle

The human is usually an aberrant, dead-end host who acquires the parasite from an environment contaminated with animal feces. The infective larvae may remain viable in soil for several weeks.

Pathogenesis

Third-stage larvae penetrate human skin and migrate up to several centimeters a day, usually between the stratum germinativum and stratum corneum. This induces a localized eosinophilic inflammatory reaction. Most larvae are unable to undergo further development or to invade deeper tissues and die after days to months.

Geographic Distribution

Cutaneous larva migrans is widely distributed and most commonly found in tropical and subtropical areas, especially the southeastern United States, Caribbean, Africa, Central and South America, India, and Southeast Asia.

Epidemiology

ACQUISITION Skin contact with the infective larvae in the soil is the means of infection. Activities that pose a risk include contact with sand or soil contaminated with animal feces, such as playing in a sandbox, walking barefoot on a beach, and working in crawl spaces under houses.
INCUBATION PERIOD AND TIME FRAME The time from exposure to onset of symptoms is usually a few (1 to 6) days. The eruption usually lasts between 2 and 8 weeks, though rarely it has been reported to last up to 2 years.

Clinical Features

The lesions of cutaneous larva migrans are characteristically erythematous, raised, and vesicular (Fig. 236-3), linear, or serpentine. Lesions are approximately 3 mm wide and may reach 15 to 20 cm in length. Lesions can be single or multiple, are intensely pruritic, and may be painful. The hookworm advances a few millimeters to a few centimeters daily. The most common anatomic sites (usually 3 to 4 cm from the penetration site) include the feet, buttocks, and genitalia. The oral mucosa has been involved. Excoriation and impetiginization are common. Systemic signs and symptoms (wheezing, dry cough, urticaria) have been reported in patients with extensive infection. *Ancylostoma caninum* larvae can migrate to the small intestine and cause eosinophilic enteritis.

FIGURE 236-3 Cutaneous larva migrans. Note vesicular and bullous lesions. (*Courtesy of Jay S. Keystone, MD, FRCPC.*)

Laboratory Findings

There may be a transient peripheral eosinophilia.

Diagnosis

Characteristic clinical findings, as well as known epidemiologic exposure, are the basis for the diagnosis of cutaneous larva migrans.

Differential Diagnosis

For cutaneous larva migrans, the differential diagnosis includes cercarial or contact dermatitis, bacterial or fungal infection, scabies, myiasis, loiasis, and several other migratory parasites (see Table 236-4).

Treatment

Therapy for cutaneous larva migrans due to dog or cat hookworm includes the use of ivermectin or albendazole, or the topical application of thiabendazole. There should be no attempt to extract the worm, because it has already migrated beyond the visible lesion by the time the infection is identified.

Prevention

Infection with animal hookworms is prevented by avoiding direct skin contact with fecally contaminated soil.

CYSTICERCOSIS [19], [20] and [21]

Synonyms

Cysticercus cellulosae, larval taeniasis

Etiology

The larval stage of the pork tapeworm, *Taenia solium,* causes cysticercosis.

Life Cycle

Humans are the definitive host for *T. solium*. Swine are the intermediate host. Eggs from the adult worm in human small intestine are passed in feces and may remain viable for weeks. If humans or swine ingest the eggs, the outer shell disintegrates in the small bowel, releasing embryos that penetrate the wall of the small bowel and enter the circulation. They disseminate widely, lodging in tissues, most often subcutaneous tissue, brain, eye, and skeletal muscle and developing into the larval stage (cysticerci), which leads to the clinical disease known as cysticercosis. In humans, *T. solium* infection causes both intestinal taeniasis and cysticercosis. The human host can have either form of infection alone. Intestinal infection with the adult parasites follows eating raw or undercooked pork containing cysticerci. The larval cysts attach to the small bowel mucosa and develop into adult worms.

Pathogenesis

Cysticerci in tissues are surrounded by a connective tissue membrane and cause little host reaction while they are alive. When the cysticerci die, however, they may release foreign antigens that provoke granulomatous changes and infiltration of plasma cells, eosinophils, lymphocytes, and macrophages. Calcification may follow. Cysts in muscle collapse and calcify, giving the characteristic spindle shape.

Geographic Distribution

Taenia solium is a common parasite in Central and South America, Africa, parts of Asia, and Eastern Europe. In the United States, this disease appears primarily in immigrants from endemic areas where poor sanitation and pig farming are common, although acquisition of infection has been well documented in the United States. Cysticercosis is the most common helminthic infection of the central nervous system.

Epidemiology

ACQUISITION Humans acquire cysticercosis by ingesting eggs in food, water, or on fingers contaminated with human feces. Humans infected with adult worms may acquire cysticercosis by ingesting eggs passed in their own feces.
INCUBATION PERIOD AND TIME FRAME The time from infection to the appearance of subcutaneous nodules is highly variable and may be from months to years. Cysticerci can survive in humans for 10 to 15 years. Symptoms may begin or continue long after the parasites are dead.

Clinical Features

The clinical features range from asymptomatic to fatal. Fifty-four percent of patients with cysticercosis present with subcutaneous nodules. The skin findings include single or multiple firm, mobile, round, well circumscribed subcutaneous nodules that may be tender or asymptomatic. The nodules vary in size from millimeters to centimeters, but are generally about 2 cm in diameter. The most common anatomic locations are the extremities and trunk. In a series from Nepal, 10 percent of patients had nodules in the oral mucosa.

Systemic manifestations reflect the presence of mass lesions. Although the central nervous system (Fig. 236-4), subcutaneous tissue, skeletal muscle, and eye (Fig. 236-5) are the most commonly affected sites, the heart, kidneys, liver, lungs, and pancreas may be involved. Seizures are the most common manifestation of neurocysticercosis. Almost 50 percent of patients with central nervous system cysticerci found at autopsy had no history of central nervous system symptoms. Intestinal taeniasis is evident in 25 to 50 percent of patients with cysticercosis. Persons with intestinal infection with the adult worms may have abdominal pain, anorexia, constipation, and diarrhea.

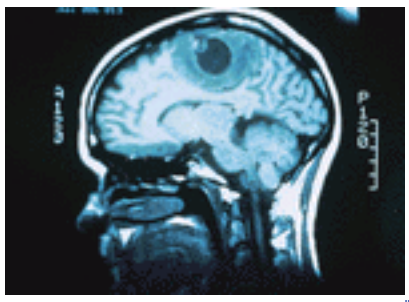

FIGURE 236-4 MRI scan of central nervous system cysticercosis. (*Courtesy of Jay S. Keystone, MD, FRCPC.*)

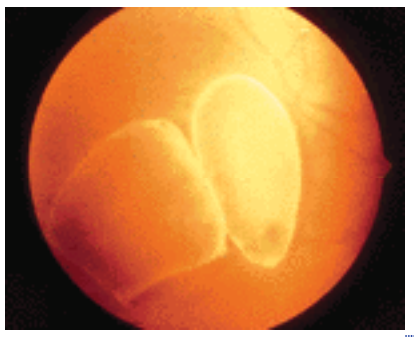

FIGURE 236-5 Cysticercosis in retina. (*Courtesy of William S. Kammerer, MD.*)

Laboratory Findings

Peripheral eosinophilia is absent in 85 percent of patients with neurocysticercosis. High-grade eosinophilia in a patient with cysticercosis should lead clinicians to a search for another process to explain the eosinophilia.

Diagnosis

Surgical excision of a nodule and identification of the parasite by characteristic morphology is the basis for a definitive diagnosis. Serologic tests are also available. High sensitivity and specificity have been reported with an enzyme-linked immunoelectrotransfer blot (EITB) assay and with an enzyme-linked immunosorbent assay (ELISA). Sensitivity is high in patients with multiple lesions, but, in one study, only 28 percent of patients with a single lesion had positive EITB results. Other immunologic tests, such as complement fixation, direct immunofluorescence, immunoelectrophoresis, and indirect hemagglutination, have been less sensitive and less specific.

For neurocysticercosis, MRI allows the evaluation of the developmental stages of larval cysts. Cerebrospinal fluid may be normal or may contain increased protein and cells, including eosinophils and plasma cells.

Differential Diagnosis

For subcutaneous lesions of cysticercosis, the differential diagnosis includes echinococcosis, onchocerciasis, benign cysts, soft tissue tumors, and other causes of nodules (see Table 236-2).

Treatment

The use of anthelmintic drugs for parenchymal cysticercosis remains controversial. Decisions about treatment depend on the location and characteristics of the lesions (viability of the cysts) and may include surgery as well as medical therapy with anticonvulsants and an anthelmintic drug. If a few subcutaneous lesions are present, they need treatment only if symptomatic or for cosmetic reasons. If multiple subcutaneous lesions are present, the drug of choice is albendazole or praziquantel. The Food and Drug Administration (FDA) considers praziquantel an investigational drug for cysticercosis. Concomitant intestinal taeniasis due to *T. solium,* if present, should be treated to eliminate a potential ongoing source of infection for the patient and contacts.

Albendazole should be taken with a fatty meal to increase absorption. In the treatment of neurocysticercosis with praziquantel or albendazole, the administration of glucocorticoids before and during treatment may reduce the inflammatory reaction that follows the death of cysticerci. Plasma levels of praziquantel may decrease by up to 50 percent when given with glucocorticoids.

The prognosis of subcutaneous cysticercosis is excellent. Prognosis involving other organ systems depends on the anatomic location of the lesions. Untreated, symptomatic cerebral cysticercosis has a mortality of 10 to 26 percent. Mortality may reach 50 percent in patients with untreated cysticercal meningitis.

Prevention

Preventive measures include proper disposal of feces, avoidance of fecal contamination of food and drink, and treatment of intestinal taeniasis.

DIROFILARIASIS[22], [23] and [24]

Synonyms

Dog heartworm infection

Etiology

The organisms responsible for dirofilariasis include the filarial nematodes of several species of the genus *Dirofilaria*. These include, most importantly, *D. immitis* (the dog heartworm), as well as *D. tenuis* (raccoon), *D. repens* (dog), and *D. ursi* (bear). *Dirofilaria immitis* causes pulmonary disease and, rarely, soft tissue infection.

Life Cycle

Dirofilaria immitis lives in the right ventricle and pulmonary artery of dogs, producing microfilariae that are ingested with a blood meal by the mosquito. The microfilariae develop into the infective larvae stage in the mosquito.

Pathogenesis

The bite of the mosquito (blackfly for *D. ursi*) introduces the infective larvae of *D. immitis*, and they undergo a growth period in subcutaneous and deeper tissues. The parasite does not complete its development in humans, so no microfilariae are produced. *Dirofilaria immitis* may enter the circulation and occlude a small pulmonary artery, resulting in an infarct. The necrotic and granulomatous tissue contains the worm and eosinophils, and may calcify.

Geographic Distribution

Widespread in dogs, *D. immitis* is thought to be most prevalent in North and South America, Australia, Europe, Japan, India, and China. Sporadic infections with other *Dirofilaria* species have been reported from all continents. In the United States, this infection occurs in the eastern, midwestern, and southern states.

Epidemiology

ACQUISITION Humans acquire the infection when bitten by a mosquito containing infective larvae. The larvae emerge from the mouth parts of the mosquito and enter through the puncture wound.
INCUBATION PERIOD AND TIME FRAME The interval between exposure and development of symptoms is usually at least 2 to 3 months. The parasite occasionally survives for years. Rarely, mature worms have been found in the heart. Dead and calcified worms may be found years after the disease was acquired.

Clinical Features

Soft tissue dirofilariasis is characterized by erythematous to skin colored, well defined, firm subcutaneous nodules that are usually single, but may be multiple. The lesion is typically 1 to 2 cm in diameter and may be tender. There may be initial soft tissue swelling, which evolves into a well circumscribed nodular lesion. Occasionally, lesions are migratory. The most common anatomic sites are the head, neck, breast, arm, leg, and scrotum. Parasites may appear in the conjunctiva and oral cavity. Subcutaneous dirofilariasis has been associated with acute arthritis.

Pulmonary dirofilariasis can cause cough, chest pain, and, rarely, hemoptysis and low-grade fever. More than 50 percent of persons with pulmonary dirofilariasis are asymptomatic.

Laboratory Findings

Peripheral eosinophilia is usually absent or low grade.

Diagnosis

The definitive diagnosis of dirofilariasis comes from surgical excision of the nodule and identification of the worm. Serologic studies using ELISA may be positive in 75 percent of patients with pulmonary dirofilariasis. However, cross-reaction with other helminthic infections (strongyloidiasis, toxocariasis, schistosomiasis, and filariasis) may limit the usefulness of ELISA particularly in tropical locations. Chest x-ray films of pulmonary dirofilariasis show a coin lesion that is usually single and may be calcified.

Differential Diagnosis

Loiasis, cysticercosis, onchocercosis, paragonimiasis, as well as epidermal inclusion cyst, lipoma or other benign tumor, and malignant tumor or metastatic disease, make up the differential diagnosis of subcutaneous dirofilariasis.

Treatment

Surgical excision of the nodule containing the worm is curative.

Prevention

Dirofilariasis caused by *D. immitis* can be prevented by controlling the heartworm infection in dogs. Prevention of other dirofilarial infections requires avoiding bites of arthropods with infective larvae.

DRACUNCULIASIS [25], [26] and [27]

Synonyms

Dracunculosis, dracontiasis, Guinea worm disease, Medina worm infection, dragon worm disease, serpent worm disease

Etiology

The nematode *Dracunculus medinensis* causes dracunculiasis (Fig. 236-6). The female is 70 to 80 cm in length and rarely exceeds 100 cm.

FIGURE 236-6 Dracunculiasis. (*Courtesy of Jay S. Keystone, MD, FRCPC.*)

The ancient symbols of medicine, the caduceus and staff of Aesculapius, may have been drawn from the practice of using sticks to extract the *D. medinensis* worm from its host.

Life Cycle

Larvae are released into water from an infected human and ingested by copepods (tiny aquatic arthropods), in which they develop. Humans ingest the copepods (*Cyclops*) to complete the cycle. Although some animals may be infected, humans are the definitive host and main reservoir of infection.

Pathogenesis

In humans, gastric acid dissolves the ingested copepods, which results in the release of larvae that then migrate through the stomach wall and reach loose connective tissue. The larvae mature into adult worms over 10 to 14 months without causing a tissue reaction. Migration of the gravid female to skin leads to a localized bulla containing inflammatory cells and many eosinophils. Over a period of 4 weeks, the worm emerges. The bulla ruptures on contact with water, releasing larvae from the uterus of the female worm, which prolapses through the skin.

Geographic Distribution

Dracunculiasis is now confined to 13 countries in Africa. It remains a serious health problem in Sudan. As of 2000, cases reported from Sudan represented approximately 73 percent of all cases reported in the world.

Epidemiology

ACQUISITION Humans acquire dracunculiasis by ingesting infected copepods, usually in drinking water taken from shallow lagoons, step wells, and other surface water.
INCUBATION PERIOD AND TIME FRAME The adult worm emerges about 1 year (range, 10 to 18 months) after the larvae are ingested. Symptoms associated with the migration of the worm may precede the emergence of the worm. The adult worm typically dies (or is removed) after reaching the skin and releasing larvae. Disabling symptoms may persist for weeks to months. Fatalities rarely result from complications.

Clinical Features

The characteristic clinical findings of dracunculiasis include a papule, 2 to 7 cm in size, that progresses over 1 to 3 days to a vesicle with an indurated border. An intense burning sensation is relieved, at least in part, by submerging the affected body part in water. The bulla ruptures and larvae are ejected into the water. The rupture of the worm in tissues provokes an intense inflammatory response and cellulitis, and may lead to abscess formation. Disruption of the skin by the worm predisposes the person to secondary bacterial infection, including tetanus. Most infected persons have only one or a small number (usually fewer than six) of worms. In 85 to 90 percent of cases the lesion is on the lower extremity, but the worm may emerge on the hands, arms, trunk, and even jaw. Systemic symptoms of nausea, vomiting, diarrhea, urticaria, and pruritus may precede the skin lesion by a few hours. The systemic symptoms improve once the larvae are ejected into the water.

Rarely, worms have been found in the pericardium, spinal canal, eye, broad ligament, testicle, and other deep tissues. Arthritis and ankylosis may result if a joint is infected. No protective immunity to this parasite develops. Reinfection is common.

Laboratory Findings

Peripheral eosinophilia is common during tissue migration.

Diagnosis

Visual inspection of the morphology of the parasite as it emerges and identification of the discharged motile larvae confirm the diagnosis. X-ray examination may reveal dead calcified worms.

Differential Diagnosis

In cases of dracunculiasis, the differential diagnosis includes a carbuncle or cellulitis associated with bacterial infection, onchocerciasis, loiasis, and syphilitic gumma.

Treatment

In endemic areas, the treatment of dracunculiasis includes extracting the worms by slowly winding them around a stick. This poses the risk of rupturing the worm, however, resulting in a severe inflammatory reaction. Medical therapy with metronidazole is not curative, but decreases inflammation and facilitates extraction of the worm. Mebendazole has been reported to kill the worm directly. Although the FDA has approved the use of metronidazole for other disorders, it is considered investigational for dracunculiasis.

Prevention

Using water that has been filtered or obtained from safe sources avoids infection. Boiling water or treating water with temephos also renders it safe.

ECHINOCOCCOSIS [28], [29] and [30]

Synonyms

For disorders associated with *Echinococcus granulosus*—unilocular echinococcosis, hydatid disease caused by *E. granulosus,* classic cystic hydatid disease; for disorders associated with *E. multilocularis*—multilocular echinococcosis, alveolar hydatid disease

Etiology

The larval stages of the cestodes (tapeworms) *E. granulosus* and *E. multilocularis* cause most cases of human echinococcosis.

Life Cycle

The definitive hosts for *E. granulosus* are dogs and other members of the family Canidae. Sheep, moose, horses, and other animals serve as intermediate hosts. The adult worm in the gut of the definitive host produces eggs that are shed into the environment and ingested by the intermediate host, where they develop into hydatid cysts in tissues that are eaten by the definitive host to complete the cycle. Humans are incidental intermediate hosts. The life cycle of *E. multilocularis* is similar to that of *E. granulosus,* except that the definitive hosts are foxes and the intermediate hosts are small rodents.

Pathogenesis

With *E. granulosus,* the oncosphere (larva) hatches from an ingested egg in the gut, penetrates the intestinal mucosa, enters the venous and lymphatic pathways, and then settles in tissue anywhere in the body and begins cystic development. The cyst increases in size at a rate of about 1 to 5 cm per year. The hydatid cyst (metacestode) has an inner germinative layer of cells, surrounded by an acellular, laminated membrane and variable granulomatous reaction. Secondary cysts bud internally from the germinative layer and produce multiple protoscolices, which, if released from the hydatid cyst by rupturing, may establish new sites of infection. The cysts may reach volumes of several liters. The cysts may cause local pressure and mechanical problems due to their large size.

Echinococcus multilocularis has no limiting membrane of parasitic or host origin, and the cyst gives rise to new cysts by exogenous budding. This produces an enlarging mass of contiguous vesicles that may invade and replace host tissue (usually the liver). *Echinococcus multilocularis* grows more rapidly than *E. granulosus* (commensurate with the short life span of its usual intermediate host, a rodent) and remains in the proliferative stage indefinitely. The mass may undergo central necrosis with cavitation. Hematogenous dissemination leads to metastatic infection.

Geographic Distribution

Echinococcus granulosus is present on all continents. Infections are sporadic in North America, Central America, northern South America, northern Europe, Australia, and New Zealand. There is a high prevalence of infection in southern South America, parts of southern Europe, parts of the former Soviet Republics, Middle Eastern countries, and northern and East Africa. The infection is present in most Asian countries. *Echinococcus multilocularis* is more limited in distribution because of greater host specificity. There are documented cases in North America, Europe, Asia, India, and Iran; one case was reported from northern Africa (Tunisia) in 1981.

Epidemiology

ACQUISITION Infection with *E. granulosus* is acquired by the ingestion of infective eggs with food or fluid or on fingers. Eggs are dispersed by wind, water, and arthropods from the site of fecal deposition. They may survive for a year or more in the environment. Transmission by inhalation of infective eggs may account for rare infections. In some highly endemic areas, the prevalence of infection may reach as high as 5 percent or more of the population. In the United States, approximately 200 cases are diagnosed yearly, with more than 90 percent being acquired outside the country. Persons at

highest risk are those who live in endemic areas, have close contact with dogs, and have poor personal hygiene. Many persons become infected in childhood. Like that with *E. granulosus,* infection with *E. multilocularis* is acquired by ingestion of infective eggs in food or fluid or on fingers. The latter is an uncommon infection in humans. In some areas, 40 to 100 percent of foxes are infected. Trappers, hunters, and persons who work with fox fur are at increased risk of infection.

INCUBATION PERIOD AND TIME FRAME The interval between acquisition of infection and onset of symptoms is usually years and may be decades for *E. granulosus*. Both of these parasites live for years, sometimes for the lifetime of the host.

Clinical Features

Most infections with *E. granulosus* are asymptomatic and go unrecognized. Skin and soft tissue manifestations are rare, occurring in less than 2 percent of infected patients. Cysts may manifest as firm subcutaneous or intramuscular nodules or masses that are fluctuant and nontender to palpation. There is no epidermal change. Skin fistulas from a hydatid cyst in a patient known to have an infection with *E. granulosus* have been reported. Infection with *E. multilocularis* may cause multiple supraumbilical cutaneous and subcutaneous nodules associated with ulceration, surrounding inflammation, and painless cutaneous fistulas. One report described an inflamed epigastric nodule where the mechanism of skin involvement was the progression of larva from the liver to the skin by the falciform ligament.

The clinical features of infection with *E. granulosus* are highly variable and reflect the location and size of cysts (Fig. 236-7 and Fig. 236-8). Mechanical pressure of a mass or an allergic reaction to foreign antigens from leaking cyst fluid causes most symptoms. Cysts are single most often, although they can be multiple (25 percent). They appear in the liver (50 to 75 percent), lung (20 to 30 percent), and other sites: kidney, spleen, heart, bones, muscles, and central nervous system (less than 2 percent). The cyst may reach a large size within the abdomen before symptoms develop. If the cyst leaks fluid, the patient may have wheezing, urticaria, or anaphylaxis.

FIGURE 236-7 Abdominal bulge from intraperitoneal cyst of echinococcosis. (*Courtesy of Jay S. Keystone, MD, FRCPC.*)

FIGURE 236-8 Surgical removal of intraperitoneal echinococcal cyst. (*Courtesy of Jay S. Keystone, MD, FRCPC.*)

Patients with an *E. multilocularis* infection remain asymptomatic for years. The signs and symptoms are epigastric and right upper quadrant pain, a palpable mass, jaundice, and hepatomegaly. Initial symptoms occasionally are related to metastatic lesions in the central nervous system and lung.

Laboratory Findings

Peripheral eosinophilia is present in one-third or fewer of patients with cysts; however, leakage of cyst fluid causes eosinophilia in a higher percentage.

Diagnosis

Examination of the contents of the cyst and identification of the parasite confirm the diagnosis. Characteristic morphology of the parasite as seen by imaging (e.g., ultrasound, CT scan, and MRI) can suggest the diagnosis and can detect clinically silent lesions. Serologic studies can aid in the diagnosis and may be useful in following patients after surgical treatment. In *Echinococcus* granulosus, negative antibody test results do not exclude the diagnosis, as some persons with cysts do not have detectable antibodies. Lesions in the liver are more often associated with positive serologic studies than are lung lesions. A combination of serologic tests may provide the best information. False-positive results can occur in persons with other helminthic infections. Tests that assess circulating antigen, including molecular

techniques using polymerase chain reaction (PCR) are being actively developed. Serologic tests are usually positive at high titers in patients infected with *E. multilocularis*.

Differential Diagnosis

When there is skin involvement, the differential diagnosis includes cysticercosis, paragonimiasis, dirofilariasis, and other cystic lesions of soft tissues.

Treatment

In the past, surgical treatment was the only option available for infection with *E. granulosus*. The use of an alternative approach, chemotherapy and puncture–percutaneous aspiration–injection of chemicals–reaspiration (PAIR), is becoming increasingly common, especially when lesions are inoperable or would pose high surgical risk. It is important to evaluate the patient's condition for silent lesions and follow the patient for recurrence. Albendazole may be useful before surgery or in the event that the cysts rupture or leak during surgery, or that surgery is contraindicated. The operative mortality of *E. granulosus* is 0.9 to 3.6 percent, which increases with subsequent surgeries. The mortality for symptomatic patients who are not treated surgically is as high as 22 to 60 percent in some series. The clinical outcome depends on the anatomic location, number, and size of the lesions.

Surgical resection can be curative in *E. multilocularis* infection if the diagnosis is made early. Albendazole may slow the progression of the infection, but will not cure late infection. Liver transplantation has been used in about 20 patients with inoperable infection. One report describes improvement in a patient with cutaneous alveolar echinococcus after treatment with albendazole. The mortality rate from infection with *E. multilocularis* has been 50 to 75 percent in the past, but may be lower with newer forms of therapy.

Prevention

The incidence of *E. granulosus* infection may be decreased by preventing dogs and other canines from feeding on infected offal.

ENTEROBIASIS [31], [32]

Synonyms

Threadworm, pinworm or seatworm infection, oxyuriasis

Etiology

Enterobiasis is caused by the nematode (roundworm) *Enterobius vermicularis*.

Life Cycle

Humans are the only host for *E. vermicularis*. See below for its life cycle.

Pathogenesis

Humans ingest the infective eggs, which hatch in the intestine and develop into adult worms in the cecum. Female worms migrate from the anus and deposit eggs in the perianal area. The eggs remain viable for up to 13 days. Worms may be found in surgically resected appendices. The migration of worms to the vagina, uterus, fallopian tubes, and peritoneal cavity may be associated with local granulomatous inflammation and peritonitis.

Geographic Distribution

Enterobiasis is found worldwide. It is the most common helminthic infection in industrialized countries. The highest rates of infection are among children.

Epidemiology

ACQUISITION The ingestion of infective *E. vermicularis* eggs can occur by direct anus-to-mouth transfer by fingers or sexual activities, contact with contaminated objects (e.g., bed linens, clothing, bathroom fixtures), and the inhalation and ingestion of airborne eggs in dust. Eggs become infective within a few hours of being deposited by the female worm in the perianal area.
INCUBATION PERIOD AND TIME FRAME A period of 4 to 6 weeks is required before eggs can be found. Symptoms may begin weeks to months after the ingestion of infective eggs. The parasite may live months or longer in the human. Autoinfection by anus-to-mouth transfer of eggs by fingers allows infection to continue indefinitely and to amplify.

Clinical Features

Nocturnal anal and perianal pruritus is the primary clinical feature. The skin may become impetiginized. Other findings have included perianal masses with recurrent cellulitis. Localized urticaria on the buttocks has occurred. In females, vulvovaginitis and vaginal discharge are common, and a nodular lesion of the vulva has been described. Rare complications include appendicitis, inguinal hernia, peritonitis, salpingitis, and urethritis. Reinfection is common.

Laboratory Findings

The results of laboratory studies are usually normal. Eosinophilia occurs only with tissue invasion (e.g., peritonitis).

Diagnosis

The identification of *E. vermicularis* eggs in the perianal area leads to the diagnosis of enterobiasis. This is most effectively done by pressing transparent tape on a glass slide to the skin in the perianal area, then reviewing it under a microscope for identification of the eggs (Fig. 236-9). Eggs may also be found in stool (less than 5 percent) and in subungual material. Occasionally, the adult worm is found in the perianal area, vagina, or underclothes. If ectopic sites are involved, the parasite may be identified in tissue sections.

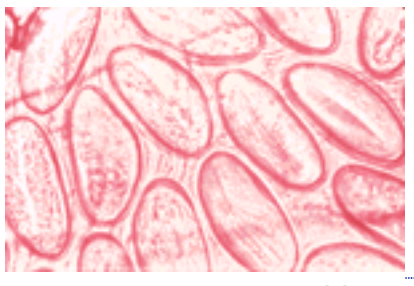

FIGURE 236-9 *Enterobius vermicularis* ova as seen under microscope (collected on transparent tape from perianal area). (*Courtesy of Herman Zaiman, MD.*)

Differential Diagnosis

Allergic and hypersensitivity reactions, neurodermatitis, and strongyloidiasis are part of the differential diagnosis.

Treatment

The administration of pyrantel pamoate, mebendazole, or albendazole is the treatment of choice.

Prevention

Treatment of infected cases and good personal hygiene are the most effective preventive measures.

FASCIOLIASIS [33], [34] and [35]

Synonyms

Sheep liver fluke disease

Etiology

Trematodes (flukes) residing in the human bile ducts cause fascioliasis. These flukes include *Fasciola hepatica,* the sheep liver fluke, and *F. gigantica*. Human infection with *F. gigantica* is rare.

Life Cycle

In water, miracidia released from eggs penetrate snails and develop into cercariae that encyst on water plants (e.g., watercress) and become metacercariae, which are ingested by herbivores (e.g., sheep and cattle).

Pathogenesis

If humans ingest metacercariae, the cyst envelope releases larvae in the duodenum; the larvae then pass through the intestinal wall and peritoneal cavity to penetrate the capsule of the liver. The parasite enters the bile ducts, where it matures and produces eggs that are released into the bile and passed in the feces. The parasite may cause hyperplasia of the bile duct epithelium, periductal fibrosis, and obstruction of the bile ducts. Flukes occasionally migrate to extrabiliary sites, most commonly to subcutaneous tissue.

Geographic Distribution

Fasciola hepatica is found worldwide in sheep- and cattle-raising areas. Sporadic human infections have been reported from all continents.

Epidemiology

ACQUISITION Fascioliasis is acquired by the ingestion of the metacercariae, usually on watercress and other plants (e.g., dandelion leaves and lettuce), or in contaminated water.
INCUBATION PERIOD AND TIME FRAME Eggs are first found in the stool 3 to 4 months after the ingestion of metacercariae. The earliest symptoms, which are related to the migration of the young fluke in the liver, may occur as

early as 2 weeks after exposure. The parasite can survive 10 years or longer in the human host.

Clinical Features

Symptoms may be absent or mild in patients with fascioliasis. In a small percentage of patients, more severe disease develops, and these patients may have acute, relapsing, or chronic symptoms. Early changes that begin during liver migration and may persist for weeks to months include hepatomegaly, fever, right upper quadrant pain, nausea, and diarrhea. Jaundice may occur. Patients may have repeated episodes of urticaria, sometimes accompanied by wheezing. Chronic infection is often asymptomatic, but may be associated with episodic cholangitis, cholecystitis, and obstructive jaundice.

The most frequent site of ectopic fascioliasis is the subcutaneous tissue. Typical findings are erythematous, painful, and pruritic subcutaneous nodules. The most common anatomic locations include the abdomen, back, and extremities. Migratory tracks cause necrosis and local inflammation, and they may lead to fibrosis. Fascioliasis may also present as eosinophilic panniculitis. Other documented ectopic sites include the brain, lung, cecum, epididymis, stomach, appendix, pancreas, peritoneum, spleen, skeletal muscle, orbit, and lymph nodes. Ectopic fascioliasis is not always associated with hepatobiliary disease.

Laboratory Findings

Marked leukocytosis and eosinophilia characterize acute infection with *F. hepatica*. In chronic infection, eosinophilia may wax and wane. Liver function test results are abnormal.

Diagnosis

The identification of eggs in the stool, duodenal contents, or bile confirms the diagnosis of fascioliasis. Eggs are typically present in small numbers in stool; hence, they may be difficult to find. Adult worms may be recovered during hepatobiliary surgery. When ectopic sites are involved, adult worms can be identified in surgical specimens. Serologic tests may aid in the diagnosis of early infection and ectopic infection, although their value is limited because of cross-reactions with other helminthic infections.

Differential Diagnosis

Included in the differential diagnosis are viral hepatitis, infection with other liver flukes, schistosomiasis (Katayama fever), toxocariasis, amebiasis, and biliary tract disease. When subcutaneous tissue is involved, the differential diagnosis includes lymphadenitis, epidermal inclusion cyst, abscess, cellulitis, and other parasites causing nodular skin lesions.

Treatment

Fascioliasis is treated with triclabendazole or bithionol available in the United States only from the manufacturer. Surgery may also be necessary.

Prevention

Preventive measures include avoiding freshwater plants, especially watercress, and untreated water.

FILARIASIS, LYMPHATIC[36], [37] and [38]

Synonyms and Diseases

Malayan filariasis *(Brugia malayi*), Timor filariasis *(B. timori*), Bancroft's filariasis, filariasis bancrofti, and wuchereriasis *(Wuchereria bancrofti*). Some of these parasites can cause elephantiasis and tropical pulmonary eosinophilia. The disease process depends on the etiologic agent. See Table 236-8 for a summary of filarial parasites.

TABLE 236-8 **Summary of Filarial Parasites***

Etiology

Lymphatic filariasis (Fig. 236-10) is caused by three filarial nematodes: *B. malayi, B. timori,* and *W. bancrofti*.

FIGURE 236-10 Lymphatic filariasis secondary to *Wuchereria bancrofti*. (*Courtesy of Jay S. Keystone, MD, FRCPC.*)

Life Cycle

Microfilariae produced by adult worms in the human are taken up by the mosquito during a blood meal. Over several days, the microfilariae develop into larvae within the mosquito, which can transmit infection to other humans when taking blood meals. *Brugia malayi* can follow an alternative life cycle that involves the leaf monkey instead of humans as the definitive host.

Pathogenesis

Infective larvae emerge from the mosquito during its feeding and migrate through the puncture wound produced by the feeding mosquito. The larvae enter the lymphatic vessels, and when they become mature adult worms, they mate in the lymphatics or lymph nodes and release sheathed microfilariae into the bloodstream. Maturing adult worms provoke an eosinophilic and chronic inflammatory cell infiltrate around lymphatic vessels, leading to dilatation and hypertrophy, damaging the lymph valves with eventual scarring, and obstructing lymphatic flow. The death of worms in lymphatics and lymph nodes results in an intense inflammatory reaction with granulomatous changes and necrosis. Late calcification may result.

Geographic Distribution

For *B. malayi,* the geographic distribution includes South and East Asia (from India to Korea), as well as adjacent islands. *Brugia timori* is limited to the small volcanic islands of southeastern Indonesia surrounding the Savu Sea (Timor, Flores, Alor, Sumba, Roti, and Savu). *Wuchereria bancrofti,* which infects 120 million people worldwide, is found in the tropical and subtropical areas of Africa, Asia, Pacific islands, Central and South America, and the Caribbean. Figure 236-11 shows the geographic distribution of *W. bancrofti* in Africa, the Americas, and the Eastern Mediterranean region. Figure 236-12 shows the geographic distribution of *W. bancrofti, B. malayi,* and *B. timori* in the Southeast Asian and Western Pacific regions.

FIGURE 236-11 Distribution of *Wuchereria bancrofti* in the African region, region of the Americas, and Eastern Mediterranean region. (*Reprinted from* Lymphatic filariasis: The disease and its control. *Fifth report of the WHO Expert Committee on Filariasis. Geneva, World Health Organization, 1992 [WHO Technical Report Series No. 821], with permission.*)

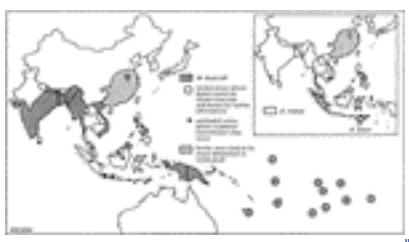

FIGURE 236-12 Distribution of *Wuchereria bancrofti, Brugia malayi,* and *B. timori* in the Southeast Asian and Western Pacific Regions. (*Reprinted from* Lymphatic filariasis: The disease and its control. *Fifth report of the WHO Expert Committee on Filariasis. Geneva, World Health Organization, 1992 [WHO Technical Report Series No. 821], with permission*.)

Epidemiology

ACQUISITION Lymphatic filariasis is acquired by the bite of an infective mosquito. Microfilariae that pass into the

bloodstream by means of transfusion or those that cross the placenta are unable to develop in humans and disappear within a few weeks. Worldwide, the filarial parasites are estimated to infect more than 100 million people. Infection is uncommon in persons who have spent only brief periods in endemic areas. Multiple bites from infective mosquitoes are generally necessary to establish symptomatic infection. In the United States, infection appears primarily in immigrants from endemic areas.
INCUBATION PERIOD AND TIME FRAME The incubation period is 5 to 18 months, although *B. malayi* microfilaremia may occur as early as 2 to 3 months after exposure. *Wuchereria bancrofti* microfilariae first appear in peripheral blood 8 to 12 months after exposure, but symptoms can begin as early as 1 to 3 months after exposure. Adult worms live an average of 10 to 15 years; the microfilariae, probably 6 to 12 months. Symptoms and sequelae can persist after the death of all parasites.

Clinical Features

The clinical presentation and course of lymphatic filariasis depend on the age at first exposure and the presence of immunity. In endemic areas, the prevalence increases after age 20, with most new cases occurring between the ages of 25 and 40 years old. The clinical course ranges from asymptomatic to severely disabling (less than 1 percent of those infected). Manifestations may be acute, chronic, and recurrent. Early findings are lymphangitis with a characteristic retrograde progression, lymphadenitis, orchitis, epididymitis, and sometimes fever. During the resolution of the acute phase of *W. bancrofti* filariasis, there may be extensive exfoliation of the skin of the affected limb. Lymphangitis is typically recurrent with 6 to 10 episodes per year, usually lasting 3 to 7 days each; the affected body part clinically appears normal between early episodes. Intermittent fevers and lymphangitis can recur for as long as 20 years after an infected person leaves the endemic area.

After 10 to 15 years of infection, chronic disease is evident in sequelae of lymphatic obstruction including lymphedema, elephantiasis, hydrocele, and chyluria. The skin over the involved area is hypertrophic, verrucous, and fibrotic with redundant folds of skin. Fissures, ulceration, and gangrene may occur. Secondary bacterial infection invariably occurs. The anatomic locations most commonly afflicted with elephantiasis include the lower extremity, scrotum, and penis. Less commonly, the upper extremity, breast, and vulva are involved, and rarely, an amputation stump, ears, oral mucosa, periorbital area, and panniculus. Treatment does not reverse the late findings of scarring and lymphatic obstruction. *Wuchereria bancrofti* has been reported to cause a skin nodule on the breast.

Tropical pulmonary eosinophilia develops in some patients with filarial infections. Clinical findings include cough, wheezing, dyspnea, chest pain, and fever accompanied by marked eosinophilia and pulmonary infiltrates. Tropical pulmonary eosinophilia may be associated with progressive restrictive pulmonary disease.

Filariasis due to *B. malayi*, usually involves the lower extremities, lymphangitis is not severe, and genital lesions are uncommon. In filariasis due to *B. timori,* lymphatic abscesses are common. Genital lesions, chyluria, and tropical pulmonary eosinophilic syndrome are not reported with *B. timori*.

Travelers to endemic areas do not manifest classic findings when first infected. Instead, they have a hyperresponsive clinical presentation, with more intense inflammatory reactions to filarial parasites. The clinical findings may include lymphangitis, lymphadenitis, and groin pain from the associated lymphatic inflammation, urticaria, and a peripheral eosinophilia. Microfilaremic patients have hyporesponsiveness to filarial antigens and a limited host response to the parasite. Persons with a more vigorous immune response may clear the microfilariae from the blood, but have more prominent local pathology and systemic symptoms.

Laboratory Findings

Patients with lymphatic filariasis have a peripheral eosinophilia, which may be high grade, and an elevated IgE. More than half of microfilaremic patients with *W. bancrofti* infection have hematuria and/or proteinuria.

Diagnosis

The basis for diagnosis is the demonstration of microfilariae in blood, urine, and other body fluids, and tissue or the demonstration of the adult worm in lymphatics or other tissues. The usefulness of serologic tests has been limited by cross-reactions with other antigens, but newer tests with better specificity are becoming available. Persons with active filarial infection may not be microfilaremic, and persons with microfilaremia may be asymptomatic. Persons with tropical eosinophilic syndrome will have pulmonary infiltrates on chest x-ray films.

Differential Diagnosis

The stage of the infection determines the differential diagnosis. Acute infection may be confused with a bacterial lymphangitis. The differential diagnosis for the chronic stage includes other filarial infections such as infection with *Onchocerca volvulus,* recurrent bacterial lymphangitis, deep fungal infection, disruption of lymphatic channels due to trauma, chronic venous insufficiency, pretibial myxedema, lymphosarcoma, fibrosarcoma, and congenital diseases such as Milroy's disease and Klippel-Trenaunay-Weber syndrome.

Treatment

The drug of choice for infections with *B. malayi* and *W. bancrofti* is diethylcarbamazine, which is active against microfilariae, but has a limited effect on adult worms. A single dose of ivermectin has been reported to be effective for the treatment of microfilariae. Tropical pulmonary eosinophilia syndrome is treated with diethylcarbamazine. When treating filariasis with diethylcarbamazine, clinicians may use antihistamines of glucocorticoids to decrease the allergic reaction that may result from disintegration of microfilariae. Severe reactions may follow the administration of diethylcarbamazine to persons infected with filariasis who also have loiasis or onchocerciasis. Combined therapy with albendazole and

ivermectin looked promising in early trials, and additional studies are under way.

Management strategies for patients with lymphedema include elevation of the affected body part, compression stockings, antiinflammatory drugs, skin care of the affected area, treatment of superficial fungal infections, as well as protection of the affected area from trauma. Surgical treatment includes debulking of the affected area, wide excision of chronic draining areas, and lymphatic shunts.

Prevention

The avoidance of mosquito bites in endemic areas is the primary means of prevention. Prophylaxis with diethylcarbamazine (500 mg/d for 2 days each month) is effective for *W. bancrofti* and could be considered for adults who plan to spend more than a month in endemic areas and are likely to have extensive exposures to mosquitoes.

GNATHOSTOMIASIS [39], [40]

Synonyms

Yangtze River edema (China), tau-chid (Thailand), choko-fushu (Japan), wandering swelling, Consular disease (Nankung), Shanghai's rheumatism, nodular eosinophilic panniculitis (Ecuador), Woodbury bug (Australia)

Etiology

The nematodes (roundworm) *Gnathostoma spinigerum* and less frequently, *G. hispidum, G. nipponicum,* and *G. doloresi* cause gnathostomiasis (Fig. 236-13 and Fig. 236-14)

FIGURE 236-13 Subcutaneous swellings of gnathostomiasis. (*Courtesy of Jay S. Keystone, MD, FRCPC*.)

FIGURE 236-14 Subcutaneous swellings of gnathostomiasis. (*Courtesy of Jay S. Keystone, MD, FRCPC*.)

Life Cycle

The adult parasite lives in the stomachs of the definitive hosts, cats and dogs. Eggs are passed in the stool and hatch in water. The larvae are then ingested by *Cyclops* (a type of copepod, which are small aquatic arthropods) that are eaten by fish, frogs, and snakes; in these hosts, the larvae develop into third-stage larvae. When vertebrates who are unsuited to be definitive hosts (including humans) ingest the third-stage larvae, the larvae do not complete development, but encyst or wander in tissues.

Pathogenesis

The ingested larvae penetrate the wall of the stomach and migrate in tissues, causing inflammation, edema, hemorrhage, and necrosis. Chronic lesions are associated with eosinophilic and granulomatous inflammation. The parasite may reach any location within the body.

Geographic Distribution

Human gnathostomiasis is endemic in Southeast Asia, especially Thailand and Japan. Since the 1970s, the prevalence of gnathostomiasis has increased in Peru, Ecuador, and Mexico. Imported fish and other animal flesh can be the source of infection outside of endemic areas. Sporadic cases have been reported in the Americas, Africa, Europe, and Australia.

Epidemiology

ACQUISITION Humans acquire gnathostomiasis by ingesting larvae in undercooked or raw flesh (e.g., fish, chicken, duck, pork, frog). Transmission may also occur by ingestion of infective copepods in water or by skin penetration when handling infected fish.
INCUBATION PERIOD AND TIME FRAME Soft tissue swellings usually begin 3 to 4 weeks after exposure, but may not

develop until months or years later. The parasite can survive in the human for 10 years or longer. One report documents recurrences for 20 years.

Clinical Features

The signs and symptoms of gnathostomiasis range from mild to severe. Within 1 to 2 days after ingestion of the larvae, fever, malaise, anorexia, nausea, vomiting, diarrhea, epigastric pain, and urticaria may develop. Migration of the larvae in the skin and subcutaneous tissue results in intermittent, migratory swellings that are associated with erythema, pruritus, and pain. The lesions may be single or multiple, and up to several centimeters in diameter. The swellings develop rapidly, persist for 1 to 4 weeks, then resolve—only to reappear in a different anatomic location after an asymptomatic interval of a week to months. Over time, episodes become less frequent, less intense, and shorter in duration. However, cutaneous gnathostomiasis may continue for months to years. Gnathostomiasis may present as a cutaneous larva migrans–like eruption and, rarely, as a skin abscess or nodule. The most common anatomic locations include the trunk, upper body, and thighs.

Visceral gnathostomiasis, involving deeper tissues and organs, may occur in the eye, lungs, gastrointestinal and genitourinary tracts, and the central nervous system. Fewer than 1 percent of patients with cutaneous disease have central nervous system infection. Signs and symptoms reflect the location and activity of the larvae. Facial migratory swellings are a sign of increased risk for both ocular involvement and possible permanent visual loss, as well as central nervous system involvement, should the worm migrate through a cranial foramen. Deaths from central nervous system involvement have been reported.

Laboratory Findings

Peripheral eosinophilia may be high grade. Leukocytosis may be present during larval migration. When the infection involves the central nervous system, the cerebrospinal fluid may be bloody or xanthochromic and contains eosinophils.

Diagnosis

The characteristic morphology of larvae in surgical specimens or at autopsy confirms the diagnosis. ELISA is available in some endemic areas to aid in the diagnosis.

Differential Diagnosis

The differential diagnosis of soft tissue gnathostomiasis includes loiasis, onchocerciasis, sparganosis, cutaneous myiasis, cutaneous larva migrans, visceral larva migrans, dirofilariasis, cutaneous paragonimiasis, and eosinophilic cellulitis.

Treatment

Surgical excision plus albendazole is the treatment of choice. Ivermectin has been shown to be effective in animals and appeared to be effective in the treatment of a human with gnathostomiasis.

Prevention

Infection can be prevented by avoiding raw and undercooked flesh of fish, eel, chicken, duck, pork, snake, dogs, cats, and frog; drinking only treated water; and wearing gloves when handling potentially infected flesh.

HOOKWORM DISEASE [41], [42]

Synonyms and Diseases

New World hookworm disease, American hookworm disease, uncinariasis, or necatoriasis (for disease caused by *Necator americanus*); Old World hookworm infection or ancylostomiasis (for disease caused by *Ancylostoma* duodenale); ground itch, hookworm folliculitis. (See also cutaneous larva migrans.)

Etiology

The major causes of hookworm disease are *A. duodenale* and *N. americanus*. Pathologic effects show some variation by species. *Ancylostoma ceylanicum* has a more limited distribution. *A. caninum* causes eosinophilic enteritis as well as cutaneous disease.

Life Cycle

Eggs embryonate and hatch in the soil and develop into infective larvae over 5 to 10 days. Humans are the main reservoir host for *A. duodenale* and *N. americanus*. Cats and dogs are hosts for *A. ceylanicum* and *A. caninum*.

Pathogenesis

The larvae penetrate the skin, reach superficial venules, and enter the circulation. They reach the lungs and penetrate the alveoli. Larvae are carried up the respiratory tract to the pharynx then swallowed. Parasites mature and attach to villi, mainly in the jejunum, where they suck blood and cause bleeding at the site of mucosal attachment. Eggs are shed in the feces. When *A. duodenale* larvae enter the host by means of ingestion instead of via the skin, they develop without

passing through the lung.

Proteolytic enzymes secreted by the infective larvae of *N. americanus* enhance skin penetration by degrading collagen types I, III, IV, and V, fibronectin, laminin, and elastin.

Geographic Distribution

The various species that cause hookworm disease have distinct, but overlapping geographic distributions. Hookworm disease is most common in rural tropical and subtropical areas but can also occur in temperate areas when sanitation is poor. In 1996, the World Health Organization (WHO) estimated that hookworm disease affected 151 million persons and caused 65,000 deaths. The majority of persons who harbor hookworms have no or few symptoms; disease develops in approximately 25 percent as a consequence of infection.

Epidemiology

ACQUISITION Humans acquire infection by penetration of intact skin or mucosa by infective larvae, or ingestion of food (e.g., raw vegetables) contaminated by *A. duodenale* larvae. Transmammary infection is possible with *A. duodenale*. There is probable infection in utero by transplacental spread. Skin contact with fecally contaminated soil poses a high risk. Walking barefoot is the most common way to acquire infection.
INCUBATION PERIOD AND TIME FRAME Skin changes usually begin 1 to 2 days after skin penetration. Eggs are found in the stool 4 to 6 weeks after skin penetration. Pulmonary symptoms may occur 1 to 3 weeks after percutaneous penetration; gastrointestinal symptoms, 1 month after penetration. *Ancylostoma duodenale* survives for approximately 1 year (and up to 5 to 7 years), and *N. americanus* survives for 2 to 6 years (and up to 15 to 20 years) in the human.

Clinical Features

The majority of hookworm infections are asymptomatic or mild. Heavy infections are debilitating and can contribute to death. Within 1 to 2 days, the area of skin penetrated by the larvae may have localized erythema, edema, and papular or papulovesicular lesions. This eruption, known as “ground itch,” is most commonly located on the feet and lasts 1 to 2 weeks. There may be an associated generalized urticaria. The area involved may also present as folliculitis, where the hookworm is identified within a hair follicle. In a minority of patients, the pulmonary migration phase produces cough, wheezing, and shortness of breath. Heavy infections are associated with abdominal pain, diarrhea, and gastrointestinal bleeding. Chronic infection is associated with signs and symptoms of hypoproteinemia and chronic anemia: edema, pallor, weakness, shortness of breath, and tachycardia. Hookworm infection in children can retard growth and intellectual development. Previous infection does not prevent re-infection, but may have a limiting effect on the worm population.

Laboratory Findings

A peripheral eosinophilia begins as early as 2 to 3 weeks after skin penetration by the infective larvae and may be high grade during tissue migration. Chest x-ray films may reveal transient pulmonary infiltrates. In chronic infection, abnormal laboratory values include iron deficiency anemia and hypoalbuminemia. There is gross or occult blood in the stool.

Diagnosis

Characteristic clinical findings in a person with appropriate epidemiologic exposure suggest a presumptive diagnosis of “ground itch.” At the time a patient presents with skin changes and pulmonary infiltrates, the results of stool examinations will be negative. A period of 4 to 6 weeks after exposure must pass before eggs can be found on stool examination. The eggs of *A. duodenale* and *N. americanus* are indistinguishable by routine light microscopy.

Differential Diagnosis

For hookworm disease, the differential diagnosis includes cutaneous larva migrans and folliculitis.

Treatment

Effective treatment includes albendazole, mebendazole, or pyrantel pamoate (considered investigational by the FDA for this infection). Albendazole appears to be more effective than mebendazole.

Prevention

The sanitary disposal of human feces can prevent hookworm infections.

LOIASIS [43], [44], [45] and [46]

Synonyms

Calabar swellings, fugitive swellings, loa loa filariasis, African eyeworm infection

Etiology

The filarial nematode (roundworm), *Loa loa,* is the parasite responsible for loiasis.

Life Cycle

The *Chrysops* (a type of fly) bites an infected human and ingests microfilariae along with the blood meal. The microfilariae develop into larvae, which are transmitted when the fly bites another human.

Pathogenesis

Larvae from the biting fly enter the human through the puncture wound. The larvae mature into adult worms that live in subcutaneous tissue and migrate along fascial planes to all parts of the body. The adult worms produce microfilariae that enter the bloodstream during the day and may reside in the lungs when not circulating.

Geographic Distribution

Loiasis is endemic in Central and West Africa.

Epidemiology

ACQUISITION The bite of the infective day-biting flies of the genus *Chrysops* spreads loiasis. The microfilariae can be transmitted via transfused blood, but will not develop into adult worms in the human host. Flies live in the canopy of the rain forest and lay eggs in muddy streams and swamps. The flies are attracted by dark clothing, wood smoke, and movement of people or vehicles. In endemic areas, infection rates exceed 50 percent in some human populations. Infections in visitors from nonendemic areas occur primarily in persons who spend at least 3 months in endemic areas.
INCUBATION PERIOD AND TIME FRAME Symptoms usually begin 1 year or longer after exposure, although first findings can appear as early as 4 months or as long as 8 years after the acquisition of infection. Microfilariae first appear in the bloodstream 5 to 6 months after the person becomes infected. The adult worm can live longer than 10 years in the human host.

Clinical Features

Loiasis is manifested by pruritus, urticaria, and Calabar swellings (Fig. 236-15), which are localized areas of angioedema associated with the migration of the adult worms through the subcutaneous tissues. Often erythematous and warm, Calabar swellings range from 5 to 10 cm in diameter. They may be associated with pruritus or pain. The lesions last several days and may recur multiple times. They occur predominantly on the extremities (upper more commonly than lower), especially around joints such as the wrist or knee. Fatigue, myalgias, arthralgias, and fever may be associated with the lesions. A migrating adult worm may be seen crossing the conjunctivae or the bridge of the nose (hence, the term “eyeworm”; Fig. 236-16). This is associated with swellings on the face, particularly of the periorbital region. Other, less common systemic findings include arthritis, lymphadenopathy, lymphedema, peripheral neuropathy, cardiomyopathy (endomyocardial fibrosis), hematuria, proteinuria, and encephalopathy.

FIGURE 236-15 Calabar swelling of loiasis. (*Courtesy of Jay S. Keystone, MD, FRCPC*.)

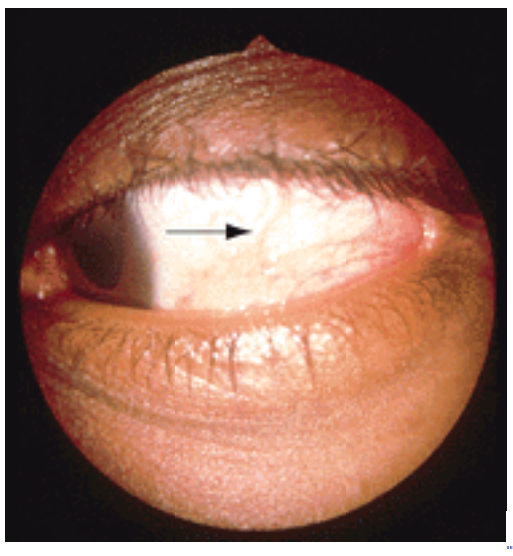

FIGURE 236-16 Loiasis. Adult worm crossing eye. (*Courtesy of Murray Wittner, MD, PhD*.)

Individuals living in endemic areas may be microfilaremic, with a wide range of symptoms. Persons from nonendemic regions who become infected often do not have detectable microfilaremia, but have prominent symptoms and immunologic hyperresponsiveness.

Laboratory Findings

Those with loiasis have a peripheral eosinophilia that may be high grade, leukocytosis, and elevated IgE. *Loa loa*–specific IgG4 is elevated. These findings are much less prominent in infected persons who have always resided in endemic areas.

Diagnosis

The basis for diagnosis is the identification of microfilariae in blood (during the day) or, occasionally, in urine, cerebrospinal fluid, sputum, or other body fluid or by the identification of an adult worm removed from the eye or other tissues. Calcified worms may be seen on x-ray films. Although the usefulness of older serologic tests is constrained by cross-reactivity with other parasites, newer approaches are being developed, including the use of PCR amplification of *L. loa* DNA from the blood.

Differential Diagnosis

The differential diagnosis includes other filarial infections, gnathostomiasis, and toxocariasis.

Treatment

The surgical removal of the worm from the eye or other tissue, if feasible, is a component of treatment. Patients may be infected with multiple worms (usually not more than 10 to 20 adult worms). Diethylcarbamazine (DEC) is currently the drug of choice for persons who are not microfilaremic. Local inflammatory manifestations may occur within 1 to 2 days of DEC treatment. These include pruritus and subcutaneous nodules that, when biopsied, reveal the adult worm. Neurologic complications, including encephalitis and death, may follow treatment of microfilaremic loiasis patients with DEC.

For patients who have an infection refractory to DEC, albendazole may be effective. Alternative approaches in patients with heavy infections have included the use of ivermectin or albendazole or apheresis to reduce microfilaremia. Encephalopathy may occur when patients with a heavy *L. loa* infection are given ivermectin for the treatment of another parasitic infection.

Prevention

Prevention includes protection from *Chrysops* bites in endemic areas to prevent infection. Prophylaxis with DEC is effective for *L. loa* in adults who may spend more than a month in endemic regions and expect to have frequent exposures to biting flies.

ONCHOCERCIASIS [47], [48], [49] and [50]

Synonyms

Onchocercosis, blinding filariasis, river blindness, coastal erysipelas, erysipela de la costa (Mexico and Guatemala), onchocercomata, onchodermatitis, sowda (Arabic speaking areas), craw-craw (West Africa)

Etiology

Onchocerciasis is caused by the filarial nematode (roundworm) *Onchocerca volvulus*.

Life Cycle

Blackflies of the genus *Simulium* bite an individual infected with *O. volvulus*. The microfilariae develop into infective larvae within the blackfly, which passes larvae to another human when taking a blood meal.

Pathogenesis

After entering the human skin when the blackfly takes a blood meal, the infective larvae mature to adult worms that are encapsulated in fibrous tissue and reside in nodules in the subcutaneous tissue and deep fascia. Necrosis and calcification may follow the death of the worm. Microfilariae migrate from adult worms and may enter the bloodstream. The presence of microfilariae in the skin, connective tissue, eyes, and lymph nodes is associated with significant pathologic findings.

Geographic Distribution

The greatest concentration of *O. volvulus* infections is in equatorial Africa. Endemic foci also appear in Latin America, Yemen, and Saudi Arabia. Fig. 236-17 shows the geographic distribution of onchocerciasis in Africa and the Arabian peninsula. Fig. 236-18 shows the geographic distribution of endemic onchocerciasis in the Americas. Onchocerciasis affects primarily people living near fast-flowing rivers where blackflies breed.

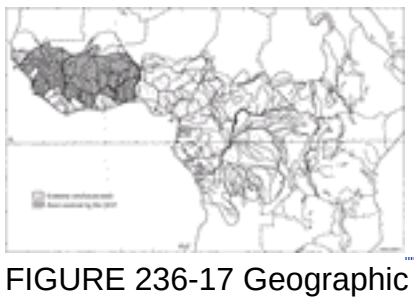

FIGURE 236-17 Geographic distribution of onchocerciasis in Africa and the Arabian peninsula. (*Reprinted from* Onchocerciasis and its control. *Report of a WHO Expert Committee on Onchocerciasis Control. Geneva, World Health Organization, 1995 [WHO Technical Report Series No. 852], with permission*.)

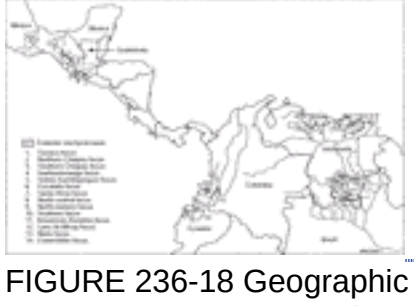

FIGURE 236-18 Geographic distribution of endemic onchocerciasis in the Americas. (*Reprinted from* Onchocerciasis and its control. *Report of a WHO Expert Committee on Onchocerciasis Control. Geneva, World Health Organization, 1995 [WHO Technical Report Series No. 852], with permission*.)

Epidemiology

ACQUISITION Onchocerciasis is acquired by the bite of an infective blackfly. Microfilariae from an infected mother can infect the fetus, and the potential exists for transmission of microfilariae by blood transfusion. It is estimated that approximately 17.5 million persons are infected and 85 million are at risk for infection. An estimated 1 million persons have significant visual impairment due to onchocerciasis, and 3 to 4 million infected persons have onchocercal skin disease. Symptomatic infection generally occurs only in persons who have lived in endemic areas for several months and usually longer. Severe disease develops only after repeated exposures over many years.
INCUBATION PERIOD AND TIME FRAME The incubation period is usually 1 to 2 years with a range of months to several years. Microfilariae may first appear 3 to 15 months after exposure. The initial symptoms can precede the presence of microfilariae in tissue, but often develop only after months or years of infection. The microfilariae can survive in humans for up to 2 to 3 years, the adult worms, for 10 to 15 years.

Clinical Features

Persons with onchocerciasis may be asymptomatic, or they may have a severe impairment, including loss of vision. The skin and the eye are the two most commonly involved organ systems.

The skin manifestations of onchocerciasis have six different patterns, including acute papular onchodermatitis (Fig. 236-19), chronic papular onchodermatitis, lichenified onchodermatitis, atrophy, depigmentation, and palpable onchocercal nodules. More than one pattern of skin involvement may be present simultaneously, or one pattern of skin involvement may evolve into another pattern. Pruritus is often the first symptom of infection. Acute papular onchodermatitis, which most often involves the face, extremities, and trunk, includes widespread small pruritic papules that may progress to vesicles and pustules in the most severe cases. There may be associated erythema and edema. Ivermectin and DEC can precipitate a rash similar to acute papular onchodermatitis. In Mexico and Guatemala, the combination of erythema, edema, and pruritus of the face is known as “erisipela de la costa” and is an acute onchocercal reaction.

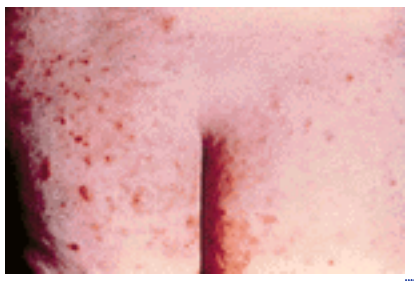

FIGURE 236-19 Onchocercal dermatitis. (*Courtesy of Herman Zaiman, MD*.)

The skin lesions of chronic papular onchodermatitis are macules and lichenoid papules varying in size from 3 to 9 mm in diameter. Pruritus is common, and postinflammatory hyperpigmentation may be present. The most commonly affected anatomic areas are the buttocks, shoulders, and waist.

Lichenified onchodermatitis, also known as “sowda” (Arabic for “black”) in Arabic-speaking regions, most commonly affects teenagers and young adults and most commonly occurs in Yemen and Sudan. Hyperkeratotic and hyperpigmented pruritic plaques become more confluent and lichenified with increased severity and time. The plaques have an asymmetric distribution with the lower extremity being the most frequently affected anatomic location. There is often associated lymphadenopathy.

Atrophy, also known as “lizard skin” in its most severe presentation, makes middle-aged persons appear elderly. The most commonly involved anatomic location is the buttocks; the secondmost, the extremities.

Depigmentation (Fig. 236-20) associated with onchocerciasis is also known as “leopard skin.” Depigmentation is associated with perifollicular pigmentation within macular or minimally depressed areas. In black skin, there may be yellow-brown hypopigmentation. Pruritus is rare in this pattern of skin involvement by onchocerciasis. The anatomic location most commonly involved is the shin area bilaterally. A previous report described the depigmentation of the shins as a useful method to screen for onchocerciasis in endemic areas. Less commonly, the buttocks, lateral groin, and lower abdomen are involved.

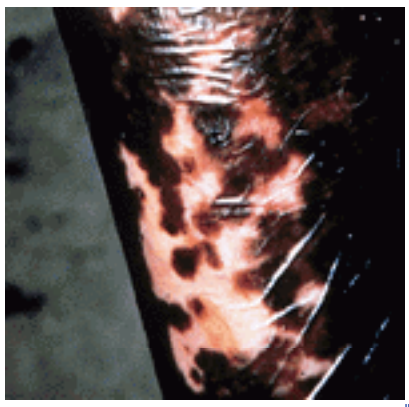

FIGURE 236-20 Depigmentation secondary to onchocerciasis. (*Courtesy of Jay S. Keystone, MD, FRCPC*.)

Palpable onchocercal nodules, containing the adult worm, involve the deep dermis and subcutaneous tissue (Fig. 236-21). Typically asymptomatic, the nodules occur over bony prominences such as the skull, iliac crest, knee, rib, sacrum, scapula, and trochanter.

FIGURE 236-21 Onchocercal nodule over iliac crest. (*Courtesy of Jay S. Keystone, MD, FRCPC*.)

Other clinical findings associated with onchocerciasis include “hanging groin,” which consists of folds of inelastic skin in the inguinal area, and associated lymphadenopathy. Groin hernias, lymphedema of external genitalia or limbs, and lymphadenopathy may occur. Ocular involvement is the most devastating aspect of this disease, as blindness is a potential outcome. Ocular findings include chorioretinitis, iritis, optic atrophy, punctate keratitis, and sclerosing keratitis.

Many psychosocial issues surround onchocerciasis, given the potential ocular involvement as well as the obvious skin manifestations that are easily recognizable to those individuals in endemic areas. The most common presentations in visitors to endemic areas are pruritus and rash. Skin nodules and eye involvement are usually absent, and microfilariae are absent or evident only in low numbers in the skin.

Laboratory Findings

Peripheral eosinophilia and elevated IgE levels are common findings.

Diagnosis

Onchocerciasis is most commonly diagnosed by the identification of the microfilariae in a skin snip or of an adult worm in an excised nodule. In heavily infected individuals, microfilariae may appear in the blood (up to one-third of cases), sputum, cerebrospinal fluid, urine, or other fluids. Microfilariae are clearly visible in the anterior chamber of the eye on slit-lamp examination. Antibody and PCR testing are being developed.

Differential Diagnosis

The skin pattern at presentation determines the differential diagnosis of the skin manifestations of onchocerciasis. Acute papular onchodermatitis may resemble miliaria, insect bites, or a hypersensitivity reaction. Chronic papular

onchodermatitis may resemble a chronic or lichenoid hypersensitivity reaction or atopic dermatitis. The differential diagnosis for lichenified onchodermatitis is broad and includes essentially any diagnosis that involves significant pruritus or rubbing of the involved area. Atrophy associated with onchocerciasis resembles that associated with aging. Onchocercal depigmentation may be confused with postinflammatory hypopigmentation or depigmentation. The differential diagnosis for onchocercal nodules includes cysticercosis, histoplasmosis, paragonimiasis, and epidermal inclusion cysts.

Treatment

The drug of choice in the treatment of onchocerciasis is ivermectin. Surgical excision of the nodules, especially if located on the head, is recommended.

Prevention

The primary means of preventing onchocerciasis is through vector control and mass treatment with ivermectin of the population in endemic areas.

PARAGONIMIASIS [35], [51]

Synonyms

Lung fluke infection, oriental lung fluke disease

Etiology

The trematode (fluke) *Paragonimus westermani* and more than 10 species of *Paragonimus* infect humans.

Life Cycle

Eggs hatch in water and release free-swimming miracidia that enter snails and develop into cercariae. The cercariae leave the snail and invade tissues of freshwater crabs, shrimp, or crayfish, where they encyst as metacercariae. The crustaceans are eaten by the definitive host, which may be a human, although other animals are more important in maintaining the life cycle.

Pathogenesis

In humans, the ingested metacercariae excyst in the small intestine, migrate through the gut wall, and enter the abdominal cavity, where they remain for several days. They migrate across the diaphragm into the pleural cavity and lungs, where they mature and produce eggs that are expectorated in sputum or swallowed. A fibrous capsule surrounds the flukes in the lungs, forming a cyst that may rupture, thus releasing ova and necrotic material into the bronchioles. The eggs provoke a granulomatous reaction. Flukes may migrate anywhere within the body, including subcutaneous tissues, and cause an eosinophilic, granulomatous reaction or abscess.

Geographic Distribution

Paragonimus westermani is widely distributed in East and Southeast Asia and Africa. Other species of *Paragonimus* are found in Asia, Africa, and the Americas.

Epidemiology

ACQUISITION Human hosts acquire paragonimiasis by ingesting metacercariae in raw or undercooked freshwater crayfish, crab, or shrimp or with other foods or fluids contaminated with metacercariae during preparation. Worldwide, an estimated more than 10 million persons are infected with paragonimiasis. The rates of infection are high in parts of Asia, where raw, undercooked, salted, pickled, or marinated crustaceans are frequently eaten. Juices from raw crustaceans are used for medicinal purposes in Korea and Japan. Paragonimiasis is also acquired by eating raw or undercooked field rats and wild boar.
INCUBATION PERIOD AND TIME FRAME Urticaria and gastrointestinal symptoms can begin within a few days of ingestion. Migratory subcutaneous nodules may appear as early as 2 weeks, and pulmonary symptoms occur as early as a few weeks after infection. Central nervous system involvement typically manifests 12 to 16 months after the onset of infection. Eggs are first produced approximately 10 weeks after the ingestion of metacercariae. The diagnosis may not be made for years. The life span of the fluke within humans is usually 10 years or less, but can be as long as 20 to 30 years.

Clinical Features

Depending on the intensity of infection and the anatomic location involved, the clinical features of paragonimiasis range from asymptomatic to fatal. The acute phase corresponds to fluke migration and tissue invasion. This is manifested by urticaria, abdominal pain, and diarrhea, followed by cough, hemoptysis, production of rusty-colored sputum, wheezing, pleuritic pain, and low-grade fever. These findings can continue for weeks. Patients with chronic infection have pulmonary and, sometimes, extrapulmonary findings. Ten percent of patients with *P. westermani* infection and 20 to 60 percent of patients with (*P. skrjabini P. szechuanensis*) infection have subcutaneous swelling or nodules (containing immature flukes). These lesions may be up to 6 cm in diameter, migratory, firm, slightly mobile, and tender to palpation. The lesions are most commonly located on the lower abdomen and inguinal region. Cerebral involvement occurs in less than 1 percent of patients and is more common in children. Five percent of central nervous system infections are fatal. Presenting findings include meningoencephalitis (early) and signs and symptoms of a space-occupying lesion (late).

Abdominal involvement may result in abdominal pain, bloody diarrhea, and palpable abdominal masses.

Laboratory Findings

A peripheral eosinophilia occurs in 80 percent of patients with paragonimiasis, but may be low grade or absent when the parasites are encysted. Eosinophils may be found in fluids adjacent to the parasite, for example, in cerebrospinal fluid, sputum, pleural fluid, and pericardial fluid.

Diagnosis

The identification of eggs in the sputum, feces, pleural fluid, or cerebrospinal fluid or the identification of the adult parasite or eggs in tissue confirms the diagnosis. An immunoblot serologic test that has high sensitivity and specificity is available from the Centers for Disease Control and Prevention (CDC) in Atlanta. Chest x-ray films may reveal many findings, including diffuse infiltrates, nodules, cavities, ring cysts, calcification, and pleural effusions.

Differential Diagnosis

For the subcutaneous nodules of paragonimiasis, the differential diagnosis includes gnathostomiasis, sparganosis, and onchocerciasis. The differential diagnosis of pulmonary involvement includes tuberculosis, lung abscess, fungal infections, malignant tumor, melioidosis, and echinococcosis. The differential diagnosis for central nervous system involvement includes cysticercosis, echinococcosis, angiostrongyloidiasis, gnathostomiasis, fungal infection, tuberculosis, schistosomiasis, and a benign or malignant tumor.

Treatment

The drug of choice in the treatment of paragonimiasis is praziquantel. Although it is an approved drug, the FDA considers it investigational for paragonimiasis. When treating cerebral paragonimiasis, clinicians can give glucocorticoids along with praziquantel to blunt the inflammatory reaction that follows the release of antigens from the dying worms. Bithionol is an alternative mode of therapy and is available under an Investigational New Drug (IND) protocol from the CDC. Triclabendazole may also be effective.

Prevention

Paragonimiasis may be prevented by eating only well cooked crustaceans.

SCHISTOSOMIASIS [52], [53], [54] and [55]

Synonyms

Bilharziasis, snail fever, Katayama fever

Etiology

Schistosomiasis is caused by trematodes (flukes) that, in the adult stage, live in blood vessels. These include primarily *Schistosoma mansoni, S. japonicum, S. haematobium, S. mekongi,* and *S. intercalatum*. (See also " Cercarial Dermatitis," above, for a discussion of disease caused by nonhuman schistosomes.)

Life Cycle

Schistosome eggs excreted by a human or animal hatch in water, releasing free-swimming miracidia that penetrate the intermediate host, the snail, where they develop over 4 to 6 weeks, then emerge as free-swimming cercariae. The cercariae must penetrate the skin of a vertebrate host to continue development to the adult stage. Humans are the only important reservoir for *S. haematobium*. In parts of Africa, baboons are important hosts for *S. mansoni*. Animals (e.g., cows, dogs) are important hosts for *S. japonicum*.

Pathogenesis

Cercariae penetrate the skin over 30 seconds to 10 minutes, become schistosomulae, and may elicit a local inflammatory response. Schistosomulae enter venules and reach pulmonary capillaries in 1 week after skin penetration. Worms mature in the hepatic sinusoids after several weeks, mate, and migrate to the mesenteric venules (*S. intercalatum, S. japonicum, S. mansoni, S. mekongi*) or rectovesical plexus and branches of the vesical plexus (*S. haematobium*), where the mature worm pairs begin to produce eggs 1 to 3 months after infection. Mature adult females lay eggs daily, of which 60 percent remain in tissues or enter the bloodstream. The remainder of the eggs reach the bowel or bladder and are excreted. Granulomas with epithelioid cells, foreign body giant cells, and many eosinophils characterize the host response to the eggs. Necrosis, fibrosis, and calcification occur late in the disease. Worms do not multiply in the human host.

Geographic Distribution

Schistosoma haematobium is widespread in Africa, western Asia, and possibly a focal area of middle Asia (India). *Schistosoma japonicum* is found in several areas in eastern and Southeast Asia. *Schistosoma mekongi* is localized to a small area in Southeast Asia. *Schistosoma mansoni* is found in more than 50 countries in Africa, tropical South America, the Caribbean, and western Asia (eastern Mediterranean region). *Schistosoma intercalatum* has been found in at least

six central African countries. Figure 236-22 shows the geographic distribution of schistosomiasis due to *S. haematobium, S. japonicum,* and *S. mekongi*. Figure 236-23 shows the geographic distribution of schistosomiasis due to *S. mansoni* and *S. intercalatum*.

FIGURE 236-22 Global distribution of schistosomiasis due to *Schistosoma haematobium, S. japonicum,* and *S. mekongi*. (*Reprinted from* The control of schistosomiasis. *Second report of the WHO Expert 5 Committee*. *Geneva, World Health Organization, 1993 [WHO Technical Report Series No. 830], with permission*.)

FIGURE 236-23 Global distribution of schistosomiasis due to *Schistosoma mansoni* and *S. intercalatum.* (*Reprinted from* The control of schistosomiasis. *Second report of the WHO Expert 5 Committee. Geneva, World Health Organization, 1993 [WHO Technical Report Series No. 830], with permission.*)

Epidemiology

ACQUISITION Schistosomiasis is acquired by coming into contact with water that contains live cercariae (which penetrate intact skin and mucous membranes) and by drinking infested water. An estimated more than 200 million persons in the world are infected, and 500 to 600 million live in endemic areas. Infection can be acquired after a brief exposure in an endemic area (e.g., during travel). Activities associated with risk in endemic areas include swimming, wading, rafting, and bathing in infested water. Pools, ponds, shores of lakes, and small dams pose a greater risk than rapidly flowing streams. Invasive schistosomes are not found in saltwater. Chlorination, iodination, and boiling eliminate infective cercariae.
INCUBATION PERIOD AND TIME FRAME The skin manifestations of infection begin within minutes. Schistosomal fever (Katayama fever), which develops in a minority of those infected, begins 2 to 10 weeks after exposure. Other symptoms may begin after weeks to years. The usual life span of the adult worm within the human is 3 to 10 years, but survival of more than 30 years has been documented.

Clinical Features

Schistosomal infections in humans produce clinical features that range from inapparent to fatal. Most light infections are asymptomatic, and even heavy infections may cause few symptoms. Serious sequelae can develop in a small percentage of those who are infected, however, typically after many years of infection.

There are several different cutaneous manifestations of schistosomiasis. Schistosomal dermatitis occurs shortly after exposure to water infested with cercariae and reflects a hypersensitivity response to the cercariae. An urticarial and erythematous papular eruption associated with pruritus develops in persons who have been previously sensitized. The rash usually resolves over 1 week. In individuals without previous exposure to the parasites, the first exposure results in erythema and pruritus that resolves within hours. A similar rash may appear after exposure to nonhuman schistosomes (sometimes also called schistosomal dermatitis). (See Cercarial Dermatitis.)

Symptoms of acute schistosomiasis, also known as Katayama fever or Katayama syndrome, are most prominent in primary infection in nonimmune persons. The findings are due to a hypersensitivity response to schistosome antigens, as well as circulating immune complexes. Symptoms include fever, myalgias, and headache that may persist for 2 to 10 weeks, sometimes longer. Patients may also have lymphadenopathy, abdominal pain, anorexia, and diarrhea. The skin manifestations include urticaria, purpura, and edema of the face, and, particularly, edema of the extremities, genitals, and trunk. Katayama fever occurs with *S. japonicum* and *S. mansoni,* but rarely with *S. haematobium*.

Late skin involvement, bilharziasis cutanea tarda, occurs in persons with visceral disease. The cutaneous manifestations result from the granulomatous, inflammatory reaction to the deposition of eggs in the dermis (Fig. 236-24). It is evident primarily in persons who live in endemic regions. When lesions are present, they manifest as skin-colored or slightly pigmented, 2- to 4-mm, oval papules that may form clusters. The lesions are firm on palpation and are associated with pruritus. The lesions appear in crops and, without treatment, remain unchanged.

FIGURE 236-24 Ectopic deposition of *Schistosoma mansoni* ova.

The trunk, particularly the periumbilical region, is the most common anatomic location for the lesions of schistosomiasis. A zosteriform distribution has been described. Soft tissue involvement that presented as a breast mass has also been described. Lesions also appear in the genital and buttocks areas, especially on the vulva in women and the scrotum and penis in men. Early in the disease, the lesions in these locations may also manifest as papules or nodules. The presentation late in the disease is that of painless, skin-colored, pink or brown erosive papules and warty, vegetative, polypoid lesions that may be ulcerated and necrotic, with fistulous tracts. Lymphedema and elephantiasis can occur. These lesions may be complicated by secondary bacterial infection and squamous cell carcinoma.

Ectopic egg deposition can involve many tissues, including the central nervous system, ovaries, fallopian tubes, uterus and cervix, eyes, and gallbladder.

The manifestations of infection with *S. mansoni, S. japonicum, S. mekongi,* or *S. intercalatum,* include hepatomegaly, portal and pulmonary hypertension and complications of such due to fibrosis, and intestinal polyps, fistulae, and strictures. Glomerulonephritis occurs in up to 10 percent of patients with hepatosplenic *S. mansoni* infection. With *S. haematobium,* patients have dysuria, hematuria, urinary frequency, chyluria, secondary bacterial urinary tract infection, renal calculi, hydroureter, hydronephrosis, renal failure from obstructive uropathy, and bladder carcinoma. Recurrent bacteremia with *Salmonella* species is a frequent complication of schistosomiasis.

Laboratory Findings

Prominent eosinophilia may be present in early infection.

Diagnosis

Clinicians can diagnose schistosomiasis by identifying viable eggs in the stool (*S. japonicum* and *S. mansoni*), urine (*S. haematobium*), or biopsy of rectal, bladder, or other tissue. Diagnosis may be difficult to establish in early infection (Katayama fever) before the worms are producing large numbers of eggs. The eggs of *S. haematobium* have a terminal spine; those of *S. japonicum,* no spine; and those of *S. mansoni,* a lateral spine (Fig. 236-25). Several serologic tests are available, although they vary in their sensitivity and specificity. Serologic tests also do not indicate the intensity or duration of infection.

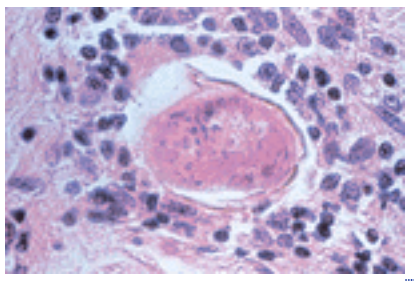

FIGURE 236-25 Skin biopsy of the patient shown in Figure 236-24, revealing *Schistosoma mansoni* ovum. (*Courtesy of Robert F. Cheek, MD.*)

In infection with *S. haematobium,* x-ray films of the pelvis may show linear calcification in the submucosa of the bladder and ureters.

Differential Diagnosis

For acute schistosomiasis, the differential diagnosis includes visceral larva migrans, infection with liver flukes, and the migration phase of strongyloides or other helminths. The differential diagnosis of bilharziasis cutanea tarda of the genital and buttocks area includes atypical syphilis or condyloma latum, condyloma acuminatum, elephantiasis and its causes, amebiasis, other granulomatous diseases, malignancy, and hemorrhoids.

Treatment

Praziquantel is the treatment of choice for *S. haematobium, S. japonicum, S. mansoni,* and *S. mekongi* infections.

Oxamniquine is an alternative treatment for *S. mansoni* infection.

Prevention

Avoiding contact with infested water in endemic areas, as well as snail control in those areas, can help to prevent schistosomiasis. Feces and urine of infected humans should be eliminated in a way that precludes contamination of freshwater.

SPARGANOSIS [56], [57]

Synonyms

Spirometrosis, sparganum infection

Etiology

The tapeworm larvae of the genus *Spirometra,* including *Spirometra mansoni, S. erinaceri,* and *S. mansonoides,* cause sparganosis (Fig. 236-26). At least 10 cases have been caused by *S. proliferum*.

FIGURE 236-26 Soft tissue swelling of sparganosis. (*Courtesy of Jay S. Keystone, MD, FRCPC*.)

Life Cycle

The development of *spirometra* involves definitive hosts (e.g., dogs, cats) and two intermediate hosts, a copepod (a tiny planktonic crustacean) and a vertebrate (e.g., amphibians, reptiles, birds). Humans are incidental hosts for the second-stage larvae, which do not mature in human tissues.

Pathogenesis

When ingested by humans, the larvae migrate widely and usually lodge in subcutaneous tissue or muscle. They provoke an inflammatory response of lymphocytes, plasma cells, neutrophils, and eosinophils. When the larvae die, there is increased inflammation and tissue eosinophilia, as well as tissue necrosis. Usually, only one or a few larvae are present. When infected flesh is applied to the skin, the larva migrate directly into the skin or wound, resulting in a localized acute inflammatory reaction.

Spirometra proliferum develops branched proliferating processes that may detach from the parent larva and develop into separate organisms, thus leading to a massive infection.

Geographic Distribution

The parasite is found in animals on all continents, but most human cases are from China, Japan, and Southeast Asia. Cases have also been reported from Africa, Australia, Caribbean islands, Southern Europe, and the Americas.

Epidemiology

ACQUISITION Sparganosis is acquired by drinking water contaminated with the copepod infected with larvae; by ingesting larvae in the raw or undercooked flesh of frog, snake, poultry, or pork; or by applying flesh that contains larvae to human skin or wound as a poultice.
INCUBATION PERIOD AND TIME FRAME The incubation period depends on the route of acquisition, with the range being 20 days to 14 months for those who eat infected frogs. Symptoms appear much sooner when transmission has taken place via direct larval migration from infected animal flesh into human flesh. The larvae can live in the human for at least 9 years.

Clinical Features

The severity of infection depends on the route of infection, the number of parasites, and the anatomic locations involved.

Sparganosis caused by ingestion of the infective larvae presents as a slow-growing, subcutaneous nodule that is occasionally migratory. The lesion may be pruritic and either tender or nontender. The infection is located in the subcutaneous tissue or skeletal muscle. Other organs affected include the brain, breast, bowel, eye, epididymis, urethra, and lung. Sparganosis due to the use of infected flesh results in localized pruritus, then erythema, edema, and subcutaneous nodules that are painful on palpation. Infection with *S. proliferum* may present as a massive systemic. infection with fever and many subcutaneous nodules.

Laboratory Findings

Peripheral eosinophilia and leukocytosis may be present during tissue migration.

Diagnosis

The definitive diagnosis is made by the identification of the parasite in the surgically excised tissue.

Differential Diagnosis

Included in the differential diagnosis for sparganosis are cysticercosis, visceral larva migrans, cutaneous larva migrans, gnathostomiasis, paragonimiasis, as well as a benign or malignant tumor, lipoma, and epidermal inclusion cyst.

Treatment

The surgical excision of the larvae is a component of treatment. Only palliative measures are available for *S. proliferum*.

Prevention

Steps to prevent sparganosis include boiling or filtering water; avoiding the ingestion of raw or undercooked frog, snake, poultry, or pork; and avoiding the use of raw flesh of such animals for poultices.

STRONGYLOIDIASIS [58], [59], [60] and [61]

Synonyms

Strongyloidosis, strongyloidal ground itch, larva currens

Etiology

Strongyloidiasis results from infection by the nematode (roundworm) *Strongyloides stercoralis*. *Strongyloides fuelleborni,* a common parasite of primates, infects humans in limited geographic areas. Other *Strongyloides* species that do not mature in humans affect the skin only.

Life Cycle

Under appropriate conditions, the parasite can multiply for several generations in the soil. Although animals can be infected with *S. stercoralis,* humans are the main reservoir host for human infection.

Pathogenesis

Filariform larvae penetrate the skin, enter blood vessels, and then travel to the lungs, where they break into alveoli and migrate up the respiratory tree to the pharynx. When they reach the upper gastrointestinal tract, the females embed themselves in the mucosa, mature, and produce partially embryonated eggs that hatch in the mucosal epithelium. The larvae migrate into the intestinal lumen and are either eliminated in the feces or develop into infective larvae that repeat the pulmonary migration, resulting in internal autoinfection. The larvae eliminated in the feces may penetrate the perianal or other skin and reinfect the host, resulting in external autoinfection.

Geographic Distribution

The distribution of *strongyloides* is worldwide, but the parasite is most common in tropical and subtropical areas. *Strongyloides fuelleborni* is endemic in parts of tropical Africa and Asia.

Epidemiology

ACQUISITION Humans acquire strongyloidiasis by the penetration of skin or mucous membranes by the infective larvae, usually from soil. Transmammary infection of *S. fuelleborni* may account for some infections in infants. Transmission also occurs via oral-anal sexual intercourse. Strongyloidiasis is a common infection with rates as high as 80 percent in some populations in tropical areas. High rates of infection are reported in institutionalized mentally impaired persons and in former prisoners of war. The risk of infection is high for persons with frequent soil contact (e.g., being barefoot) in warm, moist areas where human feces frequently contaminate the soil. Long-term glucocorticoid and immunosuppressive therapy, malnutrition, and particularly conditions that compromise cell-mediated immunity [e.g., human T-cell leukemia/lymphoma virus (HTLV-1) infection] predispose to hyperinfection and disseminated strongyloidiasis. Slow intestinal transit and achlorhydria may also contribute to an increased risk.
INCUBATION PERIOD AND TIME FRAME Larvae appear in the stool 2 to 3 weeks after exposure. Skin and pulmonary manifestations can begin within days of exposure. Because autoinfection can occur, infection can persist indefinitely.

Infection may first be recognized years after it was acquired.

Clinical Features

The signs and symptoms of strongyloidiasis occur irregularly with prolonged asymptomatic intervals. Nonspecific gastrointestinal complaints include abdominal pain, nausea, vomiting, diarrhea, constipation, malabsorption, and weight loss. Transient pulmonary infiltrates appear during pulmonary migration. Cough and wheezing may be present during this phase.

The characteristic skin manifestation of chronic strongyloidiasis is larva currens (Latin for tracing larva). The filariform larvae invade the perianal skin and travel within the skin, resulting in an urticarial serpiginous eruption. Larva currens is associated with intense pruritus. This eruption is unique in that it migrates at a rate of up to 5 to 10 cm per hour. Anatomic locations commonly include the buttocks, groin, and trunk. The duration of the eruption is hours to a few days, but it may be recurrent over the course of weeks to years. Persons chronically infected with *strongyloides* may also experience pruritus ani and chronic urticaria, consisting of fixed nonmigratory wheals on the trunk, wrists, and ankles. The secondary skin changes associated with strongyloidiasis include prurigo nodularis and lichen simplex chronicus.

Hyperinfection may cause abdominal pain, nausea, vomiting, diarrhea, and anorexia that are secondary to mucosal edema or ulcers. Malabsorption, ileus, or gastrointestinal bleeding sometimes develops. Pneumonia, adult respiratory distress syndrome, and respiratory failure may develop with disseminated infection. Filariform larvae can penetrate multiple extraintestinal sites, such as the brain, liver, and urinary tract. Bacteremia with bowel flora, carried from the gut by the larvae, and meningitis are frequent complications. The mortality rate is high in disseminated strongyloidiasis given the underlying diseases, impaired immune system, damage from the parasite, and bacterial superinfection.

The dermatologic manifestation of hyperinfection and disseminated strongyloidiasis is a rapidly and progressively diffuse petechial and purpuric eruption caused by massive filariform larvae dissemination to the skin (Fig. 236-27). The eruption typically involves the trunk and proximal extremities. The “thumbprint sign” has been used in disseminated strongyloidiasis to describe a unique pattern of periumbilical purpura that resembles multiple thumbprints.

FIGURE 236-27 Nonpalpable purpura secondary to disseminated strongyloidiasis. (*Reprinted with permission from: Grossman ME, Roth J:* Cutaneous Manifestations of Infection in the Immunocompromised Host. *Baltimore, Williams & Wilkins, 1995*.)

Laboratory Findings

Peripheral eosinophilia is common and may be high grade during larval migration. Eosinophilia may be absent when patients are on glucocorticoids or are severely immunocompromised.

Diagnosis

The identification of larvae in the stool, small bowel contents, and rarely in other body fluids confirms the diagnosis. Multiple stool examinations are often necessary to make the diagnosis. Serologic testing by ELISA has a sensitivity of approximately 90 percent.

Diagnosis of larva currens is made by its characteristic clinical morphology. Skin biopsy of the larva currens eruption typically fails to reveal larvae. Biopsy of the purpuric and petechial eruption of hyperinfection and disseminated strongyloidiasis will reveal larvae (Fig. 236-28).

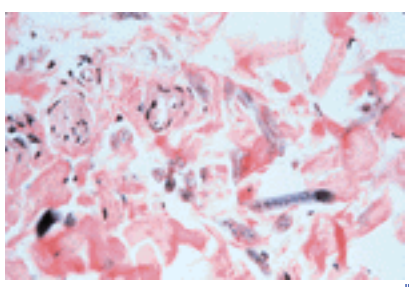

FIGURE 236-28 Skin biopsy of patient shown in Figure 236-27, revealing *Strongyloides stercoralis* larvae. (*Reprinted with permission from: Grossman ME, Roth J:* Cutaneous Manifestations of Infection in the Immunocompromised Host. *Baltimore, Williams & Wilkins, 1995*.)

Persons with a history of prior residence or activities in areas that place them at an increased risk for strongyloidal

infection should undergo screening for unrecognized infection prior to intentional immunosuppression.

Differential Diagnosis

Infection with other intestinal parasites and other causes of eosinophilic pneumonia make up the differential diagnosis. For larva currens, the differential diagnosis is cutaneous larva migrans. For the petechial and purpuric eruption, the differential diagnosis includes sepsis and causes of diffuse bleeding.

Treatment

Ivermectin or thiabendazole may be components of treatment for strongyloidiasis. Repeated courses or prolonged therapy may be necessary for patients who are immunocompromised or who have disseminated infection.

Prevention

Avoiding skin-soil contact in endemic areas can help prevent infection.

TRICHINOSIS [62], [63] and [64]

Synonyms

Trichinellosis, trichiniasis, trichinelliasis

Etiology

The pathogen in trichinosis is *Trichinella spiralis,* a filariform nematode.

Life Cycle

Animals ingest muscle containing infective larvae and become infected. Humans are incidental dead-end hosts.

Pathogenesis

Cysts surrounding larvae are digested in the upper gastrointestinal tract, releasing larvae that attach to villi in the small intestine, where the parasites mature and mate. Over 2 to 4 weeks, each female worm produces 500 to 1500 larvae that penetrate the intestinal wall and enter lymphatics and blood vessels to reach tissues throughout the body. Larvae enter striated muscle cells, where they grow, provoking an inflammatory reaction that is followed by the formation of a fibrous capsule around the larvae and an eosinophilic granulomatous infiltrate.

Geographic Distribution

Trichinosis is present in most countries, but there is marked variation in the incidence. The parasite is thought to be absent from Australia and many South Pacific islands. Sporadic infections occur worldwide via shipped meat.

Epidemiology

ACQUISITION The ingestion of raw or undercooked infected meat is the means by which humans acquire trichinosis. Sources of infection have included flesh from swine, bears, wild boars, cougars, walruses, horses, dogs, and cats. Swine fed uncooked scraps are more likely to be infected. Human infection tends to be sporadic and epidemic. Since 1947, trichinosis has been a reportable condition in the United States. State health departments reported 32 cases during 1994. Laws in the United States prohibit the feeding of offal to swine.
INCUBATION PERIOD AND TIME FRAME The usual incubation period for trichinosis is 10 to 30 days. Gastrointestinal symptoms may begin as early as 1 to 2 days after eating infected meat. Symptoms occur during larval migration, before encystment. The adult parasite is excreted within 2 to 3 months. The encysted larvae may remain viable for 5 to 10 years.

Clinical Features

The severity of trichinosis ranges from asymptomatic to fatal. The case fatality rate is 1 to 2 percent for recognized infections, usually related to complications of central nervous system or cardiac involvement.

Abdominal pain, diarrhea, and vomiting during the first week of infection are followed by fever, fatigue, myalgias, periorbital edema, and a macular and papular (sometimes urticarial) rash on the extremities. Hand swelling and volar surface erythema followed by desquamation have been reported. Subconjunctival and splinter hemorrhages are common (Fig. 236-29) Headache, cough, and shortness of breath may be reported. The central nervous system is involved in 10 to 20 percent of cases of trichinosis, as manifested by meningitis, encephalitis, paresis, and paralysis. Cardiac involvement includes myocarditis that leads to cardiac failure and arrhythmias.

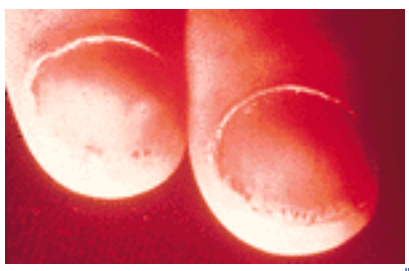

FIGURE 236-29 Subungual hemorrhage secondary to trichinosis. (*Courtesy of Herman Zaiman, MD*.)

Laboratory Findings

A peripheral eosinophilia may be marked and may persist for months.

Diagnosis

The definitive diagnosis comes from the identification of the parasite in surgically excised tissue (e.g., muscle biopsy; Fig. 236-30). Serologic testing with ELISA or indirect immunofluorescence is not useful in early infection. Antibody levels are usually low before the third week of the illness.

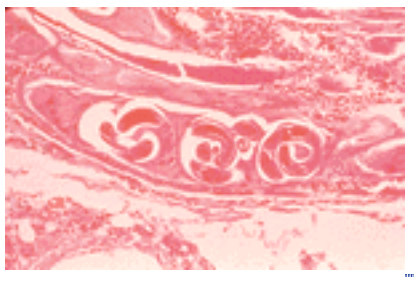

FIGURE 236-30 Muscle biopsy showing *Trichinella spiralis* larvae. (*Courtesy of Murray Wittner, MD, PhD*.)

Differential Diagnosis

The differential diagnosis includes allergic reactions, vasculitis, Katayama fever, visceral larva migrans, and eosinophilia-myalgia syndrome due to ingested tryptophan.

Treatment

Mebendazole is the treatment of choice. Although mebendazole is an approved drug, the FDA considers it an investigational drug for trichinosis. Albendazole and flubendazole (not available in the United States) may also be effective. Patients should receive steroids concomitantly when symptoms are severe.

Prevention

It is important to avoid raw and undercooked meat. Cooking the meat to a temperature of 170°F (77°C) will destroy the trichinae. Smoking and drying meat will not kill the infective larvae. Salt curing solutions may kill the trichinae, but the temperature and duration are important factors in this method.

VISCERAL LARVA MIGRANS[65], [66] and [67]

Synonyms

Toxocariasis, toxocaral visceral larva migrans, ocular toxocariasis, ocular larva migrans

Etiology

Visceral larva migrans is caused by the common dog roundworm, *Toxocara canis,* and much less frequently by the cat roundworm, *T. catis*.

Life Cycle

Dogs acquire *T. canis* infection by ingesting infective eggs or larvae, by transplacental transmission, or by the transmammary passage of larvae in milk. The eggs are passed in the stool and contaminate soil.

Pathogenesis

In humans, ingested embryonated *Toxocara* eggs reach the small intestine and release larvae that penetrate the mucosa and, by way of the portal circulation, reach the liver, lungs, and systemic circulation. When the larvae reach blood vessels that are too narrow to allow passage, the larvae bore through the vessel wall and migrate in tissues. The organs involved include the liver, heart, brain, spinal cord, eyes, and muscle. The larvae provoke hemorrhage, necrosis, and an eosinophilic and granulomatous tissue response. Because the parasite cannot mature in humans, the larvae may remain

dormant or wander in tissues for years.

GEOGRAPHIC DISTRIBUTION Visceral larva migrans is a common infection that is found worldwide. It is most common in tropical and temperate climates where both humans and dogs reside.

Epidemiology

ACQUISITION Humans become infected by ingesting the eggs from contaminated soil on fingers, fruits, vegetables, and other foods. Other reported sources of human infection include ingestion of larvae in raw liver from chickens, cattle, sheep, and other animals. Direct contact with dogs is not necessary. Warm, moist clay soil is the most favorable condition for the eggs, which must embryonate for 1 to 3 weeks before they become infective. Children and persons with a history of pica are at an increased risk. *Toxocara* eggs contaminate the soil in 10 to 30 percent of public playgrounds and parks.
INCUBATION PERIOD AND TIME FRAME The incubation period is typically 1 month or longer with a range of 1 to 2 weeks to years. The larvae may remain viable in the human for 10 years or longer.

Clinical Features

Most infections are asymptomatic or mild. Occasionally, however, infection leads to a prolonged, debilitating illness, loss of an eye, or death. Clinical findings reflect the intensity and chronicity of infection, and the anatomic location of larvae. Signs and symptoms, which may include fever, cough, wheezing, abdominal pain, anorexia, arthralgias, myalgias, fatigue, restlessness, and hepatomegaly, usually resolve over time. In heavy infections, the heart and central nervous system may be affected.

Skin manifestations may include subcutaneous nodules that may be tender, purpura, urticaria, pruritus, and an erythematous and urticarial eruption that evolves into pruritic papules on the abdomen and extremities. The palms and soles may be involved.

Patients with eye involvement, termed ocular larva migrans, usually lack systemic symptoms and have findings restricted to the eye (Fig. 236-31). Eye infection typically occurs unilaterally in children or young adults with the subacute presentation of decreased vision, strabismus, leukocoria, a fixed pupil, or a red eye. Clinically, ocular larva migrans can resemble neuroblastoma.

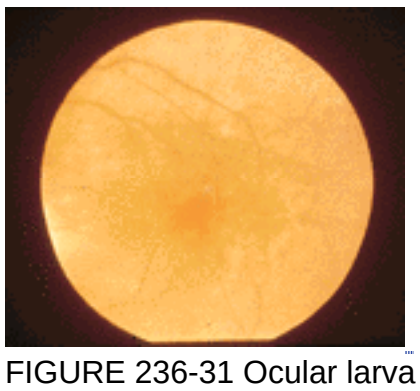

FIGURE 236-31 Ocular larva migrans. (*Courtesy of Murray Wittner, MD, PhD*.)

Laboratory Findings

Common findings are peripheral eosinophilia that may be high grade and persistent, leukocytosis, an elevated serum level of IgG, and elevated liver function test results.

Diagnosis

The identification of larvae in tissue or the combination of serologic evidence of infection and compatible clinical findings is the basis for diagnosis. ELISA testing has a sensitivity of 75 to 90 percent. Eggs and larvae are not found in human feces.

Differential Diagnosis

The differential diagnosis includes trichinellosis, schistosomiasis, strongyloidiasis, ascariasis, ancylostomiasis, fascioliasis, gnathostomiasis, filariasis, paragonimiasis, sparganosis, and infection with the raccoon roundworm, *Baylisascaris procyonis*. Ocular larva migrans may mimic toxoplasmosis, histoplasmosis, diffuse unilateral subacute neuroretinitis, Coats' disease, persistent hyperplastic primary vitreous, and retinoblastoma.

Treatment

Albendazole is the treatment of choice for visceral larva migrans. Alternative therapy is mebendazole. Although the FDA has approved albendazole and mebendazole, these medications are considered investigational in the treatment of visceral larva migrans. For severe symptoms or eye involvement, glucocorticoids can be used in addition to anthelmintic drugs. It is important to treat infected dogs.

Prevention

Avoiding exposure to soil contaminated with animal feces and treating infected dogs are primary preventive measures.

REFERENCES

The Book of Genesis promised humans dominion over the fish of the sea and every living thing that moved on the face of the earth. Unfortunately, it did not guarantee that every encounter between human and beast would be free from harm. The first two sections of this chapter consider the harmful effects of landborne animal bites, as well as the bacterial and viral infections they may transmit. The last section reviews bites and stings and other forms of injury that may be inflicted by marine life.

ANIMAL BITES

An estimated 2 million mammalian bites involving humans occur each year in the United States. [1] Dog bites constitute the largest number of these injuries, accounting for 80 to 90 percent. [1] The human victim is often a 7- to 9-year old boy, who may have been teasing or playing with the dog. Sometimes the bite occurs when a person is trying to break up a pair of fighting dogs, or the victim is the postal delivery person. Most bites are delivered by so-called friendly dogs, known to the victim. [1] Most of these injuries involve the upper extremity, especially the hands; the lower extremities are involved slightly less frequently. [1] Cat bites comprise the second most common type of mammalian bite, but the wounds are nearly twice as likely to develop an infection as wounds from dog bites. [2]

The evaluation and treatment of all bite wounds should include a careful history of the incident, the type of animal, the site of the bite, and the geographic setting. Hand wounds, puncture wounds, and crush injuries are likely to become infected. Infected bites should be cultured and a Gram-stained smear prepared; the wound should then be washed, well irrigated, and left open. Selection of an antibiotic depends on the bite history and Gram's stain results. [3] Most patients with deep cat bites, deep cat scratches, and sutured wounds should be treated with penicillin, amoxicillin-clavulanic acid, cefuroxime, or tetracycline because of the increased incidence of *Pasteurella multocida* infection. [1], [4] Tetanus immune status should be evaluated and rabies immunization considered.

Human bites and monkey bites deserve special mention as 30 percent become infected with aerobic or anaerobic mouth organisms. Anaerobic infection may spread through the metacarpal–phalangeal space and cause severe damage. The same procedure as for other animal bites should be followed; that is, culture and Gram's stain, thorough washing, and debridement. Wounds should be left open if possible, especially hand wounds. Patients with human bites should be treated prophylactically with amoxicillin/clavulanate for 7 to 10 days. Clenched fist injuries should be evaluated by a hand surgeon because of the high likelihood of infectious complications including septic arthritis and osteomyelitis. [1]

Specific Bacterial Infections Caused by Animal Bites

PASTEURELLA MULTOCIDA A common organism infecting bite wounds is *P. multocida.* Disease caused by this organism is now diagnosed more frequently; thus, its presence in the nasopharynx in 50 to 66 percent of dogs and 70 to 90 percent of cats is of public health importance. Most infections in humans fall into one of three clinical patterns:

1. The most common pattern is that of local infection with adenitis after a dog or cat bite or scratch. *P. multocida* is the most common pathogen in cat bite infections and may also complicate 26 percent of dog bite wounds. [2] The infection usually presents within 24 to 48 h, often within several hours. [2] *P. multocida* is the most common organism to be found in patients whose infection presents within the first 24 h. [5] In patients with a cat bite, the infection may be followed by tenosynovitis or osteomyelitis as a result of inoculation of the organism into the periosteum by the long, sharp tooth of the animal. Canine teeth are more blunt and less likely to penetrate the periosteum. *Pasteurella* infections have also been reported after bites of large cats, such as lions and tigers.
2. The second pattern is *chronic pulmonary infection,* in which *P. multocida* may occur as the primary pathogen or in association with other organisms. Bacteria may enter the respiratory tract through the inspiration of contaminated barn dust, or by inhalation of infectious droplets sprayed by the sneeze of an animal. In such cases, the bacteria

probably colonize the respiratory tract and lie dormant in the patient with chronic lung disease. Acute infection occurs only after trauma to the bronchial tree. Bronchiectasis, emphysema, peritonsillar abscess, and sinusitis have all been described with this organism.

3. Finally, systemic infection with bacteremia or meningitis may occur.

P. multocida is a small, gram-negative, ovoid bacillus that grows well on blood agar but does not grow on selective gram-negative media such as MacConkey agar. Because of the superficial resemblance of *P. multocida* to *Haemophilus influenzae* and *Neisseria* organisms, infections of the respiratory tract and central nervous system with this bacillus may be misdiagnosed initially. Failure of growth on routine gram-negative media is an important clue. Treatment of the patient with presumptive *P. multocida* infection (i.e., any patient with a deep cat bite or scratch or a deep dog bite) should consist of careful washing of the wound and an attempt to leave it open. The antibiotic of choice is penicillin, orally for 7 to 10 days, with careful follow-up of the wound. Ampicillin, tetracycline, ciprofloxacin, and trimethoprim-sulfamethoxazole are alternatives. To treat possible pathogens in addition to *P. multocida,* amoxicillin-clavulanic acid is the best empirical choice before culture or Gram-stain results are available.

STAPHYLOCOCCUS INTERMEDIUS *S. intermedius* is an organism associated with dogs weighing more than 40 pounds. It is more commonly found in canine gingival flora than *S. aureus* (39 percent versus 10 percent). [6] It is a gram-positive, coagulase-positive coccus that can be differentiated from *S. aureus* in the laboratory by biochemical testing. In comparison with *S. aureus, S. intermedius* does not produce acetoin from glucose and has ß-galactosidase activity. If these tests are not performed, the laboratory may mistakenly report an isolate as *S. aureus*. Antibiotic treatment is the same as that for infections with *S. aureus,* as approximately 55 percent (slightly less than *S. aureus*) are resistant to penicillin because of production of beta-lactamase.

CAPNOCYTOPHAGA CANIMORSUS *C. canimorsus* is a capnophilic, facultatively anaerobic slow-growing, gram-negative rod associated with dog bites. [7] The organism has been found in the oral cavity of 17 percent of cats and 24 percent of dogs. [8] Most infections occur in the splenectomized or immunocompromised host and present as overwhelming sepsis. Meningitis has been reported in a child. [5]

PORPHYROMONAS SPECIES *Porphyromonas* species are slow-growing anaerobic bacteria that require media enriched with vitamin K and hemin for optimal growth. They are difficult to culture, requiring 4 to 6 days for colony formation, and they have been recognized as a cause of infection in patients with dog and cat bites. [9] These organisms are found in the deep gingival pockets and cause destructive periodontitis in animals and humans. Citron and coworkers [10] found *Porphyromonas* species in 28 percent of culture specimens from patients with infected dog and cat bite wounds.

EDWARDSIELLA TARDA This bacterium is found most frequently in freshwater fish and reptiles, but has been isolated from seals living in salt water, amphibians, mammals, and birds. It is a gram-negative rod that is a member of the family *Enterobacteriaceae* and resembles *Salmonella* in various biochemical attributes. It is an unusual cause of clinical disease in humans. The most commonly identified infection in humans is gastroenteritis, but soft-tissue infection, including cellulitis or abscess, has been reported after bites or scratches from animals, including a pet turtle. [11] Osteomyelitis, intraabdominal and pulmonary infections, meningitis, and septic shock have been reported.

MARINE VIBRIOS *Vibrio carchariae,* a salt water-loving (halophilic) gram-negative bacillus, was reported as the cause of a wound infection after a shark bite. [12]

CAT-SCRATCH DISEASE *Bartonella henselae* is the most common etiologic agent of cat-scratch disease. *Afipia felis* and other *Bartonella* species may cause some cases (see Chap. 198).

PLAGUE (See Chap. 199)

TULAREMIA (See Chap. 199)

RAT-BITE FEVER (See Chap. 199)

Viral Infections Caused by Animal Bites

RABIES The most notorious viral disease caused by an animal bite is rabies. Its epidemiology has changed in the past few years as a result of improved control of rabies in the domestic animal population. Now, nonimmune dogs and domestic animals account for only 10 percent of cases, whereas sylvatic animals, such as skunks, raccoons, red and gray foxes, bats, and domestic dogs, represent the greatest potential danger; rodents, such as squirrels and hamsters, are probably inconsequential as sources of rabies. [13] Postexposure prophylaxis that is nearly 100 percent effective has reduced the number of cases of human rabies from more than 100 per year a century ago to an average of 1 to 3 cases a year in the United States today. Live virus is introduced into nerve tissue at the time of the bite. The virus multiplies at the site and then spreads to the central nervous system. It replicates in gray matter and then spreads along autonomic nerves to the salivary glands, adrenal glands, and heart. The incubation period varies with the site of the bite—from 5 days to as long as several years. Clinical features include a prodromal period of 1 to 4 days, followed by high fever, headache, and malaise. Paresthesia at the site of inoculation occurs in 80 percent of patients. The next sequence of events is familiar: agitation, hyperesthesia, dysphagia, excessive thirst, paralysis, and death.

Diagnosis The diagnosis of clinical rabies is difficult and is often not made until after death of the patient. Viral isolation may be positive in specimens of saliva or cerebral spinal fluid during the first 2 weeks of the illness. Serum antibodies may be detected as early as day 6 and usually by day 13. The fluorescent antibody method for detection of the viral antigen is the most rapid and sensitive means of making the diagnosis, and can be used on a biopsy of skin from the highly innervated hair-covered area of the neck or brain tissue.

Prevention and treatment The most effective prevention for rabies is to avoid contact with any wild animal or any unfamiliar domestic animal. Persons at risk of unavoidable contact with rabies, such as spelunkers, veterinarians, virologists, and travelers spending time in countries where rabies is enzootic, should receive preexposure prophylaxis. For people who cannot avoid exposure, a human diploid cell vaccine series (three intramuscular injections, days 0, 7, and 21 or 28) should be given in the deltoid muscle [13] and repeated every 2 years. In persons vaccinated intradermally, the neutralizing antibody titer should be followed to assess immunity. A case of rabies occurred in a Peace Corps volunteer who had been immunized by the intradermal route. Immunity may or may not be as fully protective in persons vaccinated intradermally as it is in patients who are vaccinated intramuscularly. [14] The need for postexposure prophylaxis can be determined by the answers to these questions: What is the status of animal rabies in the locale where the exposure took place? Was the attack provoked or unprovoked? Of what species and size was the animal? What was the state of health and vaccination record of the animal? Will the brain of the animal be examined within 48 h? Most animals transmit rabies virus in saliva only a few days before becoming ill themselves (dog and skunk, 5 days; fox, 3 days; cat, 1

day; bats, however, may harbor the virus for many months).

Bites by household pets If the dog or cat is healthy and available for observation for 10 days, do not treat the patient unless the animal develops rabies. At the first sign of rabies in the animal, treat the patient with rabies immune globulin (RIG) and human diploid cell rabies vaccine (HDRV). The symptomatic animal should be killed and tested as soon as possible. If the animal is rabid, or suspected of being rabid, or if it does not have up-to-date vaccination records, treat the patient with RIG and HDRV. [13] In certain states, ferrets may be kept as pets. These animals should be vaccinated against rabies, as they are large enough to survive a bite by a rabid animal and become infected.

Bites by wild animals All skunks, bats, groundhogs, foxes, coyotes, raccoons, bobcats, and other carnivores should be regarded as rabid unless laboratory tests prove negative. Treat the patient with RIG and HDRV.

Bites by other animals Consider other animals (livestock, rodents, lagomorphs, e.g., rabbits, hares) individually. [13] Local and state public health officials should be consulted about the need for prophylaxis. Bites by squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, and other small rodents almost never call for antirabies prophylaxis.

Specifics of treatment The most important step is to cleanse the wound immediately with a brush and soap so as to remove as much virus as possible. Rinse well, and then perform a second scrub with green soap or alcohol, which is rabicidal. If vaccine treatment is indicated, both RIG and HDRV should be given as soon as possible, regardless of the interval after exposure, unless the patient has been previously vaccinated and a serologic assay shows current immunity. In this case, only HDRV is needed and should be given on day 0 and day 3. [13] The administration of RIG is the more urgent procedure. If HDRV is not immediately available, start RIG and give HDRV as soon as it is obtained. RIG (20 IU/kg) should be given to the patient immediately—50 percent around the site of the bite and 50 percent in the thigh or the arm. This passive immunization will result in the early appearance of antibody but will also inhibit development of the active antibody from the human diploid vaccine—thus, the reason for prolonged dosage of the vaccines. Active immunization is accomplished with the human diploid cell vaccine. HDRV is given intramuscularly for a total of five doses. The doses are given on days 0, 3, 7, 14, and 28. Serum for rabies antibody testing should be collected 2 weeks after the fifth dose. If there is no antibody response, an additional booster should be given.

Management of the patient with clinical rabies When the rare patient is admitted with the clinical diagnosis of rabies, several steps should be taken immediately. First, the diagnosis must be made rapidly by fluorescent antibody staining of various tissues, as well as mouse inoculation with the source animal's brain tissue. Elevated antibody titers in the absence of immunization are clear evidence of infection. The first signs of clinical rabies are usually nonspecific, such as malaise, anorexia, fatigue, headache, and fever. The acute neurologic illness that follows is most commonly characterized by intermittent episodes of hyperactivity. In some cases, however, a progressive paralysis is most common. The usual period from onset of symptoms to onset of coma is 10 days. Risk of exposure for hospital staff includes contamination of open wounds or mucous membranes with saliva or other potentially infectious material such as neurologic tissue, spinal fluid, or urine. Blood, serum, and stool are not considered infectious. [15] The basic clinical management consists of anticipating and preventing all treatable complications of the rabies infection. Pulmonary hypoxia should be prevented by tracheostomy at the first sign of respiratory difficulty, monitoring of actual PO_2, and use of supplemental oxygen. There are no specific antiviral treatments for rabies. Anticonvulsant therapy should also be instituted. Extreme increases in intracranial pressure may be prevented by insertion of a cerebrospinal fluid reservoir connected to the lateral ventricle, allowing withdrawal of the intraventricular fluid and measurement of intracranial pressure. Cardiac arrhythmias may be anticipated with careful monitoring. Rabies has been regarded as uniformly fatal. There have now been several patients who have survived with prolonged cardiorespiratory support, and there is serologic evidence that some animals have survived. An aggressive approach to the patient with known rabies infection is certainly worthwhile.

LYMPHOCYTIC CHORIOMENINGITIS Lymphocytic choriomeningitis (LCM) virus is an infectious agent common to the house mouse but rarely transmitted to humans. The mode of transmission is unknown. [16] Recently, outbreaks of LCM virus infection in the United States and Germany have been traced to pet hamsters. Hamsters, like mice, may excrete LCM virus for several months and may become lifelong carriers. When humans are infected, there may be three major manifestations: a grippe-like illness, meningitis, or encephalitis. The cerebrospinal fluid usually reveals an increased mononuclear leukocyte count and hypoglycorrhachia. Symptomatic therapy is all that is available.

HERPESVIRUS SIMIAE (B VIRUS) Herpesvirus simiae (B virus) is enzootic in old world monkeys, especially rhesus, cynomolgus, and other macaques. The illness in monkeys is similar to that caused by herpes simplex in humans, and asymptomatic monkeys may shed the virus in saliva. Most cases in humans have occurred after direct exposure to macaque monkeys or monkey tissue through bites, scratches, or cuts. [17] A vesicular lesion develops at the wound site with progressive lymphadenitis and fever. Over the next few days to weeks patients develop a severe illness, which is characterized by rapidly progressive ascending neuropathy and encephalitis. [17] The illness is rare, with only 22 well-documented cases described from 1937 to 1990. Of cases diagnosed before 1987, 72 percent were fatal. A cluster of four cases occurring in 1987 in Pensacola, Florida, were treated with acyclovir. The two patients who received acyclovir when their infections were localized responded well to therapy and have been maintained on oral prophylaxis. The diagnosis can be made by viral culture, serology, or the presence of intranuclear inclusions in lymph nodes. All macaques should be presumed to be shedding B virus and should be handled accordingly. All monkey-inflicted injuries should be cleansed, specimens should be collected for viral culture, and the patient should be evaluated by a physician. Clinical and serologic monitoring is critical, and high-risk or infected patients should be treated according to established guidelines. [17] The use of acyclovir or ganciclovir initially and acyclovir for years has led to improved survival in infected patients.

SNAKE BITES

In the United States, there are approximately six deaths from snake bites and several thousand snake bite envenomations each year. [18] The largest number of venomous snake bites occur in the southwestern and Gulf states. Arizona, Florida, Georgia, and Alabama are the states with the highest incidence of snake bites. Worldwide as many as 30,000 fatal snake bites may occur each year. Because of regional differences in varieties of snakes, management recommendations differ geographically.

The two major poisonous snakes in the Americas are the pit viper (family Viperidae, subfamily Crotalinae, which includes the rattlesnake, water moccasin, and copperhead) and the coral snake (family Elapidae). Two poisonous snakes are native to New England. The northern copperhead, also called the highland moccasin, is pink or reddish brown and is

marked with large chestnut-brown barrels resembling dumbbells or hourglasses (Fig. 237-1). The bite is painful but rarely fatal. The timber rattler is dark brown with chevrons of black and brown (Fig. 237-2).

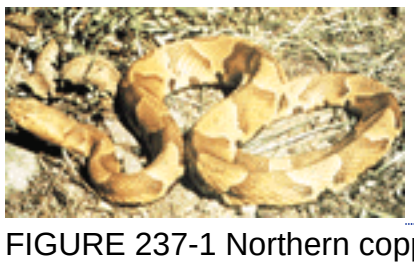

FIGURE 237-1 Northern copperhead.

FIGURE 237-2 Timber rattlesnake.

The degree of toxicity of a snake bite depends on the potency of the venom, the amount injected, the size and condition of the snake, and the size of the person bitten. [19] There are immediate local clinical manifestations of a pit viper bite. Pain occurs at the site of the bite (usually within 5 min). Signs and symptoms of the bite site include wheal with local edema, numbness, and, within moments, ecchymosis and painful lymphadenopathy (Fig. 237-3). Nausea, vomiting, sweating, fever, drowsiness, and slurred speech may develop. Bleeding of the gums and hematemesis are common hemorrhagic manifestations. If edema and erythema have not developed within 8 h after the bite, it can be assumed that significant envenomation did not occur. Recent mortality rate estimates for victims who receive antivenom in a health care facility are less than 1 percent, and probably less than 0.1 percent. [18]

FIGURE 237-3 Copperhead snake bite.

For proper treatment, it is extremely important to establish that the bite is from a poisonous snake. The patient should have distinct fang punctures and immediate local pain, followed by edema and discoloration within 30 min. It is helpful to inspect the snake, because those that are poisonous may be differentiated from those that are not by the presence of fangs and the shape of the pupils (Fig. 237-4). A photograph of snakes common to a specific geographic area is important for all hospital emergency wards to aid practitioners in deciding if the patient has been bitten by a poisonous snake.

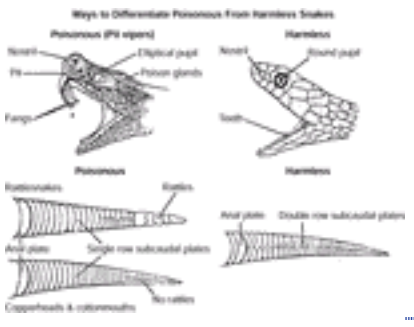

FIGURE 237-4 Identification of poisonous and nonpoisonous snakes. (*From Wingert WA, Wainschel W: A quick handbook on snake bites. Resident & Staff Physician, p 56, 1977. Reprinted with permission.*)

Although there are still insufficient evidence-based data for first aid and out-of-hospital treatment for snake bite envenomations, a rational approach based on currently available information includes these recommendations [20]:

1. The patient should be stabilized and transported as rapidly as possible to a health care facility capable of administering antivenom. [20]
2. The affected site should be immobilized and kept in a position at or slightly below the level of the heart, and the patient should be kept at strict bedrest. [20]
3. The use of venous compression bands or pressure immobilization (PIM) remains controversial. These techniques

(which should not be confused with arterial tourniquets) are designed to impede the return of venous and lymphatic flow from the bite site without sacrificing blood flow to the extremity. The potential advantage of employing these maneuvers is to forestall the systemic spread of the venom when transport to a medical facility will be measured in hours rather than minutes. In cases where there is likely to be a significant delay in transport, and the victim is developing systemic signs of envenomation such as hypotension, these techniques may be of value. [20] Arguments against using these techniques include the time that it takes to apply the treatments, which may further delay transport time. Additional arguments against the use of these techniques include the potential for concentrating the venom in the affected limb, which may worsen local necrosis, along with the possibility of a bolus effect when the compression is released. [20] Another possible disadvantage of these compression techniques is the potential for them to become arterial compression tourniquets as the affected limb swells in reaction to the toxin. If a decision is made to use a venous compression band or PIM in the field, arterial pulses should be palpable distal to the ligature, and the dressing should be checked frequently to be sure that it is has not become too tight. If a venous compression dressing has been applied in the field and is not causing vascular compromise, it should be left in place until the patient reaches a health care facility and antivenom is at the bedside. [20]

4. The value of suction devices to extract venom from the bite site remains uncertain. A mechanical suction device called the Sawyer Extractor vacuum pump can be used without incision of the bite site. If such a device is applied in the field and fluid is accumulating in the suction cup, it can be left in place until the patient reaches a medical facility. [20]
5. The use of cryotherapy, incision or excision of the bite site, arterial tourniquets, and electroshock therapy as part of emergency field therapy should be discouraged.

The role of surgical intervention in the treatment of snake bite envenomations is limited in most cases. Debridement of truly necrotic skin and subcutaneous tissues is recommended 4 to 5 days after envenomation. [21] In cases of bites to a digit, if there is severe swelling and the finger is tense, blue, or pale, a digit dermotomy may be of use. [21] This technique involves making a longitudinal excision through the skin on the medial or lateral side of the digit under local anesthesia. The purpose of this procedure is to avoid the complications of a compartment syndrome affecting the involved finger. True compartment syndrome involving an extremity is a rare complication of snake bite envenomation. Fasciotomy should be used only in cases of compartment syndrome that have been properly documented with increased compartment pressures that have not responded to prompt and sufficient treatment with antivenom. [21]

The primary treatment for crotaline snake venom poisoning is prompt and adequate dosing with antivenom. Antivenom is most effective if given within 4 h of the snake bite. Emergency information and antivenom are available in the United States through a nationwide poison control center network, which can be reached 24 h a day by calling 1-800-222-1222.

A polyvalent antiserum derived from horse serum, Antivenin (Crotalidae) Polyvalent (ACP), has been used since 1954 to treat bites of North American and South American crotaline snakes. ACP is still available from Wyeth-Ayerst (Philadelphia, PA), but a new antivenom derived from sheep serum is now available. This antivenom, Crotalidae Polyvalent Immune Fab (Ovine), trade name CroFab, is manufactured by Protherics Inc. (Nashville, TN) and is distributed by Savage Laboratories (Melville, NY). The potential advantages of the new antivenom are decreased immunogenicity and increased potency relative to that of ACP. [18] CroFab is less likely to cause acute or delayed allergic reactions because most of the more immunogenic Fc portion of the antibody is removed during the manufacturing process. Unlike ACP, which requires bedside testing with an intradermal injection to rule out hypersensitivity to horse serum, CroFab does not require pretesting. [19], [22]

Polyvalent pit viper antivenin should be used for all severe American crotaline snake bites except those of the coral snake. The dosage should be guided by the severity and progression of local changes and systemic clinical signs. [22]

The dosage of ACP antivenin for a moderate rattlesnake bite is 4 to 7 vials (10 mL); severe cases may require 15 to 20 vials. A water moccasin bite requires 1 to 4 vials. For copperhead bites, antivenin usually is necessary only if the patient is a child or is elderly. The vials should be diluted in 500 mL of normal saline and given intravenously over 30 min.

The initial recommended dose of CroFab is 4 to 6 vials. If symptoms are not controlled with the first dose, additional doses of 4 to 6 vials should be administered repeatedly until symptoms of envenomation are under control. Once the envenomation syndrome is controlled, additional 2-vial doses should be infused at 6, 12, and 18 h. [18]

Supportive treatment is important, that is, hospitalization, and careful evaluation of baseline hematocrit, platelet count, and prothrombin time. The wound should be cleansed and covered. Antitetanus therapy and antibiotic prophylaxis with penicillin, 2 g/day, or tetracycline, 2 g/day, should be initiated for severe bites.

AQUATIC BITES AND STINGS

Seal Bite

Normally, a seal bite occurs on the finger of a trainer or a seal hunter—thus the term seal finger or Spaek finger. [23] The etiologic agent is unclear; *Mycoplasma phocidae* was isolated in one case. The incubation period of 4 to 8 days is followed by throbbing pain, erythema at the site, and swelling of the joint proximal to the bite. Untreated, Spaek finger progresses to cellulitis, tenosynovitis, and arthritis. The treatment before antibiotics were available was amputation of the affected finger to relieve the severe pain and deformity. Tetracycline, 500 mg orally four times a day for 10 days, is now the antibiotic of choice. It is also helpful to immobilize and elevate the finger as well as soak it several times a day.

Injuries Caused by Jellyfish, Portuguese Man-of-War, Sea Anemones, and Corals

Stings caused by jellyfish, Portuguese man-of-war, sea anemones, and corals are the most common envenomations

encountered by humans in marine environments. All of these creatures are members of the phylum Cnidaria, formerly known as Coelenterata. They are divided into three major classes. The first class, Hydrozoa, includes the Portuguese man-of-war, fire corals, and hydroids. Jellyfish belong to the second class, Scyphozoa. The third class, Anthozoa, encompasses sea anemones and true corals. Approximately 100 of the 9000 species of Cnidaria that have been identified may cause injury to humans. [24]

Cnidarians are radially symmetric animals with body walls formed by an inner and outer layer of cells enclosing a jelly-like substance. [25] They may be either free floating in the water like jellyfish, or sessile like corals. [24] Almost all cnidarians possess nematocysts, or stinging capsules, which are usually concentrated on some form of tentacle. Each nematocyst contains a toxin or group of toxins and a coiled threadlike apparatus with a barbed end that functions like a flexible hypodermic syringe (Fig. 237-5). When the nematocyst comes into contact with a victim, the barbed end is discharged and the toxin is injected into the skin.

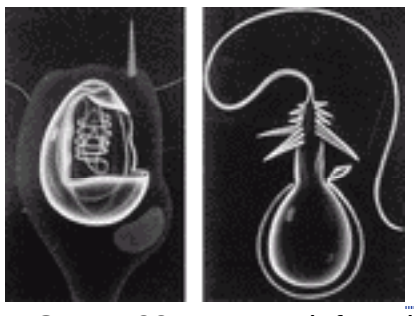

FIGURE 237-5 From left to right, a diagrammatic view of an intact and discharged coelenterate nematocyst. (*R Kreuzinger, courtesy of World Life Research Institute.*)

Cnidarian stings range from mild, self-limited irritations to extremely painful and serious injuries, depending on the toxin of the species involved and the magnitude of the envenomation. Stings from certain species such as the cubomedusae, or box jellyfish, can be fatal.

In most cases, jellyfish stings elicit toxic rather than allergic types of reactions. These toxic reactions may be localized and/or systemic in nature and are discussed below. Although they occur less frequently, immediate-type hypersensitivity reactions, including urticaria, angioedema, and anaphylaxis, require prompt medical intervention because shock and death may ensue in highly sensitized individuals. Allergic contact dermatitis, delayed and persistent hypersensitivity reactions, [26] granuloma annulare, [27] and erythema nodosum [28] are several of the possible cutaneous reactions to jellyfish stings. Table 237-1 summarizes reactions to jellyfish stings.

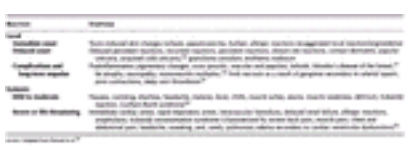

TABLE 237-1 **Local and Systemic Reactions to Jellyfish Stings**

INJURIES CAUSED BY JELLYFISH

Sea nettles Among the most common causes of jellyfish stings are the sea nettles, which comprise two different species, both of which inhabit Atlantic as well as Indo-Pacific waters. *Cyanea capillata,* and its relatives, is the larger of the two species, with a bell measuring up to 1 m and numerous tentacles reaching 30 m in length [29] (Fig. 237-6). *Chrysaora quinquecirrha* is smaller, with a white or rusty bell that may reach 30 cm with four digestive tentacles hanging from it. [29]

FIGURE 237-6 *Cyanea capillata,* also known as the sea nettle or lion's mane, is a common cause of jellyfish stings. (*BW Halstead, courtesy of World Life Research Institute.*)

Although sea nettle stings are seldom lethal, they can be quite painful. [36] Initially the victim experiences a sharp burning pain in the area contacted by the tentacles. Within minutes, the sting area develops a zig-zag shaped, whiplike pattern of raised red welts 2 to 3 mm wide (Fig. 237-7). The duration of acute pain may vary, but it often begins to subside in 30 min. The wheals usually subside by 1 h, but purplish-brown petechial and postinflammatory pigmentation may persist for several days in the sites of tentacle contact.

FIGURE 237-7 Whiplike sting pattern caused by *Cyanea capillata* in a young boy. (*JH Barnes, courtesy of World Life Research Institute.*)

Portuguese man-of-war *Physalia physalis* is the species name for the Portuguese man-of-war, which is a member of the class Hydrozoa and is therefore not a true jellyfish. *P. physalis* is encountered in both Atlantic and Mediterranean waters, and is easily recognized by its translucent blue to pink or purple, bladder-like float with multiple tentacles suspended from it (Fig. 237-8). Both the floating bell and the tentacles are composed of large colonies of hydroids. *P. physalis* is distinguished from its Pacific ocean relative *P. utriculus,* commonly known as the blue bottle, in that *P. physalis* has a larger bell ranging in size from 10 to 30 cm with multiple fishing tentacles extending up to 30 m, whereas *P. utriculus* has only a single tentacle that rarely exceeds 5 m. [29] These tentacles are armed along their entire length with hundreds of thousands of nematocysts arranged in stinging batteries, with each battery containing hundreds of nematocysts. The nematocysts remain active even after portions of the tentacles are broken off in storms or when these animals are stranded on the shoreline by high winds or waves. Beached Portuguese man-of-war can cause a severe sting when stepped on or touched. Children who are stung after handling these animals cry and rub their eyes and may develop an acute conjunctivitis.

FIGURE 237-8 *Physalia physalis,* the Portuguese man-of-war, is distinguished by its bladder-like float and numerous trailing tentacles. (*BW Halstead, courtesy of World Life Research Institute.*)

Stings from *P. physalis* are more painful and severe than those caused by sea nettles and are more extensive and serious than those caused by *P. utriculus.* At the moment of contact with the tentacles of *P. physalis,* the victim experiences a sharp, shocklike, burning pain. There may be painful paresthesias or numbness in the sting area. Initially, the sting area appears as an irregular single line or multiple lines composed of red papules, beaded streaks, or erythematous welts that correspond to the areas of tentacle contact. The wheals resolve in several hours but may progress to vesicular, hemorrhagic, necrotic, or ulcerative stages before healing [25] (Fig. 237-9). Postinflammatory striae may persist for weeks to months. Permanent scarring may occur in some instances. [31] Severe localized complications of *P. physalis* stings may also include arterial spasm in the sting site that can result in distal digital gangrene of the affected limb. [37]

FIGURE 237-9 This diver surfaced directly under a large Portuguese man-of-war and suffered a severe sting with bulla formation and tissue necrosis. (*S Anderson, courtesy of World Life Research Institute.*)

Within 10 to 15 min of a *Physalia* sting, the victim may develop symptoms of an envenomation reaction characterized by nausea, abdominal cramps, muscular pains, backache, irritability, dyspnea, and chest tightness. Intravascular hemolysis and acute renal failure have been reported in a 4-year-old girl after a severe sting by *P. physalis*. [38] Until recently, reports of deaths as a result of stings from *P. physalis* were not well documented; however, in 1989, there were two separate well-substantiated case reports of human fatalities caused by *P. physalis* envenomation. [39], [40]

Cubomedusae (box jellyfish or sea wasps) Of all the species of jellyfish that cause painful stings and distress to swimmers, the species with the most established record of lethality is the box jellyfish, *Chironex fleckeri.* [41] Since 1884, it has been responsible for at least 63 confirmed deaths in tropical Australian waters. [42] At least one death occurs each year in Australia. [41] The fatality is usually a child, presumably because the size of the victim and the total area of the sting determine the likelihood of death. Until recently, most of the published cases involving *C. fleckeri* stings reported fatal or near fatal stingings. [43] Of 40 patients presenting with jellyfish stings to an emergency department in a hospital in coastal tropical Australia over a 1 year period, 28 were typical of *C. fleckeri* envenomation. [43] None of the stings in this series were serious enough to require antivenom, or were life-threatening. [43] *C. fleckeri* nematocysts were confirmed microscopically by the tape-stripping technique in 23 of the 28 cases thought to be caused by *C. fleckeri*. [43] *C. fleckeri* (commonly known as the sea wasp) is an advanced species of jellyfish, with a semitransparent cubic bell that may grow to a volume of 9 L and weigh more than 6 kg [41] (Fig. 237-10). Trailing from the bell are up to 60 stinging tentacles, which may reach 2 to 3 m in length. [41] When a human comes into contact with a box jellyfish, some of the tentacles are torn off and adhere to the skin. Rescuers of *C. fleckeri* sting victims must exercise extreme caution, as they also are at risk of envenomation until the tentacles have been neutralized and removed.

FIGURE 237-10 The deadly box jellyfish, *Chironex fleckeri,* is found in Indo-Pacific waters off the coast of Northern Australia. (*Courtesy of R Hartwick.*)

The stings appear initially as linear welts that give the patient the appearance of having been whipped. [41] Fresh stings of *C. fleckeri* are easily recognized because they display a diagnostic frosted cross-hatched or ladder-like appearance (Fig. 237-11). Microscopic diagnosis is also possible from blade scrapings or tape strippings from the sting site. [44] Conscious victims who suffer sublethal stings describe the pain as instantaneous and excruciating. The pain may persist for many hours. Severely stung areas of skin take on a dusky cyanotic appearance and may go on to blister formation and necrosis. The healing process is slow and may be complicated by bacterial superinfection. Scarring is often permanent.

FIGURE 237-11 Characteristic frosted cross-hatched tentacle marks diagnostic of a sting caused by *Chironex fleckeri*. (*Courtesy of Townsville General Hospital, Department of Medical Illustration, Townsville, Queensland*, Australia.)

Death may ensue within minutes if >6 m of tentacles have made contact with the victim. Pharmacologic analysis of the venom of *C. fleckeri* has resulted in the isolation of dermatonecrotic, hemolytic, and lethal fractions. [45] The lethal fractions contain cardiotoxic and neurotoxic agents. [45], [46] Intravascular hemolysis caused by hemolytic fractions in the toxin can precipitate acute renal failure. The potent cardiotoxins can produce ventricular arrhythmias and cardiac arrest, and the neurotoxins lead to respiratory failure. First aid for these victims frequently requires cardiopulmonary resuscitation. Intravenous verapamil has been proposed for both treatment and prophylaxis of ventricular arrhythmias in sting victims. [47] Antivenin is available for *C. fleckeri* stings, and its early use in severe envenomations may be lifesaving. In addition to blocking or reversing the systemic effects of the toxins, the antivenin also significantly reduces the pain and inflammation at the sting site. [41], [48]

PREVENTION AND TREATMENT OF JELLYFISH STINGS

Prevention [47]

1. Swim only at patrolled beaches with properly trained lifeguards and adequate treatment facilities.
2. Avoid swimming in infested waters, especially after a storm, as stings may result from remnants of floating damaged tentacles.
3. Beware of apparently dead or beached jellyfish.
4. Wear protective clothing when snorkeling or scuba diving, such as wet suits, long-sleeved shirts, pants or long

woolen underwear, and gloves.
5. Close bathing beaches during periods of high jellyfish infestation.

Treatment

First Aid Treatment [24], [25], [29], [39], [49], [50]

1. Remove or rescue the victim from the water.
2. Stabilize vital functions: airway, breathing, circulation.
3. Immobilize the affected part to prevent further envenomation by adherent tentacles.
4. Identify the type of jellyfish sting by considering locale, time of year, and indigenous species and by observing the sting pattern. Preserve a portion of the tentacle for future identification. Tape strip or scrape the sting site for microscopic analysis of the nematocysts if no tentacles are available.
5. To prevent further envenomation of the victim and to reduce the chance of a sting to the rescuer, disarm the nematocysts before removing the adherent tentacles.
   a. If *C. fleckeri* or other box jellyfish species are suspected, douse or spray dilute acetic acid (3 to 10%) or household vinegar over all areas of tentacle contact for at least 30 s. [51]
   b. For sea nettles, mix sodium bicarbonate (baking soda) with water to form a slurry and pour over the affected area or apply the powder directly to the tentacles. [49]
   c. For *P. physalis* stings a slurry of baking soda is indicated. Vinegar had been reported to neutralize nematocysts of *P. physalis,* but work with species from Australia indicate that it may cause a discharge of nematocysts in some cases. [49], [51]
   d. If vinegar or baking soda is unavailable, papain, available as a powdered meat tenderizer, may be applied directly as a powder or mixed in water as a slurry to sting areas and tentacles of both sea nettles and Portuguese man-of-war. [24]
   e. If nothing else is available, the tentacles can be rinsed off with seawater.
   f. Do not use fresh water, methylated spirits, or alcohol in any form to deactivate tentacles as these all may cause a rapid massive discharge of nematocysts. [24]
6. After the tentacles have been disarmed, they may be carefully removed with a forceps or gently scraped away from the skin with a plastic card, shell, or knife. [50]

Treatment of Systemic Reactions

1. Support vital functions with cardiopulmonary resuscitation, oxygen, and intravenous fluids as required. [48]
2. Treat symptoms of anaphylaxis or shock with systemic epinephrine, glucocorticoids, and antihistamines. [28]
3. A venous-lymphatic constriction bandage applied proximally to the wounded site should be considered in the case of severe stings when systemic reactions are present or likely to occur, when topical deactivation of tentacles is not possible, and when transport to an acute care facility will be delayed. [28], [50]
4. Specific antivenin is available for *C. fleckeri* stings. It is prepared by Commonwealth Serum Laboratories, Parkville, Victoria, Australia. [28] The antivenin is prepared from sheep serum and may therefore pose a risk of allergic reaction in sensitive individuals. [28] The preferred route of administration is intravenous, but it may be given intramuscularly. In severe stingings, it has proved lifesaving. It is also the only treatment that can alleviate the intense pain (often within minutes of administration). It may also reduce the cutaneous inflammation at the sting site and decrease the chance of scarring.
5. Intravenous verapamil has been advocated for both treatment and prophylaxis of arrhythmias. [47]
6. For pain in severe stingings, consider parenteral narcotic analgesics, ice packs, and antivenin in cases involving *C. fleckeri.*

Treatment of Local Reactions

1. Apply topical anesthetic ointments, creams, lotions, or sprays to relieve itching or burning pain. (Benzocaine preparations should be avoided because of the risk of contact dermatitis.) [24]
2. Cleanse ulcerated or open wounds three times daily, apply a nonsensitizing antiseptic or antibiotic cream or ointment, and cover as needed with a light dressing.
3. Treat secondary infections with the appropriate parenteral antibiotics.
4. For delayed-type hypersensitivity reactions, use topical glucocorticoids, antihistamines, and systemic glucocorticoids if necessary. [29]
5. Antitetanus therapy should be considered, if indicated.
6. Ice or cold packs can relieve the pain of mild to moderate stings from many types of jellyfish.
7. Aspirin or acetaminophen, alone or in combination with codeine, can be used to relieve persistent pain. [44]

SEA ANEMONE DERMATITIS Sea anemones are members of the phylum Cnidaria, class Anthozoa. They are sessile creatures with graceful flowery tentacles armed with nematocysts (Fig. 237-12). Although stings caused by sea anemones are not as common as those caused by fire corals and jellyfish, they are a frequent cause of dermatitis in sponge fishermen, sponge divers, and beachcombers who gather snails and crabs from rocky hollows along the shore. Their toxicity to humans depends on the species. As with jellyfish stings, the acute symptoms of pain and burning from sea anemone envenomation are a result of the effects of toxins injected by nematocysts. After the immediate reaction has subsided, it is possible to see delayed-type hypersensitivity reactions develop in the sting site from sea anemones (Fig. 237-13).

FIGURE 237-12 The flowery tentacles of the sea anemone can cause envenomations similar to jellyfish stings. (*Courtesy of Marty Gilman, Worcester, MA.*)

FIGURE 237-13 Delayed-type hypersensitivity reaction to a presumed sea anemone sting. This 11-year-old girl stepped into a hole while wading in shallow waters on the South Carolina coast. She experienced an immediate burning pain with erythema and swelling of both lower legs that subsided within a day. Several days later she developed a pruritic linear eruption. A diagnosis was made of a delayed-type hypersensitivity reaction that developed in the sting site and corresponded with the tentacle marks from what was presumed to be a sea anemone envenomation.

The genus *Sagartia* is the cause of “sponge fisherman's disease.” [24] This anemone lives at the base of sponges sought by commercial fishermen. When they harvest or sort the sponges with their bare hands or forearms, they are likely to come into contact with the tentacles of *Sagartia.* Itching and burning occur at the sting site within minutes of the exposure and are accompanied by erythema, edema, and vesicles. [24] Other species of sea anemones with especially venomous stings include *Actinodendron, Anemonia sulcata,* and *Triactis producta.* Severe stings may progress to vesiculation, ulceration, necrosis, and, occasionally, abscess formation. Systemic symptoms may follow the exposure and can include headache, nausea, vomiting, fever, chills, muscle spasms, abdominal pain, malaise, thirst, and prostration. [24] The only known death caused by anemone sting resulted from fulminant hepatic failure in an individual stung by a *Condylactis* species found in the Caribbean Sea. [52] One case of acute renal failure (a result of acute tubular necrosis) was reported to occur after a probable exposure to a sea anemone. [53] Treatment of sea anemone stings is similar to that of jellyfish envenomations (see above). [54] The tentacles, if still adherent, should be removed carefully with a gloved hand and the sting area rinsed with seawater. [24] Both vinegar and Stingose (an aqueous solution of 20% aluminum sulfate and 11% surfactant) have been suggested for neutralizing the sting sites of anemones. [54] Sea anemone sting sites often heal slowly and may require treatment with antibiotics.

INJURIES CAUSED BY FIRE CORAL AND CORAL CUTS Corals are colonial organisms belonging to the phylum Cnidaria. They form calcified structures of various sizes and shapes by cementing together their limestone exoskeletons or polyps. True corals are members of the class Anthozoa. Fire corals are members of the class Hydrozoa and are not true corals, although they are similar in many ways. Coral injuries may be divided into two major types: superficial injuries caused by nematocyst stings and lacerations. Both injuries may occur at the same time. Coral injuries may be complicated by foreign-body reactions, bacterial infections, and localized eczematous reactions. Nematocyst envenomation in most true corals is a relatively innocuous experience, resulting in mild pruritic erythema that requires little if any treatment. Calamine lotion or antipruritic lotions may bring relief. [55] In contrast to true corals, the sting from the fire coral, *Millepora alcicornis,* is quite painful, as many scuba divers and snorkelers from the Florida Keys to the Caribbean will attest (Fig. 237-14). The wet mucous membrane surrounding the organism contains numerous nematocysts that readily discharge on contact with the skin, causing immediate burning and stinging pain. Within 1 to several hours a pruritic erythematous papular eruption appears, which in severe cases may become pustular, and in rare cases, may progress to necrosis and eschar formation. [56] Lesions heal in 1 to 2 weeks, often with postinflammatory hyperpigmentation. A delayed and persistent allergic contact dermatitis has also been reported to occur from a fire coral sting from the Red Sea. [57]

FIGURE 237-14 The mustard-colored finger-like outcropping in the upper left quadrant of this formation of coral and hydroids is a typical example of fire coral.

The sting may be prevented by wearing protective clothing. Fire coral stings should be rinsed with seawater to remove

undischarged nematocysts. The sting area can then be compressed with either 5% acetic acid (vinegar) or 40 to 70% isopropyl alcohol for 15 to 30 min or until the pain is relieved. [36] Seawater compresses, hot to the point of tolerance, are also reported to inactivate the toxin. A topical steroid cream or ointment may relieve pruritus and promote healing. Lacerations from the razor-sharp exoskeletons of coral are known collectively as coral cuts. Beach walkers, waders, fishermen, swimmers, surfers, and scuba and skin divers are at risk for these injuries. Coral cuts can be prevented by avoiding dangerous shorelines and by wearing protective clothing such as reef boots, gloves, long pants made of a thick cut-resistant material, or a wet suit. Coral cuts are notorious for their slow healing and propensity for secondary infection. Factors that complicate healing include the following:

1. Wounds often involve the lower extremities and these generally heal more slowly because of decreased tissue blood supply.
2. Wound edges are often irregular, contused, crushed, and abraded.
3. Contamination of wounds is likely because of pathogenic bacteria in shore waters.
4. Foreign bodies, including marine algae growing on the coral or portions of the coral itself, may be implanted in the wound.
5. Victims of coral cuts are often actively engaged in water sports and may not comply with optimal wound care.

Treatment of coral cuts should begin with vigorous cleansing of the wound with soap and water with a soft brush or rough towel, followed by copious irrigation with saline to remove foreign bodies. If the wound is extensive, local anesthesia may be required in order to adequately cleanse, explore, debride, and achieve good hemostasis. Hydrogen peroxide washing of the wound before dressing it is recommended. The decision to close a coral cut wound primarily or to allow it to heal by secondary intention depends on the location of the wound, the degree of tissue trauma at the wound margins, and the likelihood of subsequent infection. Facial and scalp wounds can often be converted to surgically clean wounds by debridement and closed primarily. Trunk and arm wounds may be closed primarily, but require more surgical judgment. Lower extremity wounds in most cases heal slowly by secondary intention. Tape stripping is preferable to suturing of leg wounds because sutured leg wounds have a high chance of abscess formation. Once the wound has been closed, an antibiotic ointment covered with a nonstick dressing, with an outer dressing applying light pressure for 24 to 48 h, is advisable. Rest and elevation promote healing. Because coral cuts are tetanus prone, the patient may require tetanus prophylaxis, depending on immunization history. Failure to remove foreign debris after a coral injury may result in foreign-body reactions. Localized episodes of dermatitis have been reported after contact with coral (Fig. 237-15). The lesions may appear within several hours as erythematous papules; these coalesce to form plaques, which may become vesicular. Biopsy of these lesions reveals a superficial and mid-dermal perivascular infiltrate of lymphocytes, eosinophils, and plasma cells resembling an arthropod bite reaction. In some patients, these eruptions have been recurrent. Topical glucocorticoids may be helpful in treating these eczematous reactions.

FIGURE 237-15 A contact dermatitis-like eruption resembling poison ivy on the unprotected leg of a scuba diver 24 to 48 h after contact with an unknown type of coral. The eruption persisted for several weeks and cleared after treatment with topical steroid creams.

Dermatitis from Sponges

Sponges are members of the phylum Porifera, class Desmospongiae. They are simple multicellular animals that live attached to the sea bottom. Sponges grow by forming a series of hollow-centered branching tubes composed of a fibrous material called spongin, which contains spicules of calcium carbonate or silica. [24], [58] Spicules from certain species of sponges are capable of penetrating the skin, causing a localized irritant or foreign-body reaction. Treatment of sponge spicule dermatitis involves tape stripping of the affected area.

At least 13 species of sponges can cause a toxic dermatitis. [59] Of these, the most commonly encountered are the West Indian and Hawaiian fire sponge, *Tedania ignis;* the poison bun sponge, *Fibula nolitangere* (Fig. 237-16); and the red sponge, *Microciona prolifera,* found in the northeastern United States. [59] These creatures are covered by a surface liquid, or slime, that produces an irritant or toxin-induced dermatitis when contacted by bare skin. [58]

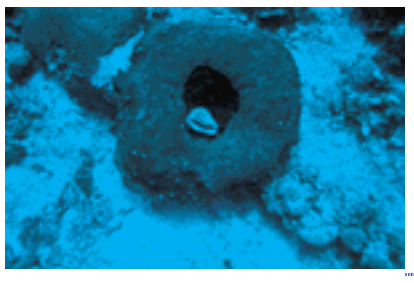

FIGURE 237-16 The poison bun sponge, *Fibula nolitangere,* can cause a severe irritant or toxin-induced contact dermatitis.

Symptoms of itching, prickling, stinging, or burning appear within minutes of exposure and are followed within a few hours by pain, swelling, and stiffness. [24], [58], [59] If the fingers are involved, they often become immovable within 24 h. [43] The first cutaneous sign of sponge poisoning is local erythema, which progresses to a papular, vesicular, or bullous eruption with weeping of a serous or purulent fluid. [58], [59] Desquamation of the site occurs within several days. Erythema multiforme and anaphylactoid reactions have been reported in highly sensitized individuals.

Treatment of sponge dermatitis is similar to that of severe poison ivy. The acute dermatitis can be treated with cool dilute vinegar soaks [30 mL of vinegar per liter of water (2 tbsp/qt water)] several times a day. [59] Soothing lotions, topical glucocorticoids, and antihistamines may relieve symptoms, which usually begin to subside in several days. Systemic glucocorticoids may be indicated for severe reactions.

Injuries Caused By Echinoderms: Sea Urchins, Starfish, and Sea Cucumbers

SEA URCHINS Sea urchins are spiny creatures that belong to the phylum Echinodermata, class Echinoidea. They are encased in a fragile, roughly spherical, calcareous shell, which is protected by a formidable array of mobile spines and pincer-like organs known as *pedicellariae* [60] (Fig. 237-17).

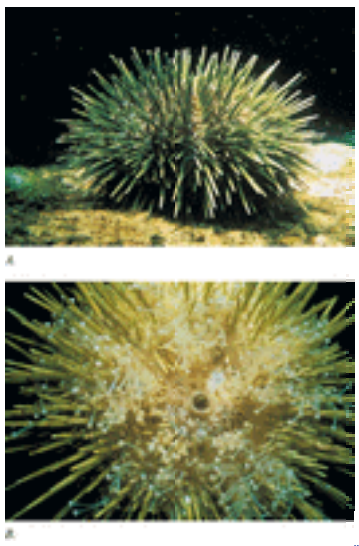

FIGURE 237-17 Lateral (*A)* and ventral (*B)* views of a sea urchin demonstrate this animal's protective spines and venomous pedicellaria underneath. (*Courtesy of Marty Gilman, Worcester, MA.*)

Bathers, surfers, divers, and fishermen are all at risk for sea urchin injuries. These may occur when the victim steps on an urchin, driving the spines into an unprotected foot, or as a result of loss of balance or wave action, in which case the hands or other body parts may be impaled. Sea urchin spines are composed of calcium carbonate and are covered with a proteinaceous membrane. [61] Injuries from sea urchins may be inflicted either by penetrating wounds from the animal's spines, which often break off and become imbedded in the wound, or by bites from the pedicellaria. In certain species, the spines or pedicellaria are venomous. This fact may explain why the pain of some sea urchin wounds is so excruciating and out of proportion to the apparent injury. Encounters with sea urchins can result in both immediate and delayed reactions. Immediate reactions are usually localized and are initially manifested by a severe burning pain in the wound site, which quickly becomes red and swollen and may bleed profusely. [59] There may be a black or purple discoloration at the site of the spine penetration due to either retained spines in the wound or to a tattoo-like effect from dye released by the spines that have exited intact. Paresthesias may develop in the wound area. Systemic symptoms are not common but can occur in injuries due to particularly venomous species. Symptoms may include nausea, syncope, paresthesias, ataxia, muscle cramps, paralysis, and respiratory distress. [59] Delayed reactions to sea urchin wounds may be nodular or diffuse; they result from a foreign-body reaction to the retained spine fragments. Delayed-type hypersensitivity reactions may occur with erythema and intense pruritus days after the initial injury. [62] In one of these cases, the diagnosis was confirmed by patch testing with extracts of the ground sea urchin spines. [63] Nodular reactions are localized to the area of spine penetration and are not usually painful. They consist of small firm nodules, which may be flesh colored, pink, or cyanotic, or may take on colors from the dye in the spines. [24], [64] Nodules may have a central umbilication or a keratotic surface [64] (Fig. 237-18).

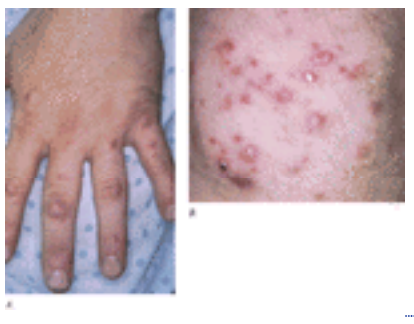

FIGURE 237-18 *A* and *B.* Nodular reactions to imbedded sea urchin spines. (*Courtesy of Karen Rothman, MD.*)

The diffuse form more commonly involves the fingers or toes and is manifested by a fusiform swelling of the affected digit with accompanying pain and loss of function. [59], [60] Two cases of sea urchin granuloma involving the nail apparatus and resulting in permanent nail deformity have been reported. [65] In addition to joint synovitis and arthritis, additional osteoarticular complications of sea urchin spine penetration may include tenosynovitis with or without destruction of the underlying bone, fasciitis, and bursitis. [61], [66] Sea urchin spine wounds may also cause direct mechanical injuries to nerves and may be complicated by secondary infection. [59] Histopathologically, a granulomatous inflammatory reaction is the most common presentation, with foreign body and sarcoidal types the most frequent patterns observed in 50 biopsy specimens in one study. [60], [67] Other histologic patterns less commonly seen in the study included tuberculoid, necrobiotic, and suppurative granulomas as well as nonspecific chronic inflammation or suppurative dermatitis. [67] Because a few of the specimens showed changes suggestive of mycobacterial infection, the same investigators reevaluated the 50 biopsy specimens with the polymerase chain reaction technique and found *M. marinum*-specific restriction patterns in three of the samples. [68] Initial first aid for the pain from immediate reactions calls for soaking the affected area in hot water [43°C to 46°C (110°F to 115°F)] for 30 to 90 min until maximal relief is obtained. [50], [59] Infiltration of the wound site with 1 to 2% lidocaine without epinephrine may be required in some cases to produce significant pain relief. [50] Spines protruding from the wound may be carefully removed. They are very fragile, however, and it is difficult to extract the entire spine intact. Tumescence of the skin with local anesthetic may allow superficially imbedded spines to be extracted when radiographs demonstrate no evidence of joint or bony impingement. [69] More invasive attempts at spine removal should not be performed without the benefit of aseptic surgical facilities and radiographs to confirm the spine locations. Removal of the spines may be aided by the use of an operating microscope. [59] There are anecdotal reports of pounding the wound site with a stone for the purpose of breaking up the spines into smaller fragments, which are more easily absorbed. This practice has been criticized. [59] The application of ammonia compresses or freshly voided urine has also been recommended, but again these remedies are anecdotal and their value has not been proved. [60] Antibiotics are indicated for secondary infections, and tetanus prophylaxis should be given if indicated. Most sea urchin wounds resolve without complications; however, those involving the digits, joint spaces, or nerves require surgical intervention. Delayed nodular reactions may resolve slowly with time. Topical and intralesional glucocorticoids may be efficacious for nodular reactions, and systemic glucocorticoids have been recommended for diffuse reactions, but their benefit has not been clearly substantiated. [24], [59], [70] Symptomatic nodular or diffuse reactions may not resolve until the spines and granulomatous tissue have been surgically removed.

STARFISH Certain species of starfish may produce puncture wound injuries similar to those caused by sea urchins. The crown-of-thorns starfish, *Acanthaster planci,* accounts for most severe starfish envenomations. [59] The ice pick-like spines of *A. planci,* which may reach 4 to 6 cm in length, are covered with a thin skin and glandular tissue that produce a poisonous slime. [50], [70] The resulting wound is quite painful and may be accompanied by numbness and paresthesias. [59] Systemic symptoms including nausea, vomiting, and muscle weakness are infrequent and short lived. [59] Fragments of spines and their surrounding integument may become imbedded in the wounded area, resulting in granulomatous reactions. Treatment is similar to that of sea urchin wounds. Initial first aid should include soaking the affected area in hot water for 30 to 90 min until there is maximal pain relief. [50] In addition to causing spinous injuries, some species of starfish may secrete a toxic substance directly into the water. When these starfish are present in large numbers, there may be sufficient amounts of this toxin to produce a pruritic papulourticarial eruption. [24], [59]

SEA CUCUMBER DERMATITIS Sea cucumbers are sausage-shaped bottom-feeding echinoderms that can produce a papular contact dermatitis by means of a toxic liquid substance, known as holothurin, which is secreted from their body walls. [24] Conjunctivitis, even blindness, can result from corneal involvement if the toxin comes in contact with the eyes. [59] These animals have also been reported to ingest intact nematocysts from marine coelenterates, which they may later secrete for defensive purposes. Prevention of sea cucumber dermatitis involves protecting the skin and eyes from contact with these creatures and educating children and curious divers about the risk of handling them. Treatment consists of washing the affected area with soap and water to remove the toxin and then treating as for a mild contact dermatitis.

Dermatitis and Bites from Marine Worms

BRISTLEWORM DERMATITIS Bristleworms are multisegmented marine worms of the phylum Annelida, class Polychaeta (which means “many bristles”) (Fig. 237-19). Each segment of the worm is armed with rows of silky or bristle-like, hollow, venom-filled setae that can easily penetrate and break off in the unprotected skin of a victim in a fashion similar to cactus spines. [70] Contact with the bristleworm results in an erythematous papular or urticarial eruption at the site, accompanied by symptoms of paresthesias, intense itching, or burning pain. [24], [70] The bristles are too small and fragile in most cases to be removed with a forceps; however, tape stripping with cellophane adhesive tape can be effective. [24] After the setae have been removed, the application of ammonia soaks or alcohol or water compresses may bring symptomatic relief. [24]

FIGURE 237-19 *Hermodice carunculata,* the West Indian bristleworm, can inflict a painful wound with its hollow, venom-filled bristle-like setae. (*Courtesy of Marty Gilman, Worcester, MA.*)

LEECHES Leeches are another class of segmental worms whose bites may be encountered in fresh or salt water as well as on land. They are members of the phylum Annelida, class Hirudinea. Leeches have specialized biting jaws that allow them to attach to their host in order to feed on a meal of blood. Although freshwater leeches are capable of attaching painlessly to their human host, salt water leeches produce bites with pain similar to that of a bee sting. [24] Leeches inject a

powerful anticoagulant, hirudin, into the wound, as well as other antigenic substances that are capable of eliciting allergic reactions (including anaphylaxis) in sensitized individuals. [24] Local symptoms of leech bites include bleeding from the puncture marks, pain, swelling, redness, and severe pruritus; urticarial, bullous, or necrotic reactions may occur in sensitized persons. [24] Severe ulcerations may result if the leech is removed forcibly and its mouth parts are left behind in the bite site. Leeches must be induced to fall off by applying a noxious agent (such as alcohol, vinegar, brine, or a match flame) to their site of attachment. [24] After the leech has been removed, the wound should be carefully cleansed and minor bleeding controlled by the application of a styptic pencil. [24] Secondary infections may be prevented by cleansing the bite site for several days with antiseptic solutions containing alcohol or boric acid. [24]

CERCARIAL DERMATITIS (CLAM DIGGER'S ITCH) Cercarial dermatitis, also known as schistosome dermatitis or swimmer's or clam digger's itch, is an acute pruritic eruption resulting from the penetration of the skin by the cercarial forms of certain parasitic flatworms of the family Schistosomatidae. Symptoms of cercarial dermatitis begin with urticarial-like lesions and a prickling sensation of the skin, which lasts about half an hour after exposure to cercarial-infested waters. Severe pruritus of the affected area occurs 10 to 12 h later. Within 24 h, erythematous papules appear that may progress to vesicles and later to pustules. Pain and swelling of the area accompanies the intense itching, which usually peaks in 48 to 72 h. Headache, fever, and superinfection with lymphangitis are occasionally present. In the Great Lakes region, several species of schistosome cercariae that cause swimmer's itch have been reported, and many other species have been discovered throughout the world in both fresh and salt water. [71] The economic impact on regions with recreational lakes in which the parasites are known to occur can be substantial. A severely disabling form of cercarial dermatitis affects the paddy workers and rice farmers of the Far East. Cercarial dermatitis has also been described in shallow coastal waters, notably on Long Island Sound where the condition affects clam diggers, giving rise to the name, “clam digger's itch” (Fig. 237-20). There is one reported case of cercarial dermatitis occurring on the hands and arms of a patient after he cleaned the aquarium in which he kept native watersnails. [72]

FIGURE 237-20 Intensely pruritic papulovesicles suggestive of a severe reaction to flea bites in a patient with clam digger's itch. The left hand, which was not in the water and was holding the pail for collecting the clams, was spared.

Humans are accidental hosts in the life cycle of dermatitis-producing schistosomes. The cycle begins when the primary host, a waterfowl, marsh bird, finch, muskrat, mouse, or deer, passes schistosomal eggs in its feces into a body of water. Each egg hatches in 10 to 15 min, releasing a secondary stage miracidium. The miracidia are free-swimming and must locate and infect their definitive snail host within 12 h or they will die. The miracidia migrate to the snail's digestive gland, where they develop into multiple sporocysts. In about 5 weeks the sporocysts give rise to hundreds of fork-tailed cercariae that measure 0.75 mm in length. The cercariae are released from the snail under favorable conditions of light and heat, and are carried toward the shore by prevailing winds and currents. [71] When an appropriate host is encountered, the cercaria attach to the skin with their oral suckers and penetrate the epidermis and dermis by means of histolytic enzymes. They lose their tails in this process and are now called schistosomula. The schistosomula migrate via the blood vessels through the heart and lungs to the intrahepatic veins, where they mature into adult male and female trematode flukes. When the worms mate, they pass in pairs through the mesenteric venules of the intestinal wall where the female lays hundreds of eggs. [71] The eggs then penetrate the gut wall and are discharged in the feces, and the cycle is repeated. When cercariae that do not cause schistosomiasis in humans accidentally attach to the skin, they may penetrate the epidermis but are unable to reach the bloodstream. The organisms die in the superficial papillary dermis and undergo total histolysis within 3 to 4 days. The cercarial protein residua stimulate a delayed-type hypersensitivity response, which may increase in severity with repeated exposures. Skin biopsies taken at 3 to 4 days reveal an amorphous eosinophilic mass at the site of the dissolved cercaria, with an intense lymphocytic infiltrate. Later, histiocytes appear in the middle and deep papillary dermis. The differential diagnosis of cercarial dermatitis includes insect bites from chiggers, mosquitoes, and fleas; contact dermatitis from poison ivy, and the stings of other marine coelenterates. In Africa, Asia, South America, and Puerto Rico, swimmer's itch must be distinguished from the dermatitis associated with human schistosomiasis, which produces an eruption with very similar but milder and more transient symptoms. [71], [73] Swimmer's itch must also be distinguished from sea bather's eruption, which is discussed in the next section. Prevention of cercarial dermatitis in waters where swimmer's itch is known to be a problem is difficult. Avoidance of all aquatic activity is not a reasonable solution, and most swimmers or workers are not willing to apply a protective coat of petrolatum before exposure. Some investigators have advocated a brisk rubdown with a towel immediately after bathing in the belief that the cercaria can be wiped off before they can penetrate the skin, but other investigators have shown that both this and alcohol rubdowns are of little benefit. Various chemical repellents have been tried, including copper sulfate and bathing with hexachlorophene soap before exposure, but the effectiveness of these methods remains unproved. Clothing barriers may be of some help, as cercarial dermatitis occurs more commonly on uncovered skin. Another preventive alternative involves the elimination of the molluscan host by a variety of means. The waters can be treated with various molluscicides, copper sulfate, or niclosamide. Drainage of lakes or ponds with the removal of aquatic vegetation can deprive the snails of shelter and nourishment. [71] In smaller ponds, hand removal of the snails from the banks of the water may be helpful. The most radical efforts reported involve draining the affected ponds and destroying the snails with flame throwers. Many of these methods are too expensive or dangerous to the environment to be practical.

Treatment of cercarial dermatitis is largely symptomatic. In mild cases, antipruritic or drying lotions, oatmeal or starch baths, and antihistamines may alleviate pruritus. Aspirin may be helpful for the pain and swelling, and a bedtime sedative may be required to allow the patient much-needed sleep. Proper washing and hygiene should be maintained to prevent bacterial superinfection. In severe cases, potent topical glucocorticoids and occasionally systemic glucocorticoids may be required.

Seabather's Eruption

Seabather's eruption (SE), also known as marine dermatitis, and more commonly as “sea lice,” is an acute dermatitis that begins shortly after bathing in seawater. Seabather's eruption is often confused with swimmer's itch (cercarial dermatitis), not only because they both occur after exposure to water, but also because the common names of these two conditions are easily confused. For many years, the cause of SE remained a mystery, but it is now known that the responsible agents in at least two types of the SE are the larval forms of marine coelenterates. In waters off the coast of Florida and in the Caribbean, the tiny larvae of the thimble jellyfish, *Linuche unquiculata,* are to blame. [74] Off the coast of Long Island, NY, researchers found that the larval forms of the sea anemone *Edwardsiella lineata* were responsible for the eruption. [75]

In addition to a different etiology, SE can be distinguished from cercarial dermatitis by several other factors (Table 237-2). Seabather's eruption primarily involves areas of the body covered by bathing suits where water evaporates slowly, as opposed to the uncovered areas typical of swimmer's itch. Most symptoms are not noted until the bather has left the water (although some of those affected have complained of a prickling sensation while still in the water.)

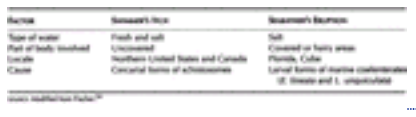

TABLE 237-2 **Comparison of Swimmer's Itch and Seabather's Eruption**

The eruption is caused by minute stings from the nematocysts of the coelenterate larvae that become trapped underneath swimwear or may adhere to hairy areas of the body. In addition to the larvae, which are most abundant in May and June, swimmers and bathers may also develop SE after contact with the other two free-swimming stages of *L. unguiculata,* the ephyrae and medusae stages. [76] Ephyrae are released in late January through March from scyphistoma, which are the sessile stage of the thimble jellyfish. The medusae stage is the adult form of the thimble jellyfish and is present in affected waters from early April until mid May. [76] Seabather's eruption is believed to be caused by an allergic reaction to these nematocyst stings. Factors that may cause the nematocysts to fire include mechanical pressure from a bathing suit or swim cap, or from lying on a surfboard or sitting on a car seat in a wet bathing suit; and changes in osmotic pressure as the bathing suit dries out or when the bather rinses off with fresh water while wearing swimwear.

The lesions begin within 4 to 24 h after exposure as erythematous macules, papules, or wheals that may itch or burn (Fig. 237-21). [24] These lesions may progress to vesiculopapules, which crust over and heal in 7 to 10 days. [24] Associated systemic symptoms may include chills and a low-grade fever as well as nausea, vomiting, diarrhea, headache, weakness, muscle spasms, and malaise. Febrile and systemic symptoms are more common in children and adolescents. [77] In the presence of such constitutional symptoms, caregivers who fail to recognize the pattern of the eruption or who fail to take a history of exposure to salt water may mistakenly make the diagnosis of a viral syndrome.

FIGURE 237-21 Seabather's eruption in a young girl after a swim at a Florida beach. (*Courtesy of Karen Rothman, MD.*)

In waters along the coast of south Florida, the season for SE is between March and August with a peak in May. The incidence among bathers during May and June 1993 in Palm Beach County was reported to be 16 percent. [77] The strongest risk factor for developing SE is a previous history of the condition, which is consistent with the theory that SE represents a hypersensitivity response to the nematocyst stings. [77] Other risk factors include age younger than 16 years and surfing. [77] Showering with swimwear removed was found to be a protective measure. [77]

Prevention of SE includes the following measures:

1. Bathers should remove their swimwear and shower as soon as possible after leaving the water. Because fresh water may cause discharge of the nematocysts, it is important that the suits be removed before showering begins. Showering with salt water may be preferable, but impractical. Bathing suits should be rinsed with soap and water and heat dried, as the eruption can recur when the suit is air dried. Persons who have had a severe case of SE may want to consider discarding the suit worn at the time of the exposure.

2. T-shirts should not be worn in the water. Women may consider wearing a two-piece suit to reduce the surface area under which larvae may be trapped. Swimming without a bathing suit may be advantageous (assuming it is permitted and proper care is taken to prevent sunburning); but because the larvae easily attach to hair-bearing areas, showering after a swim in infested waters is still required.
3. Whole-body Lycra swimsuits or wetsuits with snug-fitting collars and cuffs may be protective, but the eruption may still occur along the collar or cuff edges.
4. Highly sensitized individuals should avoid swimming in waters during outbreaks of SE.

Treatment of SE is symptomatic with antipruritic lotions, colloidal baths with starch or oatmeal, antihistamines, and topical glucocorticoids. Severe unremitting cases may warrant systemic glucocorticoids. [74] Secondary bacterial infections may complicate the condition and should be diagnosed and treated appropriately.

Injuries Caused By Mollusks

CONE SHELL ENVENOMATIONS Cone shells are univalvular gastropods whose ornate cone-shaped shells are highly prized by shell collectors and divers. A number of species have a highly developed venom apparatus that can inflict a lethal sting. Most of the dangerous cone shell species are found in shallow waters of the Indo-Pacific. Cone shells are carnivorous. They live on the ocean bottom and, depending on the species, may hunt worms, other mollusks, or fish. Cone shells kill their prey by means of a spearlike venomous radular tooth that is thrust out from the animal's proboscis. Cone shell venom contains several different kinds of neurotoxins, and death may result from respiratory paralysis. There is as yet no antivenin for cone shell envenomations, and mortality rates for the more dangerous species (*Conus geographicus* and *C. magus*) may be as high as 15 to 20 percent. [24] Injuries from cone shells are of the puncture wound variety. The degree of pain is variable, ranging from a mild stinging sensation, similar to that of an insect bite, to severe excruciating pain. Early symptoms may include edema, ischemia, numbness, and paresthesias of the wound site. Paresthesias may become widespread, with the lips and mouth commonly affected. [24], [59] Localized muscular paralysis may progress to generalized weakness or paralysis with eventual respiratory distress and cardiopulmonary failure. Neurotoxic symptoms that indicate severe envenomations include diplopia, blurred vision, aphonia, dysphagia, and coma. [24], [59] Rare cases of disseminated intravascular coagulation have been reported after cone shell envenomation. Great care must be exercised in handling live cone shells. Thick protective gloves should be worn, and the soft underportion of the animal should be avoided. Cone shells should never be placed in pockets of clothing or swimwear as they have been known to sting through clothing. [50] Treatment of cone shell envenomations is supportive. The victim should be kept at rest, and the sting area kept dependent and immobilized. A compression dressing should be applied to occlude lymphatic-venous, but not arterial, flow. [50] Local suction may be helpful if it can be applied immediately to the wound site with a plunger device, such as the Extractor (Sawyer Products, Safety Harbor, Florida). No incision of the wound is required with this device. Compresses or immersion of the sting area in hot water may be indicated in those cases where it is not practical to apply a lymphatic-venous compression dressing or to relieve pain in milder stings. [24], [50], [59] Advanced life support measures, including artificial ventilation, may be required while victims are being transported to a hospital, where they may require mechanical ventilatory support. [50]

OCTOPUS BITES Octopuses are an advanced class of mollusks belonging to the class Cephalopoda. The octopus bites with a parrot-like chitinous beak located on the ventral side of the head in the middle of its eight tentacles (Fig. 237-22). Species of octopi range in size from a few centimeters to 1 to 2 m in diameter. [78] They are shy and reclusive creatures that tend to avoid encounters with humans; however, bites can occur when curious divers, fishermen, or beachgoers encounter these animals and handle them carelessly. Most octopus bites are not life-threatening to humans. The bite site may be immediately painful, like a bee sting, and is recognized by the presence of two small puncture wounds, which may bleed profusely. [24] Symptoms from octopus bites are usually mild and transient and consist of redness, swelling, and itching. [79] One case of granuloma annulare has been reported to have developed around the site of an octopus bite [79] (Fig. 237-23). Paresthesias and numbness may develop at the site if the species is venomous. In more severe envenomations, these symptoms may be followed by more generalized neurologic symptoms similar to those occurring in cone shell stingings.

FIGURE 237-22 Ventral view of the underside of an octopus exposing the animal's centrally located mouth and parrot-like beak. (*From DD Fulghum,* [79] *with permission.*)

FIGURE 237-23 Granuloma annulare on the back of the hand of a commercial fisherman several days after being bitten by a small octopus at the same site. (*From DD Fulgham,* [79] *with permission.*)

The most dangerous species of octopus, the Australian blue-ringed octopus, *Hapalochlaena maculosa,* is found in Australian coastal waters. Mortality rates due to bites caused by *H. maculosa* may be as high as 25 percent. *H. maculosa* produces a toxin in its salivary glands, which is introduced into the bite site by the animal's powerful beak. The toxin contains a fraction identical to tetrodotoxin, which blocks peripheral nerve conduction, resulting in paralysis of the victim with subsequent respiratory failure. The bite of the blue-ringed octopus may or may not be painful, so that victims may not realize that they have been bitten until neurologic symptoms develop. [59] There is no antivenin for bites from *H. maculosa.* Treatment is supportive and similar to that recommended above for severe cone shell envenomations. Immersion of the wound in hot water does not seem to be beneficial. [59] The use of the pressure–immobilization technique with a lymphatic–venous occlusive pressure dressing or the immediate application of suction to the wound site with a suction device may be of value. [50] Excision of the bite site down to fascia has been recommended by some authors, but its value is unproven. [24], [59]

Injuries Caused by Venomous Fish Spines

Ichthyoacanthotoxicosis is the proper term for envenomations as a result of puncture wounds or lacerations inflicted by the spines of venomous fish. There are more than 200 species of venomous fish in the world that can cause injury to humans. [59] The most notorious of these species includes the stingrays, catfish, lionfish, scorpionfish, stonefish, weeverfish, toadfish, and spiny dogfish. All of these fish have in common a venom apparatus consisting of a single spine or multiple spines, in various locations, which are covered by an integumentary sheath enclosing various forms of venom glands. When the spine of the animal penetrates the victim, the sheath is torn and the venom glands release their toxins into the wound. The toxins from some of these fish may remain potent for 24 to 48 h after the death of the fish. [80]

STINGRAYS Stingrays represent one of the most common causes of venomous fish stings confronting humans, with as many as 1500 to 2000 stingray attacks reported each year in the United States alone. [70], [81] Rays are grouped into one of four categories; gymnurid (butterfly rays), urolophid (round stingrays), myliobatid (bat or eagle rays), and dasyatid (proper stingrays). The groupings are based on their relative stinging ability, which depends on the size, number, and location of the caudal stinging appendages. The most dangerous group, the dasyatid or true stingrays, have the largest spines located further out on their tails, making theirs the most potent striking weapons. The spines have retroserrated teeth, which makes removal difficult (Fig. 237-24).

FIGURE 237-24 A close-up view of a stingray stinger devoid of its outer membrane and venom glands, demonstrating the retroserrated spine. (*Courtesy of David Fulghum, MD.*)

Most stingray injuries occur when bathers, waders, or fishermen accidentally step on rays as they lie partially covered with sand in shallow waters. Severe lacerations and puncture wounds are inflicted by the ray as it defensively whips its tail upward and forward when stepped on or threatened [82] (Fig. 237-25). The majority of wounds, therefore, are located on the dorsum of the foot or lower leg. Penetrating wounds to other locations have occurred to fishermen stung while attempting to remove rays from their lines or nets; in a freak accident when a ray leapt from the water, striking a young boy in a small boat; and to divers engaged in feeding rays at popular dive locations. [82] When stingray spines penetrate the thorax or abdomen, the resulting wounds may prove fatal. [82]

FIGURE 237-25 Stingrays reflexively swing their barbed tails up when stepped on, causing painful lacerations and puncture wounds. (The leg used for this photograph was a prosthesis; the stingray was alive.) (*Courtesy of David Fulghum, MD.*)

In addition to their spines, stingrays can produce an abrasive wound with their mouths known as a “two-fathom hickey.” [83] These injuries occur when divers and snorkelers attempt to feed stingrays at popular dive sites. The rays occasionally miss the food that is being offered and may press their mouths against the unprotected hand or arm of the diver feeding them. A superficial abrasion results from the sucking action of the mouth and their abrasive rasplike-teeth.

CATFISH Both fresh- and saltwater catfish are armed with stout sharp spines located immediately in front of the soft rays of their dorsal and pectoral fins. [69] Catfish defensively lock these spines into an extended position when they are handled or threatened. Bathers may sustain stings on their feet or legs if they step on a catfish, but most catfish stings involve the hand or upper extremity of fishermen or seafood processors. [84] Fishermen are commonly stung while attempting to remove catfish from the hooks of their fishing lines. Heavy gloves, pliers, and pincer-like jaws for holding the fish afford some protection. The safest approach in the absence of these devices is to maintain a safe distance from the fish and to cut the line. Fishermen and seafood processors may even be stung while cleaning dead catfish. To prevent these injuries, it has been suggested that the offending spines be removed with a pair of pliers before attempting to clean the fish. Although most catfish stings are mild, they occasionally can result in severe necrosis and even gangrenous tissue loss, which in one case required digital amputation. One of the most dangerous venomous fish in the world whose sting can be fatal is a species of catfish, *Plotosus lineatus,* which is found in waters of Japan, the Philippines, Southeast Asia, East Africa and Australia. [85] Swimmers and bathers in the Amazon river are at risk for urologic injuries if they encounter a very small species of catfish called “candiru,” which has the ability to enter the human urethra. Barbs on the head of this fish prevent it from swimming backward out of the orifice, and surgical intervention is often required to extract the fish.

SCORPIONFISH Scorpionfish, family Scorpaenidae, are divided into three main groups on the basis of their stinging apparatus. All have venomous spines of varying sizes and toxicity that may be found, depending on the species, on the dorsal, pelvic, and anal locations. Lionfish, genus *Pterois,* live in tropical waters and are prized by fish fanciers because of their colorful and ornate fins. The spines of lionfish are long and slender with small venom glands. [59] Their stings are relatively mild and not life-threatening. [70], [86] Stings among amateur fish collectors are occurring more frequently because of the increasing popularity of these fish. [86] Scorpionfish, genus *Scorpaena,* have stings that are of intermediate severity. They are bottom dwellers with superior camouflage abilities that allow them to blend in almost invisibly with their surroundings (Fig. 237-26). Their spines are long and heavy and have moderate-sized venom glands.

FIGURE 237-26 *Scopaena plumieri,* a species of scorpion fish, is found in the waters of the West Indies. Its camouflage abilities are exceeded only by its painful sting.

Stonefish, genus *Synanceja,* are the most dangerous members of the scorpionfish family. They live in shallow waters, sometimes partially buried in sand or mud, or in holes of rocky shoals, reef areas, or tidal pools. [70] Injuries occur when a wader steps on the erect venomous dorsal spine that the stonefish raises in defense. Stonefish spines are short and thick and have very large and well-developed venom glands. [59] The wounds caused by stonefish are quite severe and may be fatal. A stonefish antivenin is available from the Commonwealth Serum Laboratories, Melbourne, Australia. [24]

WEEVERFISH In European coastal waters, the weeverfish is one of the most common and severe causes of venomous fish spine injuries. [87] These fish are equipped with between five and eight venomous dorsal spines and two venomous opercular spines (one on each side of the head near the gill plate). [88] Waders and bathers are at risk when they step on weeverfish that lie partly buried in mud or sand in shallow waters. Fishermen may suffer stings while trying to remove these fish from nets or fishing lines. Weeverfish stings produce severe pain and significant local tissue reaction characterized initially by erythema and edema. There may be associated ecchymoses, regional lymphangitis, and lymphadenitis. [88] Systemic signs and symptoms may include headache, nausea, vomiting, diaphoresis, hypotension, syncope, and respiratory depression. [87], [88] Fatalities from weeverfish stings are extremely rare and have been attributed to respiratory failure. [88]

LOCAL AND SYSTEMIC SYMPTOMS OF FISH-SPINE ENVENOMATIONS The toxicity of a given sting depends on a number of factors, including the species of fish involved, the location and severity of the wound, the amount of venom released, and the first aid and subsequent medical care provided to the victim. In general, these wounds produce pain out of proportion to the apparent severity of the injury. The pain is immediate and intense. In the case of scorpionfish stings, the pain may be so severe as to cause the victim to thrash about wildly, scream, and finally lose consciousness. Initially, the sting site may appear pale or cyanotic. The area around the wound may be anesthetic or hyperesthetic. [59] Erythema and edema soon develop, giving the appearance of a cellulitis. Vesicles may form. In severe stingings, especially those caused by stonefish, the wounded area may become indurated and develop areas of ischemic necrosis

with subsequent sloughing and ulcer formation. Fish-spine wounds may be complicated by foreign-body reactions to bits of retained spines or remnants of integumentary sheath. Secondary infections from a variety of organisms must be anticipated. Healing is slow, especially in cases plagued by abscess or ulcer formation. Systemic symptoms from toxic fish spine envenomations may range from mild to severe, depending on the species involved and the amount of venom entering the wound. They can include headache, nausea, vomiting, diarrhea, abdominal cramps and pain, fever, local lymphangitis and lymphadenitis, joint aches, muscle weakness, diaphoresis, peripheral neuropathy, limb paralysis, restlessness, delirium, seizures, cardiac arrhythmias, myocardial ischemia, pericarditis, hypotension, respiratory distress, and death. [49], [86]

PREVENTION Prevention of toxic fish-spine wounds begins with a knowledge of and an appreciation for the various venomous species that may be encountered in a given area. Waders and bathers should shuffle their feet to scare away and avoid stepping on rays or scorpionfish. Fishermen must exercise care when removing rays or catfish from their fishing lines or when cleaning fish with venomous spines. Fish hobbyists and divers should wear protective clothing and avoid handling venomous species.

TREATMENT Puncture wounds and lacerations from venomous fish spines should be irrigated immediately with sterile saline or water, if available, and with seawater as a last resort. [50] The wounded area should then be soaked as quickly as possible in hot (not scalding) water of approximately 43°C to 46°C (110°F to 115°F) for 30 to 90 min or until maximal pain relief is achieved. Hot soaks may be repeated if the pain returns. Because the wound or extremity may be partially anesthetic, it is necessary for the person administering first aid to test the water's temperature for the victim. [82] One source of hot water that is often overlooked and may be useful in an emergency is hot seawater from a boat motor's cooling system. [82] Local infiltration of the wound with 1 to 2% lidocaine without epinephrine may bring about significant pain relief and allow for exploration of the wound after x-rays have been performed to locate retained portions of spines. [70], [82] Longer-acting anesthetics such as procaine and bupivacaine may be chosen to provide a longer period of pain relief. The wound should be thoroughly cleaned to remove any remnants of integumentary sheath. Cleansing with a toothbrush and a solution of hexachlorophene in 70% alcohol has been recommended. [82] Abdominal and thoracic wounds and deep wounds to the hands, feet, or fascial compartments of the legs should be explored in the operating room. [70] Debridement of necrotic tissues may be required at the time of exploration, and sequential debridement may be necessary. [70] In general, these wounds should be left open or closed loosely with tape or suture to allow for adequate drainage and to prevent abscess formation. Tetanus prophylaxis should be administered, if indicated, and antibiotics are recommended if the wound is more than 6 h old, is extensive, or involves deep puncture wounds to the hand or foot. [70] The choice of antibiotic should be based on the bacteriology of the marine environment in which the wound occurred and subsequently on deep wound or tissue cultures. Empiric antibiotic therapy for infections of wounds occurring in salt water should include coverage for *Vibrio* species. Before final wound culture results are known, initial choices of parenteral antibiotics include IV ciprofloxacin, imipenem-cilastatin, cefoperazone, cefotaxime, ceftazidime, gentamicin, tobramycin, chloramphenicol or trimethoprim-sulfamethoxazole. [89] Choices for oral antibiotic therapy include ciprofloxacin, doxycycline, and trimethoprim sulfamethoxazole. [89] Organisms reported to cause secondary infections in catfish spine wounds include *Erysipelothrix, Nocardia, Chromobacterium, Mycobacterium terrae, Sporothrix, Actinomyces, E. tarda, Aeromonas hydrophila,* and *Vibrio* species. [90] Deep wound or tissue cultures should guide the choice of antibiotic therapy. Empiric therapy for catfish wounds may include cephalosporins or ciprofloxacin. [84] Stonefish stings complicated by severe reactions may be treated with antivenin by slow intravenous infusion. Antivenin is not usually required for the stings of lionfish and other species of scorpionfish, except for stonefish. [70] Stonefish antivenom is available from the Australian Commonwealth Serum Laboratory, (Melbourne, Australia). It is supplied in 1.2-mL ampules. The amount of antivenin given depends on the number of puncture wounds sustained by the victim and the response to treatment. The initial dosing schedule is 1, 2, or 3 ampules for 1, 3, or more than 4 puncture wounds. [91] Stonefish antivenin is prepared from horse serum, and its administration may be complicated by anaphylaxis and serum sickness in sensitized individuals. [91]

Fish Bites

There are many species of fish whose bites are dangerous to humans. Among the best known are the sharks and barracudas, whose bites may cause severe injuries.

Although they are well publicized by the news media, shark attacks are relatively rare events. The average number of shark attacks worldwide is between 30 and 100 annually. Only 32 of the 350 known species of sharks have been reported to attack humans. Most shark attacks involve surfers, scuba divers, and swimmers. Because sharks are attracted to bright or shiny objects, as well as to contrasting colors, these items should not be worn in the water. They are also attracted by any sort of blood in the water; therefore women who are menstruating should refrain from water sports in areas where sharks may be prevalent, and no one should swim with an open bleeding wound. Spearfishermen should never tie their catch to themselves, and they should place their catch in the dive boat as soon as possible. Although most shark bites are not life-threatening, more severe attacks may cause extensive soft tissue loss with massive hemorrhage, which, in the worst cases, can result in amputation of a limb or death. [92], [93]

Barracuda attacks are even more rare than shark bites. They tend to occur in murky turbid waters where these predators may mistake jewelry or other brightly colored objects worn by bathers for the baitfish on which they feed. Barracuda bites typically produce straight or V-shaped lacerations.

Other gamefish such as flounder, mackerel, and bluefish may occasionally cause bites if they are handled carelessly by fishermen. Bluefish, which run in large schools, present a menace to swimmers and surfers and to fishermen who are not wary of their vicious bites. [50]

Divers and aquarium hobbyists must be careful when feeding or handling moray eels, which have powerful jaws and knifelike teeth. Although not considered venomous by most sources, they can produce deep puncture wounds and lacerations [50] (Fig. 237-27). When biting, moray eels tend to lock onto their prey; decapitation of the eel or disarticulation of its jaw may be required to release the victim. [94] As with all deep puncture wounds or lacerations, victims of moray eel

bites should receive tetanus prophylaxis. Empiric antibiotic therapy for prophylaxis or treatment can include ciprofloxacin or cefuroxime for coverage of *Vibrio* or *Pseudomonas* species. [95]

FIGURE 237-27 Moray eel bites are uncommon but have increased because of divers feeding these animals at popular dive sites. (*Courtesy of Marty Gilman, Worcester, MA.*)

WATERBORNE INFECTIONS

A variety of infections may result from exposures to aquatic environments. Pathogenic organisms may be actively introduced into wounds of the bites, stings, or lacerations caused by marine life; preexisting wounds may be passively infected when exposed to contaminated waters. Table 237-3 summarizes those organisms commonly associated with waterborne infections. A host of other agents, such as *Streptococcus* and *Staphylococcus* spp., *Bacteroides fragilis, Clostridium perfringens, Escherichia coli, Salmonella enteritidis,* other marine *Vibrio* species, *Chromobacterium violaceum,* and *Chlorella,* also require consideration when dealing with infections derived from aquatic settings. [70]

CUTANEOUS MANIFESTATIONS OF SEAFOOD INGESTION AND OF SEAFOOD POISONING

Several dermatologic reactions may appear after the ingestion of seafood. Urticaria, angioedema, and, rarely, leukocytoclastic vasculitis may occur in individuals sensitized to fish or shellfish (Fig. 237-30). Many seafoods, such as kelp, contain large amounts of iodine, which may cause acneiform eruptions.

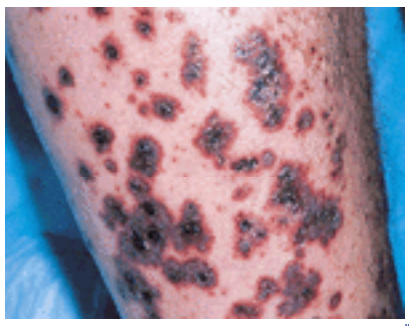

FIGURE 237-29 Leukocytoclastic vasculitis occurring in a patient, allergic to shellfish, who consumed a chowder containing quahogs, a type of clam.

Scombroid food poisoning involves the ingestion of spoiled fish from the Scombroidae family of fish, which includes tuna, mackerel, bonita, and their relatives. If these fish are not kept cold enough after being caught, their flesh develops scombrotoxins as a consequence of the bacterial breakdown of histidine into histamine, saurine, and possibly other toxic byproducts. These can cause striking erythema and flushing of the face, neck, and upper trunk, as well as pruritus and urticarial and angioedematous eruptions. Administration of antihistamines can provide symptomatic relief in severe cases.

Ciguatera toxin, which is produced during blooms of toxic dinoflagellates, is incorporated into the marine food chain and concentrated in the flesh of a variety of fish. Dermatologic symptoms of ingesting these fish may include generalized pruritus and diffuse erythematous macular and papular exanthems that may progress to blister formation and

desquamation.

FIGURE 237-30 When patients present with a bullous hemorrhagic cellulitis after eating shellfish (as was the case with this patient) or after having suffered a wound in salt water, *Vibrio vulnificus* cellulitis should be suspected.

Pufferfish poisoning, also known as Fugu poisoning, may be lethal. The toxin responsible for this illness is tetrodotoxin, a powerful neurotoxin, which can be found in the skin, entrails, and flesh of these fish. Initially, it was thought that pufferfish produced tetrodotoxin intrinsically, but it now appears to be produced by commensal microorganisms. [97] When deaths occur, they are because of an ascending paralysis of respiratory muscles. Cutaneous manifestations of Fugu poisoning may rarely include a severe erythrodermic eruption followed by extensive desquamation. Although these fish are considered a delicacy in Japan and other cultures of the Indo-Pacific, diners must take exceptional care when ordering this fare. The safest approach is to avoid eating pufferfish completely. Individuals not willing to abstain should eat only at restaurants of the highest caliber where properly licensed and experienced pufferfish cooks are employed.

The authors wish to thank Dr. Bruce Halstead of the World Life Research Institute, Colton, California, for allowing us to reprint the photographs from the first and second editions of *Poisonous and Venomous Marine Animals of the World.*

HUMAN SCABIES

Etiology and epidemiology

Scabies is the term for infestation with the itch mite, *Sarcoptes scabiei var humanus.* The mite was first described in 1687, making scabies one of the first infectious diseases with a known cause. [1] The disease is found worldwide, in all races and in all age groups. It can be transmitted sexually as well as by nonsexual close skin-to-skin contact, especially within the family and at school. When more than one member of a household is afflicted with an intensely pruritic eruption, scabies infestation must be considered.

Clinical Features

CLASSIC SCABIES The hallmark of scabies is intractable pruritus, characteristically more severe at night. The itching, often disproportionately severe, is associated with lesions that initially appear on the web spaces, then the sides of the fingers, the flexor surfaces of the wrists, elbows and anterior axillary folds. Other common sites of lesions are the penis (Fig. 238-1) and scrotum, the areolae in women, the buttocks, and the sacral and periumbilical areas. Lesions may be eczematous and often are excoriated, but the pathognomonic lesion is the burrow (Fig. 238-2), a short, wavy, dark line. The classical features are often obscured by excoriations, impetiginization or eczematization.

FIGURE 238-1 Scabies, with nodular lesions. The penis and scrotum are common sites for scabies infestations; crusted excoriated papules are seen on the glans and shaft, and nodular scabies lesions on the scrotum.

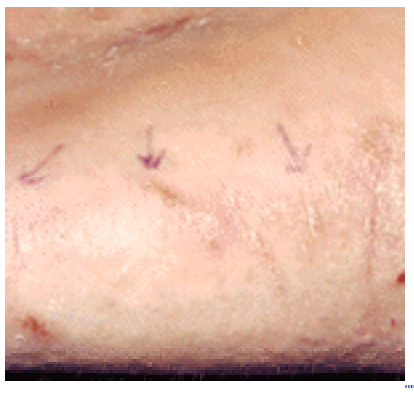

FIGURE 238-2 Scabies. Several, slightly scaling, threadlike burrows are seen on the medial aspect of the palm, associated with a more generalized eczematous process; scrapings of a burrow have the highest yield in detection of a scabies mite. (*Courtesy of M. Hebert, MD.*)

SPECIAL FORMS Orkin [2] described presentations of scabies that may present diagnostic difficulties or may suggest the diagnosis.

Scabies in patients with good hygiene Easily misdiagnosed because lesions are sparse and burrows difficult to find.

Scabies incognito Originally described in patients taking glucocorticoids, other immunosuppressive drugs also may lead to confusing presentations of scabies, including crusted scabies mimicking contact dermatitis or Darier's disease. Scabies must be considered whenever a widespread, scaly, pruritic dermatosis develops in an immunosuppressed patient.

Nodular scabies The lesions are reddish-brown, pruritic papules and nodules (Fig. 238-1) on covered areas (most frequently the male genitalia, groin, and axillary regions), which often persist long after adequate treatment for scabies. They probably represent a hypersensitivity reaction to retained mite parts or antigens.

Scabies in infants and young children In this age group, the face, scalp, palms, and soles may be involved; the most common presenting lesions are still papules, vesicopustules, and nodules, but the distribution may be atypical. [3] The diagnosis is frequently missed because of a low index of suspicion. Secondary eczematization and impetigenization are common, and burrows difficult to find. The prevalence of scabies is highest in infants younger than 2 years of age; the youngest child in the household is often affected because he or she is carried and hugged by affected adults.

Scabies in the elderly In this age group, scabies may be missed because the cutaneous changes may be minimal or atypical. The intense itching may be attributed to “senile pruritus,” xerosis, drugs or psychogenic causes. Older patients who spend prolonged periods of time in bed or in chairs may have involvement of the back. Scabies epidemics are frequently reported in group care facilities such as nursing homes, where a single patient with crusted scabies may be the index case leading to infection of other patients as well as health care workers and their families.

Crusted (Norwegian) scabies Historically, this condition has been associated with advanced age, debility, and developmental disabilities such as Down's syndrome. It is now also seen with immunosuppression of all types. Hyperkeratotic, nonpruritic lesions are most common, but the condition may range from crusting with or without pruritus to a pruritic, papular dermatitis and may mimic Darier's disease or psoriasis. Finger- and toenail involvement may simulate psoriasis or onychomycosis. Thousands to millions of organisms may be present in the scales and the nails. In the absence of other predisposing conditions, patients with crusted scabies should be tested for AIDS. Patients with crusted scabies have developed bacteremias—occasionally fatal—as a consequence of infection of the fissured and excoriated skin.

Scabies and HIV/AIDS Scabies occurs in at least 2 to 4 percent of patients with AIDS. Unusual forms of scabies in AIDS can be divided into crusted scabies (Fig. 238-3) and atypical papular scabies. [4] Patients with HIV/AIDS may present with classical scabies, and as the CD4 count drops, they may develop crusted scabies and the pruritus may decrease or disappear. Because of the atypical appearance, diagnosis may be delayed, increasing the risk of spread to others.

FIGURE 238-3 Scabies. Crusted or Norwegian scabies in an AIDS patient. The clinical presentation of generalized hyperkeratosis and scaling is often misdiagnosed; rather than an infestation with a dozen mites, many thousands to millions are present. (*Courtesy of M. Hebert, MD.*)

Scabies of the scalp Scabies rarely involves the adult scalp; when it does, it may accompany or simulate seborrheic dermatitis. However, scalp lesions do occur in infants and children, the elderly, nursing home patients, those residing in tropical areas, and patients with crusted scabies, AIDS and, recently reported, patients with dermatomyositis.

Bullous scabies Vesicles are common in children with scabies but uncommon in adults. Bullous scabies may occur in adults, associated with an eruption indistinguishable from bullous pemphigoid clinically, pathologically, and immunopathologically. [5] Patients are generally older than 65 years of age and in otherwise good health. Often, they are treated with oral glucocorticoids when routine and immunofluorescent biopsies point to a diagnosis of bullous pemphigoid, but, if sought, burrows are present in most cases. Because of the significant delay in diagnosis, there is an opportunity for spread of the disease to others.

Differential Diagnosis

Scabies can be confused with almost any pruritic dermatosis but is most commonly confused with atopic dermatitis, papular urticaria, pyodermas, insect bites, and dermatitis herpetiformis. Certain animal mites may transiently infest humans, and should be suspected in pruritic dermatoses of uncertain cause. Mite species known to cause such transient eruptions include *Sarcoptes scabiei* var *. canis, S. scabiei* var *. bovis, Notoedres cati, Cheyletiella yasguri, Cheyletiella blakei, Dermanyssus gallinae,* and *Ophionyssus natricis.* The eruption associated with these mites does not share the classical distribution of human scabies, nor have these mites been reported to cause crusted scabies. [6]

Diagnosis

Burrows are often difficult to find, and the usual clue to the diagnosis is the characteristic distribution; in males, papules, nodules and, rarely, ulcers on the penis, are a significant diagnostic feature. Definitive diagnosis rests on microscopic identification of the mites, eggs, or fecal pellets (*scyballa*). Often mites cannot be found in spite of classical lesions of nodular scabies on the genitalia, or the typical rash with a history of other family members itching. It may be appropriate to treat such a patient with a presumptive diagnosis, but both overdiagnosis and underdiagnosis are common. Useful

diagnostic methods include the following techniques.

DIRECT EXAMINATION One or two drops of mineral oil are applied to the lesion, which is scraped or shaved with a scalpel blade to remove the tops of the burrows or papules. The scrapings, along with the oil, covered with a coverslip, are examined microscopically under low power. Potassium hydroxide should not be used, because it can dissolve the fecal pellets (*scyballa*). Alternatively, the papule or burrow can be curetted with a small dermal curette. A toothpick or applicator stick may be used to clear the tissue/oil mixture from the curette, and the specimen is then examined microscopically. This technique is not frightening to children and uncooperative or anxious patients, and may be a preferred method in patients suspected of having HIV/AIDS.
DERMOSCOPY Argenziano et al. reported epiluminescence microscopy, or dermoscopy, to be an effective *in vivo* means of diagnosing scabies. The magnified view shows small, dark, triangular structures corresponding to the pigmented anterior section of the mite, and a subtle linear segment behind the triangle containing small air bubbles; together resembling a “jet with contrail” and thought to be the burrow along with the eggs and fecal pellets. [7]
POLYMERASE CHAIN REACTION Bezold et al. reported the use of PCR to prove scabies in a patient presenting with clinically atypical eczema. Epidermal scales were PCR positive for *S. scabiei* DNA before, and negative 2 weeks after, therapy. [8]

Complications

Eczema, particularly in atopics, may be prominent both during the active infestation and after the scabies has cleared. Excoriation may lead to secondary pyoderma, and colonization with nephritogenic strains of streptococci may lead to acute glomerulonephritis. This complication is seen most commonly in tropical areas. Patients who have been successfully treated for scabies (or have never had scabies) may develop *acarophobia* or delusions of parasitosis (see also Chap. 40).

Treatment

PRINCIPLES There are a number of effective treatments for scabies: selection may depend primarily on cost and potential toxicity. Patients will often apply medications more frequently and for longer periods than recommended, so knowing the appropriate quantity to prescribe can prevent irritation from overuse, which, in turn, is misinterpreted as treatment failure. Scabicides should be applied thoroughly to the area behind the ears and from neck to soles, with special attention to intertrigenous areas such as between the fingers and the toes, the umbilicus, the groin, between the buttocks, and under the fingernails and toenails. Medication should be thoroughly washed off after the recommended time period. The morning after treatment, underwear, bed linens, and towels should be machine-washed and dried, using the hot cycles. Patients should be cautioned that while the infestation has been adequately treated, itching and eczematization might persist for up to a month. All members of the affected household should receive topical treatment, although some physicians treat only those asymptomatic family members who have intimate contact with the patient (sharing a bed, sexual contact).
SPECIFIC TOPICAL SCABICIDES 1. *Permethrin 5% cream* (Elimite, Acticin), a synthetic pyrethroid, is an excellent scabicide, with low toxicity in humans even with overuse. It is minimally absorbed and rapidly metabolized. The cream is applied as described above and left on overnight. Many physicians prefer to use a second application 5 to 7 days later. Clinically significant resistance (properly termed tolerance) has not been reported. Permethrin should not be used in infants younger than 2 months of age or in pregnant or nursing women. The most common adverse reactions are mild and transient; burning, stinging or exacerbation or recurrence of pruritus, and rarely contact dermatitis may occur. 2. *Lindane 1%* (gamma-benzene hexachloride) in some studies was about as effective as permethrin. Other studies showed lindane to be somewhat inferior. Lindane is left on for 8 h and then washed off. As with permethrin, some physicians prefer to retreat 1 week later. Central nervous system toxicity may occur, generally because of failure to follow instructions, either because too much of the medication was applied or it was applied too many times. Since January 1, 2002, the state of California has forbidden the use of lindane in any products used or sold for the treatment of lice or scabies in humans. Lindane should not be used in infants, young children, or pregnant or nursing women, or in patients with seizure disorders or other neurologic diseases. Clinically significant tolerance to lindane has not been reported. 3. *Sulfur,* usually prescribed as precipitated sulfur (6%) in petrolatum, must be compounded by the pharmacist. It may be applied nightly for 3 nights and washed off thoroughly 24 h after the last application. It smells, stains, and is greasy, but it is safe, effective, and appropriate for infants younger than 2 months of age and during pregnancy or lactation. [9] 4. *Benzyl Benzoate 25%* is an effective scabicide, but is not commercially available in the United States. It is probably as effective as lindane. 5. *Crotamiton cream* (Eurax) is not believed to be highly effective in the treatment of scabies; it is inferior to permethrin, but may be about as effective as benzyl benzoate and sulfur. [10]
IVERMECTIN Ivermectin is an antiparasitic agent, approved by the FDA for onchocerciasis and strongyloidiasis in humans. Since 1993, there have been numerous reports indicating that ivermectin given in one or two oral doses of 200 µg/kg body weight is an effective treatment for scabies. Other studies suggest that higher dosages may be more effective, especially in immunosuppressed patients such as those with AIDS. Further controlled studies are needed to determine the most effective dosage and means of administration in both healthy and immunosuppressed patients, as well as the place of combined topical and oral therapy with ivermectin. Topical preparations of ivermectin such as a 1% solution in propylene glycol are also being investigated as a possible alternative treatment. [11]

Antipruritic Medications

The pruritus of scabies often persists for several weeks after adequate therapy. Sedating antihistamines may reduce the pruritus, but a short course of topical or systemic glucocorticoids is generally more effective. In children, 1% hydrocortisone cream may be helpful; in adults triamcinolone cream (0.1%) may be used. For more severe itching, a 7- to 14-day course of prednisone or intramuscular triamcinolone acetonide, 40 to 60 mg, may give relief.

Where excoriation has led to impetiginization, antibiotic therapy with topical mupirocin or a broad-spectrum antibiotic is appropriate.

Treatment of Special Forms of Scabies

CRUSTED SCABIES The scabicides used for classical scabies are effective in crusted scabies as well; however, repeated applications are usually required, clearing is slower than in noncrusted scabies, and sometimes the sequential use of two or more different agents is necessary. The entire skin should be treated, including the scalp, face (excluding the areas around the eyes, nose, and mouth), and particularly under the fingernails and toenails, brushing the medication under the free edges of the nails. Ivermectin, 200 to 250 µg/kg of body weight may be appropriate, alone or in combination with permethrin cream, followed by lindane or 6% to 10% sulfur ointment if necessary. Pretreatment with keratolytic agents (creams or lotions containing salicylic acid) may be helpful. Because the patient with crusted scabies carries huge numbers of mites (reportedly up to 2 million), the patient should be isolated until treatment is complete, and the environment and fomites should be treated. Compliance is also of concern: the scabicides should be applied under supervision. Prophylactic therapy of exposed individuals including family members and health care workers is indicated.
SCABIES IN HIV/AIDS Management is similar to that of crusted scabies. The more profound the immunosuppression, the more atypical may be the morphology and the less predictable the response to therapy. Repeated applications of scabicides, sequential use of several different agents, nd/or systemic therapy with ivermectin may be required. Isolation of the patient, supervision of treatment and treatment of contacts are appropriate as with crusted scabies.

PEDICULOSIS

Lice have infested humans for millennia. They are mentioned in the Hebrew Bible, and nits have been identified intact in ancient artifacts such as combs. There are three types of lice known to infest humans; whether they are three or only two different species is controversial. The head and body lice may be variants within a single species, but are thought by most biologists to represent two distinct species, which can hybridize or interbreed under special circumstances. They are best-termed *Pediculus humanus* and *P. capitis,* although if a single species, they are properly termed *P. humanus* var. *capitis,* and *P. humanus* var. *corporis.* The lice are tiny (1 to 4 mm) elongated, soft-bodied, wingless, dorsoventrally flattened, blood-sucking insects with six legs all terminating in small claws, which enable them to grasp hair shafts or clothing fibers. The third species, *Pthirus pubis,* is morphologically distinct from the others. The common term “crab louse” is an excellent description, the body being somewhat rounded like that of a crab, with small claws on the front pairs of legs and larger claws on the two rear pairs, which allow the louse to grip the widely spaced hairs of the pubic area, eyebrows and lashes, and other areas of short hairs.

Both head lice and pubic lice feed and reproduce on the human host, cementing their nits to the hair. Body lice, however, take their blood meals from the human host, but reproduce by attaching their eggs to the fibers of clothing. This has significance when treatment is considered. After an incubation period of 9 to 12 days, the nymphal stage emerges from the egg, or nit, and matures into an adult within another 10–15 days. Head and body lice may move as rapidly as 23 cm/min; the slower crab lice may travel only up to 10 cm/day.

Clinical Manifestations

The bite of the louse is painless, but because of hypersensitivity to the saliva of the mite, or to the anticoagulant injected at the time of feeding, the human host may develop an inflammatory lesion at the site. This lesion may be an immediate urticarial lesion, a small 2- to 3-mm red macule or papule developing hours to days later, or the classic *macula cerulea* (see pediculosis corporis). Pruritus is the most common symptom in any type of pediculosis.

Pediculosis Capitis (Head Lice)

ETIOLOGY AND EPIDEMIOLOGY Head lice are most common among children, infesting millions of elementary school students annually, spread by close physical contact as well as by the sharing of head gear, combs, brushes, and pillows. The lice are believed to survive for only about 24 to 48 h away from the human host, and therefore fumigation of homes is unnecessary. Head lice are a growing problem in the United States and around the world, and it is believed that the incidence is usually underestimated: there are numerous reports of surveys of school children showing varying incidences in different geographic areas. Head lice affect all levels of society and all ethnic groups, although in the United States, the incidence is low among African Americans. Hair length is not an important factor.
CLINICAL MANIFESTATIONS Pediculosis capitis is typically confined to the scalp (Fig. 238-4). The most common symptom is itching, often intense, and the sight of schoolchildren scratching their heads often leads to the diagnosis. There may occasionally be a tiny hemorrhagic crust at the site to indicate the louse has taken its blood meal. According to one study, bite reactions, pruritus, excoriations, lymphadenopathy, and conjunctivitis were the most common signs and symptoms, although lymphadenopathy was equally common in unaffected children of the same age. [12]

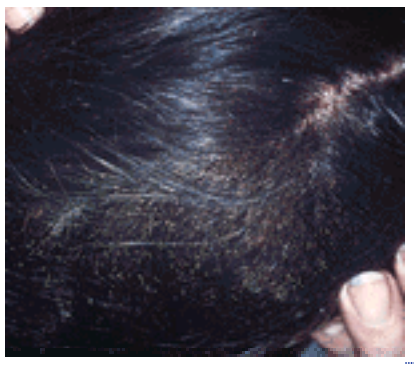

FIGURE 238-4 Pediculosis capitis. Myriads of oval, grayish-white egg capsules (nits) are firmly attached to the hair shafts. (*Courtesy of DA Burns, MD.*)

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The most common diagnostic sign of head lice is the live nits on the proximal part of the hair shaft. These eggs are cemented to the hair by the female louse at the point where the hair exits the scalp. Thus the distance of the nit from the scalp along the hair shaft is evidence of the duration of the infestation.

When all of the nits are noted to be a significant distance from the scalp (i.e., >1 cm) it is likely that the infection is no longer active and that these nits are not fertile. It is best to examine the hair under the microscope to assure that there are live larvae present within the nits and to exclude seborrheic scales, hair casts, and artifacts on the hair (e.g., hair spray) that may be brushed off easily. Finding live adult lice, immature nymphs, and/or viable-appearing eggs confirms the diagnosis. One recent study suggested that fine combing hair that has been saturated with water and conditioner yields more positive results and fewer false positives than traditional scalp examination. [13]

Pediculosis Corporis (Body Lice)

ETIOLOGY AND EPIDEMIOLOGY Pediculosis corporis is a disease of poverty, found almost exclusively among the indigent, the homeless, and groups living in crowded unsanitary conditions, such as refugees and, in wartime, the military—these patients are seen mainly in urban public hospitals. The body louse is about 30 percent larger than the head louse, but has essentially the same morphology. The infestation is usually transmitted by contaminated clothing or bedding.

CLINICAL MANIFESTATIONS AND DIAGNOSIS Occasionally, the *macula cerulea* (literally, sky-blue spot), a blue to slightly slate-colored macule, can be seen, particularly in areas where clothing binds, such as the waistband, and on the buttocks and thighs. It is an asymptomatic to slightly pruritic, somewhat bruiselike lesion, up to approximately 1.5 cm in diameter and often with a central punctum. More commonly, the only sign of body lice is excoriations, often linear and primarily on the trunk. These serve as evidence of the intense pruritus, and secondary infection of these excoriations is not uncommon. Postinflammatory pigmentation is seen in more chronic cases. Adult lice are rarely seen except in heavy infestations. Diagnosis is made by closely examining the lining of the clothing, particularly at the seams, for the presence of nits. The clothing may also be shaken out over a sheet of newsprint, at which time the lice may be seen moving about on the paper. Body lice are medically important not because of the pruritus and secondary impetiginization, but because they may act as vectors for *Rickettsia prowazekii* and *R. quintana* (typhus and trench fevers; see Chap. 227) and *Borrelia recurrentis* (relapsing fever).

Pediculosis (Pthiriasis) Pubis (Pubic Lice)

ETIOLOGY AND EPIDEMIOLOGY Most often pubic lice are a sexually transmitted disease, commonly associated with other sexually transmitted diseases. There are no racial differences in incidence (unlike pediculosis capitis). The infestation is common and tends to recur in gay men. [14]

CLINICAL MANIFESTATIONS As suggested by its name, this louse is most commonly found in the pubic hair (Fig. 238-5), although in hirsute individuals the short hairs of the thighs, trunk, and perianal area may also be involved. All the hair-bearing skin should be examined. Occasionally, the beard, moustache, and even eyelashes (Fig. 238-6) may be involved. Infestation of the eyelashes and periphery of the scalp occur mainly in children, probably a result of contact with an infested parent. Meinking and Taplin [14] reported as much as 60 percent of a homeless population had crab lice in areas of the body besides the pubic hair. Secondary infection because of excoriation may obscure the infestation and can lead to local lymphadenitis and fever. *Maculae ceruleae* (sky-blue macules) may be present as in pediculosis corporis and capitis (Fig. 238-7).

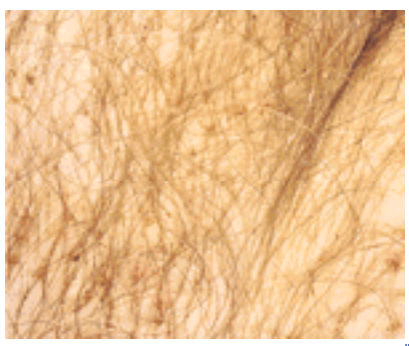

FIGURE 238-5 Pediculosis pubis. Several crab lice and their dot-like nits attached to the hair shafts can be seen in the pubic area of this patient. (*Courtesy of DA Burns, MD.*)

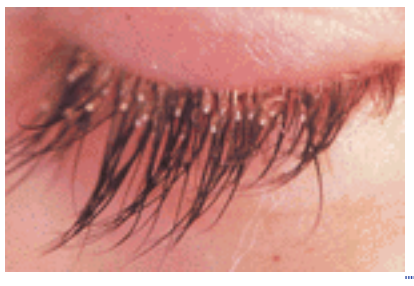

FIGURE 238-6 Pediculosis pubis. Eyelash infestation with *Pthirus pubis*. Nits can be seen attached to the eyelashes. (*Courtesy of DA Burns, MD.*)

FIGURE 238-7 Pediculosis pubis. Maculae caeruleae, slate-gray or blue-gray macules, are seen on the buttocks. (*Courtesy of DA Burns, MD.*)

DIAGNOSIS The diagnosis is most frequently made by the patient him- or herself, often identifying the louse in the pubic area. Infested patients reportedly have an average of 10 to 25 or more adult organisms (Fig. 238-8) on the body. When the lice themselves cannot be found, nits may be identified near the base of the hair. As in pediculosis capitis, the duration of infestation can be approximated by the distance of the nit from the skin surface. The diagnosis is confirmed by microscopic examination of the plucked hair to identify the nits (Fig. 238-9). Empty nits may indicate a prior infestation.

Treatment and Control

PEDICULOSIS CAPITIS The vast majority of patients with head lice are not treated by dermatologists, but by school nurses, primary physicians, pediatricians, and pharmacists. The dermatologist is likely to see those patients in whom initial treatment has failed. There are numerous published reports of tolerance to each of the approved topical medications for the treatment of pediculosis capitis. As drug resistance emerges in areas, it is impossible to be certain of the comparative effectiveness of these products. The “best” choice will now depend on local resistance patterns. [15] As a treatment becomes unpopular in a given area, susceptibility of the head lice in that area might return. In 2000, Meinking et al. studied the effects of pediculicides available in the United States, and most of the information that follows is based on that work. [16]
Topical pediculicides 1. Natural *pyrethrin* products synergized with piperonyl butoxide (RID, A-200, R&C shampoo and others) are available over-the-counter. They are applied to saturate the scalp and allowed to remain on for 10 min. The hair is then washed thoroughly, dried, and the nits can be removed with a fine-toothed comb which is often sold with the product. Meinking's study, using RID, showed only 49 percent of lice killed in 10 min, and 47 percent of lice exposed to RID survived more than 3 h, whereas A-200 killed 97 percent of lice within 20 min. The two preparations also showed significant ovicidal activity, but a second treatment is advisable 7 to 10 days later to kill the nymphs hatched after the treatment. 2. *Permethrin,* a synthetic pyrethrin, is marketed over the counter as Nix, a 1% cream rinse. After shampooing with regular shampoo, the hair and scalp are toweled dry and allowed to further air dry so as not to dilute the lotion. The hair and scalp are thoroughly saturated with the permethrin lotion, which is left in place for 10 min, rinsed thoroughly, and dried with a clean towel. The hair should be combed with a fine-toothed comb to remove any remaining nits. 3. *Malathion* lotion 0.5% (Ovide; prescription only) appears to be the fastest-acting pediculicide, killing 100 percent of lice tested in less than 10 min. In the same study, malathion showed 100 percent ovicidal activity after a 10-min exposure. The FDA-approved directions recommend application to dry hair until the hair and scalp are thoroughly moistened, then allow it to dry and remain on the hair and scalp for 8 to 12 h, before washing out with nonmedicated shampoo. 4. *Lindane* (gamma-benzene hexachloride) 1% shampoo was for many years the best known pediculicide. There has been a well-reported decline in its efficacy, and its potential toxicity has lead to its being banned in California since 2002. It remains available by prescription elsewhere. Enough shampoo is applied to dry hair (1 ounce or less for short hair, 2 ounces or less for long hair) to thoroughly wet the hair and scalp or skin of the affected and surrounding hairy areas. It is allowed to remain in place for 4 min, then, using just enough water to work up a good lather, it is rinsed out. The patient should also thoroughly rinse the entire body to remove any lindane on the skin. Lindane should not be used in infants, preschool children and pregnant or lactating females. A large number of alternative methods such as herbal treatments are being promoted on the Internet, but there is little to no published scientific evidence of their efficacy. Physical treatment methods such as extensive combing, specially designed combs, and even electrified combs that are being marketed have either not been studied or have been shown to be ineffective. Because of resistance to topical therapy a

number of alternative treatments for pediculosis capitis have been proposed. These include ivermectin 200 µg/kg, two doses given 10 days apart. Although the reports to date are all anecdotal, ivermectin may emerge as the preferred treatment for the first half of the twenty-first century. There are also reports of the use of cotrimoxazole [trimethoprim-sulfamethoxazole (TMP-SMX)] for resistant head lice infestations, but it is premature to recommend the therapy at this time. Because neither ivermectin nor TMP-SMX is ovicidal, if used, they should be readministered in 7 to 10 days.

Environmental control The only definite evidence of treatment failure is the presence of adult organisms, which clearly requires retreatment. The presence of nits does not necessarily indicate ongoing infection. With any pediculicidal treatment, it is best to follow-up by using a fine-toothed comb to remove as many of the nits as possible. An 8 percent formic acid rinse (such as Step 2) may be helpful to dislodge the nits from their attachment to the hair. All members of the affected household should be examined. Although some physicians recommend treating all household members, others recommend treating affected individuals only. Following therapy, the treated individuals should wear clean clothing, and both clothing and bedding should be washed and dried using the hot cycle; nonwashables should be dry cleaned, ironed, put in the clothes dryer without washing, or stored in a sealed plastic bag in a warm area for 2 weeks. Combs and brushes may be washed in very hot water (such as the dishwasher) and may be coated with the pediculicide first, for 10 or 15 minutes. Floors, play areas, and furniture should be carefully vacuumed to remove any hairs with viable eggs attached. Fumigation of living spaces is of no value. “No nit” policies requiring exclusion from school and treatment for all children with nits alone are likely excessive. [17]

PEDICULOSIS PUBIS Topical therapy is much the same as that for pediculosis capitis. The preparation should be applied to the infested area, paying particular attention to the pubic and perianal regions and adjacent hairy areas. A common cause of failure is treating only the pubic area in hairy individuals: the pediculicide should be applied to the thighs, trunk, and axillary regions because the mite can infest these areas as well. Sexual contacts should be treated simultaneously, even if no lice can be seen, but other family members need not be treated if there is no evidence of infestation. After the treatment, the patients should use fresh underclothing, nightwear, and bedding; used articles should be washed and dried in the hot cycle of the washer and dryer. Ironing woolens and bedding may also be helpful.

Specific agents Synergized pyrethrins (RID, A-200, and other preparations available over the counter) appear to be safe and effective. They are applied undiluted until the infested areas are entirely wet, and allowed to remain in place for 10 min. The area is then washed thoroughly with warm water and soap and dried. Dead lice and eggs are removed with a fine-toothed comb (provided with some products). A second application is used in 7 to 10 days to kill any nymphs newly hatched from eggs that survive the first treatment. Lindane shampoo may be lathered into the affected area for 5 min. The area should be rinsed thoroughly and towel-dried. Remaining nits should be removed with a fine-toothed comb or forceps. Some physicians routinely prescribe a second treatment in 1 week to kill any newly hatched nymphs. Treatment failure is usually a result of failure to follow instructions, neglecting to treat sexual contacts, or reinfestation. Persistent itching may be caused by irritation from the pediculicide (usually because of overuse) or patient anxiety. Parasitophobia is fairly common after infestation and is difficult to treat. Therapy for eyelash involvement is petrolatum applied twice daily for 8 days followed by removal of any nits. Some authors recommend use of 1% malathion ointment, 1% lindane ointment, or 0.25% physostigmine ointment. Patients with HIV/AIDS tend to have more severe infestations with pediculosis pubis and to be unresponsive to conventional therapy.

PEDICULOSIS Corporis Because lice reproduce in the clothing and not on the skin, bathing, discarding or laundering infested clothing, and restoring proper hygiene should cure the infestation. Bedding should also be laundered with hot water, boiled, or discarded. Woolens and other nonwashables may be dry cleaned or ironed at home, with special attention given to the seams. Some physicians believe that, following appropriate disposition of clothing, the patient should be treated from head to toe with a single application of permethrin 5% cream, left on for 8 to 10 h and then washed off thoroughly. The bites and stings of arthropods cause many patients to consult physicians for relief from these vexatious creatures. Occasionally, death is caused by envenomation, particularly in infants. The clinician primarily diagnoses and treats skin lesions and systemic illnesses produced or transmitted by only five of the nine classes of arthropods: Arachnida, Chilopoda, Diplopoda, Crustacea, and Insecta. [1] All arthropods are invertebrates with a chitinous exoskeleton, bilateral symmetry, true segmentation, and jointed true appendages that vary from few to many (Fig. 239-1 and Table 239-1).

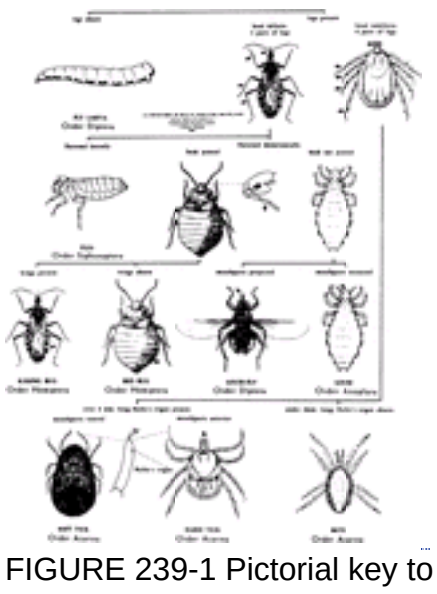

FIGURE 239-1 Pictorial key to groups of human ectoparasites. (*Courtesy of CJ Stojanovich and HG Scott, US Department of Health, Education, and Welfare, Public Health Service.*)

I. Arachnida—mites, ticks, spiders, scorpions (four pairs of legs)
  A. Acarina
    1. Mites—follicle, food, fowl, grain, harvest, murine, scabies
    2. Ticks
  B. Araneae—spiders
  C. Scorpionida
II. Chilopoda and Diplopoda—centipedes, millipedes
III. Insecta (three pairs of legs)
  A. Anoplura—lice
  B. Coleoptera—beetles
  C. Diptera—flies, mosquitoes
  D. Hemiptera—bedbugs, kissing bugs
  E. Hymenoptera—ants, bees, wasps
  F. Lepidoptera—butterflies, moths
  G. Siphonaptera—fleas

TABLE 239-1 **Arthropods That Infest, Bite, or Sting Humans**

HISTOPATHOLOGY

Most arthropod bites have a similar histologic reaction pattern. In the acute phase, there is variable epidermal necrosis, spongiosis, and parakeratosis with plasma exudate and a dermal inflammatory infiltrate extending upward. Dermal inflammation tends to extend into the deep dermis in a wedge-shaped pattern, surrounding vessels with some extension into dermal collagen. The infiltrate is typically of mixed composition including eosinophils, neutrophils, lymphocytes, and histiocytes in varying proportions. Eosinophils are usually prominent, although neutrophils may predominate in reactions to fleas, mosquitoes, fire ants, and brown recluse spiders. Bullae can form secondary to marked edema, especially in children. Insect parts are rarely seen, except for the burrowed mites of scabies within the stratum corneum and the mouth parts of ticks, which may remain within the dermis after ticks are removed.

Chronic lesions most commonly result when a portion of the arthropod lodges within the skin, although hypersensitivity to the bite can be the sole cause. Chronic lesions can present diagnostic problems when they take on a pseudolymphomatous appearance. [2]

ARACHNIDA

The Arachnida class includes three orders of medical interest: Acarina (ticks and mites), Araneae (spiders), and Scorpionida (scorpions). All adults in this class have four pairs of legs; the cephalothorax may vary, but it is typically fused. An exception to this rule is the larval stage of ticks (seed ticks), which have only three pairs of legs.

Acarina

The mites in the order Acarina of most interest to the clinician are the follicle mites, food mites, fowl mites, grain mites, harvest mites, murine mites, and scabies mites. With the exception of *Demodex* mites and scabies mites, these mites do not burrow and are known to drop off after feeding. [3] All mites may produce pruritus and/or allergic reactions through salivary proteins deposited during feeding. Although it is not possible to group all mites that cause human diseases into convenient categories, most of the more common mites can be grouped into three suborders:

Trombidiiformes: Harvest/chigger mites, family Trombiculidae; grain mites, family Pyemotidae; follicle mites, family Demodicidae.
Mesostigmata: Bird/rodent mites, family Dermanyssidae; straw mites, family Hemoganasidae.
Sarcoptiformes: Scabies mites, family Sarcoptidae; food mites, family Acaridae, family Glycyphagidae; mange, family Psoroptidae.
FOLLICLE MITES *Demodex* mites can be detected in sebaceous glands and hair follicles by skin biopsy of symptomatic and asymptomatic humans. [4] Whether *Demodex* is the etiologic agent in rosacea and other dermatoses, or whether its presence reflects asymptomatic commensalism, is not well documented. Symptoms produced by demodicidosis, if any, are more likely a result of immunologic rather than toxicologic reactions.
FOOD MITES Several species of mites that infest foodstuffs have been described. The grain mite, *Acarus,* the cheese mite, *Glyciphagus,* and the grocery mite, *Tyrophagus,* produce papular urticaria or vesiculopapular eruptions. An occupational history and negative skin scrapings are frequently required to separate these food mite–induced problems from scabies and other causes of papular urticaria. [5]
FOWL MITES Office workers, homemakers, poultry workers, and bird fanciers are all affected by mites that infest birds, especially pigeons that have nests or roosts near air conditioner intake ducts. *Dermanyssus gallinae* and *D. avium* are the most common fowl ectoparasites identified in the United States. These mites only temporarily infest humans. *Ornithonyssus bursa* transmit Western equine encephalomyelitis virus. [6]
GRAIN MITES The best studied grain mite of medical importance is the straw itch mite, *Pyemotes ventricosus*. *P. ventricosus* is primarily a parasite of insect larvae that feed on grain. *P. ventricosus* infests both animals and humans, occasionally producing unusual epidemics after an exposure to infested hay, grains, grasses, or straw. Affected patients often have systemic symptoms such as fever, diarrhea, anorexia, and malaise. Clinically, the lesions vary from bright red macules to varicelliform eruptions. However, *P. ventricosus* is often not identified in grain products because of a low index of suspicion. [5]
HARVEST MITES Perhaps the best-known cause of “bites” from mites in the United States is the chigger, mower, or harvest mite (*Eutrombicula alfreddugesi* and *E. splendeus*). In other parts of the world, trombiculid mites (*Leptotrombidium akamushi* and *L. deliense*) are the vectors for *Rickettsia tsutsugamushi,* the cause of scrub typhus. Contact with the chigger mite usually occurs during the summer and fall when outdoor activities are maximal. Frequently, the only sign of exposure is intense pruritus on the ankles, legs, or belt line, because the bright red mites (“red bugs”) typically fall off after feeding or may be scratched off. In nonsensitized individuals, usually only 1- to 2-mm pruritic macules are seen, which require minimal treatment. In sensitized or allergic individuals, the reaction to the chigger infestation may be papular urticaria, vesiculation, or a granulomatous reaction with fever and lymphadenopathy. Clinically, the distribution of the lesions may be confused with other dermatoses because the type of exposure and the clothing worn greatly affect where the mites attach. Occasionally, the mites can be identified by visual inspection. A unique clinical syndrome called “summer penile syndrome” is seen in toddler to school-age boys. Edema, pruritus, and excoriation of the glans and foreskin result from hypersensitivity to chigger bites. Partial phimosis may reduce urine stream. The mean duration is 4 days but the condition may last up to 18 days. [7]
ANIMAL MITES Two species of murine mites are of medical importance throughout the world: *Ornithonyssus bacoti* (tropical rat mite; vector of endemic/murine typhus), and *Allodermanyssus sanguineus* (the housemouse mite, a vector of rickettsialpox). Papular urticaria from bites are often acral and may exhibit secondary eczematization. Cheyletiellid mites are frequently harbored by dogs and cats, producing a condition sometimes referred to as “walking dander.” The pet may be asymptomatic, or may have seborrhea-like scale or crusted annular lesions, while the person holding the pet experiences marked pruritus when the mites penetrate clothing and temporarily feed on that individual's skin. Diagnosis depends on finding the mites on the pet by microscopically examining cellophane tape applied to the pet's skin or brushings from the animal. Treatment of the pet by a qualified veterinarian resolves the symptoms. [5], [6] Sarcoptic mange of dogs (*Sarcoptes scabiei* var. *canis*) and cats (*Notoedres cati*) may also affect humans. Lesions range from papular to pustular with intense pruritus, excoriation and crusting. The condition resolves after pets are cured. [8]
SCABIES MITES Scabies is discussed in Chap. 238. Because nonscabetic mites other than *Demodex* do not burrow into the skin, their treatment consists of a warm soapy bath to kill remaining larvae, an important step in the prevention of scrub typhus transmitted by trombiculid mites. The ultimate success of treatment in these nonscabetic cases also depends on treatment of the animal or food sources. Antipruritics are used as needed. Application of persistent pyrethroid compounds such as Permanone to cuffs, socks, shoes, and waistbands may reduce the attachment of chiggers in susceptible individuals. *N, N*-diethyl-3-methylbenzamide (DEET)-based insect repellants are of no value in preventing mite infestation. [5]
TICKS Ticks are the largest members of the order Acarina. They are important worldwide as vectors of systemic disease. Reactions to tick bites include foreign-body reactions, reactions to salivary secretions, reactions to injected toxins, and

hypersensitivity reactions. [3] Ticks are divided into the Argasidae (soft tick) and Ixodidae (hard tick) families (Fig. 239-1). The Ixodidae family is responsible for most tick-related diseases. Ticks are separated from other mites by the presence of a barbed hypostome, which they use for feeding. Using their toothed chelicerae, ticks tear open the epidermis and then insert the barbed hypostome. Salivary secretions are used to soften the epidermis as well. During the insertion process, a cement-like substance is secreted that hardens and firmly anchors the hypostome to the skin. Ticks feed for about 7 days until engorged and then drop off to continue their life cycle. [3] Tick bites occur most commonly in the spring and summer, coinciding with the life cycle of the tick. Ticks have four stages of the life cycle: egg, larva, nymph, and adult. All stages require a blood meal to advance to the next stage except the egg. Eggs are deposited in early spring and develop to larvae by summer. The larvae feed once on small rodents and then are inactive over winter. The following spring larvae develop to nymphs and again find a suitable host and feed. Generally this host is a small rodent, but larger animals and humans may also become hosts. Nymphs molt to become adults in summer. After finding a suitable host for a blood meal, the adult female survives through the winter to begin the life cycle with egg laying the following spring. Many different species of ticks are responsible for local tick bite reactions and transmission of diseases in humans. Among those most common in the United States are *Ixodes scapularis, I. pacificus, Amblyomma americanum* (Lone Star tick), *Dermacentor andersoni* (American wood tick), and *D. variabilis* (American dog tick). In Europe, *I. ricinus* and *I. persulcatus* are important vectors of disease, especially Lyme disease. Lyme disease is discussed in greater detail in Chap. 203. Depending on the species of tick, the bite of the tick may or may not be painful or pruritic. In many instances, victims are not even aware that they have been bitten and there may be only a red papule at the bite site. This papule can progress to local swelling and erythema. Blistering, severe pruritus, and ecchymosis can be seen. A cellular reaction to the bite can lead to induration and nodularity after a few days. Central necrosis and ulceration rarely occur. [3] The usual bite heals in 2 to 3 weeks, although chronic tick bite granulomas may persist for months to years. Persistent papules respond to intralesional glucocorticoid injections.

Tick paralysis Tick paralysis is thought to be caused by a toxin secreted in the saliva of the tick, although the exact nature of the toxin is unknown. Typically, the tick is attached from 4 to 7 days before the onset of symptoms. The paralysis is an acute ascending lower motor neuron paralysis that rapidly resolves after the tick is removed. [9], [10] Treatment, which may require respiratory support, is merely supportive until the symptoms resolve.

Ehrlichiosis Two new forms of ehrlichiosis transmitted by tick vectors now occur in the United States. Monocytic ehrlichiosis is caused by *Ehrlichia chaffeensis* invading mononuclear white blood cells. The more recently described human granulocytic ehrlichiosis (HGE) is caused by an organism identical to *E. equi.* The invasion of neutrophils in this disorder leads to the characteristic intracytoplasmic inclusions (morulae) in peripheral blood neutrophils. Patients present with nonspecific findings of fever, chills, headache, and myalgias along with leukopenia, anemia, and thrombocytopenia. No cutaneous findings have been reported in HGE, but a diffuse macular erythema is noted in 36 percent of patients with monocytic ehrlichiosis. [11], [12]

Southern erythema migrans A new Lyme disease–like condition has been reported in many southern U.S. states. Clinical features include erythema migrans, fever, stiff neck, headache, myalgia, and arthralgia. No neurologic, arthritic, or cardiac sequelae have been noted. The putative etiologic agent is *Borrelia lonestari,* transmitted by *Amblyomma americanum* from its primary lizard host. Although *B. burgdorferi* is found in the southern United States, lizards are poor hosts for this organism. Serologic testing with a Lyme disease enzyme-linked immunosorbent assay (ELISA) shows cross-reactivity. No cross-reactivity is seen with the Western blot technique. [11], [12] Ticks are important vectors of many other diseases to humans. They play a role in transmitting viruses, rickettsia, parasites, spirochetes, and bacteria. [11], [12] and [13] Preventing bites is the most important measure in controlling both local and systemic tick-related diseases. When exposure is anticipated, proper clothing should be worn and appropriate repellents used. Immediately after potential exposures, the skin should be carefully inspected for ticks in an attempt to remove them before they become embedded or transmit disease. Evidence suggests that the tick must remain attached for more than 24 h in most cases to transmit Lyme disease. Once the tick's hypostome is secure to the skin, the tick must be forced to remove it. A colorful array of remedies has been recommended for removing the tick. Physical methods such as slow steady pulling on the tick, with or without twisting, are advised. If the hypostome is retained in the skin when the tick is extracted, it should be removed surgically. Foreign-body reactions and persistent papules are produced if tick parts remain in the wound.

Araneae

Spiders belong to the class Arachnida and are differentiated from insects by the presence of two separate body parts with five paired appendages and the absence of antennae. Spiders are carnivorous and either capture their prey in webs or attack them and inject venom through their chelicera (mandibles). In the United States, the genera *Loxosceles, Latrodectus,* and *Tegenaria* are the only species whose venom produces significant toxic effects in humans. Wolf spiders, tarantulas, jumping spiders, orb weavers, and crab spiders rarely produce cutaneous lesions by other mechanisms, such as the trauma of the bite or secondary infection. [1]

LOXOSCELES There are 13 different species of *Loxosceles* in the United States, and five of them, *L. reclusa, L. deserta, L. arizonica, L. laeta,* and *L. rufescens,* are associated with cutaneous loxoscelism. [1], [14] The brown recluse spider, *L. reclusa,* typifies the species and is widely distributed throughout the Southeast and the Midwest. It is often called the violin or fiddleback spider because of the violin-shaped figure on its dorsal cephalothorax (Fig. 239-2). Adult body size is 8 to 9 mm, with leg span up to 5 cm, depending on diet and habitat. Although its natural habitat is outdoors under dry overhanging rocks and cliffs, human environmental controls have caused it to move indoors and expand its range. Despite its usually timid nature, this spider will bite when trapped or threatened via chance encounters with humans. Because the brown recluse spider hibernates in the winter, most bites occur between March and October when humans disturb their habitat (closets, attics, outbuildings).

FIGURE 239-2 Brown recluse spider. Characteristically there are six eyes in three pairs and fiddle-shaped markings on the cephalothorax.

The venom of the brown recluse spider contains at least nine protein fractions. [15] These include sphingomyelinase D, alkaline phosphatase, 5'-ribonucleotide phosphohydrolase, hyaluronidase, and esterase. A major fraction is the 32- to 34-kDa protein sphingomyelinase D. This venom fraction aggregates platelets, generates leukocyte chemoattractants, and liberates thromboxane B_2 in vitro. It is also responsible for direct erythrocyte lysis in a calcium-dependent mode. In addition, the venom induces release of granulocyte-macrophage colony-stimulating factor, interleukin-8, and E-selectin, effects similar to those of tumor necrosis factor-a. The venom produces typical skin necrosis when injected into rabbits. Reported responses to envenomation range from a mild local urticarial reaction to full-thickness skin necrosis. The bite itself is generally painless, and findings of a central papule and associated erythema may not be seen for 6 to 12 h. Few envenomations, perhaps less than 10 percent, lead to severe skin necrosis or other systemic manifestations. Wounds destined for necrosis generally show signs of progression within 48 to 72 h of the bite. [16] Central blistering with a surrounding gray to purple discoloration of the skin may be seen at the bite site. A surrounding ring of blanched skin is itself surrounded by a large area of asymmetric erythema leading to the typical “red, white, and blue” sign of a brown recluse bite (Fig. 239-3A). At this stage of evolution, these bites may be associated with significant pain related to incipient necrosis of skin and subcutaneous tissues. The resultant necrotic skin ulcer heals slowly (Fig. 239-3B) and may require skin grafts or flaps to reconstruct the defect. A retrospective review of confirmed cases demonstrated correlation between severity and healing time. Grade 3 lesions (necrosis >1 cm) required an average of 74 days to heal.

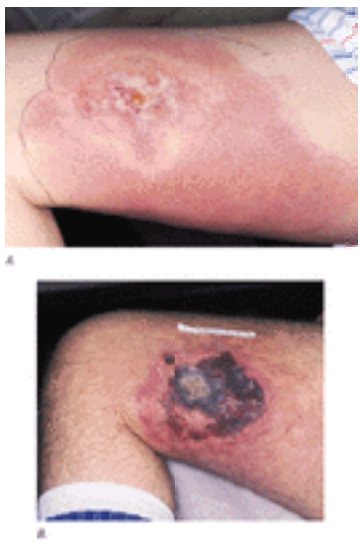

FIGURE 239-3 *A*. Clinically typical brown recluse spider bite showing the “red, white and blue” sign. *B*. Late ulcerative brown recluse spider bite with overlying eschar.

A systemic reaction may be seen in the first 24 to 48 h after envenomation. Features may include a diffuse macular erythema, fever, chills, malaise, arthralgias, headache, nausea, and vomiting. Thrombocytopenia, hemolytic anemia, transient leukocytosis, and consumptive coagulopathy have been noted. Hemolysis, if severe, may induce profound hemoglobinuria and renal insufficiency. Renal failure, seizures, and death have been reported, although the cases are often unconfirmed. Death is rare with brown recluse bites. The histologic findings of bites are nonspecific, and such studies should not generally be pursued unless other etiologies are strongly considered. Findings include acute vasculitis, platelet thrombi, and leukocyte infiltrates. [15], [16], [17], [18] and [19] Because the clinical appearance of a brown recluse spider bite is nonspecific, diagnosis may be difficult. The potential for exposure to *Loxosceles* spiders, identification of the arachnid, appearance of the lesion, and clinical course must all be considered. Of these, only identification of the captured spider allows for definitive diagnosis of *Loxosceles* envenomation. Laboratory tests for diagnosis are not currently available. Laboratory tests to assess for potential complications such as hemolysis are in order, particularly in children. A broad differential diagnosis must be entertained to include reactions to other biting organisms, allergic reactions, trauma, herpetic eruptions, skin abscesses, and pyoderma gangrenosum. The treatment of brown recluse spider bites remains controversial. Rest, ice compresses, and elevation are useful in reducing erythema and swelling. Aspirin may help reduce platelet aggregation and thrombosis. Tetanus prophylaxis must be current. Antibiotics have been found useful to reduce the comorbid secondary infection risk. Analgesics may be required. A controversial remedy used successfully by the authors, both experimentally and clinically, is the sulfone-based leukocyte-inhibitor dapsone. [15], [16], [17], [18] and [19] Years of successful anecdotal use, supportive animal studies, an uncontrolled human trial, and the neutrophil-dominant pathophysiology of the bite reaction combine to support its use. Glucocorticoids have not proved useful for the local necrotic wound but do have a role in systemic reactions with hemolysis, especially in children. The steroid membrane–stabilizing effect and relative renal protection may improve outcome. Acute excision of the bite site should be avoided because the inflammatory reaction produced by the venom will inhibit wound healing and produce an inferior clinical result. [15], [16], [17] and [18] Surgical management should be postponed until wounds have stabilized with medical management and are no longer progressing.

TEGENARIA The bite of the Hobo spider, *T. agrestis,* has become an important consideration in the differential diagnosis of necrotic skin lesions in the Pacific Northwest regions of the United States. This relatively large spider in the family Agelenidae has a body length of 10 to 13 mm with a leg span of approximately 4 cm. Funnel webs are built in bushes, cracks in masonry, window wells, stacked firewood, and other crevices. When disturbed, the spider inflicts a painless to slight pinprick bite. Erythema, induration, and local paresthesia develop within minutes. Vesicle formation occurs within 36 h, often with hemorrhage into the vesicles. Local necrosis may ensue, covered by eschar within a few days. The main systemic feature is a severe, and perhaps prolonged, headache. Nausea, weakness, paresthesias, vomiting, and diarrhea have been reported. The venom effects and appropriate treatment have not been elucidated. [17], [20], [21], [22] and [23]

LATRODECTUS Several different species of *Latrodectus* spiders exist in the United States, but the fame and fear of *L. mactans,* the black widow, far exceed the others. *L. mactans* is the most common of the North American “widow” spiders, but *L. variolus* and *L. hesperus* can also be commonly found in a more limited distribution. All three of these spiders have the characteristic red hourglass or double triangle on the ventral surface of the abdomen; the age of the spider determines the relative amount of red on the abdomen (Fig. 239-4). The red-legged widow, *L. bishopi,* is found only in southern Florida, while the brown widow, *L. geometricus,* is rarely found in the United States. Females are significantly

larger than males (leg span up to 40 mm) and are the only spiders capable of envenomation. Black widows spin their large irregular “tangled” webs close to the ground under debris, over hollow stumps, under woodpiles, or in front of rodent burrows. Clinging upside down to the web, they wait for prey to become entangled in the web and then quickly paralyze the prey with a bite. [24]

FIGURE 239-4 Black widow spider, with eight eyes; it is shiny black, usually with a red hourglass marking on the underside of its abdomen.

The venom of the black widow spider contains a neurotoxin known as alpha-latrotoxin. This toxin acts to destabilize nerve cell membranes by opening ionic channels at the synapses. Acetylcholine is then irreversibly released at motor endplates of neuromuscular synapses. The sympathetic and parasympathetic nervous systems are affected as well, with release of adrenaline and noradrenaline from peripheral nerves. [25] Clinically, bites may be sensed as a pinprick or a sharp pinch. Dull aching pain or a numb sensation ensues 30 to 40 min after the bite. Skin manifestations are limited to slight erythema, local piloerection, mild edema or urtication, local perspiration, and possibly lymphangitis. Systemic symptoms peak at 1 to 8 h after the bite and may last 24 to 48 h. Severe pain in local muscle groups spreads to regional muscle groups. The characteristic crampy abdominal and chest pain may lead to confusion with acute appendicitis, renal colic, or acute myocardial infarction. Headache, restlessness, anxiety, fatigue, insomnia, salivation, lacrimation, diaphoresis, tremors, tachycardia, bradycardia, hypertension, shock, seizures and, coma have all been associated with latrodectism. Death from documented bites occurs in fewer than 1 percent of reported cases. [26] Diagnosis depends on recognition of a consistent history and typical physical findings. Most bites do not result in severe symptoms. In a study of bites of the red-back spider in Australia, 76 percent of victims had only local symptoms. [27] Laboratory evaluation is not helpful, although hemoglobinuria, albuminuria, and leukocytosis may be found. Treatment of most cases of latrodectism is supportive and generally does not require hospitalization. Exceptions to this rule include the very young and the very old and persons with cardiovascular disease, who are at greater risk for complications. Traditional treatment with intravenous calcium gluconate (10%) and muscle relaxants (methocarbamol, diazepam) has proved effective in most patients. Relief of pain with narcotics may reduce the severity of symptoms and muscle spasms. [26] Because antivenin is prepared in horses, it should be used only for severe envenomations in persons not allergic to horse serum.
TARANTULAS Tarantula injuries (family Theraphosidae) include mild transient bite reactions, and more severe cutaneous and ocular injury from abdominal urticating hairs. When cornered or threatened, tarantulas use their hind legs to flick needle-like hairs off the dorsal abdomen. These embed in the skin, producing local pruritus to granulomatous foreign-body reactions. Topical glucocorticoids provide prompt relief. Ocular injuries range from brief keratoconjunctivitis responsive to topical steroids, to severe pan-uveitis with corneal granulomas, iritis, cataract, vitreitis, and chorioretinitis. Ophthalmologic evaluation is mandatory. [28] Numerous other spiders have been implicated in human envenomation, including the Australian funnel-web spider *Atrax robustus*. Detailed consideration of all dangerous spiders is beyond the scope of this text. [17]
SCORPIONS Scorpions are of medical interest primarily in tropical and/or arid areas such as parts of the southwestern United States, Mexico, India, and the Middle East. Although capable of producing painful local wounds, the primary concern over scorpion envenomation involves the potential for serious cardiovascular complications, which can be lethal. [3]

CHILOPODA AND DIPLOPODA

Centipedes and millipedes superficially resemble each other, having one pair of legs and two pairs of legs per segment, respectively.

Centipedes

Centipedes are nocturnal carnivores and may produce painful wounds by discharging venom through their claws as they grip the victim. In addition to severe pain, localized sweating, erythema, edema, bleeding, secondary infection, and ulceration may be seen. [29] Local injections of an anesthetic may be used to control pain. Antibiotics to control infection and glucocorticoids to control inflammation may be necessary.

Millipedes

Millipedes are generally harmless vegetarians that neither bite nor envenomate. However, when disturbed or threatened they emit a toxic substance from repugnatorial glands on each side of each segment. This fluid may produce burning, blistering, and pigmentation of the skin. If introduced into the eye, it may cause severe inflammation. For skin contact, no treatment is usually necessary other than thorough washing of the skin as soon as possible. [30]

INSECTA

Anoplura

Only two species of Anoplura, *Phthirius pubis* and *Pediculus humanus,* are host-specific parasites of humans. [1] Diseases associated with lice are detailed in Chap. 238.

Coleoptera

Five families of Coleoptera produce chemicals that induce blistering or vesiculation upon contact with human skin: Meloidae, Staphylinidae, Paussidae, Coccinellidae, and Edemeridae. The Spanish fly, *Lytta vesicatoria* (family Meloidae), is the most famous of the blister beetles. Although these beetles neither bite nor sting, they produce blisters because of the chemical cantharidin contained in their bodies. This chemical may be emitted by the beetle, but it is most often encountered when the beetle is crushed against the skin. Several other beetle species, which contain chemicals similar to cantharidin, may be the cause of blisters in various geographic areas. [31] A characteristic clinical feature of blisters from beetles is kissing or touching lesions, which may produce infection and ulceration. Rove beetles (genus *Paederus*) contain the vesicant pederin. These beetles are associated with a blistering dermatitis, *Paederus dermatitis,* in various areas of the world. [32] The common carpet beetle (*Anthrenus scrophulariae*) is associated with a papulovesicular dermatitis. This condition appears to be caused by an allergic response to the larvae of the beetle and not to the beetle itself. [33] If contact with a beetle is suspected early, washing the skin with soap and water may prevent vesiculation. Symptomatic treatment with wet compresses and topical or systemic glucocorticoids may be needed.

Diptera

The order Diptera consists of the two-winged, or true, flies. Collectively, its members are responsible for the transmission of more diseases worldwide than any other arthropod order.

MOSQUITOES The mosquitoes of the family Culicidae are vectors for disease throughout the world. These include malaria, yellow fever, dengue, and filariasis, as well as encephalitis viruses. In the continental United States, females of the genus *Aedes* are the most common cause of mosquito bites. The cutaneous reaction is produced when the female mosquito's serrated jaws disrupt the skin and she inserts her blood tube. Irritating salivary secretions are injected to anticoagulate the blood and are responsible for the edema, pruritus, and papular lesions. Mosquito bites may have an urticarial, eczematoid, or granulomatous appearance, depending on the sensitivity of the victim. Mosquitoes prefer the young to the old, warm to cool skin, and scented to unscented victims. They also are attracted to bright colors and elevated carbon dioxide concentrations in the air.
BLACK FLIES The black flies of the family Simuliidae are also bloodsuckers. Also known as buffalo gnats, these hump-backed insects are found in tremendous swarms near fast-moving water in the late spring and early summer. Because this black fly injects an anesthetic into the wound, the initial bite is painless. However, the bite subsequently becomes extremely painful with itching, erythema, and edema, which may lead to nummular eczema, vesicles, or hard pruritic papules. A systemic reaction, termed *black fly fever,* which produces headache, fever, nausea, and generalized lymphadenitis, has been reported. [1] Black flies are vectors in the transmission of onchocerciasis (river blindness) and tularemia (see Chap. 236 and Chap. 199, respectively).
MIDGES The biting midges of the genus *Culicoides* (family Ceratopogonidae), are also called punkies, no-see-ums, and sand flies. Although ordinarily producing only a painful bite, they can be the vectors for filariasis caused by *Mansonella* species. The midge bites produce immediate pain with erythema at the bite site and 2- to 3-mm papulovesicles, followed by indurated nodules of up to 1.0 cm which persist for many months. [34]
TABONIDS The large family Tabanidae are ferocious bloodsucking flies and include horseflies, deerflies, clegs, breeze flies, greenheads, and mango flies. Species of the genus *Chrysops* (deerfly) are known to transmit loiasis and tularemia. [1] Because they are large flies (6 to 25 mm) with bladelike mouth parts, their bite is painful and may bleed vigorously. The cutaneous welt that is produced may be accompanied by urticaria, dizziness, weakness, wheezing, or angioedema.
MYIASIS Cutaneous myiasis occurs when various species of fly larvae penetrate the skin or are deposited onto open wounds. Larvae may be fixed to one site or may be migratory, simulating larva migrans. Larvae of the human botfly, *Dermatobia hominis,* are a cause of furuncular myasis. This fly is distributed throughout Central and South America. These painful lesions resemble a pyogenic furuncle, but lack of response to antibiotics points to the correct diagnosis (Fig. 239-5). [35]

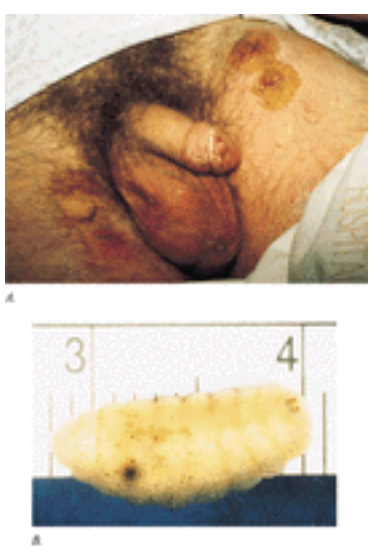

FIGURE 239-5 Myiasis. *A.* Abscesses which contain the larval form of *Dermatobia hominis* are seen in the genital area and thighs. *B.* Larva removed from the abscess.

SANDFLIES Phlebotomid sandflies are aggressive biters that produce pruritic, inflamed, indurated lesions. More importantly, they are responsible for transmission of leishmanial parasites throughout the world. Leishmania is discussed further in Chap. 235.
TSETSE FLIES The tsetse fly (*Glossina* species) serves as the vector for African trypanosomiasis. The bite produces minimal cutaneous reaction. African trypanosomiasis is discussed in Chap. 235.
TREATMENT The treatment of Diptera bites requires meticulous attention to wound care by cleansing with soap or other antiseptics to avoid secondary infection. Local application of steroid ointment and systemic treatment with antihistamines

will reduce itching and redness. Although systemic allergic reactions are rare, they should be treated aggressively with epinephrine, fluids, glucocorticoids, and supportive care. Furuncular myiasis is best treated by local surgical excision of the larva and surrounding tissue.

Hemiptera

Most of the Hemiptera order feed on plants. Only the Cimicidae and Reduviidae families commonly feed on animals, including humans.

CIMICIDAE (BEDBUGS) Several genera have members that are commonly grouped as bedbugs: *Cimex, Leptocimex, Oeciacus,* and *Hematasiphon*. Bedbugs are characteristically very flat dorsoventrally with broad bodies measuring up to 8 mm long. Given their small size and nocturnal feeding habits, the diagnosis of bedbug bites may not be clinically obvious. Bedbugs are not vectors for disease, but large numbers of pruritic bites can lead to considerable distress. The clinical findings may range from a few linear purpuric macules to generalized allergic reactions in sensitized individuals.
REDUVIIDAE (KISSING BUGS, ASSASSIN BUGS, CONE-NOSED BUGS) Several species of Reduviidae transmit *Trypanosoma cruzi,* the etiologic agent in Chagas disease. Genera involved in transmission of Chagas disease include *Triatoma, Rhodnius,* and *Panstrongylus*. Most species are encountered in the Americas with a few in Africa, Asia, and Europe. While the defensive bites of many reduviids are extremely painful, the feeding bites are typically painless. Clinically, the lesions produced by Reduviidae are similar to those from other arthropods and depend on the species, type of exposure, and individual sensitivity. However, defensive reduviid bites may produce severe local reactions, occasionally resulting in necrosis and ulceration. The pathogenesis and clinical findings of Chagas disease are discussed in Chap. 235.

Hymenoptera

The general family Hymenoptera includes bees (Apidae and Bombidae), wasps and hornets (Vespidae), and ants (Formicidae). [1] These insects are notorious for their painful stings, which may be associated with an anaphylactic reaction and/or death.

BEES, WASPS, HORNETS Stings by the female bee, hornet, or wasp from the modified ovipositor (stinger apparatus) produce immediate burning and pain followed by an intense, local, erythematous reaction with swelling and urticaria. The honeybee leaves a barbed ovipositor and paired venom sacs impaled in the victim. The method of removal of the stinger appears less important than the speed with which it is removed. [36] The honeybee dies after stinging. Other Hymenoptera do not lose their stinging units and may use them repeatedly. Severe systemic reactions occur in 0.4 to 0.8 percent of patients and are divided into three categories: angioedema or generalized urticaria; respiratory insufficiency from laryngeal edema or bronchospasm; and shock. Occasionally, major local reactions may persist at the bite site, presumably mediated by cellular immune mechanisms. [37] The acute treatment of Hymenoptera stings is based on the severity of patient response. Cutaneous reactions may be managed by application of ice and local injection of lidocaine to relieve pain. Hypotension and respiratory failure must obviously be treated vigorously. Systemic reactions require administration of subcutaneous epinephrine, while glucocorticoids and antihistamines may be helpful for urticaria or edema. If a patient experiences an anaphylactic reaction and has a positive skin test, desensitization should be strongly considered. [38]
ANTS Fire ants of the genus *Solenopsis* are aggressive and produce local skin necrosis and systemic reactions when they sting. [39] Imported fire ant venom contains a nonproteinaceous, hemolytic factor identified as a dialkylpiperidine derivative, solenopsin D, which induces the lytic release of histamine and other vasoactive amines from mast cells. Clinically, the bite site starts as an intense local inflammatory reaction that becomes a sterile pustule. [39] The imported fire ants (*S. invicta*) are particularly vicious because they attack in groups. By securing its jaw in the victim's skin, the fire ant is able to pivot, thereby leaving a ring of pustules. Because there is no specific therapy for ant stings, therapy is symptomatic. Systemic reactions occur frequently and may require glucocorticoids or antihistamines. Desensitization may be helpful to protect allergic patients. [39]

Lepidoptera

The Lepidoptera order is medically important solely because of the irritant and allergenic properties of the hairs from caterpillars and moths. Contact with caterpillars results in burning and itching or even a stinging reaction in the case of the puss caterpillar (*Megalopyge* species) (Fig. 239-6). Skin lesions typically appear as papular urticaria, which can become generalized in severe cases. Systemic reactions to some species have been reported. [40] At least one caterpillar species (gypsy moth, *Lymantria dispar*) may cause irritation because of histamine contained in the lancet hairs, but the allergic potential of the same caterpillar hairs has also been demonstrated. [41] Wind-borne dissemination of these hairs may lead to dermatitis as well as keratoconjunctivitis. [42] Whether most urticating caterpillar dermatoses are caused by histamine, by allergic reactions, or by both is not clear. [40] The caterpillars and moths most commonly assumed to cause these problems in the United States and Latin America are the following:

Caterpillars: Brown-tailed moth (*Euproctis chrysorrhoea*); io moth (*Automeris io*); puss or flannel moth (*M. opercularis*); saddleback moth (*Sibine stimulae*).
Moths: Lymantriidae family, tussock moths; brown-tailed moth (*E. chrysorrhoea*); gypsy moth (*L. dispar*); Douglas fir tussock moth (*Hemorocampa pseudotsugata*); silk or peacock moth (Saturniidae family); silk moth (*Hylesia* species); io moth (*A. io*).

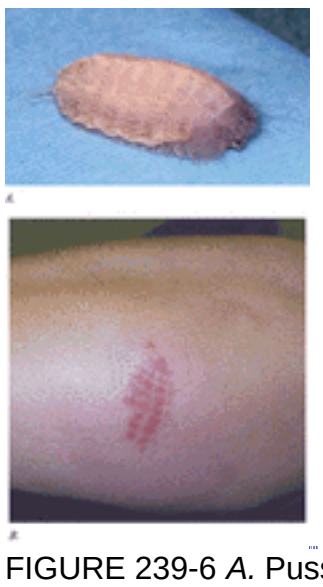

FIGURE 239-6 *A.* Puss caterpillar (*Megalopyge opercularis*) demonstrating the corresponding gridlike pattern of its hairs. *B.* Cutaneous reaction from contact with a puss caterpillar showing the typical gridlike pattern.

Siphonaptera

Fleas have a unique body shape that is flattened laterally rather than dorsoventrally. Their ability to jump to a height of 18 cm aids in their movement from host to host.

The Pulicidae family is of interest because certain species, most notably the rat fleas (*Xenopsylla cheopis* and *x*. *brasiliensis*), transmit bubonic plague and endemic typhus. Cat fleas (*Ctenocephalides felis*), dog fleas (*C*. *canus*), and bird fleas (*Ceratophyllus gallinae*) also transmit diseases. *C*. *felis* can be the vector for cat-scratch disease, bacillary angiomatosis, and endemic typhus. [43] All species bite humans because host specificity is relatively low; severe attacks may occur where infested domestic animals and birds have recently resided. Survival of adult fleas for months in the absence of host animals makes flea-borne epidemics difficult to detect and eradicate. Usually, flea bites cause minimal irritation in a nonsensitized person and produce typically linear or clustered urticarial papules. Bites are frequently found on the lower leg. In allergic individuals, lesions are much more severe; blisters and even erythema multiforme can develop (Fig. 239-7).

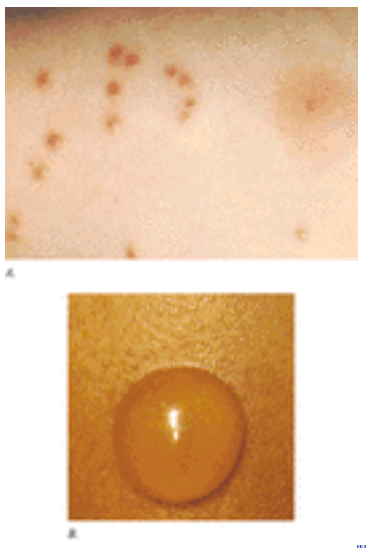

FIGURE 239-7 Insect bites. *A.* Papular urticaria. Bites of fleas and bedbugs can present with the clinical picture of multiple, extremely pruritic, edematous papules. *B.* Bullous lesions occur most commonly with flea bites, but also occur with bedbugs or contact with blister beetles on the skin.

In the Tungidae family, only *Tunga penetrans,* the chigoe or sand flea, is well known to produce problems. The female sand flea burrows into the dermis of the animal host. A painful necrotic abscess forms around the site of the female sand flea and her eggs. Secondary infection and scarring are the usual major complications, although tetanus can develop in these wounds. Treatment consists of systemic antibiotics after sterile removal of early lesions, or killing the adult female with a suitable agent. Late lesions resolve by spontaneous ulceration. [44]

PREVENTION

Insect repellents containing DEET are the most effective preventive agents for persons bothered by fleas, flies, mosquitoes, and ticks. For most circumstances, products containing 10% to 35% DEET provide protection. This product has an excellent safety record, but there are reports of encephalopathy in children exposed to excessive amounts of higher concentration products. For this reason, children should use products containing no more than 10% DEET. Passive measures such as screens, nets, and clothing, are also effective in preventing bites. Permethrin spray can be applied to clothing or other fabrics such as tents. Permethrin acts as a contact insecticide rather than as a repellent. Combined use of permethrin-treated clothing with DEET applied to skin gives maximum protection. While the protective effects of permethrin applied to fabrics remains fairly stable over time, DEET efficacy falls over several hours. Heat and humidity accelerate this loss of efficacy. Under such circumstances, slow-release formulations may provide more effective protection. [45]

Plant-derived products, such as citronella, are available. These products generally demonstrate less efficacy and shorter

duration of action relative to DEET. [45]

No preventive measures other than killing the adult or larval forms of bees, spiders, or wasps are currently available.

A variety of insecticides are available for individual or professional use. Proper use of these agents is important in the eradication of field ectoparasites inhabiting inanimate objects such as clothing, furniture, carpets, draperies, and pet bedding. Optimal results from insecticides may require consultation with a professional exterminator.

A BRIEF HISTORY OF EVIDENCE-BASED MEDICINE

Medical practitioners have had to face the problem of distinguishing treatments that are effective from those that are ineffective or harmful since the beginning of medicine. Evidence-based medicine is a method designed to help practitioners best meet this challenge. The origin of evidence-based medicine is most often traced to Pierre Charles Alexander Louis, who introduced the teaching of statistical methods into the study of medicine in postrevolutionary France. [1], [2] Epidemiologists and public health researchers have developed excellent quantitative skills, traceable in part to his "methode numerique," which is credited as forming the basis of epidemiology. [3]

There is some debate as to the identity of the first controlled clinical trial. [4] In 1545, Ambroise Paré compared the treatment of wounds with dressings of onions, traditional dressings, or no dressings. Crushed onions seemed to be more effective. In 1753, James Lind compared six alternative treatments on 12 sailors with scurvy and noted that the two sailors prescribed oranges and limes recovered more quickly than did the others. Johanes Fibiger used alternate-day allocation of patients admitted to the hospital with diphtheria to demonstrate that diphtheria serum was more effective than no serum. [4]

However, these early efforts at controlled clinical trials had little impact on medical decision making. Prior to the 1940s, determination of treatment efficacy was based on expert opinion, trial and error, uncontrolled observation, and small case series. The only treatments that could be distinguished as effective were those that produced dramatic increases in survival, such as streptomycin for tuberculosis meningitis. The publication of the randomized controlled clinical trial (RCT) that demonstrated that streptomycin was effective in the treatment of pulmonary tuberculosis was a landmark event. [5] Since then, the RCT has become the gold standard for determining the efficacy of therapeutic interventions.

Hundreds of RCTs were conducted between 1950 and the 1970s. However, their results were not catalogued or used systematically to inform medical decision making. In 1971 Archie Cochrane, a British epidemiologist and physician, published his response to being asked to evaluate the effectiveness of the British National Health Service in delivering health care to the population of the United Kingdom. In his analysis, he concluded that medical science was poor at distinguishing interventions that were effective from those that were not, and that physicians were not using available evidence from clinical research to inform their decision making. [6]

Groups of like-minded epidemiologists and physicians responded to Archie Cochrane's challenge by examining the methods by which medical decisions and conclusions were reached and proposed an alternative based on finding, appraising, and using available data from clinical research done on intact patients. [7] In 1985, Sackett, Haynes, Guyatt, and Tugwell published *Clinical Epidemiology: A Basic Science for Clinical Medicine,* which detailed the rationale and techniques of this evidence-based approach. [7] These authors and others reduced the rules of evidence to a small subset of principles that were easier to teach and to understand, and reintroduced the concept in 1992. [8] They named this technique "evidence-based medicine" (EBM). It was defined as the conscientious, explicit, and judicious use of the best current evidence in making decisions about the care of individual patients. [8] Although making decisions about therapy has been the primary focus of EBM, its principles have been extended to diagnosis, prognosis, harmful effects of interventions, cost effectiveness, and economic analyses.

Results from well-designed clinical studies on patients are at the pinnacle of the hierarchy of evidence used to practice evidence-based medicine. When reading recommendations about treatment, diagnosis, and harm made in this textbook and in other sources, one should take into account the validity, magnitude, precision, and applicability of the evidence upon which it is based.

The introduction of EBM was met with considerable hostility. It was perceived as cook book medicine, old hat, too restrictive, and an insult to those already trying to practice good medical care. The definition was softened to include the integration of individual clinical expertise, best available external clinical evidence from systematic research, and patient's values and expectations. [2]

The Cochrane Collaboration was formed to an extent in response to Archie Cochrane's challenge to organize a critical summary, by specialty or subspecialty, adapted periodically, of all relevant randomized controlled trials. [9] Through collaborative efforts of volunteers, the Cochrane Library is an impressive and useful compendium of systematic reviews, abstracts of systematic reviews, and the Cochrane Controlled Trials Registry, a database of more than 300,000

controlled clinical trials (http://www.cochrane.org/). The Cochrane Library is the most complete and best indexed database of RCTs and controlled clinical trials, and is the best and most efficient place to find evidence about therapy.

Evidence-based medicine acceptance in the specialty of dermatology has been slow. The term and principles are understood by few and misunderstood by many. It is perceived as an attempt to cut costs, impose rigid standards of care, and to restrict physician freedom to exercise individual judgment. Practicing EBM in dermatology is hampered by the continued belief among dermatologists that clinical decision can be guided by understanding the pathophysiology of disease, logic, trial and error, and nonsystematic observation. [1], [10] It is hampered also by a lack of sufficient data in many areas. This chapter reviews the guiding principles and techniques of EBM. As with EBM in general, we concentrate primarily on therapy; however, evidence-based approaches to diagnoses and harm are briefly covered.

WHAT IS “THE BEST EVIDENCE?”

Practicing EBM is predicated on finding and using the best evidence. Potential sources of evidence include understanding the etiology and pathophysiology of disease and logic, personal experience, colleagues or experts, textbooks, articles published in journals, and systematic reviews. An important principle of EBM is that the quality (strength) of evidence is based on a hierarchy of evidence. The order of the hierarchy of evidence is dependent on the type of question being asked (Table 240-1). [11] This hierarchy consists of results of systematic reviews of well-designed studies (especially if the studies have results of similar magnitude and direction, and if there is statistical homogeneity among studies), results of one or more well-designed studies, results of large case series, expert opinion, and personal experience in descending order. [9], [10] The hierarchy was created to encourage the use of the evidence that is most likely to be true and useful in clinical decision making. The ordering of this hierarchy has been widely discussed, actively debated, and sometimes hotly contested. [12]

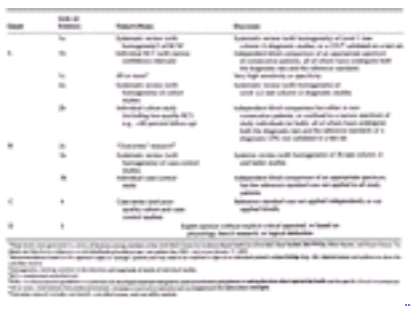

TABLE 240-1 **Grades of Evidence*†**

A systematic review is an overview that answers a specific clinical question, contains a thorough, unbiased search of the relevant literature, explicit criteria for assessing studies, and structured presentation of the results. A systematic review that uses quantitative methods to summarize results is a meta-analysis. [13], [14] Meta-analysis provides an objective and quantitative summary of evidence that is amenable to statistical analysis. [13] Meta-analysis is credited with allowing recognition of important treatment effects by combining the results of small trials that individually lacked the power to demonstrate differences among treatments. For example, the benefits of intravenous streptokinase in acute myocardial infarction were recognized by the results of a cumulative meta-analysis of smaller trials at least a decade before it was recommended by experts and before it was demonstrated to be efficacious in large clinical trials. [15], [16] Meta-analysis has been criticized for the discrepancies between the results of meta-analysis and the results of large clinical trials. [16], [17], [18] and [19] For example, results of a meta-analysis of 14 small studies of calcium to treat preeclampsia showed benefit of treatment, whereas a large trial failed to show a treatment effect. [16] The frequency of discrepancies ranges from 10 to 23 percent. [16] Discrepancies can often be explained by differences in treatment protocols, heterogeneity of study populations, or changes that occur over time. [16]

Publication bias is an important concern about systematic reviews. It results from allowing factors other than the quality of the study to influence its acceptability for publication. Several studies show that factors such as sample size, direction, and statistical significance of findings, or investigators' perception of whether the findings are “interesting,” are related to the likelihood of publication. [20], [21] For example, in a study by Dickersin et al., reasons given that completed studies were not published included “negative results” (28 percent), “lack of interest” (12 percent), and “sample size problems” (11 percent). [20] Studies with small samples are less likely to be published especially if they have negative results. [20], [21] This type of publication bias jeopardizes one of the main goals of meta-analysis (i.e., an increase in power when pooling results of small studies). Creation of study registers and advance publication of research designs have been proposed as ways to prevent publication bias. [22], [23] Publication bias can be detected by using a simple graphic test (funnel plot) or by calculating the “fail-safe N.” [24], [25] In addition, for many diseases, the studies published are dominated by drug company–sponsored trials of new, expensive treatments. The needs for studies to answer clinical questions of most concern to practitioners are not addressed because sources of funding are inadequate.

Not all systematic reviews and meta-analyses are equal. A systematic review can only be as good as the clinical trials that it contains. The criteria to critically appraise systematic reviews and meta-analyses are shown in Table 240-2. Detailed explanations of each criterion are available. [13], [26]

Are the results of this systematic review valid?
Did the review address a focused clinical question?*
Were the criteria used to select articles for inclusion appropriate?*
Is it unlikely that important, relevant studies were missed?*
Was the validity of the included studies appraised?*
Were assessments of studies reproducible?†
Were the results similar from study to study?†
Are the valid results of this systematic review important?
What are the overall results of the review?
How precise were the results?
Can you apply this valid, important evidence in caring for your patient?
Can the results be applied to my patient's care?
Were all clinically important outcomes considered?
Are the benefits worth the harms and costs?

TABLE 240-2 **Critical Appraisal of a Systematic Review**

The type of clinical study that constitutes best evidence is determined by the category of the question being asked. Questions about therapy and prevention are best addressed by randomized controlled trials. [13], [26], [27] and [28] Questions about diagnosis are best addressed by cohort studies. [13], [26], [29], [30] Randomized controlled trials, cohort studies, or case-control studies best address questions about harm. [13], [26], [31] Methods for assessing the quality of each type of evidence are available. [13], [26]

With regard to questions about therapy and prevention, the RCT has become the gold standard for determining treatment efficacy. Thousands of RCTs have been conducted. Studies have demonstrated that failure to use randomization or adequate concealment of allocation resulted in larger estimates of treatment effects, predominantly caused by a poorer prognosis in nonrandomly selected control groups compared with randomly selected control groups. [32] However, studies comparing randomized and nonrandomized clinical trials of the same interventions have reached disparate and controversial results. [32], [33] and [34] Some found that observational studies find stronger treatment effects than randomized controlled trials. [32] Others found that the results of well-designed observational studies (with either a cohort or a case-control design) do not systematically overestimate the magnitude of the effects of treatment as compared with randomized controlled trials on the same topic. [33], [34] Sifting through the controversy leads to the following limited conclusions. Trials that use historical controls do result in larger estimates of treatment effects when compared to randomized controlled trials. Large, inclusive, fully blinded randomized controlled trials are likely to provide the best possible evidence about effectiveness. [12], [35], [36]

Whereas personal experience is an invaluable part of becoming a competent physician, the pitfalls of relying too heavily on personal experience have been widely documented. [7], [37], [38] Nisbett and Ross extensively reviewed people's ability to draw inferences from personal experience and documented several pitfalls [39] including:

- Overemphasis on vivid, anecdotal occurrences and underemphasis on significant statistically strong evidence;
- Bias in recognizing, remembering, and recalling evidence that supports preexisting knowledge structures (e.g., ideas about disease etiology and pathogenesis) and parallel failure to recognize, remember and recall evidence that is more valid;
- Failure to accurately characterize population data because of ignorance of statistical principles, including sample size, sample selection bias, and regression to the mean;
- Inability to detect and distinguish statistical association and causality; and
- Persistence of beliefs in spite of overwhelming contrary evidence.

Nisbett and Ross provide examples from controlled clinical research. Simple clinical examples abound. Physicians may remember patients who improved, often assume that patients who did not return for followup improved and conveniently forget the patients who did not improve. A patient treated with a given medication may develop a severe life-threatening reaction. On the basis of this single undesirable experience, the physician may avoid using that medication for many future patients, although, on average, it may be more efficacious and less toxic than the alternative treatments that the physician chooses. Few physicians keep adequate, easily retrievable records to codify results of treatments with a particular agent or of a particular disease; and even fewer actually carry out analyses. Few physicians make provisions for tracking those patients who are lost to follow-up. Therefore statements made about a physician's “clinical experience” may be biased. Finally, for many conditions, a single physician sees far too few patients to enable reasonably firm conclusions to be drawn about the response to treatments. For example, suppose a physician has treated 20 patients with lichen planus with tretinoin and found that 12 (60 percent) had an excellent response. The confidence interval for this response rate (i.e., the true response rate for this treatment in the larger population from which this physician's sample was obtained) ranges from 36 to 81 percent. Thus the true response rate might well be substantially less (or more) than the physician concludes from personal experience.

Expert opinion can be valuable particularly for rare conditions in which the expert has the most experience or when other forms of evidence are not available. However, several studies demonstrate that expert opinion often lags significantly behind conclusive evidence. [7] Experts suffer from relying on bench research, pathophysiology, treatments based on logical deduction from pathophysiology, and from the same pitfalls noted for relying on personal experience. Experts should be aware of the quality of evidence that exists.

It is widely believed that a clinical decision can be made on the basis of understanding the etiology and pathophysiology of disease and logic. [1], [10] This paradigm is problematic because the accepted hypothesis for the etiology and pathogenesis of disease changes over time. Therefore the logically deduced treatments change over time. For example, in the last 20 years, hypotheses about the etiology of psoriasis have shifted from a disorder of keratinocyte proliferation and homeostasis, to abnormal signaling of cyclic adenosine monophosphate, to aberrant arachidonic acid metabolism, to aberrant vitamin D metabolism, to the current favorite—a T cell–mediated autoimmune disease. Each of these hypotheses spawned logically deduced treatments. The efficacy of many of these treatments has been substantiated by rigorous controlled clinical trials, whereas others are used even in the absence of systematically collected observations. Therefore, we have many options for treating patients with severe psoriasis (e.g., UV-B, Goeckerman, psoralen–UVA, methotrexate, and cyclosporin) and mild to moderate psoriasis (e.g., anthralin, topical corticosteroids, calcipotriene, and

tazarotene). However, we lack a clear sense of which is best, in what order they should be used, or in what combinations. We do not know how well methotrexate works or the optimal dose or dosing schedule for it. [10], [40] Treatments based on logical deduction from pathophysiology may have unexpected consequences. For example, the observation that antiarrhythmic drugs could prevent abnormal ventricular depolarization after myocardial infarction logically led to their use to prevent sudden death after myocardial infarction. However, an RCT showed increased mortality of patients treated with antiarrhythmic drugs compared to placebo. [28], [41], [42]

Textbooks can be valuable particularly for rare conditions and for conditions for which the evidence does not change rapidly over time. However, textbooks have several well-documented shortcomings. They tend to reflect the biases and shortcomings of the experts who write them. By virtue of how they are written, produced, and distributed, most are about 2 years out of date at the time of publication. Most textbook chapters are narrative reviews that do not consider the quality of the evidence reported. [7], [13]

FINDING THE BEST EVIDENCE

The ability to find the best evidence to answer clinical questions is crucial for practicing EBM. Finding evidence requires access to electronic searching, searching skills, and available resources. Evidence about therapy is easiest to find. The best sources for finding the best evidence about treatment include:

- The Cochrane Library
- Searching the Medline and Embase databases
- Secondary journals and books (e.g., ACP Journal Club, *Evidence Based Medicine Journal,* and *Clinical Evidence*)
- Primary journals
- The National Guideline Clearinghouse (http://www.jcaai.org/)
- Bandolier (http://www.jr2.ox.ac.uk/Bandolier)

The Cochrane Library contains systematic reviews of the treatment of diseases, a Database of Abstracts of Reviews of Effectiveness (DARE), and the Cochrane Controlled Trials Registry (CCTR) (http://www.update-software.com/Cochrane/default.HTM).

Volunteers, according to strict guidelines developed by the Cochrane Collaboration, write the systematic reviews in the Cochrane Library. The Cochrane Library contains over 1200 completed systematic reviews. The number of reviews of dermatologic topics is steadily increasing.

The CCTR is a database of more than 300,000 controlled clinical trials. The Cochrane Controlled Trials Registry is compiled by searching the Medline and Embase databases, and hand searching many journals. Hand searching journals to identify controlled clinical trials and RCTs was undertaken because members of the Cochrane Collaboration noticed that many trials were incorrectly classified in the Medline database. As an example, Dr. Finola Delamere of the Cochrane Skin Group, hand searched the *Archives of Dermatology* from 1990 through 1998 and identified 99 controlled clinical trials. Nineteen of the trials were not classified as controlled clinical trials in Medline, and 11 trials that were not controlled clinical trials were misclassified as control clinical trials in Medline. [43] DARE is a database of abstracts of systematic reviews published in the medical literature. It contains 2100 abstracts and bibliographic details on more than 800 other published systematic reviews.

The Cochrane Library is the best source for evidence about treatment. It is easily searched by using simple Boolean combinations of search terms, as well as by more sophisticated search strategies. The Cochrane Library of systematic reviews, DARE, and the CCTR can be searched simultaneously. The Cochrane Library is available on a subscription basis on CD, and on the World Wide Web from Update Software (www.update-software.com/cochrane/default.html). Subscriptions to the Cochrane library are updated quarterly. The Cochrane Library is, or should be, available at medical libraries.

The second-best method for finding evidence about treatment and the best source for finding most other types of best evidence in dermatology is by searching the Medline database by computer. [44], [45] Medline is the National Library of Medicine's (NLM) bibliographic database covering the fields of medicine, nursing, dentistry, veterinary medicine, the health care system, and the preclinical sciences. The MEDLINE file contains bibliographic citations and author abstracts from approximately 3900 current biomedical journals published in the United States and 70 foreign countries. The file contains approximately 9 million records dating back to 1966. [46]

Medline searches have inherent limitations that make their reliability less than ideal. [45] For example, Spuls et al. conducted a systematic review of systemic treatments of psoriasis. [47] Treatments analyzed included UVB, PUVA, methotrexate, cyclosporin A, and retinoids. The authors used an exhaustive strategy to find relevant references including Medline searches, contacting pharmaceutical companies, polling leading authorities, reviewing abstract books of symposia and congresses, and reviewing textbooks, reviews, editorials, guideline articles, and the reference lists of all papers identified. Of 665 studies found, 356 (54 percent) were identified by Medline search (range, 30 to 70 percent for different treatment modalities). No references beyond those identified by Medline searching were provided by the 17 of 23 authorities who responded. Specific search strategies (“filters”) have been developed to help find relevant references while excluding irrelevant references for best evidence about diagnosis, therapy, prognosis, harm, and prevention. [48] These filters have been incorporated into the PubMed Clinical search engine of the National Library of Medicine and are available at http://www.ncbi.nlm.nih.gov/entrez/query/static/clinical.html. [49] Pub- Med Clinical Search is the preferred method for searching the Medline database for best evidence. It can be freely used by anyone with Internet access.

More than 20 vendors of Medline online and on CD are available. Haynes et al. compared several vendors of Medline online and on CD to determine which was best in terms of finding relevant articles and excluding irrelevant articles. Assessed on combined rankings for the highest number of relevant and the lowest number of irrelevant citations

retrieved, SilverPlatter's CD-ROM Medline clinical journal subset performed best for librarians' searches, whereas PaperChase's online system worked best for clinicians' searches. For cost per relevant citation, Dialog's Knowledge Index performed best for both librarian and clinician searches. [50]

Embase is Excerpta Medica's database covering drugs, pharmacology, and biomedical specialties. [13] The overlap in journals covered by Medline and Embase is about 34 percent (range, 10 to 75 percent depending on the subject). [51], [52] Unfortunately, most currently available platforms for physician Medline searches in the United States are not capable of searching the Embase database. Embase searches are available in many libraries.

Structured abstracts of articles are published in secondary journals (e.g., ACP Journal Club, *Evidence-Based Medicine,* and the *Evidence-based Dermatology*). The articles are strictly selected on the basis of methodologic quality and are accompanied by commentary putting the information in clinical perspective. All of the articles from ACP Journal Club and *Evidence-Based Medicine* are available on the CD, *Best Evidence*. It is available through the American College of Physicians and the British Medical Association. It is updated annually. *Evidence-based Dermatology* is published quarterly in the *Archives of Dermatology*. *Clinical Evidence* is a six monthly-updated compendium of evidence on the effects of common clinical interventions. Skin-related diseases are included. It is available through the British Medical Association.

Full text versions of many primary journals are available on the Internet. Journals in this category include the *British Medical Journal,* the *New England Journal of Medicine, Annals of Internal Medicine, JAMA,* the *Lancet,* and the *Canadian Medical Association Journal*. The following Web site provides a handy portal to these journals (http://www.uib.no/isf/people/atle/ebm.htm#BM4_secondary).

The National Guideline Clearinghouse maintains a database of guidelines for the treatment of disease written by panels of experts following strict guidelines of evidence. The database is accessible through the Internet (http://www.guideline.gov/index.asp). The current coverage of dermatologic topics is limited. Bullet points of EBM (reviews and EBM-related articles) are published in *Bandolier,* which is available on the Internet at http://www.jr2.ox.ac.uk/Bandolier/. Reviews of treatment of warts and on the new oral antifungals have appeared in it.

CRITICALLY APPRAISING THE EVIDENCE

After finding evidence, the next step in practicing EBM involves critically appraising the quality of the evidence and determining its magnitude and its precision. The criteria to critically appraise papers about treatment, diagnostic tests, and harmful effects of exposures are shown in Table 240-3, Table 240-4, and Table 240-5. [13], [26] Papers that meet these criteria are more likely to provide information that is true and useful in the care of patients. [13], [26] Detailed explanation of each criterion [13], [26] and an example using a patient with a dermatologic complaint are available. [45]

TABLE 240-3 **Critical Appraisal of a Paper about Therapy**

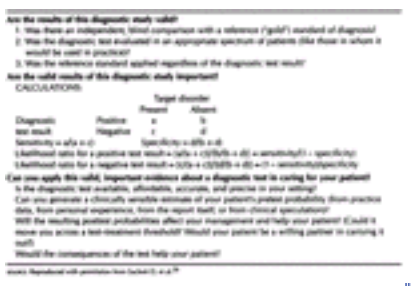

TABLE 240-4 **Critical Appraisal of a Paper About a Diagnostic Test**

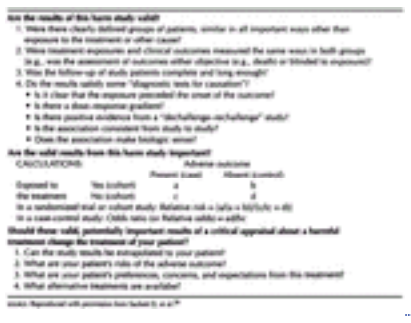

TABLE 240-5 **Critical Appraisal of a Paper About Harm**

Critically appraising evidence consists of three steps: determining whether the results are (1) *valid* (i.e., as unbiased as possible), (2) *clinically important*, and (3) *applicable* to the specific patient being seen.

Determining the validity of evidence centers on ascertaining whether the evidence was produced in a manner most likely to eliminate and avoid bias. The critical questions to ask to determine validity for papers about therapy, diagnostic tests, and harm are shown at the tops of Table 240-3, Table 240-4 and Table 240-5 respectively.

EVIDENCE ABOUT THERAPY AND PREVENTION

Therapeutic studies should have concealed randomization, nearly complete follow-up of all entered patients, an intent-to-treat analysis of results, blinding where possible, equal treatment of groups, and similar prognostic variables among treatment groups. These criteria represent only a small subset of features of a well-designed and reported clinical trial. [37] A more complete set of criteria has been published and is required by many of the leading medical journals. [53]

Important terms and concepts that must be understood to determine whether the results of a paper about therapy are clinically important include the magnitude of the treatment effect, its precision, the difference in response rates, its reciprocal, the number needed to treat, and the confidence interval.

In evaluating a clinical trial, look for clinical outcome measures that are clear-cut and clinically meaningful to you and your patients. [37] For example, in a study of a systemic treatment for warts, complete disappearance of warts is a meaningful outcome, whereas a decrease in the volume of warts is not. Historically, two principal methods are used to determine patient outcomes in dermatologic clinical trials. The first involves examining patients before, during, and at the conclusion of treatment, and reporting how the patients appear at the various time points. The second involves determining the degree of improvement during treatment. [54] A third method, determining the impact of therapy on the quality of the patient's life, is being increasingly used in dermatologic trials. [37]

An example of the first method is commonly encountered in therapeutic trials of psoriasis. A common practice is to assign numerical values to the amount of erythema, scaling, and degree of infiltration, to determine the area of the body surface involved, and to formulate an “index” by calculating a derivative of some product of these four numbers. [55], [56] The overall condition of the patient can then be represented by this index. A common example is the psoriasis area and severity index (PASI) which ranges from 0 to 72. [55] The major problem with indices is that they confound area of involvement with severity of disease. [54] For example, a patient with thick plaque-type psoriasis of the knees, elbows, and scalp may have the same index as a patient with diffuse but minimal psoriasis of the trunk and arms. Whereas the former patient is notoriously difficult to treat, the latter will generally respond rapidly and easily to many forms of therapy. [54] The second problem with indices is that they lend an air of accuracy to the analysis and presentation of data that are not warranted. [54] For example, Tiling-Grosse and Rees demonstrated that physicians and medical students were poor at estimating the area of skin disease; consequently, some of the components that make up indices may be inaccurate. [57] Finally, calculating the means, differences in means, and percentages of change in indices in response to treatment often do not convey an accurate clinical picture of the changes that have occurred. [54]

The second method of assessment groups patients according to their degree of improvement. Treatments are then compared by their ability to move patients to higher degrees of improvement. There are two major problems with this form of assessment. The first is that the categories of improvement are often not well defined. The second problem is that the categories are not additive. [54] That is, 60 to 80 percent improvement is often assumed to be twice as good as 20 to 40 percent, although no such numerical relationship exists between these subjectively defined categories.

To be most useful, the outcome variables to measure must be clearly defined, as objective as possible, and have clinical and biologic significance. [37], [54] The best indices and scales are the ones that accurately reflect the state of the disease and the ones whose validity and reliability have been verified by previous work. [37], [54], [58] The development of scales and indices for cutaneous diseases and testing their validity, reproducibility, and responsiveness has been inadequate. [37], [54], [59] Therefore a lack of clearly defined and useful outcome variables remains a major problem in interpreting dermatologic clinical trials.

Until better scales are developed, trials with the simplest and most objective outcome variables are the best. They lead to the least amount of confusion and have the strongest conclusions. Thus, trials in which a comparison is made between death and survival, patients with recurrence of disease and those without recurrence, or patients who are cured and those who are not cured are studies whose outcome variables are easily understood and verified. For trials in which the outcomes are less clear-cut and more subjective in nature, a simple ordinal scale is probably the best choice. [54] The best ordinal scales involve a minimum of human judgment, have a precision that is much smaller than the differences being sought and are sufficiently standardized that they can be used by others and produce similar results. [38]

In addition to being clearly defined, outcome variables should have clinical and biological significance. [27], [28] For example, in a therapeutic trial of patients with severe acne, treatment was associated with a decrease in lesion count from a mean of 400 to a mean of 350. This numerical difference may be of statistical significance, but it does not convey what the biologic significance of the change in lesion number represents. [54] This result may mean that some patients with severe acne cleared completely, whereas other patients remained the same or got worse. It could also mean that most patients got slightly better. Furthermore, does an individual patient look better when their lesion number has been reduced from 400 to 350? Are scarring and complications less?

To strengthen clinical trials and to help validate their conclusions, the outcome variables should be few in number and should be chosen before initiation of the study. Many outcome variables increase likelihood that spurious, chance differences will be detected. An ineffective treatment may be found efficacious when tested using poorly designed outcome assessment tools. Conversely, an effective therapy may be found ineffective by an insensitive scale.

Special precautions are recommended in recognizing and being skeptical of “substitute or surrogate end points” especially when no differences are detected in clinically important outcomes. [28], [60] Examples of such end points include CD4/CD8 ratios instead of survival in studies of treatments of AIDS, antinuclear antibody (ANA) levels, or sedimentation rates instead of clinical measures of disease activity in lupus erythematosus, and volume of warts instead of proportion of patients cleared of warts. Carefully chosen and validated surrogate end points often enable studies to provide answers to questions that would typically require much larger or longer trials if the targeted clinical end point were used. For example, a well-designed, short clinical trial may be sufficient to demonstrate that a new drug effectively lowers serum cholesterol or that another drug is effective in controlling hypertension. In both cases, much longer and larger studies would be required to demonstrate that the cholesterol lowering drug and the antihypertensive drug reduced morbidity and mortality from atherosclerotic and hypertensive cardiovascular diseases respectively. Surrogate end points must, however, correlate with clinical outcomes and their validity must be demonstrable in prior studies.

Once sound, clinically relevant outcome measures are chosen, the magnitude of the difference between the treatment groups in achieving these meaningful outcomes should be determined. The precision of the estimate of the differences among treatments should be estimated. Useful measures of the magnitude of the treatment effect are the difference in response rate and its reciprocal, the number needed to treat (NNT). [13], [26], [45] The NNT represents the number of patients one would need to treat to achieve one additional cure.

The confidence interval provides a useful measure of the precision of the treatment effect. [13], [26], [45], [61], [62] The calculation and interpretation of confidence intervals has been extensively described. [63] In simple terms, the reported result (known as the “point estimate”) provides the best estimate of the treatment effect. Values become increasingly less likely as they move away from the reported result within the confidence interval. [13], [26], [45] The confidence interval provides a range of values in which the “population” or true response to treatment is likely to lie.

Examples of the application of the concepts of numbers needed to treat and confidence intervals are given by a paper identified by a search of the Cochrane Library for treatment of herpes zoster with corticosteroids or antivirals that reported a randomized-controlled trial comparing placebo, acyclovir, prednisone, and acyclovir-prednisone in the treatment of herpes zoster. [64] At day 30 of the trial, 48 of 52 patents treated with acyclovir were totally healed compared to 22 of 52 patients who received placebo. The response rates for acyclovir and placebo were .92 and .42, respectively, and the difference in response rates was .5. The NNT was 2 (1/.5). This result means that for every two patients treated with acyclovir instead of placebo, one additional patient would be totally healed by day 30. The 95 percent confidence interval for the difference in response rates is from .35 to .65, and the 95 percent confidence interval for the NNT is 2 to 3.

What does the fact that the confidence interval for the difference in response rates in the example above is .35 to .65 actually mean? If the investigators of this study had the opportunity to repeat this study many times using the same design and procedures, sampling variability would prevent obtaining the same exact results in each study. Repeated trials were simulated using resampling (resampling is a computer-intensive method that uses the reported results of a trial to simulate results that would be obtained if the trial were to be repeated many times). [45], [65] The results when the trial was repeated 10 or 1000 times are shown in Fig. 240-1A and Fig. 240-1B, respectively. The 95 percent confidence interval of .35 to .65 means that if the trial is repeated many times, and a confidence interval is calculated for each trial, the true result or response to treatment will be included in 95 percent of the confidence intervals so produced. Alternatively, if the trial were repeated multiple times, the results would lie within that interval (.35 to .65) 95 percent of the time.

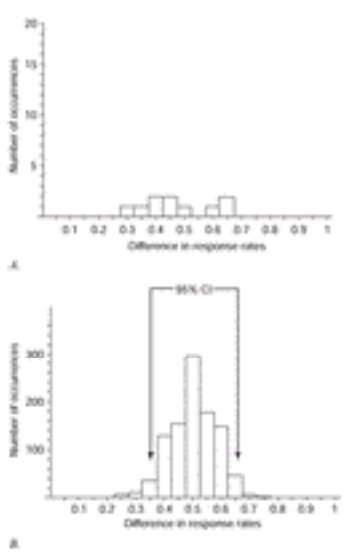

FIGURE 240-1 If the acyclovir trial were repeated (*A*) 10 or (*B*) 1000 times, the results in *A* and *B* might be obtained. CI, confidence interval.

The population or true response to treatment will most likely lie near the middle of the confidence interval and will rarely be found at or near the ends of the interval. The population or true response to treatment has only a 1 in 20 chance of being outside of the 95 percent confidence interval. Unless a patient is very different from the patients included in the study, his or her response will most likely lie near the middle of the confidence interval. If the 95 percent confidence interval of the difference in response rates excludes the zero difference, one can reject the null hypothesis that the two treatments are the same. [26], [45], [61], [62]

Misinterpreting trials that fail to show statistically significant differences among treatments is a common error of

interpretation in dermatology clinical trials. It is important to remember that “not statistically significant” means that a difference has a reasonably high probability of having been a result of chance; it does not mean that there is no difference or that treatment is necessarily ineffective. [37] Significant differences in treatment effects in comparison trials may be missed if the number of subjects tested is small. For example, in a 1978 survey of 71 published trials with negative results, Freiman et al. found that a 25 or 50 percent improvement in outcome might have been missed in 57 (80 percent) and 34 (48 percent) of the studies, respectively. [66] A follow-up study conducted by Moher et al. in 1994 indicated that 25 or 50 percent improvements in outcome might have been missed in 84 and 64 percent of 102 negative studies, respectively. [67] The sample sizes of many dermatologic trials are often inadequate to detect clinically important differences.

The acceptance of a significance level of .05 as the cutoff for rejecting the null hypothesis is a tradition based on quality control standards and is not an absolute truth. At times, more stringent standards are required (e.g., treatments with substantial side effects) and, paradoxically, tests that do not meet the P=.05 standard sometimes may be clinically significant. For example, consider a hypothetical trial of new chemotherapeutic agent involving 30 randomized patients with metastatic melanoma that produced a 5-year survival of 7 of 15 patients treated with the new agent, and of 3 of 15 in control patients treated with conventional surgery, chemotherapy, and radiation. Whereas the result does not achieve statistical significance when compared by chi-square testing (Yates corrected chi-square = 1.35; P=.25), the result is, nonetheless, potentially significant. If the therapy is beneficial and the estimated difference in response rates is the true difference in response rates, it may result in the saving of 2400 lives annually (based on 7200 deaths from melanoma annually and the improvement in survival in this hypothetical example). Because of the biologic and clinical importance of the results suggested by the study, the treatment should be subjected to study in a larger patient population with more power to detect a significant difference if one exists. [37]

The potential benefit of the treatment may be further revealed by the use of confidence intervals. To determine whether a treatment effect may have been missed in a study reporting negative (not statistically significant) results, one should look at the upper boundary of the 95 percent confidence interval. If this value would be clinically important if it were the true response, then an important treatment effect may have been missed in the study. Consider our hypothetical new treatment for metastatic melanoma. The cure rates for the new treatment and conventional treatment were 47 and 20 percent, respectively, and the difference between them was 27 percent. The 95 percent interval for the difference in cure rates was -10 to +51 percent. The upper boundary of the difference in cure rates was 51 percent. This difference would clearly have a significant impact on the treatment of patients with metastatic melanoma (the NNT is 2!); consequently, a significant treatment advance may have been missed in this study. Also note that the 95 percent confidence interval of the difference in proportions includes the zero difference; therefore, we cannot conclude with a high degree of confidence that the response rates of the two treatments are different. However, when zero is included as one of the values in the confidence interval, the inference that the therapy is not efficacious fails to consider the fact that the best estimate of effect is the point estimate (e.g., the observed difference in cure rates of 27 percent in our hypothetical example). [68] In other words, the values contained in the confidence interval are not equally likely, and become less and less likely as they move away from the point estimate. Thus, in the example, a difference of 25 percent (close to the observed 27 percent) is much more likely than one of -5 percent (far from the observed 27 percent). [37]

EVIDENCE ABOUT DIAGNOSTIC TESTS

To be valid, studies about diagnostic tests should include blind comparison with a criterion (“gold”) standard, evaluation in an appropriate spectrum of patients, and consistent application of the criterion standard. Few studies in dermatology meet this standard.

Important terms and concepts that must be understood to determine whether the results of a paper about a diagnostic test is clinically important include likelihood ratio, pretest probability, posttest probability, and threshold for action.

The likelihood ratio is the percentage of people with the disease who have a positive test divided by the percentage of people who do not have the disease who have a positive test. [45] The likelihood ratio is traditionally taught as the *sensitivity/1 - the specificity* and provides an estimation of how much higher the likelihood of the disease is, given a positive test (posttest probability), when compared to the probability before the test is done (pretest probability). [13], [26] An ideal test is one that will almost always be positive when the disease is present and negative when the disease is absent. Thus, it is one with a high sensitivity and specificity. Such a test would have a very high likelihood ratio.

In order for the likelihood ratio to be useful, one has to have an idea of how likely the disease is to be present before the test is done (i.e., the pretest probability) and a sense of how certain one needs to be to conclude that the patient has the disease and to act on it (i.e., the threshold for action). [45], [69] The pretest probability is determined from available published data or based on physician experience and judgment. [26], [45] Once the pretest probability is known or estimated, and the likelihood ratio determined, a nomogram can be used to estimate the post-test probability (Fig. 240-2). [26]

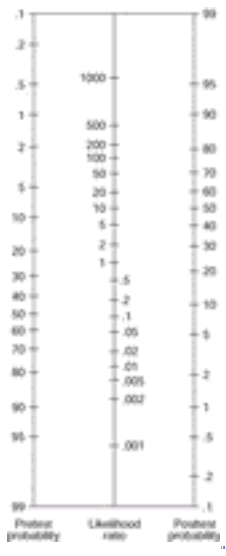

FIGURE 240-2 Nomogram for determining the posttest probability. To determine the posttest probability, draw a straight line through the pretest probability and the likelihood ratio, and read the posttest probability on the right. (Reproduced with permission from Sackett D, et al. [26]

If the nomogram is not available, the calculations can be done manually, but require conversion of probabilities to odds. The odds of disease is defined as the probability of disease divided by one minus the probability (*odds = probability/1 - probability*). For a defined group of individuals or patients, it can be also calculated as the ratio of the number those with disease to those without disease. Thus, if the probability (proportion) of a disease is 0.20 (20 percent), the odds of that disease is 0.20/1 - 0.20, or 0.20/0.80, or 1:4. This result means that for every person with the disease, there are four people without the disease. The posttest odds are equal to the pretest odds times the likelihood ratio (*posttest odds = pretest odds × likelihood ratio*). [26] The formula *probability = odds/odds + 1* is used to convert odds back to probability.

For example, suppose that based on clinical judgment the estimated probability that a patient with a cluster of vesicles on his cheek has herpes zoster is 0.6 (60 percent), then his odds of having zoster are 1.5:1 (0.6/1 - 0.6). Assume, for this example, that the sensitivity and specificity of antibody tests for herpes zoster are 80 percent and 96 percent, respectively. Then the likelihood ratio for a positive antibody test is 20 (.80/1 - .96). If this patient's antibody test is positive, his posttest odds are 30 (1.5 × 20) and the posttest probability of herpes zoster is .97 (97 percent) (30/30 + 1). This probability is certainly high enough to act upon.

Whether formally or informally, physicians develop thresholds of certainty at or above which they are comfortable with establishing a diagnosis and acting on the diagnoses. Action may take the form of communicating the diagnosis or prognosis to the patient, prescribing treatment, or referring the patient. When historical and physical evidence leads a clinician to suspect a diagnosis but the degree of certainty does not exceed the threshold for establishing a diagnosis, a test is done to increase the probability that the disease is present above the clinician's threshold for action. [69]

EVIDENCE ABOUT HARM

To be valid, studies about the harmful effects of exposures should include cohorts with comparable groups of exposed and unexposed individuals, or cases and controls, objective outcome measures, and adequate follow-up. In addition, the results should make clinical and biologic sense. [13], [26] Few dermatologic studies meet these criteria.

Important terms and concepts that must be understood to determine whether the results of a paper about harmful effects of exposures is clinically important include case-control and cohort studies, risk ratios, and odds ratios.

In a cohort study a group of individuals who are exposed to an agent is compared with an appropriately selected unexposed control group and both groups are followed until an event of interest occurs or for a prespecified length of time. The association of exposure to the harmful outcome is expressed as the relative risk (see Table 240-5 for relative risk calculations). A relative risk of 1 implies no association. If the relative risk is greater than 1, then the result implies a positive association between exposure and the harmful outcome. If it is less than 1, then the implication is of an inverse association. However, in order to infer a causal association reflected by either an increase in risk (relative risk greater than 1), or a protective effect (relative risk less than 1), it is important to evaluate the validity and precision of the relative risk estimate. The precision can be readily assessed by means of the 95 percent confidence interval. A confidence interval that does not include 1.0 denotes a statistically significant association. Because the most the likely result of a study is the point estimate (i.e., the reported result), the observed association (expressed by the point estimate) may be causal, even if the confidence interval includes 1.0 as a result of a small sample size. [13], [26]

Case-control studies are used when the bad outcome is recognized and the causative agent is not yet discovered. They are also used when there is a very long time lag between exposure and outcome, or when the frequency of adverse events is very small. In a case-control study, patients with a disease of interest are compared with appropriately selected controls. The odds of exposure to suspected etiologic agents are ascertained in cases and controls (Table 240-5). Recall that the odds of an event are the ratio of the number of events to the number of nonevents. [70] Events are exposures to potentially harmful risk factors in case-control studies. The odds of exposure of cases are divided by the odds of exposure among controls to derive the odds ratio, which is a good estimate of the relative risk when the outcome (e.g., disease, death) is relatively rare (i.e., when it is less than 5 percent in exposed subjects). The association between exposure and outcome is expressed as the odds ratio in case-control studies. An odds ratio of 1 implies no association. If the odds ratio is greater than 1, then the result implies a positive association between exposure and the harmful outcome. If the odds ratio is less than 1, then the result implies a protective effect of the exposure. [13], [26] As noted above, it is important to evaluate the validity and precision of the odds ratio estimate by examining the 95 percent confidence

interval.

For example, suppose a case-control study was performed to study the relationship between limb deformity and exposure to thalidomide. The results of the study indicated that patients with limb deformities were more likely than controls to have been exposed to thalidomide in utero. The odds ratio for thalidomide exposure was 3.5 and the confidence interval was from 1.8 to 6.6. Thus the odds that patients with limb deformities were exposed to thalidomide in utero was 3.5 times the odds of thalidomide exposure in controls. Because the odds ratio is greater than 1, and its 95 percent confidence interval does not include 1, the result implies a positive association between thalidomide use and limb deformities, not likely to have been the result of random error. These results (an odds ratio of 3.5 and confidence interval of 1.8 to 6.6) were actually the results of a study by Wolf et al. who studied the relationship between sunscreen use and melanoma in a case-control study in Austria. [71] Their results indicated that patients with melanoma were more likely than controls to have used sunscreen often. In order to infer causality, it is important to assess whether the results could have resulted from bias and that the results are biologically plausible.

To add confusion to an already difficult area, clinical researchers will often report results of meta-analyses, cohort studies, and randomized-controlled trials by using odds ratios. Odds ratios are used because they have stronger statistical properties than other measures. [70] For example, odds ratios can take any value between zero and infinity, are symmetric in a log scale, and can be used to make adjustments for confounding factors by using multiple regression. [70] Unfortunately, they are the measure of association least intuitively understood. If a meta-analysis, controlled trial, or cohort study is reported by using odds ratios, the relative risk, difference in response rates, or NNT can often be calculated if the primary data are provided. Alternatively, these more readily understandable measures can be derived if the number of subjects in each group, odds ratio and overall event rate are provided.

APPLYING EVIDENCE TO SPECIFIC PATIENTS

Applying the evidence to specific patients involves determining whether the evidence from studies is applicable to a specific patient. This decision is based on the patient's condition and values. It involves asking a series of questions that are specific to the type of evidence being considered (see Table 240-3, Table 240-4 and Table 240-5). When faced with the task of determining whether the results of a particular study are applicable to specific patients, physicians should determine whether there are any compelling reasons that the result should not be applied. [37] Applying evidence to a specific patient always involves physician judgment.

SAVING THE CRITICAL APPRAISAL OF THE EVIDENCE

Once you have made the effort to ask a clinical question, find the best evidence, and critically appraise it, you should save your analysis in a place and format in which it can be easily retrievable for future use. Worksheets for recording evidence about papers dealing with diagnosis, therapy and prevention, prognosis, and harm, are available (http://ftp://cebm.jr2.ox.ac.uk/pub/centre/docs/workshee.doc). [26] These worksheets can be saved electronically or filed physically.

The Influence of Pathologic Processes on Skin Barrier Function

REFERENCES

Pharmacokinetics related to topical applications of drugs describes the time-dependent drug concentration following the application of the drug to the skin surface, its subsequent passage through the skin barrier into the underlying skin layers and its distribution into the systemic circulation. The subject continues to hold the attention of research scientists and clinicians alike because of its relevance to dermatologic therapy and the possibility of topical application of current systemic medication, such as peptides or proteins. However, this is an inherently complex subject, despite the advent of new insights into the principal factors that govern diffusion of a drug into and across the skin.

The major difficulty in developing an accurate description of the percutaneous absorption of a drug is related to the size of the compartments. A topical application of a cream or ointment is generally spread to a thickness of not greater than 10 µm. The thickness of the *stratum corneum* is also approximately 10 µm, whereas the viable epidermis, dermis, and, to a greater extent, the systemic compartment represent a large sink in which absorbed drugs undergo dilution to levels that often remain undetectable to all but the most sensitive techniques. The determination of the time-dependent changes in the concentration of a drug in individual compartments is technically challenging. Following topical application of a drug formulation, these parameters can affect this process:

1. Formulations may undergo drastic changes in composition and structure;
2. The drug or its formulation may affect effectiveness of the skin barrier, resulting in time-dependent changes of the barrier function;
3. The skin barrier may be affected by the type and progression of a disease;
4. There are significant regional variations in the barrier properties of the skin;
5. Viable skin tissues themselves may respond to a topical application of a drug formulation resulting in enhancement or retardation of percutaneous absorption;
6. Skin has a significant metabolic capacity; often enough, the resulting systemic exposure may be not only to the parent drug, but also to pharmacologically more or less active metabolite(s);

DIFFUSION

Compounds applied topically to the skin surface migrate along concentration gradients according to well-described laws governing diffusion of solutes in solutions and/or their diffusion across membranes. For a detailed discussion of relevant equations, readers are referred to several comprehensive reviews. [1], [2], [3] and [4]

Fick's Laws

Diffusion of uncharged compounds across a membrane or any homogenous barrier is described by Fick's first and second laws. The first law states that the steady state flux of a compound (J = moles/cm per second) per unit path length (d, cm) is proportional to the concentration gradient (?C) and the diffusion coefficient (D, cm^2/s).

$$J = -D(\Delta C/\Delta \delta)$$

The negative sign indicates that the net flux is in the direction of the lower concentration. This equation applies to diffusion-mediated processes in isotropic solutions under steady-state conditions. Fick's second law predicts the flux of compounds under non–steady-state conditions. It is worthwhile to point out that diffusion is a very effective transport mechanism over very short distances but not over long ones. The relationship between the time (?t) it takes for a

molecule to migrate along a path length (x) and its diffusion coefficient is governed by the following equation:

$$\Delta t = x^2/2D$$

For example, the diffusion coefficient for water in an aqueous solution is: 2.5×10^{-5} cm^2/s, suggesting that a water molecule would migrate over a 10-µm path (the equivalent of the width of the stratum corneum) in 0.4 ms. However, because diffusion depends upon the square of the distance, longer distances are not efficiently covered; a 100-µm path would take 40 ms.

THREE-COMPARTMENT MODEL

Although pharmacokinetic analysis of topical preparations may require the description of a relatively large number of compartments, this discussion is confined to the three outlined in Fig. 241-1: the skin surface, the stratum corneum, and the viable tissue. The formulation itself forms a reservoir, from which the compound must be released; in order to undergo percutaneous absorption, the compound then must penetrate the stratum corneum, diffuse into and through the viable epidermis into the dermis, and, finally, gain access to the systemic compartment through the vascular system. In addition, the substance may diffuse through the dermal and hypodermal layers to reach underlying tissues. As summarized in Table 241-1, within each compartment, the compound may diffuse down along its concentration gradient, bind to specific components, or be metabolized. The size or characteristics of each compartment may alter with time, and the factors determining diffusion within each compartment may be affected by disease state as well as the nature or the pharmacologic/biologic activity of the drug or its excipients.

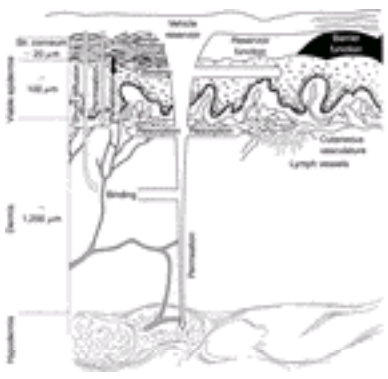

FIGURE 241-1 Diagrammatic representation of three compartments of the skin: surface, stratum corneum, and viable tissues. Following surface applications, evaporation and structural/compositional alterations in the applied formulation may play an important role in determining the bioavailability of drugs. The stratum corneum, the outermost layer, plays the most significant role in determining the diffusion of compounds into the body. Following absorption, compounds may bind or diffuse within the viable tissues, or become resorbed by the cutaneous vasculature.

Compartment	Processes	General Relevance to Bioavailability[a]
Vehicle	diffusion	++
	thermodynamic activity	++
	evaporation	+
	precipitation	+/–
Stratum corneum	reservoir function	+++
	diffusion	+++
	binding	–/+
	metabolism	–
Epidermis	diffusion	+/–
	metabolism	+/–
	binding	++
Cutaneous vasculature	resorption	+
Underlying tissues including dermis	diffusion	+/–
	metabolism	+/–
	binding	–

[a]–, Although theoretically possible, this process is probably not of general relevance; +/–, this process is of direct relevance, but only in a restricted number of cases; +, the process is generally relevant, but not as important as ++ or +++.

TABLE 241-1 **Compartments Encountered by Substances Undergoing Percutaneous Absorption: General Relevance of Processes to Bioavailability**

THE SKIN SURFACE

Surface Applications of Formulations

Formulations differ in their physicochemical properties, and, as discussed below, this influences the kinetics of release and/or absorption. However, the principal consideration is that topically applied drug products represent a physically small compartment, which limits the amount of compound that can be applied to the skin surface. When a patient applies a dermatologic preparation, the layer of a formulation covering the skin is very thin (approximately 0.5 to 2 mg/cm^2). Thicker layers are felt as “unpleasant” and are consciously or subconsciously rubbed off or spread to larger surfaces. This restricts the amount of compound that can effectively come in contact with the skin surface to approximately 5 to 20 $\mu g/cm^2$ for a 1% (wt/wt) topical formulation.

However, even after being rubbed in, formulations do not remain homogeneous over the time course of penetration. For example, topical applications containing water, alcohol, or similar solvents undergo rapid evaporation.[5] This phenomenon is readily recognized by patients as a cooling sensation. The evaporation results in rapid concentration of nonvolatile substances on the skin surface, which may result in the formation of supersaturated “solutions” or, alternatively, precipitation of active ingredients. Formulations may also mix with skin-surface lipids or undergo

time-dependent changes in their composition as excipients and drugs undergo absorption. Altogether, these considerations suggest that dramatic changes in the composition and structure of formulations may occur following surface application, all of which may determine the subsequent bioavailability of active ingredients.

Reservoir

The reservoir function was first described by Vickers, [6] who observed that simple occlusion lead to the renewed onset of a glucocorticoid mediated vasoconstriction several hours after it had declined. He interpreted this effect as renewed liberation of the glucocorticoid from a “reservoir” stored in the upper skin layers.

We define as reservoir the amount of an active ingredient, that is still in contact with the nonvolatile constituents of its formulation after the latter had been massaged into the skin surface. The compound has not yet penetrated, but it cannot be removed by simple rubbing or contact with clothing or other tissues. The reservoir thus adheres to the skin surface and resides in the wrinkles and the upper layers of the stratum corneum. Reservoirs on eczematous skin may become even more prominent because of the scaliness of the skin. Recently, we discovered that the upper volume of the follicular channels serves also as a reservoir, which may result in a relative increase in absorption through appendages. This phenomenon may be increased in formulations that contain particles or precipitates given the evidence that appropriately sized particles can rapidly penetrate along the shafts of hair follicles to a depth of up to 100 to 500 µm. [7], [8], [9] and [10]

Formulations

Formulations can be differentiated on the basis of whether they are designed to remain on the skin surface (sunscreen products and cosmetics), to be delivered to compartments in the skin (topical formulations), or to migrate across the skin into the central compartment (transdermal formulations).

Formulations may affect the kinetics and the degree of percutaneous absorption and, subsequently, the onset, duration, and extent of a biologic response. In the context of percutaneous absorption, there are several different parameters that should be considered when selecting a formulation: [1], [11] the thermodynamic activity of the active ingredient; [12] the amount of compound that can be incorporated into the formulation; [13] the stability of the formulation on the skin surface (e.g., emulsions should break easily); [14] the partition coefficient of the active ingredient between the vehicle and the stratum corneum; [15] and the enhancer activity.

In general, percutaneous absorption is proportional to the thermodynamic activity of the compound. Thus, the greatest flux is observed at the active ingredient's maximum solubility in a vehicle. Vehicles that are very good solvents should be avoided because they may retain the active ingredient on the skin surface.

Liposomes as Transdermal Delivery Systems

Liposomes are microscopic spheres comprising a bilayer that encloses an inner aqueous core. A wide variety of cosmetics contain liposomes. Liposome-based formulations have proved to be safe, cosmetically attractive, and well accepted. There is considerable evidence that, at least for some preparations, application of liposomes is mildly occlusive and improves the hydration level of the stratum corneum. Interest in the use of liposomes to enhance the delivery of drugs across the skin has been spurred by several observations in animal models: liposome formulations were believed to enhance the penetration of compounds across the skin or to optimize the retention of bioactive compounds in target tissues. [16] However, these early studies, which rested largely on animal models, were followed by relatively few in vivo studies for humans [17] conducted under standard conditions.

There is good evidence that particles can penetrate along the hair shaft and this route may be appropriate for delivery of bioactive compounds into sebaceous glands or hair follicles. [9], [10]

THE SKIN BARRIER

The primary compartment that limits the percutaneous absorption of compounds is the stratum corneum. This thin (10 to 20 µm) layer effectively surrounds the body and represents a highly differentiated structure that determines the diffusion of compounds across the skin. The physical description of the stratum corneum is well documented, [18] and it can be accurately described as “bricks” of bundled, water-insoluble proteins, embedded in a “mortar” of intercellular lipid (see Chap. 9).

The general consensus today is that the stratum corneum is a highly organized, differentiated structure. To participate fully in forming an effective barrier to diffusion, the biogenesis of the corneocytes as well as the synthesis and processing of the intercellular lipid must proceed in an orderly manner. Recent evidence suggests that disruption in the kinetics of skin barrier formation by accelerating the division of the keratinocytes in the underlying layers will lead to a disruption in the barrier properties of the skin. [19] Thus, the concept of dead or dying skin forming a passive barrier to diffusion is now replaced by a model of the stratum corneum as a highly differentiated structure with unique properties that are particularly suited for its role in forming the skin barrier. [20]

Corneocytes

Fully 85 percent of the stratum corneum is protein (as a percentage of dry mass), mostly associated with the cornified cells, termed *corneocytes*. These structures contain a core of keratins surrounded by an envelope made up of cross-linked proteins. [21] The keratins may account for up to 80 percent of the total dry mass of the corneocytes, and thus represent their most important constituent. In addition to these fibrous proteins, the core contains low-molecular-weight polar compounds, such as amino acids, urocanic acid, and pyrrolidone carboxylic acid. These compounds play a role in

maintaining the hydration properties of the stratum corneum. Unlike living cells, which contain approximately 80 to 90 percent water by weight, corneocytes contain only 15 to 30 percent water by weight.

Recent investigations into the nature of the corneocytes have focused on the role of the corneocyte envelope proteins, because they may be responsible for the integrity of the stratum corneum as well as for its resistance to irritants. The composition of the envelope was recently reviewed. [21] It is composed of several proteins termed *loricrin, involucrin,* a family of proline-rich proteins (also termed *cornifin* and *pancornullin*), and *cystatin,* also termed *keratolinin*.

Intercellular Lipid

Interspersed between corneocytes, the intercellular lipid is organized into sheets that provide the primary barrier to diffusion across the stratum corneum. [19] This lipid is located in an extracellular domain and thus is not morphologically equivalent to a cellular membrane. The lipid accounts for approximately 15 percent of the dry weight of the stratum corneum or 20 percent of the volume. It is composed of roughly equimolar mixtures of ceramides, cholesterol, and long-chain free fatty acids. There is now substantial evidence that these lipids form structures [22] wherein diffusion of the lipids is more than 1000-fold less than that found in normal cellular membranes. [23]

These properties of the intercellular lipid are particularly suited to its role as a barrier to diffusion. [18], [24]

Appendages

A variety of appendages penetrate the stratum corneum and epidermis, facilitating thermal control and providing a protective covering. Appendages are potential sites of discontinuity in the integrity of the skin barrier. Though appendages account for only 0.1 to 1 percent of the area of the skin, they appear to present the predominant pathways for percutaneous absorption in nondiseased skin. [9], [10] This can be explained by the fact that only the upper wall of the follicular apparatus (the *acroinfundibulum*) is protected by a coherent stratum corneum, whereas in the lower part (*infrainfundibulum*) the corneocytes appear undifferentiated and protection is incomplete, if not absent. Even solid particles may enter deep into the follicular orifice, [7], [8], [18] a phenomenon that lends itself to the concept of follicular targeting of drugs. [18]

It follows that in relationship to the integral protection against the passage of xenobiotics in general, and drugs specifically, the barrier function of the interfollicular stratum corneum is even more potent than thought, whereas more research is needed relative to the follicular pathway. Recent investigations hint to the presence of active follicles (open to penetration) and passive ones. [9]

Pathways Across the Stratum Corneum

Several studies have directly visualized penetration pathways across the stratum corneum electron microscopically. Osmium vapor can be used to precipitate *n*-butanol that has penetrated the stratum corneum. [25] Following a brief (5 to 60 s) exposure of murine or human stratum corneum, the alcohol was found to be enriched in the intercellular spaces (threefold), although significant levels were also found in the corneocytes. By using a different approach that involved rapid freezing, water, ethanol, and cholesterol were also found preferentially concentrated in the intercellular lipid spaces. [26] Similarly, the penetration of mercury chloride through the intercellular lipid can be detected following precipitation with ammonium sulfide vapor. [27]

However, in most of these investigations, there was also significant localization of compounds in the corneocytes, more prevalent in the upper layers (stratum disjunctum). Thus, corneocytes undergoing desquamation appear to be relatively permeable, even to rather bulky ions such as mercury. There is additional evidence that other compounds can and do penetrate corneocytes. It is well established, for example, that occlusion or immersion of skin in a bath leads to swelling of the corneocytes, consistent with the entry of water. Other compounds have also been localized in corneocytes, such as the anionic surfactants that are bound to keratins. Low-molecular-weight moisturizers such as glycerol are likely to partition into the corneocytes and alter their water-binding capacity. Thus, the penetration of compounds into corneocytes cannot be excluded from considerations of percutaneous absorption pathways. The relevance of this step is related to whether it is rate-determining, that is, whether the diffusion of compounds within the intercellular lipid is restricted by the corneocytes.

Inter- and Intraindividual Variation in Skin Barrier Function

Finally, it is worthwhile to consider the level of inter- and intraindividual variation in skin barrier activity, including that of follicles. The most accurate and reproducible measurement of skin barrier activity is transepidermal water loss (TEWL). [28] The extent of interindividual variation in this parameter for the same individual are estimated to be 8 percent by site and 21 percent by day to day. The variations between individuals are reported to be somewhat larger, ranging from 35 to 48 percent. [29] There appear to be no significant gender- or ethnic-dependent differences in skin barrier activity. The skin barrier activity of premature babies (delivered more than 3 weeks premature) [30] is markedly impaired, although skin barrier function appears normal for full-term infants. There seems to be no significant alteration in skin barrier activity as a function of age. Differences in skin barrier activity among different sites have been observed; barrier function can be ranked as arm ˜ abdomen > postauricular > forehead. [28]

VIABLE TISSUE

Although the primary barrier to percutaneous absorption lies within the stratum corneum, diffusion within the viable tissue, as well as metabolism and resorption, also influence the bioavailability of compounds in specific skin compartments. These processes are interrelated, and factors that increase the rate of one of these processes inevitably

influence the others. Because the development of dermatologic formulations is often focused on “targeted” delivery to living tissues, the manipulation of these processes offers a clear-cut rationale for increasing therapeutic efficacy.

The passage of compounds from the stratum corneum into the viable epidermis results in a substantial dilution. This reflects not only the relatively larger size of the epidermis as compared with the stratum corneum, but also the lower resistance to diffusion within viable tissues, approximately corresponding to that of an aqueous protein gel. [29] Drug concentrations of 10^{-4} to 10^{-6} M may be attained in the epidermis and dermis for substances that permeate readily. Although the actual concentration gradient of a compound is influenced both by the physicochemical properties of the compounds as well as by the time of application, the presence of a concentration gradient is visible at all times. In other words, strategies to enhance percutaneous absorption generally result in a relatively uniform increase in the concentration of compounds in all compartments.

Skin Metabolism

The skin contains a wide range of enzymatic activities, including phase I oxidative, reductive, hydrolytic, and phase II conjugation reactions, as well as a full complement of drug-metabolizing enzymes. [31] Metabolic activity is a primary consideration in the design of prodrugs and may influence the bioavailability of drugs delivered via dermatologic or transdermal formulations. Alterations in skin metabolism have been implicated in a range of diseases including hirsutism and acne, and they may be relevant to risk assessment of topical exposure to carcinogens. Metabolic processing of antigens by Langerhans cells is involved in the presentation of allergens to the immune system. Thus, metabolism in skin compartments plays a significant role in determining the fate of a topically applied active compound.

Significant cutaneous metabolism has been demonstrated for a wide variety of compounds of differing physicochemical properties, including the steroid hormones estrone, estradiol, and estriol, as well as glucocorticoids, prostaglandins, retinoids, benzoyl peroxide, aldrin, anthralin, 5-fluorouracil, nitroglycerin, theophylline, and propranolol. [31] For example, cutaneous metabolism reduced the systemic bioavailability of nitroglycerin administered in a transdermal drug formulation in rhesus monkeys by 16 to 21 percent and hydrolyzed virtually 100 percent of a salicylate diester. [32] It is convenient to classify metabolic reactions in terms of their cofactor dependence. Processes that require cofactors are likely to be energy dependent, and these are located within viable tissues. Among the best-studied examples are the interconversion of steroids (e.g., estrone and estradiol), and the oxidation of polycyclic aromatic hydrocarbons with mixed-function monooxygenases. In contrast, cofactor-independent processes involve catabolism and may be located outside of viable tissues, that is, in the transition region between the stratum corneum and stratum granulosum. The best-characterized of these involve hydrolytic reactions such as nonspecific ester hydrolysis.

Metabolic activity is found in (1) skin-surface microorganisms, (2) appendages, (3) the stratum corneum, (4) the viable epidermis, and (5) the dermis. In considering the site of the most significant metabolism, one has to take into account the relevant enzymes and their specific activity, as well as their capacity relative to the size of the compartment. Thus, although the level of many enzymes is highest in the epidermis, the relatively large size of the dermal compartment may result in a significant role in the metabolism of topically applied substances. A further consideration is that enzymes involved in cutaneous metabolism may be induced upon exposure to xenobiotics. This has been well described for various mixed-function monooxygenases. [33] Finally, the qualitative and quantitative extrapolation of results from animal models to humans is uncertain owing to the significant species differences in the metabolism of compounds.

Percutaneous absorption and metabolism of compounds can be viewed as two events in kinetic competition with each other. [34] Generally, compounds that remain in the skin for longer periods of time undergo significantly more metabolism. Furthermore, the type of metabolism of a substance may also be influenced by the nature of its formulation, as illustrated by investigations on the metabolism of several transdermal nitroglycerin formulations. [35] The inclusion of enhancers in the formulation not only increased the bioavailability of the nitroglycerin but also the ratio of one metabolic compound (1,2-glyceryl dinitrate) in relation to another (1,3-glyceryl dinitrate). This may limit the suitability of in vitro experiments for estimating the significance of cutaneous metabolism, because the vasculature is not functional in vitro. It further emphasizes that it is difficult to extrapolate quantitatively the level of metabolism obtained for different formulations. This has significant implications for the estimation of bioequivalence.

However, despite the variety of skin-associated metabolic processes, the extent of metabolism is normally modest, that is, in the order of 2 to 5 percent of the absorbed compounds. Metabolism is limited not only by the relatively short period of time that a compound spends in the viable layers of the skin, but also by the overall low level of enzyme activity. Thus, under many circumstances, the available enzymes are saturated by the level of compound undergoing percutaneous absorption. [31]

Resorption

Resorption, defined as the uptake of compounds by the cutaneous microvasculature, is directly related to the surface area of the exchanging capillaries as well as their blood flow. Total blood flow to the skin may vary up to 100-fold, a process primarily regulated by vascular shunts, but also by recruitment of new capillary beds. It is estimated that under resting conditions only 40 percent of the blood flow passes via exchanging capillaries capable of acting as a sink for absorbed compounds. However, this value demonstrates considerable variation between body sites, individuals, and species and is influenced by disease states and environmental conditions. In particular, changes in temperature and humidity as well as the presence of vasoactive compounds may directly influence skin blood flow. [36]

For most compounds and situations, resorption does not limit the delivery of compounds to the central compartment after topical applications. This is a result of the relatively high resistance to diffusion within the stratum corneum as compared with uptake by the vasculature. However, for compounds or situations in which diffusion across the stratum corneum is rapid, resorption limits the maximum rate of absorption. [36] The evidence that resorption can limit the delivery of compounds to the central compartment comes primarily from studies that examine the influence of blood flow on this

process. The percutaneous absorption of methylsalicylate is increased by elevated ambient temperature or strenuous exercise, an observation consistent with increased resorption as a result of cutaneous blood flow. [37] Moreover, intravenously administered nicotine (a vasoconstrictor) reduces the percutaneous absorption of topically applied nicotine. [38] Regional differences in the percutaneous absorption of piroxicam, a nonsteroidal anti-inflammatory agent, are dependent upon the local vasculature rather than upon skin barrier function. [39] Perhaps the most convincing evidence that resorption can limit delivery to the vasculature comes from in vitro studies on the perfused porcine skin flap. [40]

An additional consideration is that the rate of resorption may indirectly influence the diffusion of compounds to the underlying musculature, tissues, and joints. [41] The principle of locally enhanced delivery to underlying musculature has been demonstrated for piroxicam as well as several local anesthetic preparations. [42]

The Influence of Pathologic Processes on Skin Barrier Function

Reduced skin-barrier function has been observed in a number of pathologic conditions including the ichthyoses, [43], [44] psoriasis, [18], [45] atopic dermatitis, [46] and contact dermatitis. [47] It is generally accepted that this is attributable to structural alterations in the stratum corneum. [18] These structural deficiencies may arise from an absence of an enzyme or structural protein in the underlying viable tissues or may be related to the improper formation of the stratum corneum resulting from an increase in keratinocyte proliferation. Thus, in individuals predisposed to a defective barrier, a minor perturbation may become amplified as the skin “attempts to compensate” by increasing keratinocyte proliferation. [48] A further consideration is that the homeostatic mechanisms responsible for recovery of barrier activity after perturbation may be altered in some diseases or physiologic states.

For example, whereas the skin of aged people exhibits normal barrier function, the recovery of barrier activity after perturbation is markedly reduced. [43], [44] This kinetic basis for reduced barrier function may also account for interindividual variation in barrier function and/or the apparently increased susceptibility of certain individuals to contact dermatitis. [47]

In summary, the principal factors determining the pharmacokinetics of a topical application are the physiochemical properties of the bioactive molecule. Hydrophobicity, molecular weight, and ionic charge determine the feasibility of transdermal delivery for any particular compound. Formulations influence the pharmacokinetics largely from considerations of the thermodynamic activity of the compound. However, one should not exclude the impact of changes in the formulation that occur following topical application. Evaporation, and changes in the structure of emulsions, may result in dramatic changes in the thermodynamic activity of the compound at the skin surface. Under some circumstances, this may lead to the retention of the drug on the skin surface, that is, the reservoir.

The rate-limiting step for percutaneous absorption of most compounds is their penetration through the stratum corneum. There is substantial evidence that this is related to diffusion through a tortuous path around the corneocytes within the highly structured intercellular lipid, the constituents of which exhibit diffusional properties consistent with their role in the skin barrier. The follicular pathway is also important. For skin diseases exhibiting reduced skin-barrier function, the absence of a differentiated stratum corneum may account for the decreased barrier activity. The progression of a disease and the inherent biologic variability makes predictions of percutaneous absorption for diseased skin inherently difficult. This contributes significantly to the challenges of developing topical drugs.

Processes occurring in viable tissues can have a significant, though generally less important, influence on the bioavailability of compounds undergoing percutaneous absorption. It has been difficult to establish in vivo the level of skin-related metabolism of drugs undergoing percutaneous absorption. Effective manipulation of the rates of resorption with vasodilators or vasoconstrictors offers an attractive opportunity to influence the delivery of compounds to underlying tissues. However, this is likely to be of most importance with those compounds that, on their own, exhibit rapid rates of percutaneous absorption.

REFERENCES

After correctly diagnosing a cutaneous disease, the dermatologist must consider a myriad of options in formulating an effective treatment plan. Sensible topical drug therapy involves not only the selection of an appropriate agent, but also a thoughtful consideration of the areas of the body affected, the state of the diseased skin, the concentration of the drug in a suitable vehicle (i.e., ointment, cream, lotion, etc.), the method of application, and a defined duration of use that both maximizes efficacy and minimizes adverse side effects. Behind each of the aforementioned considerations are basic principles that help guide the practitioner toward a rational plan of therapy.

CUTANEOUS DRUG DELIVERY

The therapeutic efficacy of a topical drug relates to both its inherent potency and the ability of that drug to penetrate the skin. In fact, many potent agents, such as hydrocortisone and fluocinolone acetonide, are quite poorly absorbed into the skin. Conversely, many well-absorbed agents with weak potency have negligible therapeutic use. Percutaneous absorption requires a drug to pass through the stratum corneum, epidermis, papillary dermis, and into the bloodstream. But for most drugs, the limiting barrier to absorption is solely the stratum corneum.

When a thin layer of a finite amount of drug is applied to the skin, its rate of absorption, or *flux,* can be described in three phases: the lag, rising, and falling phases. [1] The lag phase reflects the period when no drug has transversed the stratum corneum, and thus no drug can be measured in the bloodstream. After a period of time, the rising phase begins as some drug crosses the stratum corneum and ultimately enters the dermal capillaries, and thus can be detected in the bloodstream. As it leaves the applied surface film, the drug increasingly fills the stratum corneum. This increase in concentration within the stratum corneum will lead to an increased rate of drug delivery to the epidermis, dermis, and dermal capillaries. Of course, because the amount of drug in the surface film is finite the amount delivered to the stratum corneum will ultimately diminish. The falling phase of absorption reflects the exhaustion of drug from the surface film and the resultant lower supply of the agent within the stratum corneum that can be delivered to the dermal capillaries. It should be noted that in addition to absorption, other factors, such as exfoliation, rub-off, and wash-off, reduce the drug's surface concentration. The pharmacokinetics of topical drugs are discussed in Chap. 241.

OTHER FACTORS THAT AFFECT ABSORPTION

Stratum Corneum

As mentioned previously, the stratum corneum is the rate-limiting barrier to percutaneous drug delivery. Of course, the stratum corneum thickness, and thus drug penetration, varies depending on body site. [1] Table 242-1 lists varying body sites and their relative resistance to percutaneous absorption. An important consideration in topical therapy is that diseased skin may have an altered (increased, decreased, or absent) stratum corneum, thus changing the body site's barrier function; for example, abraded or eczematized skin presents less of a barrier.

10. Nails

*Have penetration with number 1 and low penetration with increasing numbers.

TABLE 242-1 **Regional Differences in Penetration***

Occlusion

Occlusion via closed, airtight dressings or greasy ointment bases increases the hydration and temperature of the stratum corneum and limits rub-off/wash-off of the drug, enhancing drug penetration. To derive the greatest benefit from occlusion, the patient should hydrate the skin by immersion in water for approximately 5 min prior to the application of a cream or ointment. With many drugs, occlusion increases drug delivery by 10 to 100 times the amount of drug delivered when not occluded. [2] On the other hand, occlusion may also lead to a more rapid appearance of the drug's adverse effects such as the ability of topical corticosteroids to induce local skin atrophy or suppression of the hypothalamus-pituitary-adrenal axis. Occlusion might also promote infection, folliculitis, and miliaria.

Frequency of Application

The frequency of drug application likely has little effect on increasing a topical drug's overall efficacy. [3], [4] One daily application is enough for most topical glucocorticoids, for example, but the nonspecific emollient or protective effect of creams and ointments are likely enhanced by more frequent applications. Regardless, increasing the contact time for a topical drug augments its total absorption.

Quantity of Application

The quantity of the drug applied likely has a negligible effect on drug absorption, but enough must be dispensed and spread to cover the affected areas. Furthermore, the quantity of drug applied can affect patient adherence to prescribed regimen. For example, too much applied drug might negatively alter the subjective experience of having the salve on the skin, that is, either the drug feels “wrong” (greasy, caked, chalky, etc.) or is cosmetically unattractive. Regardless, the amount prescribed must be adequate to treat the affected body surface area for the necessary length of time. In this regard, patient education is critical to prevent wasteful overuse or ineffective underuse of the medication. Table 242-2 presents the amounts of topical medications to dispense based on the estimated body surface area, frequency of application, and duration of therapy.

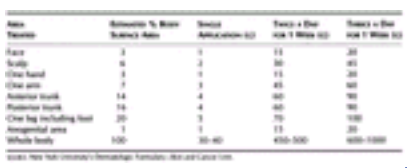

TABLE 242-2 **Suggested Amounts of Topical Medications to Dispense—Cream or Ointment**

Miscellaneous Factors

Vigorous rubbing or massaging of the drug into the skin not only increases the surface area of skin covered, but also increases blood supply to the area locally, augmenting systemic absorption. The presence of hair follicles on a particular body site also enhances drug delivery, with the scalp and beard areas presenting less of a barrier than the relatively hairless body sites. While having a thinner stratum corneum, the skin of older individuals is poorly hydrated and has fewer hair follicles, and therefore may impede drug delivery. Reducing the particle size of the active ingredient increases its surface area to volume ratio, allowing for a greater solubility of the drug in its vehicle. This forms the basis for the increased absorption of certain micronized drugs. [5]

CLASSIFICATION AND CLINICAL APPLICATION OF TOPICAL FORMULATIONS

The vehicle is the preparation that brings a drug in contact with the skin. Prior to the mid-1970s pharmaceutical companies performed limited testing of the impact of the vehicle on the potency of a given formulation. The lack of a scientific analysis of the vehicle led to the marketing of topical drugs that, while having different concentrations of the same active ingredient, displayed similar bioavailability and potency. For example, older preparations of triamcinolone acetonide showed no real differences in potency among the 0.025%, 0.1%, and 0.5% concentrations. By contrast, modern drug development attempts to maximize drug bioavailability by optimizing the vehicle formulation. Additionally, during the current drug development process dose–response studies determine the maximal effective concentration within a given vehicle, above which any further increase in concentration serves no therapeutic benefit.

The vehicle of a topical formulation often has beneficial nonspecific effects by possessing cooling, protective, emollient, occlusive, or astringent properties. Rational topical therapy leads to an appropriate vehicle that contains an effective concentration of the drug. The vehicle functions optimally when it is stable both chemically and physically and does not inactivate the drug. The vehicle also should be nonirritating, nonallergenic, cosmetically acceptable, and easy to use. Additionally, the vehicle must release the drug into the pharmacologically important compartment of the skin. Finally, the patient must like the vehicle or else compliance will be poor. For example, while ointments are often pharmacodynamically better than creams, patients generally prefer creams, and thus it should not surprise that more prescriptions are written for cream-based formulations. Table 242-3 lists many commonly used ingredients in topical preparations. Many of these compounds may serve more than one function in a particular formulation.

Emulsifying agents	Solvents
Cholesterol	Alcohol
Disodium monooleamidosulfo-succinate	Diisopropyl adipate
Emulsifying wax	Glycerin
Polyoxyl 40 stearate	1,2,6-Hexanetriol
Polysorbates	Isopropyl myristate
Sodium laureth sulfate	Propylene carbonate
Sodium lauryl sulfate	Propylene glycol (PG)
Auxiliary emulsifying agents/emulsion stabilizers	Water
Carbomer	Thickening agents
Cetearyl alcohol	Beeswax
Cetyl alcohol	Carbomer
Glyceryl monostearate	Petrolatum
Lanolin and lanolin derivatives	Polyethylene
Polyethylene glycol (PG)	Xanthan gum
Stearyl alcohol	Emollients
Stabilizers	Caprylic/capric triglycerides
Benzyl alcohol	Cetyl alcohol
Butylated hydroxyanisole (BHA)	Glycerin
Butylated hydroxytoluene (BHT)	Isopropyl myristate
Chlorocresol	Isopropyl palmitate
Citric acid	Lanolin and lanolin derivatives
Edetate disodium	Mineral oil
Glycerin	Petrolatum
Parabens	Squalene
Propyl gallate	Stearic acid
Propylene glycol (PG)	Stearyl alcohol
Sodium bisulfite	Humectants
Sorbic acid/potassium sorbate	Glycerin
	Propylene glycol (PG)
	Sorbitol solution

TABLE 242-3 **Vehicle Ingredients Commonly Used in Topical Preparations**

Powders

Powders absorb moisture and decrease friction. Because they adhere poorly to the skin, their use is limited to cosmetic and hygienic purposes. Generally, powders are used in intertriginous areas and on the feet. Adverse effects of powders include caking (especially if used on weeping skin), crusting, irritation, and granuloma formation. Furthermore, powders may be inhaled by the user. Most powders contain zinc oxide for its antiseptic and covering properties, talc (primarily composed of magnesium silicate) for its lubricating and drying properties, and a stearate for improved adherence to the skin. Calamine is a popular skin-colored powder composed of 98% zinc oxide and 1% ferric oxide that acts as an astringent to relieve pruritus. Other drugs formulated as powders include some over-the-counter antifungals. [5]

Poultices

A poultice, also referred to as a cataplasm, is a wet solid mass of particles, sometimes heated, that is applied to diseased skin. Historically, poultices contained meal, herbs, plants, and seeds. The modern poultice often consists of porous beads of dextranomer. Poultices are used as wound cleansers and absorptive agents in exudative lesions, such as decubiti and leg ulcers. [5]

Ointments

Ointments are semisolid preparations that spread easily. They can be protective, hydrating, and lubricating. Ointment bases used in dermatology can be classified into five categories: hydrocarbon bases, absorption bases, emulsions of water-in-oil, emulsions of oil-in-water, and water-soluble bases. Dermatologists commonly refer to the hydrocarbon bases and absorption bases as “ointments,” and the water-in-oil/oil-in-water emulsion bases as “creams.” In pharmaceutical terms, all of these preparations are ointments.

HYDROCARBON BASES Also called oleaginous bases, hydrocarbon bases are often referred to as emollients because they prevent the evaporation of moisture from the skin, and are composed of a mixture of hydrocarbons of varying molecular weights, with petrolatum being the most commonly used (white petrolatum, except for being bleached, is identical to yellow petrolatum). They are also greasy and can stain clothing. The silicon ointments are composed of alternating oxygen and silicon atoms bonded to organic groups such as phenyl or methyl and are excellent protectants. They can be used for diaper rash, incontinence, bedsores, and colostomy sites. Hydrocarbon bases are generally stable and do not contain preservatives. They cannot absorb aqueous solutions and thus are not used for water-soluble drugs. [6]

ABSORPTION BASES Absorption bases contain hydrophilic substances that allow for the absorption of water-soluble drugs. The hydrophilic (polar) compounds may include lanolin and its derivatives, cholesterol and its derivatives, and the partial esters of polyhydric alcohols such as sorbitan monstearate. These ointments are lubricating, hydrophilic, and can form emulsions. They function well as emollients and protectants. They are greasy to apply, but are easier to remove than the hydrocarbon bases. They do not contain water. Examples include anhydrous lanolin and hydrophilic petrolatum. [5]

WATER-IN-OIL EMULSIONS (CREAMS) Emulsions are two-phase systems involving one or more immiscible liquids dispersed in another with the assistance of an emulsifying agent. A water-in-oil emulsion by definition contains less than 25 percent water, with oil being the dispersion medium. The two phases may separate unless shaken. The emulsifier (or surfactant) is soluble in both phases and surrounds the dispersed drops to prevent their coalescence. Examples of surfactants used include sodium lauryl sulfate, the quaternary ammonium compounds, Spans (sorbitan fatty acid esters), and Tweens (polyoxyethylene sorbitan fatty acid esters). Preservatives are frequently added to increase the emulsion's shelf life. Water-in-oil emulsions are less greasy, spread easily on the skin, and provide a protective film of oil that remains on the skin as an emollient, while the slow evaporation of the water phase provides a cooling effect. [5]

OIL-IN-WATER EMULSIONS An oil-in-water emulsion contains greater than 31 percent water. In fact, the aqueous phase may comprise up to 80 percent of the formulation. This type of formulation is the one most commonly chosen to deliver a dermatologic drug. Clinically, oil-in-water emulsions spread very easily, are water washable and less greasy, and are easily removed from the skin and clothing. Invariably, they contain preservatives such as the parabens to inhibit the growth of molds. Additionally, oil-in-water emulsions contain a humectant (an agent that draws moisture into the skin) such as glycerin, propylene glycol, or polyethylene glycol to prevent the cream from drying out. The oil phase may contain either cetyl or stearyl alcohol (paraffin alcohols) to impart a stability and velvety smooth feel upon application to the skin. After application, the aqueous phase evaporates leaving behind both a small hydrating layer of oil and a concentrated deposit of the drug. [5]

WATER-SOLUBLE BASES Water-soluble bases consist either primarily or completely of various polyethylene glycols (PEGs). Depending on their molecular weight, PEGs are either liquid (for example, PEG 400) or solid (PEG 4000). These

formulations are water soluble, will not decompose, and will not support the growth of mold; consequently, they do not require preservative additives. They are much less occlusive than water-in-oil emulsions; in addition, they are nonstaining, greaseless, and easily washed from the skin. Without water this ointment poorly delivers its coformulated drug. Therefore, it will be useful in scenarios where the practitioner desires a high surface concentration and low percutaneous absorption of the drug. For example, topical antifungal drugs and topical antibiotics (i.e., mupirocin) are formulated in this type of base. *Gels* are made from water-soluble bases by formulating water, propylene glycol, and/or PEGs with a cellulose derivative or carbopol. A gel consists of organic macromolecules uniformly distributed in a lattice throughout the liquid. After application, the aqueous or alcoholic component evaporates, and the drug is deposited in a concentrated form. This provides a faster release of the drug independent of its water solubility. Gels are popular because of their clarity and ease of both application and removal. They are also easy to use on the hair-bearing body sites. Nevertheless, they lack any protective or emollient properties. If they contain high concentrations of alcohol or propylene glycol they tend to be drying or cause stinging. Gels require preservatives. [5]

Pastes

Pastes are simply the incorporation of high concentrations of powders (up to 50 percent) into an ointment such as a hydrocarbon base or a water-in-oil emulsion. The powder must be insoluble in the ointment. Invariably, they are “stiffer” than the original ointment. The powders commonly used are zinc oxide, starch, calcium carbonate, and talc. Pastes function to localize the effect of a drug that may be staining or irritating (i.e., anthralin). They also function as impermeable barriers that serve as protectants or sunblocks. Pastes are less greasy than ointments, more drying, and less occlusive. [5]

Liquids

Liquids can be subdivided into solutions, suspensions, and emulsions (discussed in the section on ointments).

SOLUTIONS A solution involves the dissolution of two or more substances into homogenous clarity. The liquid vehicle may be aqueous, hydroalcoholic, or nonaqueous (alcohol, oils, or propylene glycol). An example of an aqueous solution is aluminum acetate or Burow's solution. A hydroalcoholic solution with a concentration of alcohol of approximately 50 percent is called a *tincture*. A *collodion* is a nonaqueous solution of pyroxylin in a mixture with ether and ethanol, and is applied to the skin with a soft brush. *Flexible collodions* have added castor oil and camphor and are used, for example, to deliver 10% salicylic acid as a keratolytic agent and cantharidin for the treatment of warts. *Liniments* are nonaqueous solutions of drugs in oil or alcoholic solutions of soap. The base of oil or soap facilitates application to the skin with rubbing or massage. Liniments can be used as counterirritants, astringents, antipruritics, emollients, and analgesics. [5]
SUSPENSIONS (LOTIONS) A suspension, or *lotion,* is a two-phase system consisting of a finely divided, insoluble drug dispersed into a liquid in a concentration of up to 20 percent. Nonuniform dosing can result if the suspended particles coalesce and separate out of a homogeneous mixture, therefore shaking of the lotion prior to application may be required. Examples include calamine lotion, steroid lotions, and emollients containing urea or lactic acid. The applied lotion leaves the skin feeling cooler via evaporation of the aqueous component. Lotions are easier to apply and allow for uniform coating of the affected area, and are often the favorite preparation in treating children. Lotions are more drying than ointments, and preparations with alcohol tend to sting eczematized or abraded skin. [5]
SHAKE LOTIONS These are lotions to which a powder is added in order to increase the surface area of evaporation. As a result of the increased evaporation, the application of shake lotions effectively dries and cools wet and weeping skin. Generally, shake lotions consist of zinc oxide, talc, calamine, glycerol, alcohol, and water, to which specific drugs and stabilizers may be added. Shake lotions tend to sediment, and derive their name from the need to shake the preparation prior to each use in order to obtain a homogeneous suspension. In addition, after water has evaporated from the lotion, the powder component may clump together and become abrasive. Therefore, patients should be instructed to remove the residual particles prior to the reapplication of shake lotions. [5]

Aerosols

Topical aerosols may be used to deliver drugs formulated as solutions, suspensions, emulsions, powders, and semisolids. Aerosols involve formulating the drug in a solution within a propellant. Usually, the propellant is a blend of nonpolar hydrocarbons. When applied to abraded or eczematized skin, aerosols lack the irritation of other formulations, especially when the quality of the skin makes direct application painful or difficult. Further, aerosols dispense a drug as a thin layer with minimal waste, and the unused portion cannot be contaminated. Aerosol foams, a relatively new vehicle for drug delivery, are commonly used to deliver corticosteroids such as betamethasone valerate and clobetasol propionate. The foam contains the drug within an emulsion formulated with a foaming agent (a surfactant), a solvent system (such as water and ethanol), and a propellant. Upon application, a foam lattice forms transiently until it is broken by both the heat of the skin and the heat of rubbing the foam onto the skin. Foams that are alcohol based leave very little residue within seconds of their application. Furthermore, a given corticosteroid formulated in a foam vehicle demonstrates comparable potency when compared to the same corticosteroid in other vehicles. [6] While aerosols allow for the ease of application (especially to hair-bearing areas) and high patient satisfaction, they suffer from the disadvantages of being expensive and potentially ecologically damaging. [5]

Stabilizers

Stabilizers are nontherapeutic ingredients and include the *preservatives, antioxidants,* and *chelating agents*. Preservatives protect the formulation from microbial growth. Ideally, preservatives are effective at a low concentration against a broad spectrum of organisms, and are nonsensitizing, odor-free, color-free, stable, and inexpensive. Unfortunately, the ideal preservative does not exist. The parabens are the most frequently added preservatives, and are active against molds, fungi, and yeasts, but less effective against bacteria. Alternative agents include the halogenated phenols, benzoic acid, sodium benzoate, formaldehyde and the formaldehyde-releasing agents, and thimerosal. Most

commonly used preservatives can act as contact sensitizers.

Antioxidants prevent the drug or vehicle from degrading via oxidation. Examples include butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT), used in oils and fats. Ascorbic acid, sulfites, and sulfur-containing amino acids are used in water-soluble phases. Chelating agents, such as sodium ethylenediaminetetraacetic acid (EDTA) and citric acid, work synergistically with antioxidants by complexing heavy metals in aqueous phases.

Thickening Agents

These are agents that serve to increase the viscosity of products or to suspend ingredients in the formulation. Examples include beeswax and carbomers. In addition to functioning as an ointment vehicle, petrolatum may be added to an emulsion to increase its viscosity. Therefore, an ingredient simultaneously may be both therapeutic and nontherapeutic.

TOXICITY OF TOPICAL DRUGS

Local Effects

Either the vehicle or its active ingredients may cause local toxicity to the applied site. Local toxic effects are usually minor and reversible. Major cutaneous side effects include irritation, allergenicity, atrophy, comedogenicity, formation of telangiectases, pruritus, stinging, and pain. The mechanism of toxicity might be as simple as the desiccation of the stratum corneum (the removal of sebum and oils by the preparation's emulsifiers, for example), or involve a more complex effect on either the cells of the epidermis or dermis and the structures these cells comprise (i.e., epidermis, adnexae, etc.). Local damage may occur either directly at, or within close proximity to, the treated site. Furthermore, irritation and damage may appear even after the drug has been discontinued. Often the therapeutic effects of the active ingredient mask or immediately treat the toxic effects of the formulation so that the acutely toxic effects are transient. [7]

Irritation relies less on drug penetration and more on drug concentration. Thus, lowering the concentration of an irritating drug may lower the risk of side effects. But such a change in formulation may reduce the preparation's efficacy. Nevertheless, often using a less-concentrated preparation over a greater period of time is as therapeutically efficacious while minimizing adverse effects; for example, using benzoyl peroxide 2 to 5% preparations instead of 10% preparations. [7] In some instances, however, skin irritancy might be central to drug efficacy. For example, although not conclusively shown, the power of immunomodulating agents such as imiquimod might rely on an increased innate (inflammatory or irritant) immune response.

In contrast to local irritation, the development of contact allergy depends on local penetration. Allergy, of course, relies on antigen recognition and presentation; consequently, percutaneous absorption of the drug must be at a level that guarantees interaction with the immune effector cells of the epidermis and dermis. Therefore, the contact allergic properties of a drug relate to all of the parameters that influence percutaneous absorption.

Systemic Effects

Although not always considered while formulating a treatment plan, one should be aware of the potential systemic toxicities of topical drugs. While generally safer than the other routes of administration, topical application can result in systemic toxicities ranging from end-organ toxicity (central nervous system, cardiac, renal, etc.), teratogenicity and carcinogenicity, to drug interactions. These outcomes may relate to the drug itself, its metabolites, or a component of the vehicle.

The kinetics of topically applied drugs differ significantly from those administered by other routes. An important consideration is the lack of hepatic first-pass metabolism of a topical drug. This is especially relevant to drugs such as salicylic acid that are relatively innocuous when given enterally, but may manifest central nervous system toxicity when applied topically. Additionally, acting as a reservoir, the stratum corneum may store large amounts of a topical drug and a subsequently long diffusion period of many days may ensue, delivering a steady supply of drug to the systemic circulation.

Percutaneous toxicity directly relates to percutaneous absorption. Therefore, factors that modulate absorption also influence toxicity: the concentration of the drug, its vehicle, the use of occlusion, the body site treated, frequency of dosage, the duration of therapy, and the nature of the diseased skin. For example, 6% salicylic acid in Eucerin used for 11 days in the treatment of psoriasis results in epistaxis and deafness, while the same concentration of salicylic acid in hydrophilic cream under occlusion for 4 days for the treatment of dermatitis (involving the same amount of body surface area) may result in hallucination. [7] Similar to their effect on systemically administered drugs, renal and hepatic diseases, by influencing drug clearance, also contribute to an increased potential for drug toxicity.

Young children have a greater surface area-to-volume ratio, and thus are at greater risk of percutaneous toxicity than adults. This phenomenon necessitates alternative drugs, formulations, and dosing schedules for children with widespread cutaneous disease. Patients with acute flares of cutaneous illness (e.g., psoriasis or atopic dermatitis) may require the treatment of a larger body surface area in a relatively abbreviated period of time. These patients may also increase their dose and frequency of application during such flares. Coupled with the likely increased percutaneous absorption of the diseased skin, these scenarios exponentially increase the possibility of systemic toxicity, and patient education is vital to prevent adverse outcomes. [8] To reduce the risk of toxicity from topical drugs and to increase treatment efficacy, many practitioners rationally will advocate nontopical approaches (e.g., methotrexate, cyclosporine, or ultraviolet radiotherapy) to patients whose disease exceeds 20 to 25 percent of their body surface area.

In rare instances, anaphylactic shock can be precipitated by topical drug application. For example, when applied to diseased or abraded skin, bacitracin ointment can induce an immediate-type (type I) hypersensitivity reaction in

susceptible individuals. Such reactions might be represented by a local and then subsequently generalized pruritus leading to cardiopulmonary arrest. [8] Nonimmunologic acute toxicity results from substances such as pesticides and chemical warfare agents that rapidly diffuse through the skin and reach target organs.

DRUG INTERACTIONS

REFERENCES

Hydrocortisone, the first topically effective glucocorticoid, was introduced by Sulzberger and Witten in 1952. [1] The success associated with hydrocortisone led to the design and development of an ever-growing list of more potent analogues. Currently, topical steroids are the most frequently prescribed of all dermatologic drug products.

PHARMACOLOGY

Modifications of cortisol, the basic molecule (Fig. 243-1) by addition or alteration of functional groups at certain positions, have led to compounds of varying potencies and side effects. Addition of a fluorine molecule at positions 6 and/or 9 enhances the potency of the steroid, but is accompanied by an increased mineralocorticoid activity. [2] Substitution at the position 16 with an a-hydroxyl (triamcinolone), a-methyl (dexamethasone) or ß-methyl (betamethasone) increases efficacy without a concomitant increase in the sodium-retaining properties. [3] The removal, replacement or masking of hydroxyl groups increases the molecule's lipophilicity, therefore rate of percutaneous absorption as well as the glucocorticoid receptor-binding activity. Masking of hydroxyl groups can be achieved by esterification at positions C16, C17, and C21 (i.e., butyric acid at position 17 in the hydrocortisone molecule yields hydrocortisone butyrate); or formation of acetonide groups by addition of a 16-a-hydroxy substituent, producing triamcinolone acetonide and fluocinolone acetonide. Replacement of the 21-hydroxyl group in the betamethasone molecule with a chlorine moiety, creates clobetasol 17-propionate, the strongest molecule to date. [3], [4] and [5]

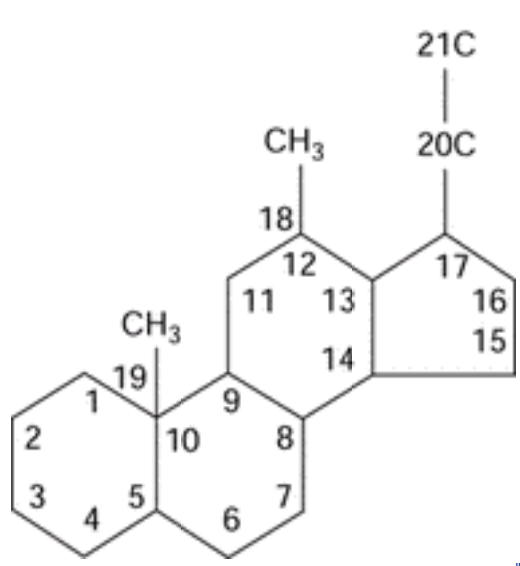

FIGURE 243-1 Basic steroid molecule.

The clinical potency of a topical corticosteroid depends not only on the inherent potency of the molecule but also on factors such as the vehicle and the nature of the skin onto which it is applied. The vehicle in which the steroid is incorporated may be as important as the steroid molecule itself because the vehicle affects the amount of steroid that is released in any given period of time (see Chap. 242). Very occlusive vehicles, such as ointments, potentiate glucocorticoid effects because they provide increased hydration of the stratum corneum and increase its permeability. By covering the skin with an occlusive dressing such as plastic wrap, this effect can be heightened as much as 100-fold. The solubility of the glucocorticoid in the vehicle also affects penetration into the epidermis. Propylene glycol is one agent commonly used to dissolve the glucocorticoid in the vehicle, and it is found in many topical glucocorticoid preparations. [6] In general, compounds that contain higher amounts of propylene glycol tend to be more potent.

Treatment of the skin prior to application of the topical steroid may also affect the absorption of the compounds into the skin. For example, use of keratolytics or fat solvents such as acetone enables increased penetration by disrupting the epidermal barrier. Tape stripping of the skin also increases the absorption of hydrocortisone by 78 to 90 percent. [7]

Topical glucocorticoid research has focused on strategies to optimize potency while minimizing side effects. One strategy is to develop compounds with enhanced anti-inflammatory effects and minimal unwanted atrophogenic and adrenal suppressive effects. In this sense, progress has been made with the development of glucocorticoid molecules that, while retaining high activity in the skin following topical application, are quickly broken down into inactive metabolites, thereby

mitigating systemic and possibly some local toxic effects (“soft” glucocorticoids). Examples of these compounds include fluticasone propionate, prednicarbate and methyl prednisolone aceponate. [8] However, data on long-term safety following prolonged topical application of these agents is currently lacking. Research to develop a nonsteroidal compound with the same anti-inflammatory effects of glucocorticoids but without the side effects is currently ongoing. [9]

CLINICAL USES

The clinical effectiveness of glucocorticoids is related to four basic properties: vasoconstriction, antiproliferative effects, immunosuppression, and anti-inflammatory effects. Topical steroids cause capillaries in the superficial dermis to constrict, thus reducing erythema. The ability of a given glucocorticoid agent to cause vasoconstriction usually correlates with its anti-inflammatory potency, and thus vasoconstriction assays are often used to predict the clinical activity of an agent. These assays in combination with double-blind clinical trials have been used to separate the topical glucocorticoids into seven classes based on potency. Class 1 includes the most potent, while class 7 contains the least potent. Table 243-1 lists many of the available topical glucocorticoids according to this classification.

TABLE 243-1 **Potency Ranking of Some Commonly Used Brand-Name Glucocorticoids**

The antiproliferative effect of topical glucocorticoids is mediated by inhibition of DNA synthesis and mitosis. Control of cellular proliferation is a complex process composed of cascades of stimulating influences that are counteracted by multiple inhibitory circuits. Many of these processes are probably influenced by glucocorticoids. [10]

The effectiveness of glucocorticoids, in part, may also be due to their immunosuppressive properties. The mechanisms responsible for immunosuppression are poorly understood. Several studies have shown that glucocorticoids can cause mast cell depletion in the skin. [11] This may explain the utility of topical glucocorticoids in patients with urticaria pigmentosa. Experiments also show that topical glucocorticoids cause a local inhibition of chemotaxis of neutrophils [12] in vitro, and decrease the number of Ia+ Langerhans cells [13] in vivo. In addition, several cytokines are directly affected by glucocorticoids, including interleukin (IL)-1, tumor necrosis factor-a, granulocyte-macrophage colony-stimulating factor, and IL-8. These effects may also be a result of the steroid action on antigen presenting cells. [14]

It is believed that glucocorticoids exert their potent anti-inflammatory effects by inhibiting the formation of prostaglandins and other derivatives of the arachidonic acid pathway. [15] It is known that glucocorticoids inhibit the release of phospholipase A_2, the enzyme responsible for liberating arachidonic acid from cell membranes, thus inhibiting the arachidonic acid pathway. For many years it was believed that glucocorticoids caused macrophages and other cells to release a specific protein, lipocortin, that was thought to have a direct inhibitory action on phospholipase A_2. [16] Although lipocortins have since been purified and their genes cloned and sequenced, their role in the anti-inflammatory action of glucocorticoids has been questioned. [17] It is the current belief that glucocorticoids inhibit phospholipase A_2 in cells by directly inducing phosphorylation of the enzyme. [18] Other proposed mechanisms for the anti-inflammatory effects of glucocorticoids include inhibition of phagocytosis and stabilization of lysosomal membranes of phagocytizing cells. [19]

Certain variables must be considered when treating skin disorders with topical glucocorticoids. For example, the responsiveness of diseases to topical glucocorticoids varies. In this setting, diseases can be divided into the three categories shown in Table 243-2: highly responsive, moderately responsive, and least responsive. Highly responsive diseases will usually respond to weak steroid preparations; less-responsive diseases require medium potency steroids; and the least-responsive category requires high-potency topical steroids.

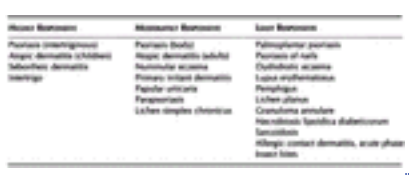

TABLE 243-2 **Responsiveness of Dermatoses to Topical Application of Corticosteroids**

Before choosing a topical glucocorticoid preparation, one must consider the area of the body that is to be treated because regional differences greatly affect the activity of the topical agent. Penetration of the glucocorticoid varies according to the skin site, which, in turn, is related to the thickness of the stratum corneum and the vascular supply to the area. For example, penetration of topical steroids through the eyelids and scrotum is 4 times greater than for the forehead and 36 times greater than for the palms and soles. Inflamed, moist, and denuded skin also shows increased penetration. Areas of the body where the skin is inherently thin not only allow for increased penetration of the drug but are more susceptible to develop side effects than other areas where the skin is thick (see Table 242-3). Potent topical steroids (classes 1 and 2) should rarely, if ever, be used in the areas with the highest level of penetration, such as the

eyelids.

Pediatric Uses

Topical glucocorticoids are highly effective, and few side effects are observed when a low-potency preparation is used for brief periods of time without occlusion in children. Infants, however, are at an increased risk for side effects for several reasons. Because they have a higher ratio of skin surface area to body weight, application to a given area results in a greater potentially systemic dose of steroid. Infants may also be less able to metabolize potent glucocorticoids rapidly. [20] Premature infants are especially at risk because their skin is thinner and the penetration rate of topically applied drugs is greatly increased. [21] Application of topical steroids to the diaper area results in occlusion of the steroid by the diaper, and increased penetration occurs. Excess absorption of topical glucocorticoids can suppress endogenous cortisol production. Consequently, subsequent cessation of topical steroid therapy after an extended treatment period can result in an addisonian crisis characterized by nausea, anorexia, postural hypotension, and vascular collapse. Deaths from addisonian crisis have been reported with the use of topical steroids, [22] and the risk of this occurring is greater in children. Chronic suppression of cortisol production can also lead to growth retardation. A morning plasma cortisol level can be performed to screen for adrenal suppression. If suppression is present, the child should be slowly weaned from the steroids to prevent these complications.

Geriatric Uses

Elderly patients similarly can have thin skin, which allows for increased penetration of topical glucocorticoids. They are also more likely to have preexisting skin atrophy secondary to aging and may be diaper-dependent, so the same precautions used in the treatment of infants should be used when treating elderly patients. Topical glucocorticoids should be used infrequently, for brief periods, or under close supervision in those patients with preexisting skin atrophy to avoid unwanted side effects.

Uses in Pregnancy

Appropriate human studies using topical glucocorticoids in pregnancy have never been undertaken. Studies in animals, however, show that topical steroids are systemically absorbed and may cause fetal abnormalities, especially when used in excessive amounts, under occlusive dressings, for prolonged periods of time, or when the more potent agents are used. However, numerous studies of pregnant patients taking systemic glucocorticoids throughout pregnancy show no increases in the incidence of fetal abnormalities. Most topical steroids are rated by the US Food and Drug Administration (FDA) as category C drugs, which implies that caution must be exercised when used in pregnancy. It is currently unknown whether topical glucocorticoids are excreted in breast milk; however, they should be used with caution in breast-feeding mothers and should never be used on the breasts prior to breast feeding.

DOSAGE SCHEDULES AND FORMULATIONS

Twice-a-day topical application of glucocorticoids is recommended on the labels of most formulations, although no scientific evidence has ever established this as the optimal schedule. To decrease the risks of side effects, it is best to establish, with the aid of the patient, the longest elapsed time between successive applications that still controls the disease. This method may help to decrease the development of side effects and tachyphylaxis. Tachyphylaxis has been demonstrated in experimental conditions by diminished vasoconstriction, rebound of DNA synthesis, and recovery of histamine wheals after application of topical steroids in patients with a history of long-term topical steroid usage. [23]

Topical steroids come in many different vehicles and dosage forms. Ointments are water-insoluble mixtures of oil and petrolatum and are the best preparation when treating dry skin conditions because they provide the most moisture of the available preparations. They are also useful for treating conditions on areas of the body with thick skin, such as the palms and soles. The occlusive nature of the ointment and its ability to moisturize the stratum corneum allow for increased penetration and enhanced potency of the drug. Peanut oil has also been combined with steroids to form a preparation that is thinner and easier to apply while retaining the hydrating capability of ointments. However, patients may feel that ointments and oils are too greasy. New emollient creams have been devised that contain an increased amount of petrolatum but with less greasiness than ointments, and some patients find them more cosmetically appealing.

Creams are suspensions of oil in water. They vary in their composition and generally are far less greasy than ointments, but they do not provide the same degree of hydration to the skin. Many patients find creams easier to spread on the skin and more cosmetically pleasing than ointments. However, creams may contain emulsifiers and preservatives that can lead to allergic reactions in some patients.

Lotions are suspensions of oil in water and are similar to creams. They contain agents to help solubilize the glucocorticoids and to allow them to be spread more easily on the skin. Solutions contain no oil but are composed of water, alcohol, and propylene glycol. Gels are solid components at room temperature but melt on contact with the skin. Lotions, solutions, and gels have less penetration than ointments but are useful in treating hair-bearing areas such as the scalp where greasiness is cosmetically displeasing to the patient. Steroid-impregnated tapes are useful because they provide occlusion with increased penetration and provide protection of the skin lesion from manipulation, such as scratching, by the patient. Sprays containing steroids are available, and while they represent a convenient mode of applying these agents, the inefficiency of the delivery system is such that they are seldom recommended.

More recently, foam products have been added to currently available topical formulations. They are highly efficacious, cosmetically superior, and well tolerated. When first dispensed, the foam is stable; but when applied to skin, body heat causes the foam structure to break down and the active ingredient is deposited on the skin with very little residue. [24] (For a more complete discussion of vehicles for topical preparations, see Chap. 242.)

ADVERSE EFFECTS

Side effects from the use of topical steroids have become more prevalent since the introduction of the higher potency topical steroids. Using these products on thin or denuded skin, on the elderly or pediatric population, or under occlusion increases the incidence of side effects. Striae and atrophy, the most commonly observed side effects, occur with prolonged use and are more likely to occur in areas of sweating, occlusion, or high penetration such as the axilla or groin. In general, atrophy does not occur until the agent has been used for 3 to 4 weeks and is usually reversible. Striae, which develop when the weakened skin is stretched, are not reversible. Prolonged treatment can also result in “steroid acne,” which is characterized by crops of dense, inflamed pustules in the same developmental stage. These lesions occur on the face, chest, and back. Perioral and periocular dermatitis have been associated with the use of topical steroids and usually improve with cessation of the steroid. Patients with rosacea who are given topical steroids may initially improve, but a severe rebound phenomenon consisting of edema and pustules may occur. For these reasons, in most situations steroid use should be discouraged in the treatment of rosacea and perioral and periocular dermatitis. Purpura, which represents easy bruising, may develop when steroids are used in areas of thin skin.

Topical steroids can also cause suppression of the pituitary–adrenal axis. Growth retardation and iatrogenic Cushing's syndrome are known, but rare, complications of topical steroid therapy. Morning plasma cortisol serologic tests can be performed to screen for adrenal suppression. If these levels are abnormal, adrenal function can be assessed further by using the cosyntropin stimulation test. Most topical and systemic side effects are readily reversible if recognized early by the clinician. The incidence of side effects, however, can be significantly reduced if appropriate guidelines for topical steroid use are followed.

Patients treated with topical glucocorticoids may develop a contact or irritant dermatitis to the steroid itself or, more commonly, to one of the ingredients used as a preservative. An increase in contact dermatitis caused by the steroid component has been reported. [25] Most topical steroid ointments are free of preservatives and are less likely than other topical agents and steroid creams to cause an allergic or irritant contact dermatitis. The most common preservatives that cause allergic contact dermatitis include parabens, polyethylene glycol, and benzyl alcohol (Table 243-3). Fragrance and local anesthetics are also sensitizers that may be included in the topical preparations.

Parabens
Propylene glycol
Benzyl alcohol
Chlorocresol
Ethylenediamine hydrochloride
Isopropyl palmitate
Polysorbate 60
Stearyl alcohol

TABLE 243-3 **Common Sensitizers in Topical Steroids**

DRUG INTERACTIONS

Topical glucocorticoids have few, if any, known drug interactions. For this reason they are often mixed with other topical medications, such as antifungals and antibiotics, to form combination products. Although a few combination products are available, development of new combination products has not been encouraged by the FDA. In fact, the FDA recently rejected new drug applications for combinations of topical antibacterials such as neomycin, bacitracin, and hydrocortisone, because the manufacturers were unable to provide proof of effectiveness of each component. However, many of these combination products are found in many countries outside the United States. Theoretically, there should be no need for a combination when each component can be obtained separately.

REFERENCES

The term *retinoid* was coined by Michael Sporn and his colleagues in 1976. The original description referred both to the naturally occurring compounds with vitamin A activity and to synthetic analogues of retinol. Hence, retinoids were defined in both functional (vitamin A activity) and structural (retinol-derivative) terms. The discovery of intranuclear retinoic acid receptors (RARs) in 1987, by two independent groups, [1], [2] was pivotal to our understanding of the mechanism of retinoic acid action because it demonstrated for the first time the existence of a retinoid-responsive transcription factor. This also gave rise to the concept that retinoids are like hormones. Therefore, a retinoid can be defined as any molecule that, by itself or through metabolic conversion, binds to and activates the RARs, thereby eliciting transcriptional activation of retinoic acid-responsive genes that results in specific biologic responses.

PHARMACOLOGY

Nomenclature

Vitamin A is a 20-carbon molecule that consists of a cyclohexenyl ring, a side chain with four double bonds (all arranged in *trans* configuration), and an alcohol end group. Hence, it is also known as all- *trans* retinol. Oxidation of the alcohol end group of all- *trans* retinol results in the formation of an aldehyde (all- *trans* retinaldehyde), which can be further oxidized to carboxylic acid (all- *trans* retinoic acid = tretinoin) (Fig. 244-1A). The numbering of the carbon atoms is as shown in Fig. 244-1B. The terms 9- *cis* and 13- *cis* retinoic acid refer to stereoisomers of all- *trans* retinoic acid in which the double bond that begins with the ninth and thirteenth carbon atoms, respectively, is in the *cis*- rather than *trans*-configuration. The fourth carbon atom is located in the cyclohexenyl ring of all- *trans* retinoic acid and is involved in a hydroxylation reaction to generate 4-hydroxy-all- *trans* retinoic acid (Fig. 244-1C). The addition of a hydroxyl group to the cyclohexenyl ring renders the molecule more polar, making it more amenable for excretion/elimination from cells and organisms. It is also much less active biologically. 4-Hydroxy-all- *trans* retinoic acid can be further oxidized to 4-oxo retinoic acid.

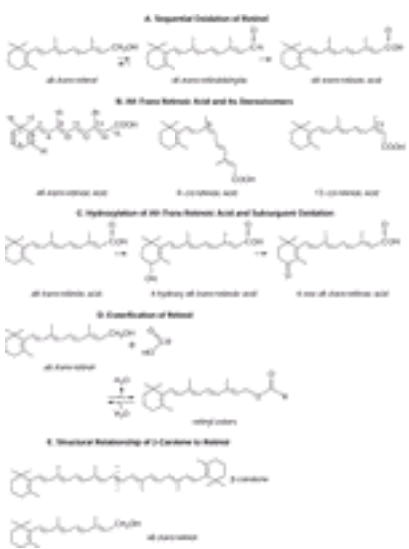

FIGURE 244-1 Nomenclature of natural retinoids.

A group of compounds referred to as *retinyl esters* functions as the molecular storage form of retinol. The compounds are formed by esterification of retinol with fatty acids (Fig. 244-1D). The fatty acids involved specify the ester. For example, retinyl palmitate is generated when retinol is esterified with palmitic acid. Hydrolysis of retinyl esters regenerates retinol. Finally, beta-carotene is a symmetric 40-carbon molecule (twice the number of retinol or retinoic acid) present in green and yellow-orange fruits and vegetables. As suggested by stoichiometry, one molecule of this carotenoid can potentially generate two molecules of retinol (cleavage of the central double bond) (Fig. 244-1E).

Metabolism of Retinoids in Human Skin

As the vitamin designation implies, all- *trans* retinol cannot be synthesized in the body and is thus an essential nutrient. Retinyl esters and beta-carotene are the two major precursors of retinol present in our diet. Once taken in from the diet, retinyl esters and beta-carotene are converted to all- *trans* retinol in the intestine and stored in the liver after reconversion to retinyl esters. Retinol released from the liver is carried in the circulation by plasma retinol-binding proteins. Once transported to target cells, it is taken up, apparently through passive diffusion. Consistent with the fact that retinol is a hydrophobic molecule, it associates intracellularly with a ubiquitously expressed binding protein called cellular retinol-binding protein (CRBP). In human skin, CRBP-bound all- *trans* retinol (holoCRBP) can be metabolized to at least three important products: retinyl esters, all- *trans* retinoic acid, and all- *trans* 3,4-didehydroretinol (vitamin A_2) and its esters. The functional significance of vitamin A_2 formation is unknown.

ESTERIFICATION AND OXIDATION OF RETINOL Topical treatment of human skin with all- *trans* retinol increases retinyl ester levels in the epidermal layer by more than tenfold. [3] This reaction is catalyzed by two enzymes: lecithin/retinol acyltransferase (LRAT) and acyl-CoA/retinol acyltransferase (ARAT). In human keratinocytes, LRAT is the predominant retinol-esterifying activity. [4] All- *trans* retinoic acid is formed by sequential oxidation of all- *trans* retinol, with all- *trans* retinaldehyde as the intermediate metabolite. The first step (oxidation of all- *trans* retinol to all- *trans* retinaldehyde) is rate limiting for all- *trans* retinoic acid formation. Topical application of all- *trans* retinol to human skin results in histologic and molecular alterations that mimic those following all- *trans* retinoic acid treatment. [3] These include epidermal hyperplasia caused by keratinocyte proliferation, epidermal spongiosis, compaction of the stratum corneum, and induction of CRBP, cellular retinoic acid binding protein (CRABP) II, and retinoic acid 4-hydroxylase. [3], [5] In retinol-treated skin, all- *trans* retinoic acid is minimally detectable, which is no different from untreated normal skin. The lack of significant accumulation of all- *trans* retinoic acid in retinol-treated skin is a result of the tightly regulated conversion of retinol to retinaldehyde and the effective hydroxylation of all- *trans* retinoic acid that is formed by retinoic acid 4-hydroxylase. The observation that all- *trans* retinol and retinoic acid elicit similar responses in human skin but that retinol does so without detectable increases in retinoic acid levels indicates that endogenously synthesized retinoic acid is a much more efficient activator of retinoid pathways than exogenously supplied retinoic acid. Metabolically formed all- *trans* retinoic acid is bound to CRABP. This cytoplasmic protein, of which there are two species (CRABP I and II), binds all- *trans* retinoic acid selectively and with high affinity. The fact that the CRABPs are highly conserved proteins found in multiple species showing distinct patterns of expression in developing embryo and adult organisms suggests that their functions are important in retinoid signaling. In addition to all- *trans* retinoic acid, 9- *cis* and 13- *cis* retinoic acid have been isolated from tissues. It is not known whether the interconversion among the retinoic acid occurs through specific isomerases. When equal amounts (0.1 percent) of all- *trans,* 9- *cis,* or 13- *cis* retinoic acid are applied topically to human skin, all- *trans* retinoic acid is extracted in significant amounts (36 to 72 percent of retinoic acid isomers) regardless of the isomer applied. [5]

HYDROXYLATION OF ALL- *TRANS* RETINOIC ACID In human skin all- *trans* retinoic acid is catabolized primarily to the more polar 4-hydroxy-all- *trans* retinoic acid, which is further metabolized to 4-oxo retinoic acid. 4-Hydroxy retinoic acid is tenfold less potent in inducing retinoid responses in human keratinocytes and mouse skin than is all- *trans* retinoic acid. [6] In untreated normal human skin, all- *trans* retinoic acid 4-hydroxylase activity is minimally detectable. Topical administration of all- *trans* retinoic acid or all- *trans* retinol to human skin, however, increases its activity several fold. [5], [7] The 4-hydroxylase is a cytochrome P450 enzyme (now termed CYP26) whose activity can be effectively inhibited by ketoconazole and a related azole, liarozole. [7], [8] By blocking this major inactivation pathway of all- *trans* retinoic acid pharmacologically, topical liarozole can amplify human skin responses to all- *trans* retinol and retinoic acid. [8] Although this hydroxylase activity is also induced in skin treated with 9- *cis* or 13- *cis* retinoic acid, remarkably it has substrate specificity for the all- *trans* retinoic acid isomer only and it does not hydroxylate 9- *cis* or 13- *cis* retinoic acid, retinol, or retinaldehydes. [5] With all- *trans* retinoic acid, the 4-hydroxylase activity is maximally induced after 24 h of occlusive treatment.

The Retinoid Receptors

The landmark discovery of RARs and characterization of their molecular features revealed the similarity of RARs to steroid/thyroid hormone receptors. [1], [2] A characteristic common to these receptors is that they bind to regulatory regions in DNA called hormone response elements, or target sequences, and activate gene transcription in a ligand-dependent manner. Hence, they are referred to as ligand (hormone)-dependent transcription factors. At the amino acid level, the nuclear receptor superfamily members are organized into six domains, each with a distinct function. Two domains of major importance are the DNA-binding domain and the ligand-binding domain. A short sequence within the DNA-binding domain, called the P box, has allowed categorization of the receptors into at least four different subfamilies. RARs, vitamin D receptors (VDRs), and thyroid hormone receptors (TRs) all possess the same P-box amino acid sequence. When their respective ligands are bound, these receptors bind to similar DNA recognition sequences located in the promoter region of target genes. The recognition sequences (hormone-response elements) are composed of two half-sites, each 6 base pairs long (AGGTCA). The base pair spacing between the half-sites determines, in part, the specificity of the receptor recognition sequences. The two half-sites are arranged as direct repeats for RAR, VDR, and TR, whereas for classic steroid hormone receptors (e.g., glucocorticoid, mineralocorticoid, progesterone), the two are in a palindromic (i.e., inverted repeat) configuration. These nuclear receptors bind to their response elements as dimers. Unlike receptors for the steroid hormones, which form homodimers (two identical monomers), RAR, VDR, and TR bind to their elements with greater affinity as heterodimers (two different monomers). The key partner for heterodimerization and ultimate functioning of RAR, VDR, and TR is the retinoid X receptor (RXR). [9] 9- *cis* retinoic acid is a key physiologic ligand for RXR. [10] In addition to RARs, VDRs, and TRs, RXRs heterodimerize with other receptors. This ability of RXRs to interact with many receptors suggests their importance as regulatory proteins. There are three different members of RAR (a, ß, and ?) and RXR (a, ß, and ?), each encoded by different genes. In addition, each of the receptors has isoforms, adding to the diversity of retinoid receptors.

Receptor-Selective Retinoids

Identification and functional characterization of these families of retinoid receptors provided an attractive target for drug discovery. Synthetic molecules could be screened for their ability to bind and activate the specific receptors. Many of these compounds have no structural similarities to all- *trans* retinol or retinoic acid, yet by virtue of their ability to activate the receptor(s), they can mediate the retinoid effect and thus be considered retinoids. Two synthetic retinoids that fit this description and have been used topically in humans are adapalene and tazarotene (Fig. 244-2). Adapalene has restricted receptor specificity, possessing poor affinity for RAR-a, higher affinity for RAR-ß and -?, and no interaction with RXR-a. [11] Although adapalene does not bind to CRABPs, it is capable of inducing CRABP II mRNA like all- *trans* retinoic acid. [12] Unlike retinoic acid, however, adapalene does not induce clinical erythema, epidermal hyperplasia, or spongiosis following a short-term (4 days) occlusive treatment. Tazarotene is another synthetic molecule that has biologic activity when topically applied. Tazarotene cannot directly bind to RARs or RXRs. However, its acid metabolite (AGN 190299) has a weak, but relative, receptor selectivity for RARs (RAR-ß > RAR- ? > RAR-a), [13] and is felt to be the principal active form.

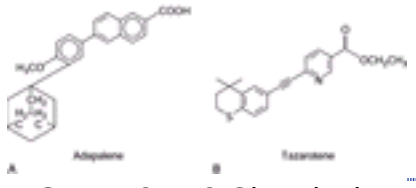

FIGURE 244-2 Chemical structures of the synthetic retinoids adapalene and tazarotene.

The Retinoid Receptors in Human Skin

Skin remains the only human tissue in which systematic analysis of the relative levels of each RAR and RXR protein has been made. Human epidermis expresses RAR-a, RAR-?, RXR-a, and RXR-ß mRNAs. [14] RXR-? mRNA is undetectable, and the transcript for RAR-ß is barely detectable. A similar pattern is observed in cultured human keratinocytes and dermal fibroblasts. These relative levels of retinoid receptor mRNAs mirror their relative protein levels. In nuclei from human epidermal cells, there are five times more total RXRs than RARs. [15] For RAR proteins, 87 percent are RAR-? and 13 percent are RAR-a with no detectable RAR-ß. Of the RXR proteins, 90 percent are RXR-a. In gel-shift studies performed on nuclei isolated from human skin and cultured keratinocytes, which in both cases are expressing their normal endogenous receptors, only RXR-a and RAR (mostly ?) heterodimers bind to retinoic acid-response elements (RAREs) spaced by two (DR-2) or five nucleotides (DR-5). [15], [16] Neither RAR nor RXR homodimers are detectable. Therefore, normal human epidermis is regulated by RXR-a and RAR-? heterodimers. In terms of the ligands needed to activate RXR/RAR-bound RAREs, based on chloramphenicol acetyltransferase reporter gene activity in keratinocytes, the heterodimer requires only the RAR ligand. Furthermore, the presence of RXR ligand does not confer additional transactivation induced by RAR ligand. Therefore, at their physiologic levels, RARs and RXRs in human skin bind RAREs (DR-2 or DR-5) as heterodimers and transactivate these response elements in response to RAR, but not to RXR, ligands. However, the RXR is key as the heterodimer will not bind to the RARE without the presence of the RXR protein. Ultraviolet (UV) irradiation of human skin causes a rapid and significant reduction of retinoid receptors, both RAR-? and RXR-a. [17] Although the decrease in the receptor levels is transient, returning to pre-UV treatment levels within 2 days, topical application of all- *trans* retinoic acid shortly after UV irradiation fails to activate CRABP-II and RA-4 hydroxylase genes which contain functional RAREs in their promoters. This indicates that the reduction of RAR and RXR by UV results in functional impairment of receptor-dependent retinoid responsiveness in human skin. Interestingly, pretreatment of skin with all- *trans* retinoic acid before UV irradiation reduces receptor loss and accelerates receptor recovery. [17]

Retinoid Target Genes and Their Activation Cascade in Human Skin

Based on current information, retinoid actions are primarily, if not solely, mediated by retinoid receptors. Given that the receptors are transcription factors, the ultimate skin effects of retinoids (phenotypic changes) must be accomplished through regulated gene expression. The best-established mechanism by which retinoid receptors modulate gene expression is activation of retinoid target genes through direct binding to RARE in the gene promoter, thereby stimulating the basal transcriptional machinery. In skin, CRABP II, CRBP, and keratin 6, all of which contain RAREs, are regulated by all- *trans* retinoic acid. [3], [18], [19] and [20] However, the products of these genes are probably not the effectors of the retinoid response and hence cannot account for the pleiotropic effects of retinoids in skin. Undoubtedly, additional RARE-regulated genes will be identified that encode for proteins that function to modulate cutaneous growth and differentiation directly or indirectly. A likely scenario is that these protein products, in turn, activate other non–RARE-containing genes in a cascading reaction to produce the clinical features of retinoid action in skin (Fig. 244-3). Because most genes expressed within the cascade would contain no functional RAREs, their activation by retinoids would be indirect. Therefore, the retinoid response in human skin is mediated both by direct and indirect activation of genes, initiated by a retinoid signal.

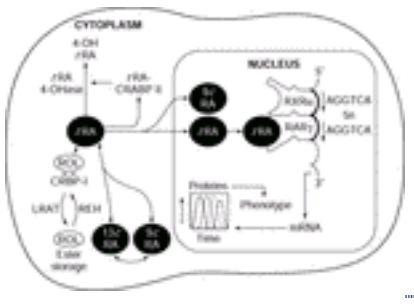

FIGURE 244-3 Cellular metabolism of natural retinoids and molecular mechanism of retinoid-specific gene activation.

CLINICAL USE

Until quite recently, clinical use of topical retinoids has been limited to all- *trans* retinoic acid (tretinoin). Although the initial use of this retinoid was in actinic keratosis, currently the only approved dermatologic indications in the United States are for acne and photoaged skin. Topical adapalene and tazarotene have also received approval from the U.S. Food and Drug Administration for acne; tazarotene has also received approval for psoriasis. For acne therapy, it is widely accepted that, especially for the comedonal variant, topical retinoids are extremely effective. Of the different classes of antiacne medications, retinoids are thought to be the best, if not the only, agents to normalize the abnormal follicular epithelial differentiation/desquamation viewed to be important in the pathogenesis of acne lesions. Therefore, the use of retinoids would also provide protection against the development of new lesions. This prophylactic property is the basis for including topical retinoid in almost all antiacne regimens. A potential for aggravating inflammation exists in treating inflammatory acne (i.e., papules and pustules) with topical retinoids, but when properly administered, this type of acne also responds well to retinoids (see " Dosage Schedule and Forms"). Fine wrinkles and dyspigmentation are two salient features of photoaged skin that are improved by topical tretinoin. Several weeks of treatment are required before clinical improvement is appreciated. For the effacement of fine wrinkles by topical tretinoin, partial restoration of markedly reduced levels of collagen in sun-exposed skin toward those seen in sun-protected skin appears to be responsible. [21] Tretinoin's ability to improve photoaging is specific and does not result from the irritation or retinoid dermatitis frequently produced by this compound. [22] Although the molecular basis of photoaging prevention by topical tretinoin was recently demonstrated, [23] its value in clinical practice is as yet unstudied. Neither topical adapalene nor tazarotene are approved for the treatment of photoaging. However, recent studies indicate that both retinoids hold promise in ameliorating the clinical features of photodamage. [24], [25]

Besides the approved indications, topical retinoids have been demonstrated, through well-controlled studies, to be effective in the treatment of several other conditions. Most of these have been with tretinoin because it is the first topical retinoid to be developed and has been available the longest. Studied conditions include, but are not limited to, postinflammatory hyperpigmentation in blacks, [26] actinic dyspigmentation in Chinese and Japanese individuals, [27] melasma, [28], [29] and early stretch marks. [30] The controlled studies show more than therapeutic efficacies. They also provide valuable information to dispel some of the myths about retinoid use in humans. For example, African Americans and Asians tolerate topical tretinoin as well as, if not better than, [26], [27], [29] whites. [24], [28], [30] Furthermore, the often observed retinoid dermatitis does not usually lead to postinflammatory hyperpigmentation in those with greater constitutive pigmentation.

Many other skin disorders have been reported to be improved by topical retinoids, but most of these have not been as rigorously studied and their therapeutic claims should thus be interpreted with caution. Molluscum contagiosum, warts, and various forms of ichthyosis may be improved by topical retinoids to a variable degree. In psoriasis, especially, irritation of treated skin has limited the use. Topical tazarotene, which is approved for psoriasis, does not appear to have fully overcome the irritation problem; [31] thus, it is typically used in combination with topical steroids. The beneficial effects of topical retinoids in treating actinic keratoses have been confirmed through clinical trials. However, there is no role for topical retinoids in the treatment of established cutaneous tumors.

With such a wide variety of skin conditions treatable by topical retinoids, their use has included practically all age groups, perhaps with the exception of neonates. Similar considerations in dose schedule and forms are made in both young and old patients. The use of topical retinoids in pregnancy is an emotional issue. As discussed below, based on fact, teratogenicity is not caused by topical retinoids (see " Adverse Effects"). However, because none of the dermatologic conditions seen in pregnancy that may respond to topical retinoids (i.e., acne, melasma, stretch marks) are life-threatening to the mother or the fetus, it seems prudent to delay the treatment until after delivery. In a study which demonstrated that early, inflammatory stretch marks were improved by topical tretinoin, all pregnancy-related stretch marks were treated postpartum. [30] Therefore, even in this pregnancy-associated condition, the therapeutic benefit could be achieved by instituting the treatment after delivery.

DOSAGE SCHEDULES AND FORMS

Until very recently, tretinoin was the only topical retinoid available for clinical use. Under the trade name Retin-A, three different formulations are available for acne therapy: cream (0.025%, 0.05%, 0.1%), gel (0.01%, 0.025%), and solution (0.05%). For photoaging treatment, tretinoin (0.05%, 0.02%) was introduced as Renova cream. A recent addition to acne therapy, adapalene (Differin) is available in 0.1% gel and lotion formulations. For acne and psoriasis, topical tazarotene (0.05% and 0.1%) is available in gel and cream formulations. Different formulations allow some flexibility in terms of tailoring the therapy to an individual's skin dryness or oiliness.

Regardless of the retinoid preparation or the patient's age, the most important element in topical therapy is patient/guardian education. It must be explained clearly to each patient that, as part of the treatment, local skin irritation, characterized by redness and peeling, can be expected. It was once believed, especially for the treatment of photoaged skin, that clinical improvement correlated with the degree of irritation. This concept was erased through a large,

controlled clinical study in which 0.025% and 0.1% tretinoin were shown to be equally efficacious, but the former was significantly less irritating than the latter. [22] Therefore, unlike most medications for which the dosing schedule may be set as once or twice daily, administration of a topical retinoid should be titrated depending on the skin reaction. For some individuals it may be applied only twice a week, for others four times a week, and so on. The frequency of drug application can be increased, as tolerated, to a once-daily regimen. This method of individualizing topical therapy minimizes unwanted acute retinoid dermatitis.

Under the nonprescription category, there are countless “natural retinoid” preparations with various claims (mostly antiaging) being sold throughout the world. Most of these contain retinyl esters, especially retinyl palmitate, retinaldehyde, or retinol. Whether any of these products can deliver retinoid activity to human skin is subject to question. Percutaneous absorption (especially for retinyl esters), adequate concentrations, and stable formulations (especially for retinol) are some of the important unknowns for this group of products. Based on human in vivo work, all- *trans* retinol and all- *trans* retinaldehyde hold the most promise of these natural retinoids in being biologically active, [3], [32] provided the stability of the compound can be maintained with a proper formulation. When the sun-protected skin of individuals older than 80 years of age was treated for 7 days with 1% retinol, the fibroblast growth and dermal collagen were increased significantly. [33] Concomitantly, retinol markedly reduced the levels of matrix-degrading metalloproteinases that are elevated in the aged skin as compared to the young skin. These findings suggest that retinol may reverse and partially prevent skin atrophy that accompanies intrinsic aging.

ADVERSE EFFECTS

By far the most common adverse effect associated with topical retinoid use is local skin irritation characterized by erythema, peeling, dryness, and pruritus. This is a predictable skin response that is temporary, but troubling, for many patients. The so-called retinoid dermatitis tends to peak within the first month of treatment and diminishes thereafter. It responds to a temporary reduction in the frequency or amount of retinoid application and to liberal use of emollients.

It has been well documented that the most striking histologic feature of all- *trans* retinoic acid-treated skin is the marked thickening of the epidermis [3], [8], [22] caused by the increased proliferation of basal keratinocytes. An increase is also seen in the number of cell layers expressing the differentiation markers involucrin, loricrin, filaggrin, and epidermal transglutaminase. [20] These epidermal changes collectively translate to clinical desquamation and peeling. This hyperproliferative response of epidermis to retinoic acid is mediated by its nuclear receptor, as was recently demonstrated in transgenic mice expressing either a dominant-negative (dn) RXR-a [34] or dn RAR-a [35] mutant proteins targeted to the suprabasal epidermis by the keratin 10 promoter. The mutant proteins impaired retinoid signaling by competing with endogenous RAR-?/RXR-a heterodimers. In these mice, the ability of topically applied retinoic acid to stimulate proliferation of undifferentiated keratinocytes in the basal layer and resultant peeling of stratum corneum from the surface was significantly reduced. [34], [35] Therefore, the peeling component of retinoid dermatitis is a part of the retinoid-specific skin response. Among the genes regulated by retinoid receptors involved in the cell growth control (keratinocyte proliferation), heparin-binding epidermal growth factor (HB-EGF) appears to be a critical one. Retinoid induction of HB-EGF stimulates basal cell growth via the cell surface EGF receptor activation. The importance of this signaling pathway in the hyperplastic response of the epidermis to topical retinoid was recently demonstrated when pharmacologic antagonists of EGF receptor tyrosine kinase activity blocked retinoid-induced epidermal thickening in human skin organ culture. [36] This observation suggests that it may be possible to reduce the clinically undesirable effects of retinoids on epidermal keratinocytes. The erythema response, however, may not to be retinoid-receptor mediated, because all- *trans* retinol, which induces epidermal hyperplasia and CRABP II mRNA-like retinoic acid (two indicators of receptor activation), is unassociated with clinical erythema. [3]

Systemic retinoid exposure has been well documented and established as a cause of embryonic death and congenital malformation. Therefore, concerns about potential teratogenicity from long-term topical retinoid use are completely justified. However, systemic absorption of retinoids from topical application is negligible, and the levels of endogenous retinoic acid in the blood are not increased by twice daily application of 0.025% tretinoin to more than 40 percent of body area over 1 month. Furthermore, controlled topical administration of tretinoin at doses used for acne therapy (2 g of 0.025% gel applied daily to the face, neck, and upper part of the chest for 14 days) has less influence on plasma levels of endogenous retinoids than diurnal and nutritional factors. [37] Indeed, a large population-based study demonstrated no excess risk of birth defects in offspring born to mothers who were exposed to topical tretinoin during pregnancy. [38] Therefore, no evidence exists for teratogenicity of topical tretinoin in humans. As mentioned under “Pharmacology,” topical use of tretinoin induces in the skin the enzyme retinoic acid 4-hydroxylase that inactivates tretinoin. Therefore, the induction of this enzyme would serve as a protective mechanism to partially reduce the amount of tretinoin for systemic absorption. In this regard, topical use of natural retinoids would be even safer than any of the synthetic compounds, because there already exists self-inducible enzymatic machinery that will inactivate excess tretinoin, but probably not synthetic retinoids.

“Sun sensitivity” is a frequently discussed subject with topical retinoid use and requires clarification. When formally tested in humans, topical tretinoin does not lower the minimal erythema dose of UVB light. [23] Because its presence in human skin does not increase the likelihood of sunburn reaction, tretinoin is not a phototoxic agent. When one talks to patients who complain of such sun sensitivity, they describe an uncomfortable skin sensation that is felt within minutes of being in the sun rather than hours later. This time line is certainly in disagreement with a typical sunburn reaction which takes longer to be noticed (hours to a day). Furthermore, this sensation is often said to be accentuated in warmer temperatures, which suggests participation of infrared irradiation (heat).

Related to the sun-sensitivity is the issue of photocarcinogenesis. In an animal model of photocarcinogenesis, topical tretinoin has caused skin cancer. However, this seems to be restricted to susceptible animals under contrived experimental conditions, and no evidence exists of a comparable process in humans. Indeed, by using a model in which human skin was grafted onto mice with severe combined immunodeficiency disease, gross inadequacy of the commonly used rodent model of photocarcinogenesis was demonstrated. [39] Specifically, the traditional rodent models significantly

overestimate the human carcinogenic potential of tested agents. Topical retinoids, on the contrary, appear to have a protective effect against UV-induced premalignant and malignant lesions. In those predisposed by nevoid basal cell carcinoma syndrome or xeroderma pigmentosum to the development of nonmelanoma skin cancer, systemic retinoids have provided effective protection. In this regard, topical tretinoin's ability to prevent UV induction of c-Jun is relevant. [40] c-Jun is a protooncoprotein that is minimally detectable in normal human skin in vivo. Its partner c-Fos, however, is constitutively expressed. UV irradiation to human skin does not affect the level of c-Fos expression, but it markedly induces c-Jun protein which can then heterodimerize with c-Fos, forming a complete active AP-1 transcription factor. [40] The critical importance of AP-1 in mediating carcinogenic transformation of papillomas has been demonstrated. [41] In human squamous cell carcinomas, c-Jun expression is elevated and systemic retinoids prevent carcinomas of the head and neck. Mechanisms involved in this chemopreventive effect of the retinoid likely include c-Jun suppression. These clinically observed anticarcinogenic activities of retinoids are also supported by in vitro data demonstrating that tretinoin treatment of human skin upregulates the antigen-presenting activity of Langerhans cells without concomitant increase in autoreactivity. [42] Such a retinoid effect would improve cutaneous immune responsiveness to tumor antigens. Therefore, topical retinoic acid is not a carcinogen in humans.

DRUG INTERACTION AND INCOMPATIBILITIES

Retinoids in general are photolabile and therefore can be photoinactivated. Based on this chemistry, it is prudent to apply the agents in the evening rather than before the start of the day. Because the major avenue of tretinoin inactivation is through a cytochrome P450 retinoic acid 4-hydroxylase, drugs that modulate the activity of this enzyme can potentially cause drug interactions. Ketoconazole and liarozole are effective inhibitors of this hydroxylase. [7], [8] Therefore, concurrent use of these azoles and topical tretinoin can increase the amount and prolong the half-life of tretinoin locally in the skin, thereby aggravating the local side effect. Indeed, this was observed in one topical tretinoin study when a patient inadvertently started oral ketoconazole for tinea infection and experienced a severe and prolonged dermatitis, which could be reproduced by ketoconazole challenge. Other than retinoids, no other compounds have been shown to induce the retinoic acid 4-hydroxylase.

The use of vitamin D_3 and its analogues has increased in dermatology (see Chap. 251). Vitamin D effects in human skin are largely mediated via its nuclear receptor VDR. As previously discussed, VDR is a member of the steroid/retinoic acid/thyroid hormone receptor superfamily. Like RAR, VDR functions in human skin mainly as a heterodimer with RXR (VDR-RXR). In contrast with retinoid signaling via RAR-RXR in which the presence of RXR-ligand confers no additional effect, RXR-ligand provides a synergistic effect with VDR-ligand in vitamin D signaling. [43] Therefore, topical retinoids that possess, or through metabolic conversion, acquire RXR selectivity can positively influence vitamin D pharmacology in human skin.

Chapter 245

Mark Bonner Paul Benson William James

Topical Antibiotics

AGENTS USED IN THE TOPICAL TREATMENT OF ACNE
Erythromycin
Clindamycin
Tetracycline
Metronidazole
Azelaic Acid
AGENTS USED FOR THE TOPICAL THERAPY OF SUPERFICIAL BACTERIAL INFECTIONS
Mupirocin
AGENTS USED TO PREVENT INFECTION FOLLOWING SURGICAL PROCEDURES OR INJURIES OR TO TREAT CHRONIC DERMATITIS
Bacitracin
Polymyxin B
TOPICAL AMINOGLYCOSIDES, INCLUDING NEOMYCIN, GENTAMICIN, AND PAROMOMYCIN
MISCELLANEOUS AGENTS
Gramicidin
Chloramphenicol
Sulfonamides
Clioquinol
Nitrofurazone
Fusidic Acid
REFERENCES

Topical antibiotics play an important role in the management of many common dermatologic conditions. They are prescribed most often by dermatologists for the management of mild to moderate acne vulgaris or as adjunctive treatment with oral agents. For localized superficial infections, such as impetigo, the use of a topical agent (e.g., mupirocin) may eliminate the need for oral antibiotics and the accompanying problems of compliance, gastrointestinal side effects, and potential drug interactions. Lastly, topical antibiotics frequently are prescribed as prophylactic agents following minor surgery or cosmetic procedures (dermabrasion, laser resurfacing) to reduce the risk of postoperative wound infections and to speed wound healing. The usefulness of topical antibiotics for prophylaxis following such minor procedures has been questioned recently and will be discussed more fully below.

AGENTS USED IN THE TOPICAL TREATMENT OF ACNE

The efficacy of topical antibiotics for the treatment of acne vulgaris and rosacea may be due to their direct antibiotic effect, but there are some suggestions that many of the topical antibiotics exhibit anti-inflammatory properties by suppressing neutrophil chemotactic factor or by other mechanisms. There are mounting concerns about the use of topical antibiotics in the treatment of acne vulgaris because of the increasing levels of antibiotic resistance to common topicals. This has led investigators to look at combination therapy for acne vulgaris that reduces the development of antibiotic resistance.

Erythromycin

Erythromycin belongs to the group of macrolide antibiotics and is active against both gram-positive cocci and gram-negative bacilli. It is a fermentation product of *Streptomyces erythreus* and is used principally as a topical agent for the treatment of acne. Erythromycin binds to the bacterial 50S ribosome and blocks translocation of the peptidyl-tRNA molecule from the acceptor to the donor site, interfering with the formation of the polypeptide chain and inhibiting protein synthesis. [1] In addition to its antibacterial properties, erythromycin has anti-inflammatory activity, which makes it especially useful in the management of acne. [2]

Erythromycin is available as a 1.5% to 2% solution, gel, pledgets, and ointment as a single agent (Table 245-1). It is also available in combination with benzoyl peroxide, which may slow the development of antibiotic resistance to erythromycin. [3] The combination of 1.2% zinc acetate and 4% erythromycin may be superior to clindamycin, although it is not currently available in the United States.

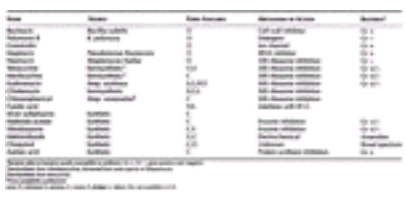

TABLE 245-1 **Topical Antibiotics**

Clindamycin

Clindamycin is a semisynthetic lincosamide antibiotic that is derived from lincomycin. The mechanism of action is very similar to that of erythromycin, with binding to the 50S ribosome and suppression of bacterial protein synthesis. [1] Clindamycin is used topically as a 1% gel, solution, and suspension (lotion) (see Table 245-1) primarily for the treatment of acne. It is also available as a combination with benzoyl peroxide, which may slow the development of antibiotic resistance to clindamycin. Pseudomembranous colitis rarely has been reported to occur with the topical use of clindamycin. [4]

Tetracycline

Topical tetracyclines, in the form of meclocycline sulfosalicylate and tetracycline hydrochloride solution, have been available in the past for the treatment of acne but have never gained wide acceptance. Meclocycline sulfosalicylate currently is not available, probably because of a lack of efficacy. Undesirable side effects of tetracycline topical solution include odor and yellow staining of skin.

Metronidazole

Metronidazole, a topical nitroimidazole, is currently available as a 0.75% gel, lotion, or cream and as a 1% cream for the topical treatment of rosacea. In the lower strength, it is applied twice daily, and in the higher strength, it is used once daily. Orally, metronidazole has broad-spectrum activity against many protozoal organisms and anaerobes. The mechanism of action of topical metronidazole in the skin is unknown; however, the antirosacea effect may be due to the antibiotic, antioxidant, and anti-inflammatory properties of the drug. [5]

Azelaic Acid

Azelaic acid is a dicarboxylic acid found in food (whole-grain cereals and animal products). There is a normal human plasma level (20–80 ng/mL), but topical application does not significantly alter this level. The mechanism of action is thought to be normalization of the keratinization process (decreased thickness of the stratum corneum, decreased number and size of keratohyaline granules, and decreased amount of filaggrin). There are reports of in vitro activity against *Propionibacterium acnes* and *Staphylococcus epidermidis,* which may be due to inhibition of bacterial protein synthesis (the exact site is not known at this time). In aerobic microorganisms, there is inhibition of oxidoreductive enzymes (such as tyrosinase, mitochondrial enzymes of the respiratory chain, 5-alpha-reductase, and DNA polymerases). In anaerobic bacteria, there is disruption of glycolysis. Azelaic acid is used principally in the treatment of acne vulgaris, although there are some advocates for its use in the treatment of hyperpigmentation (such as melasma). However, the U.S. Food and Drug Administration (FDA) has not approved the drug for this indication. Azelaic acid is available as a 20% cream preparation. [6]

AGENTS USED FOR THE TOPICAL THERAPY OF SUPERFICIAL BACTERIAL INFECTIONS

Mupirocin

Mupirocin, which was formerly known as pseudomonic acid A, is a topical antibiotic agent derived *from Pseudomonas fluorescens*. The drug reversibly binds to isoleucyl-tRNA synthetase and inhibits bacterial protein synthesis. The activity of mupirocin is limited to gram-positive bacteria, especially staphylococci and most streptococci. Its activity is enhanced in an acid pH environment (5.5), which is the normal pH of the skin. Mupirocin is somewhat temperature-sensitive and thus should not be exposed to high temperatures. Mupirocin ointment 2% is applied three times daily and is principally indicated for the treatment of localized impetigo caused by *S. aureus* and *Streptococcus pyogenes*. [7] However, widespread impetigo or disease occurring in immunocompromised individuals should be treated with systemic therapy to reduce the risk of serious complications. Bacterial resistance to mupirocin was first reported in 1987. [8] Since then, there have been additional reports of mupirocin resistance with the widespread use of the topical antibiotic to control methicillin-resistant *S. aureus* (MRSA) carriage in health care facilities. [9], [10] A recent study at a Tennessee Veterans' Affairs Hospital demonstrated that prolonged use of mupirocin ointment to control MRSA carriage, especially in bedridden patients with decubitus ulcers, led to significant resistance. [11] Further, Japanese researchers found that low concentrations of mupirocin are achieved after intranasal application and postulated that this might explain the selection of mupirocin-resistant strains of *S. aureus.* [12] A small pilot study using intranasal application of a combination antibiotic ointment containing bacitracin, polymyxin B, and gramicidin successfully decolonized 80% (9 of 11) of patients who remained clear after a mean follow-up period of 2 months. [13] All cases (6 of 6) of mupirocin-sensitive MRSA were eradicated, whereas only 3 of 5 cases of mupirocin-resistant MRSA were eliminated. New formulations that involve the use of the calcium salt of mupirocin (the calcium aids in chemical stability in the intranasal preparation) are available for intranasal use as a 2% ointment and a 2% topical cream.

AGENTS USED TO PREVENT INFECTION FOLLOWING SURGICAL PROCEDURES OR INJURIES OR TO TREAT CHRONIC DERMATITIS

It is common practice to use topical antibiotics to reduce the potential for wound infections following minor surgical procedures, in cases of chronic dermatitis such as stasis dermatitis or atopic dermatitis, or following minor abrasions of the skin. Recent studies have focused on the incidence of infection after skin biopsy or minor surgery with the use of topical antibiotics or their vehicles. In some cases, the topical antibiotic seemed to decrease the rate of wound healing. In other studies, use of the vehicle alone appeared to be as effective as the topical antibiotic in wound healing without the risk of irritant or allergic contact dermatitis to the antibiotic agent. The results of one large study comparing bacitracin and petrolatum in over 1200 minor surgical procedures and biopsies demonstrated that the active agent, bacitracin, did not statistically decrease the already low rate of infection during such procedures but was associated with a small risk of

allergic contact dermatitis. [14]

Bacitracin

Bacitracin is a topical polypeptide antibiotic originally isolated from the Tracy-I strain of *Bacillus subtilis,* which was cultured from a patient with a compound fracture contaminated with soil. Thus the baciportion is derived from *Bacillus,* and the *-tracin* from the name of the patient who had the compound fracture (Tracy). Bacitracin is a cyclic polypeptide antibiotic with multiple components (A, B, and C). Bacitracin A is the major component of commercial products and is often used as the zinc salt. [1] Bacitracin interferes with bacterial cell wall synthesis by binding to and inhibiting the dephosphorylation of a membrane-bound lipid pyrophosphate. [15] It is active against gram-positive cocci such as staphylococci and streptococci. Most gram-negative organisms and yeast are resistant to the drug. It is available as bacitracin ointment and as zinc bacitracin, with 400 to 500 units per gram.

Topical bacitracin is effective for the treatment of superficial bacterial infections of the skin such as impetigo, furunculosis, and pyodermas. It is often combined with polymyxin B and neomycin as a triple antibiotic ointment applied several times daily for the treatment of secondarily infected eczematous dermatitis such as atopic dermatitis, nummular dermatitis, or stasis dermatitis. [1] Unfortunately, the topical application of bacitracin carries with it the risk of allergic contact sensitization [8] and, rarely, anaphylactic shock. [16]

Polymyxin B

Polymyxin B is a topical antibiotic derived from a spore-forming soil aerobe *B. polymyxa,* which was isolated originally from a soil sample in Japan. Polymyxin B is a mixture of polymyxin B_1 and B_2, which are both cyclic polypeptides. They function as cationic detergents that interact strongly with bacterial cell membrane phospholipids, thus disrupting the integrity of the cell membrane. [1]

Polymyxin B is active against a wide range of gram-negative organisms, including *P. aeruginosa, Enterobacter,* and *Escherichia coli.* [1] Polymyxin B is available in ointment form (5000–10,000 units per gram) in combination with bacitracin or bacitracin and neomycin. It should be applied one to three times a day. [15]

TOPICAL AMINOGLYCOSIDES, INCLUDING NEOMYCIN, GENTAMICIN, AND PAROMOMYCIN

The aminoglycosides are an important group of antibiotics used both topically and systemically for the treatment of infections caused by gram-negative bacilli. Aminoglycosides exert their bactericidal effects by binding to the 30S ribosomal subunit and interfering with protein synthesis. [17]

Neomycin sulfate, the aminoglycoside most often used topically, is a fermentation product of *Strep. fradiae.* Commercial neomycin is a mixture of neomycin B and C, whereas framycetin, used in Canada and some European countries, is pure neomycin B. [18] Neomycin sulfate has activity against aerobic gram-negative bacteria and is used most commonly for prophylaxis against infection in superficial abrasions, cuts, and burns. [17] It is available in ointment form (3.5 mg/g) and is packaged in combination with other antibiotics such as bacitracin, polymyxin, and gramicidin. Other agents, such as lidocaine, pramoxine, or hydrocortisone, also may be found in combination with neomycin. [19]

Neomycin is not recommended by many dermatologists because of the allergic contact dermatitis that occurs after widespread, indiscriminate use of the drug, especially in over-the-counter products. [16] The prevalence of contact dermatitis is high, with 6 to 8 percent of patients undergoing patch testing being positive. [20] Neomycin sulfate (20%) in petrolatum is used to assess for contact allergy. [20]

Gentamicin sulfate is derived as a fermentation product from *Micromonospora purpurea.* It is available as a topical 0.1% cream or ointment. [21] It is used by some dermatologic surgeons when operating on the ear, especially in diabetic or other immunocompromised patients, to provide prophylaxis against malignant otitis externa due to *P. aeruginosa.* [22]

Paromomycin is closely related to neomycin and has antibacterial and antiparasitic activities. A topical formulation consisting of paromomycin sulfate and methylbenzethonium chloride is used in Israel to treat Old World cutaneous leishmaniasis. [23]

MISCELLANEOUS AGENTS

Gramicidin

Gramicidin is a topical antibiotic derived from *B. brevis.* [15] The gramicidins are linear peptides that form stationary ion channels in susceptible bacteria. The antibiotic activity of gramicidin is restricted to gram-positive bacteria. [24]

Chloramphenicol

Chloramphenicol is available in the United States with use limited to the treatment of minor bacterial skin infections. Chloramphenicol was isolated originally from *Strep. venezuelae,* but it is now synthesized because of its simple chemical structure. The mechanism of action is similar to that of erythromycin and clindamycin, with inhibition of the 50S ribosome blocking translocation of peptidyl tRNA from the acceptor to the donor site. [16] Chloramphenicol is available as a 1% cream. It is used infrequently because fatal aplastic anemia or dose-related bone marrow suppression has been reported

following topical exposure. [25]

Sulfonamides

The sulfonamides are structurally similar to *para*-aminobenzoic acid (PABA) and compete with it during the synthesis of folic acid. Sulfonamides are used infrequently as topical agents, with the exception of silver sulfadiazine (Silvadene) cream and mafenide acetate cream. Silver sulfadiazine is thought to release silver slowly. The silver exerts its effect on the bacterial cell walls and membranes. [26] The mechanism of action of mafenide is not the typical sulfonamide mechanism of action because PABA does not antagonize its performance. [27] Mafenide acetate, if used over large areas of skin, has the potential to cause a metabolic acidosis, and it can cause intense pain on topical administration. Both agents are broad-spectrum antibacterials useful in the treatment of burns. *Candida* superinfection may be a problem with mafenide cream. [27]

Clioquinol

Clioquinol (also known as *iodochlorhydroxyquin*) is a broad-spectrum antibacterial/antifungal topical that is currently indicated for the treatment of inflammatory skin disorders and tinea pedis and has been used for minor bacterial infections. It is a synthetic hydroxyquinoline whose mechanism of action is unknown. [28] The disadvantages of clioquinol include discoloration of clothing, skin, hair, and nails and the potential to cause irritation. Clioquinol may interfere with thyroid function determination because the iodine moiety interferes with tests that rely on iodine uptake (this effect can last for up to 3 months after application). However, clioquinol does not interfere with testing for T3 or T4. [28]

Nitrofurazone

Nitrofurazone (Furacin) is a nitrofuran derivative used for the treatment of burn patients. The mechanism of action involves the inhibition of bacterial enzymes involved in the aerobic and anaerobic degradation of glucose and pyruvate. Nitrofurazone is available as a 0.2% cream, solution, or soluble dressing, and its spectrum of activity includes staphylococci, streptococci, *E. coli, Clostridium perfringens, Aerobacter enterogenes,* and *Proteus* spp. [29]

Fusidic Acid

Fusidic acid is a topical preparation that is not currently available in the United States but is in use in Canada and Europe as an antibacterial available as a cream, ointment, and impregnated gauze. [30] Fusidic acid is a steroidal antibiotic with a mechanism of action that interferes with the function of the elongation factor (EF-G) by stabilizing the EF-G-GDP-ribosome complex, preventing translocation of the ribosomes and EF-G from recycling. Topical Antifungal Agents

DERMATOPHYTE INFECTIONS
CANDIDIASIS (CANDIDOSIS)
PITYROSPORUM (MALASSEZIA) INFECTIONS

REFERENCES

Superficial fungal infections such as dermatophytoses, candidiasis, and pityriasis versicolor are typically restricted to epithelial tissues. When presented with such infections, the option is to treat with either systemic or topical antifungal therapy. The decision requires consideration of numerous factors, including extent of infection, severity of infection, site of infection (e.g., nails as opposed to glabrous skin), underlying diseases, efficacy of treatment, potential drug interactions, side effects, known allergies, cost, the patient's health care plan, ease of use, patient's preference, and finally the physician's familiarity with different antifungal therapies. In general, patients with limited disease and fungal infections confined to glabrous skin are best treated with topical antifungal therapy while patients with extensive disease and infections of hair and nails are best treated with systemic therapy. In some cases, either option can be used. Topical antifungal therapy has numerous advantages over systemic antifungal therapy, including the absence of serious side effects (e.g., hepatitis as seen with the oral imidazoles), absence of drug interactions, no requirement to monitor laboratory tests, ability to localize treatment to affected sites, over-the-counter availability of some medications, and ease of use for patients who experience difficulty swallowing pills. The oral medications are discussed in Chap. 261.

Today there are numerous topical antifungal drugs available (Table 246-1). Prior to 1945, specific antifungal drugs were not available and nonspecific therapies such as keratolytics (e.g., salicylic acid) and antiseptics (e.g., gentian violet, Castellani's paint) were the cornerstones of therapy. Although topical antifungal drugs have been available since the development of undecylenic acid in 1945, there is no consensus as to the best topical antifungal agent. The ideal topical antifungal agent should demonstrate these properties:

- Fungicidal at therapeutic concentration
- Absence of resistance
- Broad spectrum of action that includes all known superficial fungal pathogens
- Keratinophilic
- Penetrates keratin but is not absorbed systemically
- Hypoallergenic
- Nonirritating
- Anti-inflammatory properties
- Once-per-day (or less) application
- Short duration of therapy required for cure
- Availability in a wide variety of formulations (e.g., cream, solution) and sizes
- Inexpensive

Class/Generic Name	Name	Availability
Allylamines		
Naftifine	Naftin	Prescription
Terbinafine	Lamisil	Prescription
	Lamisil AF	OTC
	Desenex Max	OTC
Benzylamine		
Butenafine	Mentax	Prescription
Hydroxypyridone		
Ciclopirox olamine	Loprox	Prescription
	Penlac	Prescription
Imidazoles		
Clotrimazole	Lotrimin	Prescription
	Mycelex	Prescription

Oxiconazole	Oxistat	Prescription
Sulconazole	Exelderm	Prescription
Polyenes		
Amphotericin B	Fungizone	Prescription
Nystatin	Mycostatin	Prescription
	Nystop	Prescription
Nystatin/triamcinolone	Mycolog II	Prescription
Miscellaneous		
Tiacetin/sodium propionate/benzalkonium chloride/cetylpyridinium chloride/chlorocresol	Fungoid	Prescription
Tolnaftate	Equate	OTC
	Tinactin	OTC
Undecylenic acid/zinc undecylenate	Cruex	OTC
	Desenex	OTC
Undecylenic acid/chlorocresol	Cordo/Kem	OTC

OTC, over the counter

TABLE 246-1 **Topical Antifungal Agents**

None of the drugs developed to date fully meets all of the desired properties. Despite the fact that topical antifungal agents have been used for decades and there are numerous studies that demonstrate the efficacy of each drug, it remains difficult to compare the efficacy of the various agents. In part this is because the pharmaceutical companies sponsor most antifungal studies and the antifungal therapy is often compared to the vehicle. Comparing the results among these studies is fraught with error because the studies differ in design, duration of therapy, site of infection, patient selection, method of determining response, and duration of follow-up. There are a number of studies that compare one topical antifungal agent with another, but the conclusions are always limited to that study and the data cannot be compared with data from other studies. Because the two most important medical factors are the type of

pathogen and the site of infection, the discussion of topical antifungal therapy that follows is organized in this fashion.

DERMATOPHYTE INFECTIONS

Dermatophyte infections are limited to three genera (i.e., *Trichophyton, Microsporum,* and *Epidermophyton*) that use keratin as a substrate (see Chap. 205). The specific species producing infection is usually not a consideration in the selection of topical therapy, although in vitro studies show that *T. mentagrophytes* species are less sensitive to most antifungal drugs than are other species. Because the location of infection (i.e., hair, glabrous skin, nails) is critical in selecting therapy, the treatment of dermatophyte infections is individually discussed for each area.

Dermatophyte infections of hair most commonly present as tinea capitis but may also present as tinea barbae or Majocchi's granuloma. In follicular dermatophyte infections, viable hyphae can invade as deep as the bottom one-third of the hair follicle to a region referred to as Adamson's fringe. It is at this level that there is a transition from keratin to viable keratinocytes, which cannot serve as a substrate for dermatophyte growth. Because of the depth of Adamson's fringe, topical antifungal agents should probably not be used as primary therapy for hair infections, although studies regarding their use in this situation are lacking. Ketoconazole shampoo and selenium sulfide have both been demonstrated to decrease the shedding of viable organisms and are useful adjunctive therapies to prevent the spread of infection to other family members.[1], [2] Although, ketoconazole shampoo as a monotherapy for tinea capitis reportedly produces long-term clinical and mycologic cures in as many as one-third of children,[2] this is a low cure rate when compared to systemic therapy and it is not recommended as a primary therapy.

Dermatophyte infections of glabrous skin, which are classified by site of involvement including face (tinea faciei), trunk and extremities (tinea corporis), groin (tinea cruris), hands (tinea manuum), and feet (tinea pedis), are the most common indication for topical antifungal therapy. Topical therapies may be used interchangeably among these sites with the possible exception of tinea cruris, where the skin is sensitive and easily develops an irritant contact dermatitis to some topical antifungals.

The two earliest topical antifungal agents, undecylenic acid and tolnaftate, are still available but are only rarely used. Undecylenic acid, which is often combined with one of its salts (i.e., zinc undecylenate), is the original specific topical antifungal agent. Although the initial study reported a high cure rate, subsequent studies reported cure rates as low as 27 percent. In addition this antifungal also has a disagreeable odor and may require prolonged use (up to 26 weeks in some studies). Tolnaftate, synthesized in Japan and introduced as a topical antifungal agent in 1964, is a thiocarbamate derivative, not related to any other antifungal drug. Its mode of action is similar to the allylamines in that it inhibits squalene epoxidase, which results in accumulation of squalene in the fungal cell. Although early studies reported cure rates as high as 73 to 93 percent, at least one study reported a 0 percent cure rate for tinea pedis.[3] While earlier studies suggested that tolnaftate was superior to undecylenic acid preparations, later studies concluded that the two drugs were equivalent. Although definitive comparative studies are lacking, it is probably less effective than newer antifungal agents and is only rarely used.

The advent of the topical imidazoles in the early 1970s produced the class of drugs that are most commonly used on fungal infections of glabrous tissue. The imidazoles are considered to be fungistatic drugs, although at very high levels some are fungicidal. The imidazoles act by inhibiting the cytochrome P450-dependent enzyme, lanosterol 14a-demethylase, that is necessary for the conversion of lanosterol to ergosterol, a fungal cell wall sterol necessary for normal cell membrane permeability and structural integrity. The topical antifungals currently available in this class include miconazole, clotrimazole, econazole, ketoconazole, oxiconazole, and sulconazole. Although all of these drugs have the same mechanism of action, in vitro studies have shown that not all dermatophytes are uniformly susceptible to different imidazoles at identical concentrations. The clinical significance of this finding is not yet resolved.

The reported cure rates for the imidazole class of drugs are highly variable and depend on the design of the study; as stated earlier, it is impossible to compare cure rates between different studies. For example, one may conclude that topical miconazole produces either a 63 percent cure rate[4] or a 100 percent cure rate[5] in dermatophyte infections, depending on the study quoted. A review of the literature of topically applied imidazole agents does not provide convincing evidence that there is a significant difference among any of the members of this group in overall cure rate or relapse rate, although they appear to be marginally superior to both undecylenic acid products and tolnaftate. Miconazole and clotrimazole are the two drugs in the class that are also available over the counter at a considerable savings over their prescription counterparts (Table 246-2). Although mycologic cure rate is not a determining factor in drug selection within this group, there is a difference in irritancy between different preparations, particularly in sensitive areas such as the groin. In at least one study of clotrimazole, it was reported that it produced severe erosive irritant reactions in 4 of 27 patients when used to treat tinea cruris. In the same study, sulconazole did not produce any irritant reactions, was well tolerated, and seemed to accelerate healing in denuded areas.[6] In a second study, it was reported that there were severe irritant reactions in miconazole-treated patients, but not in sulconazole-treated patients.[5] Until better studies regarding irritant reactions of topically applied imidazoles are available, sulconazole is an excellent choice for sensitive or macerated skin.

TABLE 246-2 **Topical Antifungal Cost (Retail)**

Topical imidazoles are available in creams and lotions. Limited studies from manufacturers seem to indicate that creams are marginally more effective than lotions. For example, oxiconazole cream is reported by the manufacturer to produce a clinical and mycologic cure in 52 percent of cases of tinea pedis, whereas oxiconazole lotion only produces a 41 percent cure. [7]

A second issue is that of how often the drug should be applied. Several imidazoles, including econazole, ketoconazole, and oxiconazole, have received once-daily application approval from the US Food and Drug Administration, while the remaining imidazole regimens recommend twice-daily application. Sulconazole is recommended by the manufacturer to be applied twice daily, but a study comparing once-daily to twice-daily application regimens for the treatment of tinea cruris and tinea corporis reported identical cure rates. [6] This result is not unexpected, because all imidazoles have the same mechanism of action. This is an important point because drug companies with once-per-day indications promote their drugs as being more economical than drugs with twice-daily regimens.

A third important issue is the use of topical imidazoles combined with topical glucocorticoids. The combination of clotrimazole and betamethasone dipropionate is the most frequently prescribed topical agent in the United States, with the majority of the prescriptions being written by primary care providers. The rationale for this combination has been that the addition of a topical glucocorticoid will relieve symptoms of pruritus and burning more quickly and produce quicker resolution of erythema and scaling. Early studies reported that the clotrimazole and betamethasone dipropionate combination was more effective than clotrimazole alone in producing resolution of erythema and pruritus. The mycologic cure rate was reported to be equivalent to that of clotrimazole, although these studies had short follow-up periods that did not permit proper assessment of the relapse rate. Subsequent striae and persistent dermatophyte infections have prompted many dermatologists to eschew the use of this combination product. [8] In a subsequent study comparing naftifine to clotrimazole/betamethasone dipropionate, it was reported that the combination was less efficacious than naftifine alone. In contrast to prior studies, this study had an 8-week follow-up period that demonstrated a high relapse rate (36 percent) for the antifungal/steroid combination. [9] In sum, based on limited studies and anecdotal reports, this antifungal/steroid combination is more likely to produce permanent side effects and a high relapse rate.

Ciclopirox olamine, a broad-spectrum antifungal agent, is a hydroxypyridone and is not related to any other known antifungal agent. In contrast to the imidazoles, which are fungistatic, ciclopirox olamine is both fungicidal and fungistatic. This antifungal acts by chelating trivalent cations such as Fe^{3+}, thus inhibiting metal-dependent enzymes required for the degradation of toxic metabolites. This affects cell membrane synthesis, alters cell permeability, and inhibits respiratory activity. Resistance of dermatophytes to ciclopirox olamine has not been reported. The compound also demonstrates anti-inflammatory activity by inhibiting prostaglandin and leukotriene synthesis and has been shown to be more effective than either imidazoles or allylamines in suppressing UVB-induced erythema. [10] Ciclopirox olamine also penetrates keratin easily, with cadaveric studies demonstrating levels in the dermis that are 10 to 15 times that of minimum inhibitory concentrations (MICs). [11] In clinical trials, ciclopirox olamine has demonstrated excellent mycologic and clinical response rates. [12] Despite its excellent pharmaceutical properties, its efficacy has not been compared to that of other antifungal agents in treatment of glabrous skin, and it has been used interchangeably with the imidazoles, allylamines, and benzylamines. Although allergic contact dermatitis to ciclopirox olamine has been documented, it is rare.

Another of the newer classes of topical antimycotic drugs are the allylamines (naftifine and terbinafine). These drugs act by specific inhibition of squalene epoxidase. As with the imidazoles, this inhibits ergosterol biosynthesis, which is a fungistatic effect, but it also produces an accumulation of intracellular squalene, which is a fungicidal effect. In vitro studies to determine MICs on 80 strains of dermatophytes revealed that naftifine was superior to clotrimazole, miconazole, and ketoconazole as determined by both the dilution method and the disk-diffusion method. In addition to their antifungal effects, naftifine and terbinafine demonstrate anti-inflammatory activity as measured by their ability to suppress UVB-induced erythema. [10] Naftifine is also lipophilic and demonstrates penetration to deep portions of the hair follicle. Terbinafine, the newest allylamine, demonstrates properties similar to naftifine except that it demonstrates in vitro activity that is 10 to 100 times greater. [13] Pharmokinetic studies have shown that topical application of 1% terbinafine on hyperkeratotic tinea pedis produces concentrations that are 50,000 times higher than the minimum inhibitory concentration needed to treat dermatophyte infection. [14] Numerous clinical studies compare the allylamines to the imidazoles, often producing conflicting results. In some studies, topical naftifine has been comparable to topical imidazoles, whereas in other studies, it has demonstrated marginal superiority to topical imidazoles. When compared to topical miconazole combined with hydrocortisone cream, naftifine was markedly superior in the treatment of inflammatory dermatophyte infections. [15] The number of studies comparing topical terbinafine to other antimycotics is limited, but in two large multicenter comparisons of topical terbinafine with clotrimazole in the treatment of tinea pedis, a significantly higher cure rate and lower relapse rate for terbinafine was reported. [16], [17] In summary, topical allylamines, especially terbinafine,

are marginally superior to topical imidazoles in cure rates and probably require shorter duration of therapy. Terbinafine is now available over the counter.

Butenafine, the newest topical antifungal agent, is the only member of the benzylamine class of antifungals. It is structurally similar to the allylamines, and like the allylamines, it works by inhibiting squalene epoxidase. Like the allylamines it is both fungistatic and fungicidal. The minimal fungicidal concentrations for butenafine are 4 to 130 times lower than for naftifine, tolnaftate, clotrimazole, and bifonazole. [18] Like the allylamines, this drug also demonstrates anti-inflammatory effects as measured by reduced cutaneous erythema in response to UVB irradiation. [19] Results in clinical trials suggest that it is very similar to the allylamines in terms of clinical responses.

Tinea unguium is the third major category of superficial dermatophytoses. Although pharmacokinetic studies demonstrate that imidazoles and allylamines are capable of penetrating the nail plate in concentrations sufficient to exceed the MICs of most dermatophytes, [20] they typically fail to produce clinical cures. A prescription product composed of triacetin, sodium propionate, benzalkonium chloride, cetylpyridium chloride, and chloroxylenol has been marketed in a tincture base (Fungoid) for the treatment of onychomycosis. An uncontrolled study has reported a 100 percent cure rate after 12 months of treatment; however, treatment also included monthly nail débridement and there was only a 2-month follow-up. Because of its excellent penetration of the nail plate, ciclopirox nail lacquer 8% solution was developed and introduced for the topical treatment of onychomycosis. The most commonly used treatment regimen is to apply the lacquer to the affected nail once per day for 48 weeks. The reported mycologic cure rates have ranged from 29 to 85.7 percent with the meta-analytic average cure rate being 53 percent. The reported relapse rate is 21 percent. [21] Ciclopirox nail lacquer has an advantage over systemic antifungal agents in that it does not require physician monitoring, laboratory testing is not required, and it has a reduced cost per mycologic cure. [21]

CANDIDIASIS (CANDIDOSIS)

Candida albicans is the primary pathogen in most cases of superficial candidiasis, although other species, such as *C. parapsilosis* and *C. guilliermondii,* may also produce infection (see Chap. 206). *Candida* species are commensal organisms that usually require a change in the host milieu, usually alterations in nutrition (e.g., diabetes mellitus), microbial flora (e.g., antibiotic therapy), or host immune defenses (e.g., neutropenia) to produce infections. This is an important consideration in assessing the efficacy of topical therapies, since the recurrence rate is very high if the underlying disease is not corrected.

Before the advent of the imidazoles, the polyenes were the mainstay of topical candidial therapy. There are more than 80 polyene antibiotics, but only nystatin and amphotericin B have been used as topical agents. Polyene antimycotics are primarily fungistatic at low concentrations and fungicidal at high concentrations. They act by binding irreversibly with ergosterol in the cell membrane, which leads to altered cellular permeability and leakage of cell contents. Nystatin is available in powder, suspension, lozenges, and as creams for topical therapy. The suspension and lozenge formulations are used for oral candidiasis, and the powder and creams are used for cutaneous infections. Older studies comparing topical nystatin with imidazoles suggested that the two were comparable in efficacy, but more recent studies suggest that imidazole drugs are more effective than nystatin in vaginal candidiasis. [22] This may be related to the increased nystatin resistance which is now observed in up to 20 percent of isolates. Nystatin resistance may be encountered in wild strains (primary resistance) but may also be induced during therapy (secondary resistance). Nystatin and amphotericin, while effective against candidial infections, are not effective against dermatophytes.

Topical imidazoles are the mainstay of topical therapy for candidiasis. Imidazoles are available as lotions, creams, and troches (clotrimazole). Clotrimazole troches are used for the management of oral candidiasis, and imidazole lotions and creams are used for superficial cutaneous candidiasis. The susceptibility of different strains of *C. albicans* to imidazoles is highly variable (MIC of 0.5 to 100 µg/mL). The implication of this difference in susceptibility to imidazoles has not been studied to determine if it is clinically significant in terms of response rates. All of the topical imidazoles are clinically and mycologically effective in treating superficial candidal infections and can be used interchangeably. As discussed in the management of dermatophyte infections, there is evidence to suggest that clotrimazole and miconazole are potentially irritating and may not be the preferred imidazoles in sensitive flexural areas infected with *Candida*.

Ciclopirox olamine, like the imidazoles, is a broad-spectrum antimycotic drug that is effective against *Candida* species. Ciclopirox olamine is indicated for the management of cutaneous candidial infections but it does not come in formulations for oral use. Head-to-head studies comparing this drug to the topical imidazoles have not been done, but ciclopirox olamine appears to be equivalent to the topical imidazoles in terms of clinical efficacy.

Topical allylamines (naftifine, terbinafine) demonstrate moderate activity against yeast, including *Candida* species. In vitro studies demonstrate that *Candida* species are more sensitive to the imidazole class of drugs than the allylamines. [8] Despite the higher measured in vitro MICs for yeasts, clinical studies have demonstrated that most cases of cutaneous candidiasis can be successfully treated with topical allylamines; they compare with topical imidazoles in terms of mycologic cure. Despite the therapeutic efficacy of the allylamines, they should not be considered as a primary topical therapy for candidiasis because they are expensive, have not received approval for this indication, and demonstrate less-favorable MICs.

PITYROSPORUM (*MALASSEZIA*) INFECTIONS

Pityrosporum orbiculare is a lipophilic yeast that produces superficial fungal infections in the form of tinea (pityriasis) versicolor and, less commonly, as a folliculitis (see Chap. 206). Because these two forms of infection respond to the same topical therapies, they are discussed together. Because this yeast is a normal component of the skin flora, its total eradication is usually not possible by using topical therapies. The ubiquitous nature of the organism also accounts for the high recurrence rate following treatment. For this reason, it is difficult to compare different studies since the follow-up periods are usually of different lengths. Patients with extensive involvement are usually best treated with oral

antimycotics, whereas patients with limited involvement may be treated with either systemic or topical antimycotics. A number of less-conventional agents that are not regarded as antimycotics have been reported in the literature, including salicylic acid, propylene glycol, and zinc pyrithione. These are not discussed because they do not appear to offer significant advantages over specific antimycotic agents.

Selenium sulfide (2.5%) lotion has been shown in uncontrolled and controlled studies to be useful in the management of both tinea versicolor and *Pityrosporum* folliculitis. A variety of different methods and durations of applications have been utilized but one of the most common regimens is to have patients apply the lotion daily for 10 min for 7 consecutive days. [23] Cure rates have been reported to be as high as 87 percent [23] in tinea versicolor and 90 percent in *Pityrosporum* folliculitis. [24] Advantages of this treatment modality include low cost and the ability to treat large areas of the body since the lotion is easy to apply. The major disadvantage that limits its use is that the lotion is irritating, with almost one in five patients developing an irritant dermatitis that may range from mild to severe. Some patients also find the odor objectionable.

Numerous studies demonstrate the efficacy of topical imidazoles for the treatment of both tinea versicolor and *Pityrosporum* folliculitis. The clinical and mycologic cure rates vary from 76 to 100 percent in different studies. The most common regimen for all imidazoles is a once-daily application for 2 weeks. The results of all studies, including those in which there is a head-to-head comparison between different imidazoles, do not demonstrate a significant difference between any of the antifungals in this class. The choice of topical imidazole is primarily based on price. Topical ciclopirox olamine is also effective against *Pityrosporum* species and can be used interchangeably with the imidazoles, although at least one head-to-head study between ciclopirox olamine and clotrimazole demonstrated marginally higher cure rates with ciclopirox olamine.

Although topical allylamines are clinically and mycologically effective against *Pityrosporum* infections, they have not received an indication for use in this disorder. Although in vitro data suggest that allylamines have higher MIC values than imidazoles against yeast, MIC values do not always correlate with clinical efficacy. There are only a limited number of studies using topical allylamines in *Pityrosporum* infections, but the clinical and mycologic cure rates appear to be equivalent to that of topical imidazoles. Despite the clinical efficacy, topical allylamines are not a good choice for the treatment of either tinea versicolor or *Pityrosporum* folliculitis because this is the most expensive class of topical antimycotics and they have not received an indication for treatment of these infections.

REFERENCES

With the start of the twenty-first century, we mark more than 50 years of sunscreen use. Over this period of time sunscreens have evolved from a topical preparation used to prevent sunburn to agents with the desired capability of protecting the skin against various kinds of damage—both short-term and long-term. Regarding the former, this was a simple goal and concept that was easily measured for effectiveness, and hence quite easily achieved. If the exposure of skin to sunlight caused sunburn and this process could be stopped by a topical application of a UVR-absorbing chemical, the effects were observable by visual inspection. However, the protection versus long-term effects such as photoaging and skin cancer present a different challenge—the analysis of long-term effects (most likely extending over years). While this is an admirable and desirable goal, its solution cannot be met with simple procedures and must not be based on faith alone. Skin aging and skin cancer are complicated biologic processes with myriad interlocking steps, many of which may be affected by the exposure to sunlight. Furthermore, certain effects may arise from particular regions of the solar spectrum and/or potential synergistic or antagonistic wavelength interactions. There are several recent reviews available and Chap. 133 contains much relevant data. [1], [2], [3], [4], [5], [6], [7], [8] and [9] This chapter presents cutting edge issues regarding sunscreens.

There is no question that sunscreens prevent sunburn on the basis of their UVR-absorbing capacity to attenuate the amount of “burning” rays of the sun that reach skin cells. Skin cancer, the most common type of cancer in humans, is primarily caused by exposure to sunlight. Therefore, reducing the exposure of skin to solar UVR would be expected to prevent skin cancer. However, although public health authorities have advocated use of sunscreens for skin cancer prevention for many years, there is little actual human data to support this recommendation. In the summer of 2000, a panel of experts in sunscreen-related fields was convened by The International Agency for Research on Cancer (IARC), part of the World Health Organization (WHO). The results of this meeting have been published by IARC, [9] and its overall evaluation for cancer-preventive activity of sunscreens is shown in Table 247-1.

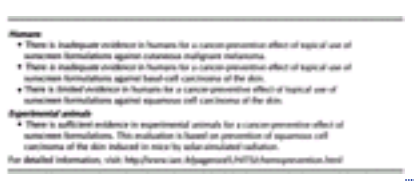

TABLE 247-1 **Evaluation of Sunscreens for Cancer-Preventive Activity**

There are three major types of skin cancer: the highly curable basal cell and squamous cell carcinomas and the highly malignant cutaneous melanoma. The scientific evidence concerning the impact of sunscreens on the development of skin cancer was evaluated by the IARC panel of experts. The Working Group concluded that the appropriate use of sunscreens probably prevents squamous cell carcinoma, the most frequent type of skin cancer, which mainly develops at exposed sites (face, arms, and hands). For malignant melanoma, which is potentially metastatic—with fatal consequences, the impact of sunscreen use is more complex. The relevant epidemiologic studies show significantly higher risks for melanoma in users of sunscreens than in nonusers of sunscreens. Although this apparent paradoxical observation has been attributed to the possibility that sunscreen users, feeling they are protected, may deliberately spend more time in the sun, this is unproven. Further research is needed to determine if the protective effect of sunscreens can be outweighed by overexposure based on the false assumption that sunscreens are an invincible armor against the adverse effects of UV light.

As shown in Table 247-1 the IARC Working Group concluded that sunscreens do prevent sunburn and may reduce the risk of squamous cell carcinoma, but only if people do not extend their outdoor exposure time. The Working Group recommended that sunscreens should be part of an overall sun avoidance program that includes seeking shade whenever possible, wearing protective clothing, scheduling outdoor activities for times of least solar insolation, and using

sunscreens with a sun protection factor (SPF) of at least 15.

SUNSCREEN ACTIVE INGREDIENTS

Sunscreens are commonly referred to as chemical and nonchemical. Of course, all sunscreens are made up of chemicals. The chemical versus nonchemical concept refers to whether the active ingredient—ultraviolet radiation absorbing chemical (UVRAC)—is organic (made up of carbon-containing compounds) or inorganic (not containing carbon). The former include active ingredients such as the cinnamates and benzophenones. The nonchemical group includes pigment agents that, as originally developed, form a visible layer on the skin. The inorganic sunscreens are also commonly known as physical agents. The distinction between these two categories of sunscreens is arbitrary. In fact, while once thought to differ in their mechanism, recent studies show that both agents act by the direct absorption of solar UVR.

Organic sunscreens have been the primary ingredient(s) for sunscreen formulation from their original development early in the last century. Although inorganic sunscreens are gaining in popularity, organic sunscreens are still used in greater amounts. Table 247-2 lists the most common chemicals used in sunscreens, as well as the maximum percentage that can be used. [10] These compounds usually contain conjugated aromatic structures and therefore absorb a specific portion of the UVR spectrum. Depending on the details of each compound's molecular structure, the absorbance may be effective for UVB or UVB and some UVA.

	Ingredient	Maximum Amount (%)	UVB Protection	UVA Protection
Chemical absorbers	Avobenzone (Parsol 1789)	3	No	Yes
	Cinnamates	7.5	Yes	No
	Octocrylene	10	Yes	No
	Oxybenzone (benzophenones)	6	Yes	Yes
	PABA (para-aminobenzoic acid)	15	Yes	No
	Padimate-O (octyl dimethyl paba)	8	Yes	No
	Salicylates	5	Yes	No
Physical blockers	Titanium dioxide	25	Yes	Yes
	Zinc oxide (including transparent)	25	Yes	Yes

*[illegible]

TABLE 247-2 **Common Sunscreen Ingredients***

The absorption of photons creates an excited state in the molecule that persists only for a very short time before the energy is dissipated. [10] Dissipation may occur by one or some combination of the following: release of heat, emission of longer wavelength (lower energy) photons, and/or photochemical transformation. Although the exact fate of the excited state photon of sunscreens applied to skin has not been studied under in vivo conditions, it is generally assumed that there is a reemission of photons at a less energetic, longer wavelength (i.e., heat or light). In some cases, these photons may be used in a photochemical reaction, such as *cis-trans* or keto-enol photochemical isomerization that probably cannot lead to any kind of adverse effect, or perhaps minimally causes a slight change in effective SPF for the sunscreen. However, recent studies show that some UVRACs are transformed into ineffective agents. Prime among these are studies on avobenzone, the major UVA-absorbing chemical sunscreen. Several studies show that avobenzone (also called parsol 1789) undergoes photodegradation when exposed to the very wavelength against which it is designed to protect skin.

Although there are 16 organic sunscreen agents currently available in the United States for use in over-the-counter (OTC) sunscreen products, just 9 are commonly used in sunscreen products (see Table 247-2). The organic sunscreens are almost always used in combination because no single organic sunscreen agent, used at levels currently allowed by the US FDA, can provide a high SPF (=15). The intended use of the product, recreational or daily photoprotection, and its attributes, such as waterproof or sweatproof, dictates which combinations of sunscreens will be used. Recently, formulations with the combination of organic and inorganic sunscreens became very popular and inorganic compounds have been used with increasing frequency. To some degree this shift has been driven not only by the effectiveness of the inorganic compounds, but also by a concern regarding potential adverse effects of the organic sunscreens. Generally, inorganic sunscreens are viewed as harmless pigments that cannot enter the skin and are largely unaffected by light energy. The two most commonly used physical sunscreens are titanium dioxide (TiO_2) and zinc oxide (ZnO). These two metal oxides differ substantially in their appearance and attenuation spectra. [11] Both are odorless white powders that have a normal distribution of particle sizes. Microfine powders are used in sunscreen products because their particle size does not scatter light and hence does not appear white on the skin. In fact, they function on the basis of their UVR absorbance properties just like organic sunscreens. These pigments have also found photochemical uses. Therefore, when used in sunscreen preparations they are often coated with other materials such as silicones, fatty acids, or oxides of aluminum, silicon, or zirconium, to render them less reactive. [12]

MEASURING AND RATING EFFECTIVENESS: UVB AND UVA

The Sun Protection Factor

The concept of the SPF was originally proposed by the Austrian scientist Franz Greiter and subsequently adopted by many regulatory authorities and the cosmetic and pharmaceutical industries. It is popularly interpreted as how much longer skin covered with sunscreen takes to burn as compared to unprotected skin. More precisely, the sun protection factor is defined as the ratio of the least amount of ultraviolet energy required to produce a minimal erythema on sunscreen-protected skin to the amount of energy required to produce the same erythema on unprotected skin. [1] Internationally agreed procedures define protected skin as that to which a 2 mg/cm^2 layer of sunscreen has been applied.

Determination of SPFs by in vivo phototesting is subject to increasing variability with increasing SPF. Table 247-3 shows the results of a series of interlaboratory ring tests performed by seven major European sunscreen manufacturers. [13] It can

be seen that, even under the same laboratory conditions, there is a threefold variation in measured SPF for the high factor (SPF 20 to 25) sunscreen. The principal factor accounting for variability in measured SPF between individuals is differences in topology of the skin surface.

Nominal SPF	Measured SPFs	
	Mean	Range
4	4.2	3.9–4.6
15	12.7	11.1–14.1
15	15.5	14.2–18.2
20–25	22.4	11.3–33.9

TABLE 247-3 **SPF Obtained on Four Products Tested in Seven Laboratories Using the COLIPA SPF Test Method** [13]

The numerical value of the SPF appearing on sunscreen products is usually not identical to the measured mean SPF, because other factors, such as regulatory requirements and commercial considerations, also influence the choice of the declared SPF. In 1990, most commercially available sunscreen products had SPFs less than 10, but by 2000 there was a trend for higher factors, with most manufacturers producing products with factors of 15 to 20 and, not uncommonly, products claiming a factor of 50 or higher.

Sunscreens and UVA Protection

A number of in vivo and in vitro methods have been described to measure sunscreen photoprotection in the UVA region. [14], [15] In vivo methods rely on using erythema or tanning as the end point when the skin is irradiated with or without prior sensitization with, for example, psoralens. In vitro methods are based on the spectral transmission of UV radiation through either a dilute solution of the sunscreen or, preferably, the sunscreen applied to a substrate with a roughened surface. No one method has yet met with universal acceptance and the relative strengths and weaknesses of the different methods have been reviewed. [14], [15]

Additionally, ex vivo methods using excised human epidermis as the substrate have been described. [16], [17] This “middle way” shares the speed and simplicity of in vitro methods, but at the same time accounts for sunscreen–skin interactions that are inherent in in vivo methods.

Perspective: Sunscreens, UVA, and Public Health

The increasing concern over the past 20 years of the known and postulated deleterious effects of UVA exposure in human skin resulted in considerable efforts made during the 1990s to establish a robust and meaningful assay of the UVA, or broad spectrum, protection provided by topical sunscreens. A number of in vivo and in vitro methods have been proposed, [16], [17] but none has yet met with universal approval by manufacturers and adoption by regulatory authorities. This intense activity by academic and industrial researchers has led to a somewhat narrow approach to photoprotection. Yet the spectral profile of a sunscreen, and its summary by some “UVA index” is just one component of the role of sunscreens in reducing the burden of solar ultraviolet A exposure to the population.

From a public health perspective, it is clear that the UVA exposure of sunscreen-protected skin depends not just on the absorption characteristics of the product but also on a number of other factors, including the amount of sunscreen applied, how it is spread over the skin, resistance to water immersion and sand abrasion, and when and how often sunscreen is reapplied. A mathematical study [18] that examined the relative importance of three of these factors—amount applied, how it is spread, and UVA-absorbing properties of sunscreens—found that in a population of sunscreen users, approximately 75 percent of the variance in UVA protection achieved depends upon how much sunscreen is applied, with how well it is applied and how well it absorbs UVA contributing approximately equally to the remaining 25 percent of variance. So what advice should be given to someone who wishes to achieve the maximum benefit in terms of UVA protection from applying a sunscreen of a given SPF? This analysis demonstrated that by far the most important factor is to apply a liberal quantity. However, many studies [19] show that users feel uncomfortable with applications of 2 mg/cm^2 (the thickness used when the SPF is measured), and prefer to apply quantities averaging half this thickness. It is likely, therefore, that campaigns to encourage people to apply a greater quantity of sunscreen at a single application will fail. Another important factor in sunscreen performance is the uneven nature of the skin surface. If an opaque sunscreen is applied to the skin, particularly at the low surface densities typical of practical usage, the epidermal markings become visible as the surface grooves, or sulci, are filled. With further application, the intervening ridges are also covered and the surface becomes more featureless. The situation is analogous to painting a wall with a textured surface when two coats of paint are almost always required for satisfactory coverage. In the same way two “coats of sunscreen” may be required for adequate protection.

Advising people to reapply sunscreen early in their sun exposure period will result in better protection [20] than will the common public health recommendation [21] to reapply every 2 to 3 h. The summary advice given to sunscreen users should be as follows:

- Apply sunscreen liberally to exposed sites 15 to 30 min before going out into the sun.
- Reapply sunscreen to exposed sites 15 to 30 min after sun exposure begins.
- Further reapplication of sunscreen is necessary after vigorous activity that could remove sunscreen, such as swimming, toweling, or excessive sweating and rubbing.

EVALUATION OF SUNSCREEN PRODUCT EFFICACY

Conceptually, sunscreen products are quite simple. The UV filter or filters in these topically applied products absorb,

reflect, or scatter sunlight, thereby reducing the amount or a “dose” of energy to which the skin might otherwise be exposed. Based on this empirical construct, when evaluating sunscreen product efficacy it is important to consider (1) the wavelengths of sunlight human skin needs protection from; (2) which end point(s) can be measured reproducibly and are a biologically meaningful consequence of sunlight exposure; and (3) how this information regarding protection can be communicated to patients and consumers in an understandable manner.

Sunlight reaching the surface of the earth consists of UV, wavelengths (?) < 400 nm, visible, between 400 and 700 nm, and infrared, ? > 700 nm, radiation. Experimental and observational evidence supports the view that solar UV has the most pronounced impact on biologic systems. As such, it has become the practice of many to divide specific wavebands of the terrestrial UV spectrum as UVB (290 to 320 nm) and UVA (320 to 400 nm). In addition, the UVA waveband is often subdivided into UVA II (320 to 340 nm) and UVA I (340 to 400 nm), generally reflecting the higher erythemogenic efficiency of shorter UVA wavelengths. Importantly, the division between these UV wavebands is arbitrary and humans are exposed simultaneously to all UV wavebands from the sun (see also Chap. 133).

A reduction in all wavelengths of UV would apparently afford the greatest protection to human skin against sunlight-induced damage. However, many biologic responses to UV exposure are weighted with the shorter, more energetic wavebands between 290 and 330 nm producing the greatest effects, as much as 100 to 1000 times that of longwave UV, that is, ? > 340 nm. Thus, knowledge of the action spectrum, [22] the relative biologic response versus wavelength of UV, is critical and possibly essential for understanding the current and any future end points used to evaluate sunscreen product efficacy. Regardless, it is empirically obvious that a reduction in all wavelengths of UV would provide the greatest protection against solar damage much as clothing and staying indoors do.

It should not be surprising then that erythema continues to be the most universally recognized end point in sunscreen photobiology. Considering its widespread appeal—that is, noninvasive threshold end point, relatively reproducible, UV-dose reciprocity, and short duration of exposure—it has become the standard for evaluating sunscreen products. Specifically, the SPF test measures erythema as an end point.

The protection factor, displayed as a number on most sunscreen products, is dependent on a number of variables and as such should be viewed as a relative measure, which is more meaningful as a product comparison. This is particularly true as the SPF exceeds 30 because the relationship between absorption of erythema energy versus SPF is nonlinear, as illustrated in Fig. 247-1. Despite several shortcomings of the SPF test method and labeling, it remains the most recognized efficacy measure of sunscreen products. More important, the end point—erythema—is biologically meaningful and a likely surrogate for chronic effects of UV exposure such as nonmelanoma skin cancer.

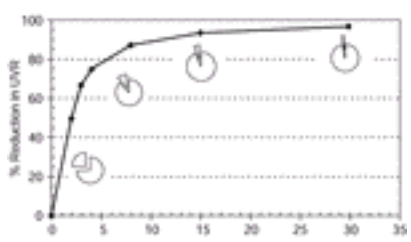

FIGURE 247-1 The theoretical effectiveness of sunscreens with different SPF values at reducing the amount of UVR reaching skin. Also shown are pie chart representations for SPFs 4, 8, 15, and 30.

Beyond erythema, long wavelengths of solar UV (i.e., >340 nm) can contribute to skin damage. This assertion is based on both clinical evidence and theoretical considerations. The studies by Lavker et al. [23], [24], Lavker and Kaidby, [25] and Lowe et al. [26] provide evidence that repeated exposure to an artificial source of long wavelength UVA produces morphologic changes in human skin indicative of photodamage. These data corroborate studies in animals where exposure to UVA was reported to accelerate photodamage [27] and the induction of skin tumors. [28], [29] Because the overwhelming majority of sunscreen products available to consumers provide protection primarily limited to UVB and short wavelength UVA II (320 to 340 nm), it has been hypothesized that the use of such products may paradoxically increase exposure to long wavelength UVA I (340 to 400 nm) [30] by selectively changing the spectrum of solar sunlight received by the skin. [31]

Given the need for long wavelength UVA protection and the absence of meaningful information regarding such protection on currently marketed sunscreen products, there is an urgent demand for a reliable, versatile, and universally applicable method that provides purposeful, SPF-independent information regarding UVA photoprotection. Several in vivo methods using human subjects have been proposed, [32], [33], [34], [35] and [36] but not widely accepted. Although there are several reasons for this, the limitation of all proposed human studies of UVA photoprotection is the absence of an end point measure that is a true surrogate marker for long wavelength (i.e., >340 nm) UVA-induced skin damage. From a more practical perspective, the existing human studies use end points that (1) are redundant with SPF testing, that is, erythema; (2) are oxygen and, by definition, UV dose-rate dependent; (3) are skin-type dependent; (4) have a high degree of variability; and (5) may require extraordinary exposures to an artificial UVA source, the human health consequences of which are unknown.

SIDE EFFECTS OF SUNSCREENS

That sunscreens, when liberally and frequently applied, [18] reduce sunburn is beyond dispute. As sunburn is the most obvious and immediate form of damage, it seems intuitively obvious that agents that reduce the intensity of the sunlight that reaches the skin must be universally protective. It is very tempting to conclude that sunscreens will also protect against other forms of damage. Support for that view stems mainly from a large body of work on hairless mice, which shows that sunscreens reduce, or at least delay the onset of, skin cancers. But the WHO is not convinced that what

applies to mice applies to men. As noted above, the WHO conclusion is that “there is sufficient evidence [in mice] for a [squamous cell carcinoma] preventive effect of sunscreen formulations,” but that corresponding evidence in humans is only “limited” and that “evidence in humans for a cancer-preventive effect [of topical sunscreens] against cutaneous malignant melanoma and basal cell carcinoma [is] inadequate.” Consequently, the recommendation that “sunscreens should not be used as a means of extending the duration of solar exposure, such as prolonging sunbathing,” sits uneasily with the perception that the sun protection factor describes the “allowable” increase in exposure. In other words, the advantage of using sunscreens to extend exposure without burning may be offset by a potential failure to protect against the skin cancer that is associated with increased exposure of skin to solar wavelengths transmitted by the sunscreen. We need to explain this paradox in which protection against one kind of damage does not necessarily confer corresponding protection against another, more serious kind. Here, it is important to distinguish indirect effects of sunscreens from potential direct effects such as sensitization reactions (Table 247-4).

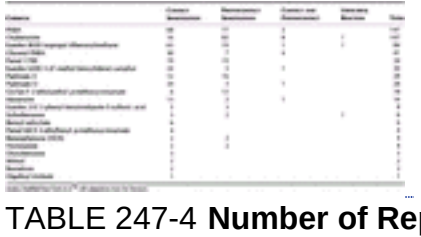

TABLE 247-4 **Number of Reports of Sunscreen Sensitization Reactions**

Indirect Effects of Photoactivated Sunscreen Ingredients

Indirect effects are largely attributable to (1) increasing exposure and (2) receiving, in consequence, unusually large doses of UVR not attenuated by the sunscreen. Until recently, many sunscreens absorbed UVB very effectively, but UVA much less effectively. Sunburn is caused almost entirely by UVB, so that sunbathers who increased their exposure according to the SPF of their sunscreens received almost as much UVA as they would have done had they not used a sunscreen and had endured the sunburn that the increased time in the sun would have caused. While the relation between UVA and carcinogenesis remains uncertain in humans, it may be that the action spectrum will turn out to be similar to that for the induction of melanoma in a hybrid fish, [37] in which case excess melanoma in sunscreen users could be ascribed simply to excess UVA.

The potential dangers of UVA led to the incorporation of UVA-absorbers in sunscreens. When examined individually in simple systems, some absorbers, both UVA and UVB, exhibit varying degrees of instability. [38] High-performance liquid chromatographic methods have been used for the comparison of the photostability of five sunscreen agents. [39] A problem with this approach is that stability depends upon the solvent used, [38] a finding that resembles the fact that widely used solvents such as ethanol and dimethylsulfoxide can quench DNA-damaging effects of some illuminated sunscreens, [40] so that when measuring photostability, studies on the actual products may be more valuable. Maier et al. showed that in 7 of 16 products exposure to simulated sunlight reduced absorption of UVA by up to 48 percent while UVB absorption was not affected. [41] Furthermore, the photochemical behavior of the products was not predictable from the ingredients, emphasizing the need for measurements on actual commercial products. Partly for such reasons, there is increasing interest in “physical” sunscreens (i.e., titanium dioxide and zinc oxide). They have the merit of photostability, are far less likely to penetrate human skin than organic sunscreens, and, unlike many organic sunscreens, do not induce allergic reactions which, although limited to a small fraction of users, can pose severe problems for those affected.

Direct Effects of Photoactivated Sunscreen Ingredients

Concern about direct effects stems from the fact that all sunscreens are energy transducers. Their function is to absorb UV energy and convert it to other forms, and for that reason the terms “sunscreen” and “sunblock” are somewhat misleading. In most cases, the mechanisms by which they absorb and convert are uncertain, but in some cases there is direct evidence for the formation of reactive oxygen species. [10] In others, free radicals are formed, [42] and the generation of excited states can be deduced from the ability of illuminated sunscreens to attack organic chemicals, [43] DNA, [44] or cells in culture. [45], [46]

Animal and epidemiologic studies have suggested a role for UVA radiation in the induction of melanoma. [37], [47] Melanin in the upper layer of the epidermis protects against direct attack by light on DNA in viable cells deeper down, but melanin found deeper down can absorb light that penetrates and, acting as a sensitizer, forms excited states that then attack DNA. If an endogenous chemical can behave in this way, an exogenous one could, too. However, most work to date on DNA damage in human cells, and its modulation by sunscreens, has concentrated on direct photoproducts rather than on other lesions such as nonligatable strand breaks. A vital point here is that while direct photoproducts are repaired by mechanisms that restore the original DNA sequence, both single- and double-strand breaks can initiate recombinogenic events, which, although regenerating an intact DNA molecule, can lead to disruption of the sequence of the gene originally affected. [48] In other words, the process of “repair” does not restore the original sequence, with potentially serious results. Such disruptions in tumor-suppressor genes are associated with various tumors, including some melanomas. [49] For these reasons it is very important to define the damage induced and to examine its consequences by using appropriate assays; concentrating on suppression of direct photoproducts may mean that other, equally important aspects are overlooked.

SUNSCREENS AND IMMUNE PROTECTION IN HUMANS

The question of whether sunscreens protect humans from the immunosuppressive effects of solar UVR, and how well, remains one of the most complex issues in sunscreen development. Animal experimentation has progressed from the

earliest studies using unfiltered UVB sources (280 to 320 nm) containing environmentally irrelevant UVC (280 to 290 nm), to solar-simulated UVR (SSUV; 290 to 400 nm), and has taught us clearly that the latter source is essential for assessing sunscreen effects. [50] Furthermore, small doses administered through highly protective sunscreens have been of limited usefulness, because this does not simulate the conditions under which humans acquire their sunlight exposure—conditions most commonly encompassing prolonged sunlight exposure (in spite of official warnings to dissuade this behavior). The available data from animal experimentation is far more substantial than from human studies, but very confusing as the results of the studies vary greatly, with the effectiveness of sunscreens in preventing immune suppression ranging from no protection, through partial protection to total protection. A comprehensive review highlights the interpretative difficulties. [51] From studies in mice, it seems that most sunscreens do afford some protection from immune suppression by UVR, but that the protection is less than that from sunburn for which the products were designed. However equivalent data in humans are lacking. Current controversies about the need to filter out the UVA waveband (320 to 400 nm) in addition to the UVB, by using broad spectrum sunscreens, were initially driven by the evidence that the UVA waveband is the prime cause of photoaging. [52] On the other hand, the contributory role of the UVA waveband to erythema, immune suppression, and carcinogenesis, remains unclear. Certainly, UVA at high doses that would not be easily attained in daily sunlight exposure, can induce erythema in humans, and even carcinogenesis in chronically exposed mice.

Several relevant immune markers and functions has been used to measure sunscreen immune protection: contact hypersensitivity (CHS) and delayed-type hypersensitivity (DTH) induced either locally at the irradiated skin site or at nonirradiated distant sites, epidermal Langerhans cell numbers, nickel allergy elicitation, or mixed epidermal cell lymphocyte reactions, combined with various UV spectra, dosages, and treatment regimes.

Sunscreen Protection from Suppression of DTH or CHS

Several studies provide evidence for protection from the immune functions by sunscreens. Simple sunscreens blocking predominantly UVB have been compared with broad spectrum sunscreens that also provide varying degrees of added UVA protection. In addition, the DTH response induced at the site of irradiation, known as the “local” response, has been compared with DTH induced at a distant nonirradiated site, known as the “systemic” response. Serre et al. [53] used an SPF 15 broad spectrum sunscreen (UVA protection factor 9) to examine protection in humans from a single exposure of 3 × MED of SSUV. The irradiation suppressed the CHS reaction to dinitrochlorobenzene (DNCB) in 50 percent of the subjects, but sunscreened SSUV did not impair the reaction at all. Moyal et al. reported that a UVB sunscreen failed to prevent both local and systemic immune suppression after repeated SSUV exposures, whereas a broad-spectrum sunscreen prevented the systemic effects and significantly reduced the local immune suppression. [54] Further trials with two sunscreens matched at SPF 9, but with different UVA protection (9 versus 2) showed that the systemic suppression induced by 10 exposures to SSUV was prevented, and the local suppression was reduced, by the superior UVA-protecting sunscreens, whereas the inferior UVA sunscreen failed to protect. [55] These findings suggested that UVA must play a more important role in establishing local immune suppression than systemic, however the possible immunologic pathways by which the local and the systemic impairments are induced remain unclear.

Other studies have used daily sunlight exposures. Moyal tested two sunscreens of different capacity: SPF 15 with UVA protection factor of 6, and SPF 30 with UVA protection factor of 12, against the sunlight suppression of the DTH reaction [56] and showed that SPF 15 did not protect, but that SPF 30 protected significantly. More recently, two SPF 25 sunscreens (with UVA protection factors of 14 versus 6) were compared in subjects treated with six daily sunlight exposures, and the superior UVA protection again prevented the suppression of DTH, while the inferior UVA sunscreen failed to protect. [55] The implication from these findings is that a higher SPF, and superior UVA protection from a broad-spectrum sunscreen, provides the best immune protection from the sun.

CHS to a topical nickel challenge in nickel-allergic subjects is suppressed by UVR, an impairment that has been used to assess the protection by sunscreens from elicitation of the existing immune response. Damian et al. compared two sunscreens with SPF of 9 and 24, and reported similar protection from the SSUV-elicited nickel reaction as predicted by the SPF. [57] This study attempted to produce SSUV dose response data and to establish, as for the sunscreen SPF, similarly derived sunscreen immune protection factors (IPF). Human subjects were irradiated with suberythemal doses of SSUV through three SPF 10 sunscreens differing in their UVA protection capacity, and their nickel allergic reactions were monitored. [58] The SSUV suppressed the nickel reaction to 35 percent, which remained unaffected by the UVB-blocking sunscreen, but the suppression was reduced to 7 to 10 percent by the broad-spectrum sunscreens. This suggested again that UVA does contribute to the systemic suppression of nickel CHS, although little is understood about the pathways involved.

Sunscreen Protection from Epidermal Langerhans Cell Depletion

An early response to UVR is the depletion of the epidermal Langerhans cells with the concomitant failure of normal antigen presentation by the skin. Measurement of Langerhans cell number has been a useful assessment of local immune competence in human skin following UV exposure, and has been used to assess sunscreen efficacy in immune protection. Le Vee et al. investigated the ability of an SPF 4 UVB-blocking sunscreen to protect from Langerhans cell depletion by increasing SSUV doses. [59] They found complete protection from 2 MED, partial protection from 4 MED, and no protection from 8 MED. Thus, protection from this immune marker appeared to match the sunscreen SPF, and it is apparent that the immune protection fails as the ratio of the SSUV dose to sunscreen SPF becomes too great.

That the depletion of the epidermal Langerhans cells might be caused primarily by UVAI (340 to 400 nm) was examined when Dumay et al. irradiated human skin with a large dose of UVAI. [60] A decreased Langerhans cell number resulted, and partial protection was observed by a predominantly UVB sunscreen. It was predicted that a higher UVA protection factor would provide better protection, but the role of UVA in Langerhans cell depletion remains unclear. Langerhans cells were also found to be significantly and chronically depleted in sun-exposed skin sites compared with sun-protected skin sites of subjects enrolled in a long-term skin cancer prevention trial, in spite of their regular sunscreen usage during

the past 3 years. This suggests that chronic immunologic damage of the skin is not prevented by sunscreens. However, further Langerhans cell depletion by recent high sun exposure in these subjects was reduced by sunscreen usage. [61]

In general, these studies lead us to believe that protection from the UVA waveband provides better immune protection for the skin. However, studies that conform to the prerequisite of the correct UV spectrum for testing sunscreen protection are few. It has also been pointed out that, in addition to the use of SSUV, dose responses need to be constructed in order to establish correct and reliable data for sunscreen protection from immune defects resulting from environmentally feasible exposures. [51] Furthermore, only limited models of immune function have been appropriately assessed in human subjects, whereas murine models have identified numerous additional immune impairments that probably apply equally to SSUV-exposed humans.

Does UVA Suppress Immunity?

A number of studies in experimental animals report that UVA has no effect on immune function when administered at suberythemogenic doses from a defined UVR source. Both hairless and haired mice have been UVA-exposed acutely or chronically for 4 weeks, and the local CHS reaction was found to be normal (Ref. [62] and references cited therein). Two studies in the marsupial *Monodelphus domestica,* also found no immunosuppression caused by UVA, [62], [63] and a study in mice and guinea pigs reported systemic potentiation of CHS by UVA. [64] When Langerhans cell structure and function were the targets in mice, these were unaffected by repeated high doses of UVAI. [65] In contrast, chronic suberythemal UVA suppressed the local, but not the systemic CHS in mice, [66] with the cumulative UVA dose equating to the innocuous UVA administered as a single exposure in other studies. [62]

In humans, UVAI resulted in Langerhans cell depletion from the epidermis and reduced epidermal antigen-presenting cell function, [60] as did UVAII. [67] However, Dittmar et al. reported that UVAI did not alter the mixed epidermal cell leukocyte reaction in human subjects, nor the functional upregulation of Langerhans cell costimulatory molecules. [68] Skov et al. described a decrease in the production of the immunosuppressive cytokine tumor necrosis factor (TNF)-a in suction blister fluid from UVAI-irradiated human skin, as compared to an increase in TNF-a release in response to UVB. [69] In cultured human keratinocytes, UVA caused the release of the proinflammatory immune-protective cytokine interleukin (IL)-12, with no evidence of release of immunosuppressive IL-10. [70] That the human immune-altering effects of UVA and UVB differ was suggested by an altered time course for detectable UVA immunosuppression compared with UVB, and the transience of the UVA-induced defect reported by Damian et al. [71]

Does UVA Modify UVB-Induced Damage?

Some recent studies in mice indicate that immunologically innocuous suberythemal UVA effectively protects from the immunosuppressive effect of UVB by inactivating the immunosuppressive pathways initiated by *cis*-urocanic acid produced in the epidermis by UVR. [62], [72], [73] The immune function was assessed either by the systemic CHS reaction or by the DTH reaction to infection by *Listeria* monocytogenes. These observations are consistent with a moderating function of UVA on other UVB effects, such as from UVB-induced erythema, melanogenesis, and photocarcinogenesis observed in mice. [74] A pioneering study of photocarcinogenesis in hairless mice some years ago also noted an apparent UVA protective effect, although the authors had no plausible explanation for this observation at the time. [75]

It is important to obtain evidence for such waveband interactions in human skin. Evidence has existed, almost unnoticed for many years, of an ameliorating effect of UVA-induced pigmentation on UVB-induced erythema and sunburn cell formation in human subjects. [76] Most convincingly, Skov et al. provided the first study in which pretreatment with UVAI significantly reduced the UVB-induced suppression of CHS to diphenylcyclopropenone in 22 subjects. [77] Thus far the evidence is sparse and needs further confirmation in human subjects. If substantiated, it might argue against the use of broad-spectrum sunscreens for optimal immune protection from solar UV.

Unfortunately, the data regarding sunscreen prevention of immune suppression by solar UVR in humans are few and inconsistent. Until there is further clarification of the immunosuppressive role of the UVA and the potential interactions of the UVA and UVB wavebands, it is difficult to assess or design improvements for immune protection by topical sunscreens. More human studies with appropriate sources and rigorous treatment regimens that enable reliable comparisons to be made between sunscreens offering differing UVB and UVA protection factors, as well as different active ingredients and/or vehicles, are urgently needed.

Keratolytic Agents

GENERAL PRINCIPLES OF KERATOLYSIS
KERATOLYTIC AGENTS
MECHANISM
RETINOIDS AS KERATOLYTICS
SPECIAL KERATOLYTICS

REFERENCES

Keratolysis describes the shedding of stratum corneum cells, although the rate of loss varies in different body areas. [1] The adhesion of viable epidermal cells is primarily a result of the interaction of desmosomes [2] and cadherins, [3] calcium-dependent glycoproteins, on the surfaces of adjacent cells. The intercellular structures of cells change in the stratum corneum, with modification of desmosome morphology and secretion of lamellar bodies rich in nonpolar lipids, giving rise to an orderly layered structure. [4] There is evidence that the lipids are cross-linked to the cornified envelopes by ester bonds. [5] A number of hydrolytic enzymes are also present in the secreted lamellar bodies, and these are thought to play a role in natural keratolysis. [6] The desmosomes undergo a progressive series of morphologic changes in the upper layers of the stratum corneum, leading to their apparent disappearance. In diseases associated with hyperkeratosis, the progressive alteration in desmosome morphology is markedly lessened, pointing to their role in cell adhesion. [7], [8]

The mechanism by which the intercellular lipid, covalently linked to the cornified envelope of one cell, is bound to lipids attached to adjacent cells has not been clarified. Extraction of stratum corneum in vitro with organic solvents followed by aqueous solutions, even when they contain a surface-active agent or detergent, does not disperse the tissue into a single cell suspension. This extraction removes considerable intercellular lipid, but it is hypothesized that the residual lipid covalently linked to the envelope alters the configuration of the surface, so that dispersion by aqueous solvents is not possible. However, prolonged treatment of trypsin-treated stratum corneum with an aqueous solution of sodium lauryl sulfate does result in such dispersion. The use of a proteolytic enzyme may alter structural proteins attached to lipids or activate other hydrolytic processes in the intercellular spaces.

GENERAL PRINCIPLES OF KERATOLYSIS

Accumulation of excessive stratum corneum is a common problem; it may be a result of a primary disorder of keratinization such as ichthyosis vulgaris, or a result of a secondary change in the epidermis, as in cutaneous fungal infection. The clinical presentation is a scaly, white skin surface, which often results in shedding of stratum corneum when the skin is rubbed. The color is white because of light scattering from air trapped in the scale; the normal skin color can be restored by moistening the skin or rubbing on a lubricant that displaces the air.

Removal of the excess stratum corneum necessitates loosening the cohesive attachment of the cornified cells by topical treatment followed by mechanical débridement. When thickening of the stratum corneum is minimal, this may be accomplished by applying a cream or ointment that moisturizes the skin by the addition of water and/or produces an occlusive film that prevents loss of water, which has diffused outward from below. Numerous products sold as moisturizers or emollients can accomplish this. The increased water content allows the normal mechanism of cell separation described above to occur, and gentle rubbing of the skin during bathing mechanically removes the cornified tissue. Such a treatment is particularly effective for the xerosis that occurs during the winter months in cold regions of the country. Water-binding materials added to moisturizing creams are said to diffuse into the stratum corneum and help bind water. Two common compounds used for this purpose are urea [9] and lactic acid. [10] The latter is much more widely used and is an example of an a-hydroxy acid, discussed below. [11] These are generally well tolerated except in young children in whom a-hydroxy acids often cause a burning sensation. Glycerin has also been used to increase water binding and has been shown to result in enhanced desmosomal degradation. [12]

KERATOLYTIC AGENTS

The oldest keratolytic agent used in dermatology is salicylic acid, which is usually prepared in an ointment or cream base at a concentration of 3 to 6%. [13] Salicylic acid decreases the cell-to-cell cohesion as measured by the ease by which layers of cells can be stripped from the surface of treated skin. Excessive use of ointments containing salicylic acid can result in salicylism and its use should not exceed 30 g of a 6% preparation in a 24-h period. This is especially important in children.

The application of propylene glycol at a concentration of 40 to 60% in water will result in the removal of scales, particularly when used under an occlusive plastic dressing. Although the glycol is not toxic, an occasional patient may develop an unpleasant burning sensation of the skin with its use. Propylene glycol has been used at lower concentrations with organic acids, and that combination has proved effective.

Lactic acid, in addition to being a humectant, acts as a keratolytic agent and results in the separation of stratum corneum cells as judged by the peeling off of scales from the surface of the skin. Stirring stratum corneum in solutions of lactic acid results in the release of desmogleins, suggesting that its mode of action is breakdown of desmosomes. Lactic acid

comes in a variety of commercial preparations and can be sold over the counter at a concentration of no higher than 5%. Epilyt, which is a liquid preparation containing 5% lactic acid and propylene glycol as the active agents, is extremely effective relieving the symptoms of dryness and removing scales [14] (Fig. 248-1). Being a liquid preparation, it can be easily used in the scalp to remove scales and has been a popular treatment for the management of seborrheic dermatitis and psoriasis. It is applied to the scalp at bedtime and shampooed out in the morning. A popular prescription cream preparation of lactic acid (Lac-Hydrin) contains 12% lactate neutralized to pH 5.0 in order to make a stable emulsion possible. [15] One can compound lactic acid at different concentrations in a suitable base such as Aquaphor. Adults will tolerate concentrations up to 12%, and this is very effective in scale removal. If the ointment is applied to moist skin, as after a bath, it spreads much more easily and is more cosmetically acceptable to the patient. Lactic acid in Aquaphor is well tolerated by children, particularly at low concentrations of the acid.

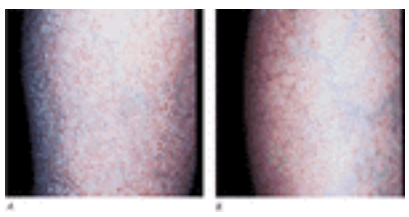

FIGURE 248-1 *A* and *B.* Treatment of ichthyosis vulgaris with Epilyt twice a day for 1 week; before (*A*) and after (*B*) treatment.

Lactic acid is an a-hydroxy acid, and this family of acids has received considerable attention as peeling agents for sun-damaged skin. The a-hydroxy acids derive their name from the presence of a hydroxyl group on the a carbon atom. Glycolic acid [16] is probably the most popular as judged from the number of products that have appeared on the market. There is no compelling evidence, however, indicating an advantage of one acid over another; the ability of an acid to loosen scales is more related to its concentration and the composition of the base in which it is compounded. Molecular weights and dissociation constants of glycolic and lactic acids are almost identical. In general, more anhydrous preparations are less irritating and allow the use of higher concentrations of acid without side effects.

Some general principles must be kept in mind in considering the use of keratolytic agents. A plastic occlusive dressing, although not necessary, in many situations will enhance the therapeutic effect and result in more rapid and complete clearing. In treating the palmoplantar surface, occlusive dressings are essential and little effect will be observed without their use. In treating the scalp, wearing a lightweight plastic shower cap enhances the effect of the treatment and prevents staining of the pillow. In combining topical corticosteroids with keratolytics, as in the management of psoriasis, it is important to choose a drug that is stable in the presence of acid (e.g., fluocinolone). Although keratolytic agents loosen scales, they do not dissolve them, so that mechanical removal is necessary. Patients should be told to rub the skin with a washcloth or rough sponge while bathing. This will result in the shedding of large quantities of scale after the skin has been treated for several days.

Children are very sensitive to a-hydroxy acid, and small areas of the skin should be tested before applying it over wide areas. The irritation occurs rather quickly, so it is easy to determine whether a particular product is a problem. This sensitivity usually disappears at the time of puberty. It must be remembered that salicylic acid can be absorbed through the stratum corneum, and no more than 2.0 g of salicylic acid should be applied to a child's skin over a 24-h period.

MECHANISM

The mechanism of action of all organic acids is thought to be the same, and release of desmogleins indicating disintegration of the desmosomes is a consistent finding. It is possible that the acids work directly by solubilizing the protein components of desmosomes. An alternative explanation is that they activate an endogenous proteolytic or other hydrolytic enzyme as a result of a change in pH. However, no acid proteases have been described in the stratum corneum. [17] The desmosome is unlikely to be the only site of action of the acids, because the lipid layer between cells is important in holding cells together. Furthermore, in some of the ichthyoses (e.g., X-linked), it would appear that an abnormality of the lipid layer is responsible for increased coherence of cells, so one would not expect disintegration of the desmosomes by acids to result in cell separation. It seems likely that, in addition to a direct effect on desmosomes, there is an indirect one involving activation of some endogenous pathway responsible for normal cell separation.

RETINOIDS AS KERATOLYTICS

Retinoids exhibit a keratolytic effect, but this is mediated by alteration in the keratinization pathways in the epidermis. This has been demonstrated for retinoic acid used topically and acitretin and isotretinoin given orally. The application of retinoic acid to the skin of patients with psoriasis and ichthyosis resulted in shedding of thickened stratum corneum. [18] Later studies using retinoic acid for acne suggested loss of cohesion of cornified cells in the sebaceous duct. [19] A side effect of the treatment was scaling of the skin, indicating loss of cell cohesion in the interfollicular stratum corneum. Retinoic acid is now approved for the treatment of photoaging, and a number of changes in the epidermis have been reported. The stratum corneum changed from a basket-weave structure to a more compact form. [20] There was a reduction in turnover time of the stratum corneum and an increase in transepidermal water loss. Altered cell surface glycosylation has been reported as well. Patients with photoaging have reported a smoother feel to the skin surface and removal of keratotic lesions. [21] Tazarotene is a new topical retinoid with keratolytic effects that is effective in acne and psoriasis.

Isotretinoin is used to treat a number of inherited disorders of keratinization and has proven very effective in reducing the thickness of the stratum corneum in, for example, lamellar ichthyosis (Fig. 248-2). [22] The mechanism for this decrease in cell cohesion is unknown, but reduction in the number of desmosomes and altered glycosylation of cell surface proteins

has been mentioned. Acitretin has had a similar effect on the scale of patients with psoriasis and in addition has resulted in clearing of the lesions.

FIGURE 248-2 Treatment of lamellar ichthyosis (*A*) with isotretinoin at 2 mg/kg per day for 6 weeks (*B*).

SPECIAL KERATOLYTICS

The hyperkeratosis associated with calluses, clavi, and warts is treated with high concentrations of salicylic and/or lactic acid in a liquid formulation or incorporated into a tape. A 40 percent salicylic acid preparation in tape is available, which results in marked softening of these lesions. They can then be abraded to remove the hyperkeratotic surface. A personal preference is to mix an equal volume of flexible collodion and 85% lactic acid. After thorough stirring, the solution is applied to the lesion, allowed to dry, and covered with waterproof tape. The lesion is mechanically débrided following hydration on a regular basis. This process is extremely effective in removing thickened stratum corneum, but can be very irritating if applied to normal skin. The softened thick skin must be hydrated before it is removed with an abrasive such as a pumice stone.

Hyperkeratosis of the nail bed has been treated by an ointment containing 40% urea, 5% paraffin, 20% anhydrous lanolin, 25% white petrolatum, and 10% silica gel type H. [23] The normal skin around the nail is protected by adhesive tape. The urea ointment is applied to the involved nail, covered with an occlusive dressing, and left in place for 1 week. The treated nail is then soaked in water and the keratotic material removed by gentle brushing. A second application may be necessary. Others have modified the ointment without much change in efficacy.

Topical Cytotoxic Agents

5-FLUOROURACIL
MECHLORETHAMINE (NITROGEN MUSTARD)
BCNU (CARMUSTINE)
VINBLASTINE
BLEOMYCIN

REFERENCES

5-FLUOROURACIL

5-Fluorouracil (5-FU) has been used in clinical practice since the 1960s and has proved to be efficacious as a topical cytotoxic drug for a variety of diseases. Current developments in the use of this drug focus on different methods of delivery and use in an increasing variety of skin diseases. 5-FU is a structural analogue of thymine, halogenated with fluorine at position 5. It interferes with pyrimidine metabolism and action by conversion to 5-fluoro-2'-deoxyuridine-5'-phosphate (F-dUMP). F-dUMP is a potent inhibitor of thymidylate synthetase; thus, DNA synthesis is blocked. 5-FU itself is also incorporated into RNA and DNA.

Systemic absorption of topically applied 5-FU is limited to approximately 6 percent of the applied dose. [1] Absorption is selectively higher from abnormal skin than from surrounding normal skin. [2] Normal skin appears to be unaffected clinically, but there are ultrastructural changes. [1] Systemic effects of 5-FU include nausea and anorexia, stomatitis, diarrhea, myelosuppression, alopecia, neurologic manifestations, and cardiac toxicity.

Topical or parenteral 5-FU should not be used in patients with dihydropyrimidine dehydrogenase (DHD) enzyme deficiency, [3] a rare pharmacogenetic syndrome that is inherited as an autosomal codominant trait. Approximately 3 to 5 percent of the population may be heterozygous for the syndrome. Because 80 to 90 percent of an administered dose of 5-FU is catabolized by the enzyme DHD, DHD enzyme deficiency can result in elevated systemic levels of 5-FU, leading to cytotoxic activity and potential toxicities. Rarely, life-threatening toxicities such as diarrhea, neutropenia, and neurotoxicity occur following intravenous administration of 5-FU in patients with DHD deficiency. A case of life-threatening systemic toxicity in a DHD deficient patient after treatment with topical 5-FU has been reported. This patient was found to be homozygous for the mutation. Homozygosity for the mutation appears to be the most common one responsible for DHD deficiency. Symptoms included severe abdominal pain, bloody diarrhea, vomiting, fever, and chills. Physical examination revealed stomatitis, erythematous skin rash, neutropenia, thrombocytopenia and inflammation of the esophagus, stomach, and small bowel. After cessation of treatment, the patient experienced a complete reversal of the toxicity. Although this case was observed when 5% fluorouracil cream was used, it is unknown whether patients with profound DHD enzyme deficiency would develop systemic toxicity with lower concentrations of topically applied fluorouracil. [3] Currently, phenotypic and genotypic tests to diagnose DHD deficiency exist. However, these tests are complex and labor intensive and cannot be recommended for routine screening. For further information and updated references visit http://www.dpdenzyme.com/. [3]

Topical 5-FU is commercially available as a solution (1%, 2%, and 5%) and as a cream (0.5%, 1%, and 5%). A 20% ointment can be compounded by using commercially available intravenous 5-FU solution. The intravenous solution can also be used for intralesional injection. Side effects of the topical preparation are generally local cutaneous reactions of irritation, erythema, pain, swelling, pruritus, hyper- and hypopigmentation, allergic contact dermatitis, and photosensitivity. Unusual reactions may include onycholysis, onychodystrophy, and the appearance of telangiectasias. [1] The use of injectable preparations may be complicated by local ulceration, erosion, and desquamation.

Successful use of topical 5-FU has been reported in many skin diseases (Table 249-1); however, its use is most established in the treatment of actinic keratoses, [4] particularly in patients with many lesions. It is used twice daily until an inflammatory response is seen, usually 2 to 4 weeks. This inflammation of actinic keratoses is also seen in patients undergoing systemic 5-FU treatment for malignancy, and it is this observation that initially led to the development of the drug as a topical treatment for actinic keratoses. Pretreatment with a keratolytic agent may be useful for particularly hyperkeratotic lesions. Irritation during treatment sometimes requires reduction or interruption of treatment and the addition of emollients or topical steroids. Another strategy to reduce irritant dermatitis caused by 5-FU is weekly pulse dosing. This involves applying the medication for 1 to 2 days per week for 6 to 7 weeks. [5] During 5-FU treatment, other actinic keratoses may be revealed, and basal and squamous cell carcinomas may become unmasked. [6] Occasionally the therapeutic response is inadequate, and occlusive dressings, more frequent applications, prolonged therapy, or the use of an adjunctive agent such as tretinoin cream is required. Continuous use of 5-FU as a prophylactic measure for actinic keratoses is not of proven benefit, [6], [7] and [8] although its use in xeroderma pigmentosum has been advocated. There are reports of cutaneous resistance to 5-FU treatment after 18 months of use. [9]

Precancerous lesions

Kyrle's disease

*On rare occasion, porokeratosis of Mibelli is associated with Bowen's disease, squamous cell carcinoma, and invasive squamous cell carcinoma.

TABLE 249-1 **Diseases in Which 5-Fluorouracil Is Useful**

Basal cell carcinomas have been extensively investigated for treatment with topical 5-FU. [3] Some researchers report adequate tumor clearance, [10] but others find unacceptable recurrence rates and persistence of tumor on biopsy. [11] The 5% cream is approved by the US Food and Drug Administration for treatment of superficial basal cell carcinomas.

Warts such as verrucae vulgaris, verrucae plana, plantar warts, and condylomata acuminata, can be treated with varying response rates to topical and intralesional injection of 5-FU. Condyloma acuminata have been reported to have response rates to topical 5-FU of up to 69 percent in men and 90 percent in women. [12], [13] Most clinicians, however, would reserve this treatment for warts not easily treated with conventional therapy or for recalcitrant or extensive condylomata. [14]

Actinic cheilitis and mucosal leukoplakia have been well managed with topical 5-FU. [15], [16] and [17] Topical treatment of the lip has the advantage of good cosmetic results, and it may preclude the necessity for surgery. Several reports have shown varying responses to the treatment of radiodermatitis with topical 5-FU. [7], [18] Bowen's disease, Bowenoid papulosis, and erythroplasia of Queyrat have all been reported as having a range of poor to excellent responses to treatment with topical 5-FU. [19], [20] and [21] Topical 5-FU as well as intralesional injection have been reported to cure most keratoacanthomas, [22] and porokeratosis of Mibelli has reportedly been cured after treatment with topical 5-FU. [23]

Over the past decade there has been experimental use of topical and intralesional 5-FU for the treatment of psoriasis. Continuous topical fluorouracil under occlusion can be given for 2 to 3 days per week for about 16 weeks or until clearance occurs. [24] Alternatively, weekly intralesional fluorouracil has been tried for treatment of psoriatic papules and portions of larger psoriatic plaques with some beneficial effect. [25] The responses observed after injection of 5-FU in an investigational sustained-release gel suggest clinical usefulness in treatment of chronic, recalcitrant, plaque psoriasis that is unresponsive to other therapies. [26] However, this preparation remains commercially unavailable.

MECHLORETHAMINE (NITROGEN MUSTARD)

Mechlorethamine [methyl- *bis* (2-chloroethyl) amine hydrochloride] was the first nitrogen mustard to be used in clinical medicine. Sulfur mustard, of which mechlorethamine is a nitrogen analogue, is a vesicant and was developed as a chemical warfare agent. Mechlorethamine acts as an alkylating agent and is not cell-cycle specific; however, it has most effect on cells in the late G1 or S phases. The primary target of mustard is the 7-nitrogen atom of guanine, although other bases may also be alkylated.

Topical preparations of nitrogen mustard are used primarily for cutaneous T cell lymphoma (CTCL). They are generally very well tolerated. Systemic side effects from IV nitrogen mustard include nausea, vomiting, myelosuppression, menstrual irregularities, oligospermia, alopecia, cardiac abnormalities, hypocalcemia, and central nervous system abnormalities. The drug is also teratogenic. There are no reports of systemic side effects following topical nitrogen mustard application. [27] Exposure to vapors released during topical application does not induce pulmonary fibrosis.

The side effects of topical mustard include contact sensitivity (both immediate and delayed), hyperpigmentation, irritant dermatitis, telangiectases, bullous eruptions, and an increased incidence of skin cancers. Delayed-type hypersensitivity (DTH), also known as cutaneous intolerance to topical mechlorethamine (CIM), may occur in 35 to 60 percent of patients on long-term treatment. [28], [29] This reaction consists of erythema and pruritus, and histologically is typical allergic contact dermatitis. If hypersensitivity occurs, discontinuation of therapy is not necessarily required. Desensitization has been achieved using intravenous [30] and topical [31] methods. UV therapy can delay development of contact sensitization to mustard; however, this modality is not recommended because nitrogen mustard is radiomimetic and, when coupled with UV, will increase the incidence of skin cancers. Although desensitization may be achieved, it may not be desirable as DTH is possibly of therapeutic benefit. CTCL may resolve clinically after the development of DTH, and regression has been reported after application of dinitrochlorobenzene to induce DTH. [27] Most clinicians continue topical mustard in individuals who have developed DTH, employing dilutions below the threshold for clinically observable contact dermatitis. Up to 8 percent of patients may develop an immediate-type hypersensitivity to topical mechlorethamine, manifesting as urticaria. Treatment must be discontinued if urticaria develops to avoid a potential anaphylactic reaction. Desensitization is not achievable in this situation. The incidence of hypersensitivity is reported to be less with the ointment preparation than with the aqueous solution of nitrogen mustard. [32]

Changes in pigmentation may also occur secondary to use of topical mechlorethamine. Hyperpigmentation is especially prone to develop in areas of previous CTCL and tends to resolve spontaneously, although slowly. [27], [30], [31] Hypopigmentation occurs rarely.

A potential troubling property of topical nitrogen mustard is its carcinogenicity. It is associated with an increased risk of basal and squamous cell carcinomas and keratoacanthomas, and a report exists of lentigo maligna. [33], [34] It is difficult to determine the exact extent of the problem as topical nitrogen mustard is often used in patients who have had other known

carcinogenic therapies such as PUVA. Overall the risk is small, [35] and because the lesions are easily treatable, this should not dissuade one from using topical nitrogen mustard. Nevertheless, it is important to advise patients to avoid sun exposure during therapy to minimize the risk.

Whether or not topical nitrogen mustard increases the incidence of internal malignancies in patients with CTCL remains unclear. [36] Some studies have reported an increased risk of colon cancer, whereas others have not. CTCL itself is associated with an increased incidence of systemic lymphoma. High-dose systemic mechlorethamine is not associated with these other malignancies, so perhaps CTCL patients have an underlying increased risk for these second malignancies. [28]

The main role of topical mustard in dermatology is in the treatment of CTCL patches and plaques. [28] There are reports of topical mustard producing complete remission in up to 75 percent of patients, [36] particularly if used in the early stage. [28], [37] Topical nitrogen mustard has also been used with some success in the treatment of psoriasis, [38] alopecia areata, [39] and histiocytosis X. [40] One of the authors (JLS) has used topical mustard successfully in the treatment of alopecia mucinosis.

Topical mustard is usually prepared as either an aqueous solution or an ointment preparation. The aqueous solution needs to be prepared daily by the patient. This is done by mixing 10 mg of nitrogen mustard with 60 mL of water. The solution should be applied immediately with a gauze pad to the entire body but sparingly to intertriginous sites. The genitalia should be excluded. The solution has a shelf life of approximately 1 day. However, refrigeration of the solution extends the usefulness for up to 6 months. With proper application, there is minimal contamination to the surrounding environment. [32] Those assisting in the application of the drug should limit their exposure by wearing protective gloves, avoiding direct contact, and washing thoroughly after handling the preparation. Effort should be made to dispose of empty vials or unused solution in accordance with Environmental Protection Agency guidelines. Dissolving the mustard in anhydrous petrolatum provides an alternative to the aqueous preparation. Generally, 10 mg of nitrogen mustard powder is first dissolved in 99% isopropyl alcohol, and then compounded with 100 g of anhydrous petrolatum. This creates an ointment with 0.01% concentration of mechlorethamine. The ointment has a shelf life of approximately 50 days.

BCNU (CARMUSTINE)

Carmustine [bischloroethylnitrosourea (BCNU)] is a nitrosourea that acts by alkylation to inhibit DNA, RNA, and protein synthesis. Its action is not cell-cycle specific. The topical formulation, introduced in 1971, is used predominantly in the treatment of CTCL. BCNU is effective in patch- and plaque-stage CTCL, with complete clinical response rates of 48 to 86 percent and remission durations of 18 to 66 months. [41]

Systemic side effects include profound myelosuppression, renal failure, mucositis, pulmonary fibrosis, alopecia, nausea and vomiting, and azoospermia. These side effects have not been seen resulting from topical treatment, apart from mild myelosuppression. Cutaneous reactions are very common with the topical formulations. Erythema is seen in almost all patients and generally appears after 4 to 8 weeks of therapy. If severe, this may be associated with skin tenderness and telangiectasia. Allergy is uncommon and occurs in fewer than 10 percent of patients, manifesting as DTH. Urticaria is not seen, and an increased incidence of skin cancers is not observed. Mild bone marrow depression can be found, and patients should have regular blood counts while undergoing topical BCNU treatment.

BCNU is available as a powder for reconstitution as a solution or ointment. A 0.2% alcoholic stock solution is made by mixing 300 mg of BCNU with 150 mL of 95% ethanol. This solution is stable for 3 to 12 months if refrigerated. The patient is instructed to mix 5 mL (10 mg) of the stock solution daily with 60 mL of water. This should be applied immediately to the skin, avoiding the face, hands, genitals, and intertriginous areas, unless these are directly involved with CTCL. The applications should be continued until clearing is seen, usually in 8 to 16 weeks. If the response to 10 mg daily is inadequate, the dose may be doubled for a further 4 to 8 weeks if tolerated. The ointment is prepared by combining BCNU powder in 95% alcohol and then mixing with white petrolatum USP up to concentrations of 10 mg% (10 mg/100 g base), 20 mg%, and 40 mg%. The ointment is easier for patients to use and leads to fewer cutaneous reactions. However, it is associated with an increased incidence of myelosuppression. The ointment is stable for about 6 months if kept refrigerated.

VINBLASTINE

Vinblastine is a vinca alkaloid. It is an antimitotic agent and acts by disrupting microtubules, blocking cell division in metaphase. In dermatologic practice, this agent is used primarily as an intralesional injection for cutaneous and oral lesions of Kaposi's sarcoma.

Potential systemic side effects are myelosuppression, neuropathy, anorexia, nausea, vomiting and diarrhea, alopecia, mucositis, and dermatitis. Side effects of intralesional injection are usually limited to pain, ulceration, and hyperpigmentation at the injection site. To reduce the pain involved with injection, local anesthesia before injection has been tried, as has mixing lidocaine into the vinblastine solution. [42], [43] This does not reduce postinjection pain, which may persist for up to 48 h. Pain can usually be managed with simple oral analgesics.

The method of intralesional injection generally reported is 0.1 to 0.2 mg of vinblastine per mL of normal saline, with doses escalating to 0.6 mg/mL. Some authors use one injection only, whereas others recommend injections every 2 to 4 weeks until complete response is seen. [44] Complete or partial clinical response is of the order of 88 percent. [43] However, as treatment is local, progression of Kaposi's sarcoma may occur at other sites.

BLEOMYCIN

The bleomycins are a group of antibiotics produced by *Streptomyces verticillatus*. The drug in clinical use is a mixture of

bleomycins A2 and B2. Bleomycin acts by disrupting DNA synthesis, causing cells to accumulate in G2. At 48 h after injection, apoptotic keratinocytes are seen in the epidermis. [45] Systemic toxicity from bleomycin includes myelosuppression, hyperpigmentation, hyperkeratosis, ulceration, pulmonary fibrosis, headache, nausea, vomiting, hyperthermia, and hypotension.

Intralesional bleomycin has largely been used as a successful treatment for recalcitrant warts. Additionally, intralesional injections of bleomycin have yielded some success in the treatment of keratoacanthomas. [46] Significant systemic exposure does occur, although systemic toxicity has not been found. [45], [47] Local side effects of pain, swelling, and Raynaud's phenomenon have been reported. [48] Local injection for periungual warts may result in permanent nail loss or dystrophy. Lidocaine may reduce the pain associated with the injection.

Bleomycin is available as a powder. It should be reconstituted with 0.9% sodium chloride into a 1 U/mL solution. Stability in this formulation has been shown at 6 to 8 weeks if the preparation is refrigerated at 4°C (39.2°F), and for several months if stored at -20°C (-4°F). [45] The solution should be injected intralesionally until the wart blanches; one to two injections may be required. Using this technique, a 77 percent cure rate has been found for warts on extremities; however, the rate falls to about 48 percent for plantar warts. [49] A multiple puncture technique has been employed by one group, which may result in a more uniform distribution of drug into the wart. [50]

Topical Immunomodulators

TOPICAL MACROLACTAM IMMUNOSUPPRESSIVES

Tacrolimus (FK506)

PIMECROLIMUS AND OTHER MACROLACTAM AGENTS
IMIQUIMOD

Other Clinical Uses

REFERENCES

The topical immunomodulators represent an entirely new realm of therapeutic agents that act via immunologic pathways to either inhibit or enhance immune and inflammatory reactions in the skin. The immunosuppressive agents are all within the macrolactam class of immunophilin-binding cytokine inhibitors. In the immune-enhancing category, there is currently only one drug, the interferon-inducing agent, imiquimod.

Therapy with topical immunomodulators is presently in a relatively primitive phase. The range of indications is limited, yet the full potential for such agents might be perceived as almost limitless. Knowledge of mechanisms of action is sketchy, as are basic pharmacologic parameters such as absorption kinetics, metabolism (cutaneous and systemic), and tissue retention. In general, short-term safety has been assured, but side effects over many years must be a continuing concern. The outlook seems bright at present and many investigations can be foreseen as we expand the range of diseases that can be helped by the current and future immunomodulators.

TOPICAL MACROLACTAM IMMUNOSUPPRESSIVES

Tacrolimus (FK506)

This drug was originally isolated from *Streptomyces tsukubaensis* and developed for use in organ transplantation. The mechanism of action involves tacrolimus binding to the immunophilin-binding protein (FKBP), in turn blocking calcineurin dephosphorylative activation of NFAT (nuclear factor of activated T cells), which translocates to the nucleus where it initiates cytokine gene expression (Fig. 250-1).In vitro effects include inhibition of T cell proliferation and inhibition of production of a variety of cytokines including interleukin (IL)-2, IL-3, IL-4, IL-12, tumor necrosis factor (TNF) and interferon (IFN)-?. [1], [2]

FIGURE 250-1 Tacrolimus: Mechanism of action. Calcineurin-dependent inhibition of inflammatory cytokine gene transcription.

Tacrolimus is one to two logs more potent than cyclosporin, its molecular weight is less, and its ability to penetrate the skin is greater. These properties provided a basis for experiments demonstrating topical inhibition of contact hypersensitivity and then development as an ointment for treating atopic dermatitis.

Tacrolimus ointment, 0.03% and 0.1% applied twice daily, was studied extensively in clinical trials that included adults and children as young as 2 years of age. [1], [3] Pharmacokinetic studies showed percutaneous absorption initially in 10 to 20 percent of patients with atopic dermatitis, but generally blood levels were undetectable by 1 week as healing and reestablishment of the skin barrier occurred. Rarely were blood levels greater than 2 ng/mL (compared to trough levels of 5 to 15 ng/mL in transplant patients treated systemically).

With topical tacrolimus therapy, more than 70 percent of patients have had moderate to excellent improvement in 3-week controlled trials, and 30 to 40 percent have had greater than 90 percent improvement. [4], [5] In general, response to therapy with topical tacrolimus has been best and most rapid in thinner skin areas such as the face, neck, and trunk. During remissions, dosing may be reduced in frequency but flares occur with discontinuance. Responsiveness is slow and often incomplete on extremities, especially hands and feet, and in patients with lichenified lesions. Roughly 25 percent of patients, especially those with the most severe disease, do not have a satisfactory therapeutic response. Additionally, patients should realize that exacerbations of atopic dermatitis may occur and require occasional intervention with topical or systemic corticosteroid therapy. The main advantage of topical tacrolimus is the provision of chronic maintenance therapy without the need for continuous topical corticosteroids. Long-term therapy with tacrolimus has shown no evidence of cutaneous atrophy, increased infection, hypertension, renal toxicity, or cumulative blood levels.

Adverse effects have been primarily an intense burning and itching in 30 to 40 percent of patients at application sites, especially in areas of flaring, excoriation and erosion. [3], [5] These symptoms usually subside in a few days, in concert with

healing of the skin. However, some patients continue to have bothersome burning, and this effect seems to be more prominent when the skin is exposed to heat such as summer weather, baths, or hot tubs. In general, these problems with burning sensations seem to be less in children. Up to 10 percent of adults experience symptoms of flushing with alcohol ingestion. Infections have not been a notable problem in tacrolimus-treated patients. [4] Occasional staphylococcal skin infections occur, but they are no worse than before treatment, and studies actually demonstrate a reduction in *S. aureus* colonization during prolonged therapy. In spite of the theoretical concern about immunosuppression, there have been no significant increases in frequency or severity of herpes simplex, wart, varicella, or molluscum contagiosum infections. All continue to occur as usual in these patients with atopic dermatitis but severity is unremarkable. Immunosuppression also carries the theoretical risk of cutaneous cancer and lymphoma predisposition but, to date, there has been no evidence of increased occurrence. However, such effects would likely require many years of constant immunosuppression and thus close surveillance is indicated along with careful counseling of patients to use sun protection.

OTHER CLINICAL USES One can envision an almost endless list of inflammatory dermatoses that might benefit from topical tacrolimus therapy (Table 250-1). Anecdotal reports suggest value in oral lichen planus, vitiligo, and pyoderma gangrenosum, but no evidence-based information yet exists. Psoriasis responses have been disappointing, presumably because of impaired drug penetration, but there are indications of efficacy for facial and intertrigenous lesions. Increased hair growth in animal models suggests a possible role for tacrolimus in alopecia areata but evidence of clinical success is lacking. [1]

Cutaneous	Mucosal
Psoriasis (especially flexural)	Aphthae
Miscellaneous eczemas	Lichen planus
Stasis dermatitis	Pemphigus, pemphigoid
Eyelid dermatitis	Vernal conjunctivitis
Bullous disease	Keratoconus
Cutaneous lupus erythematosus	Pruritus ani
Alopecia areata	Vulvovaginal inflammation
Vitiligo	
Hidradenitis suppurativa	
Inflammatory scalp disease	

TABLE 250-1 **Conditions Potentially Amenable to Treatment with Topical Macrolides**

PIMECROLIMUS AND OTHER MACROLACTAM AGENTS

The ascomycin derivative pimecrolimus (ASM 981) has been studied extensively as a topical 1% cream. The drug has a very similar structure to tacrolimus and interacts with the same binding protein to inhibit calcineurin activation of NFAT. Cutaneous effects appear to be lower, however, as reflected in the need for the higher drug concentration in the topical cream and the necessity for twice daily application. [6] Available information indicates that the drug's lipophilicity helps keep it in the skin, enhancing the local effect and reducing clearance. It also appears to have little systemic immunosuppressive effect, which may reflect a wider margin of safety. Clinical trials have included infants as young as 3 months of age. Prolonged therapy up to 1 year has shown no significant adverse events in adults or children. [7] Blood levels have been detected in occasional patients but no high or prolonged levels were seen. Pimecrolimus is also being tested as an oral agent and to date, no renal, hypertensive, or other side effects have been noted in short-term study. This aspect may provide greater safety assurance for use of the topical agent and may eventually give us a much-needed oral agent for patients with widespread disease.

A third topical macrolactam agent, ABT281, has undergone preclinical testing in vitro and in animal contact allergy models. The potency appears, from these early studies, to be intermediate between tacrolimus and pimecrolimus but its safety and efficacy for human use remains to be demonstrated.

IMIQUIMOD

Imiquimod, an imidazoquinolone amine, was initially found to protect guinea pigs from herpes virus infection. Subsequent animal studies revealed both an antiviral and antitumor effect. Imiquimod is unique in that it appears to enhance both acquired and innate immune function. In comparison, tacrolimus functions to inhibit pathways involved in immune activation. The precise mechanism is unknown but appears related to induction of inflammatory cytokines. In vitro and in vivo studies demonstrate that topically applied imiquimod induces local cytokine production from keratinocytes and other cells. [8] In vitro effects include induction of interferon (IFN)-a, tumor necrosis factor (TNF)-a, IL-1, IL-1 RA (interleukin-1 receptor antagonist), IL-6, IL-10, IL-12, G-CSF (granulocyte colony-stimulating factor), GM-CSF (granulocyte-monocyte colony-stimulating factor), as well as the chemokines IL-8, macrophage inflammatory protein (MIP)-1a, and monocyte chemotactic proteins (MCP)-1. [8] Imiquimod also stimulates the innate immune response by increasing natural killer cell activity, activating macrophages, inducing proliferation and maturation of B lymphocytes, and activating Langerhans cells. The major systemic metabolite of imiquimod, S26704, is a hydroxylation product that achieves plasma concentrations 25 times greater than imiquimod. The half-life of intravenously administered imiquimod is 14 h, and less than 1 percent of the drug is recovered in the urine after a single topical application. [8]

Many published reports show that imiquimod is an effective treatment for anogenital warts. A 16-week study of 311 immunocompetent adults with external anogenital warts compared three times weekly 5% imiquimod cream, 1% imiquimod cream, and placebo. Clearance was achieved in more than 70 percent of women and 30 percent of men with the 5% cream, both significantly better than placebo. [9] This greater response in females has been demonstrated in a number of trials. Comparable response rates have been seen in uncircumcised males treated under the foreskin, suggesting that increased moisture may account for this gender discrepancy. Similarly, local factors may account for lower response rates seen in nongenital warts. The primary benefit of imiquimod cream relative to other available wart therapies is ease of administration. In adults, home therapy for genital warts is preferred given the sensitive nature of this problem. Likewise in children, genital warts may be a result of sexual abuse, and an atraumatic topical therapy that can be rapidly applied in a nonthreatening environment is ideal.

Recurrence rates following use of imiquimod cream have ranged from 13 to 19 percent. Adverse effects relate primarily to cutaneous irritation at the application site, especially with thrice weekly application leading to moderate erythema and

erosion in roughly one-third and one-tenth of patients, respectively. [9] Further studies suggest that both the response rate, particularly in males, and the likelihood of side effects will increase with daily therapy. Imiquimod is a category B drug, and it is not known to what extent topically applied imiquimod is excreted in the breast milk of nursing mothers. Imiquimod has not been thoroughly studied in children younger than 18 years of age. Other infectious conditions for which imiquimod holds promise include acyclovir-resistant herpes simplex, [10] molluscum contagiosum, [11] and leishmaniasis. [12]

Other Clinical Uses

In vitro antitumor effects formed the basis for evaluation of imiquimod's efficacy in the treatment of cutaneous neoplasia. Beutner et al. conducted a double-blind, dose-escalating placebo-controlled pilot trial that suggested a role for imiquimod in the treatment of superficial basal cell carcinoma (sBCC). [13] A multicenter, randomized, open-label dose-response trial subsequently showed an almost 90 percent histologic clearance rate of sBCC when 5% imiquimod cream was applied daily for 6 weeks. Increased frequency of application again led to an improved response rate, but a higher incidence of local skin reactions. [14] Response has also been demonstrated in nonfacial BCC in a patient with basal cell nevus syndrome. [15] Imiquimod is presently being evaluated as a treatment for a number of other neoplastic conditions including actinic keratosis, superficial squamous cell carcinoma, Bowen's disease, and lentigo maligna. Analogues of imiquimod such as S28463 and R848 (resiquimod) may prove to be more potent inducers of inflammatory cytokines.

REFERENCES

Topical therapies are one of the foundations of a dermatologist's therapeutic armamentarium. This chapter reviews the latest additions to the dermatologist's repertoire of treatments and reevaluates many of the older therapies that are still highly effective.

ACNE THERAPIES

Adapalene

Adapalene, derived from naphthoic acid, has potent retinoid and anti-inflammatory properties. As a 0.1% gel, it was developed for use in acne vulgaris and has slightly lower irritant effects than tretinoin. Adapalene has comedolytic, antiproliferative, and anti-inflammatory activity. [1] It acts on cell proliferation and differentiation via retinoic acid receptor-binding proteins, and gene transcription. [1] Follicular penetration is observed with adapalene, which presents an advantage in treating acne. In 12-week international multicenter studies comparing adapalene gel 0.1% to tretinoin gel 0.025%, adapalene was as effective and in some cases superior to tretinoin. [2] Side effects associated with adapalene 0.1% gel include burning, pruritus, dryness, and scaling.

a-Hydroxy Acids

The a-hydroxy acids are keratolytic. These drugs reduce follicular hyperkeratosis and facilitate stratum corneum desquamation.

Azelaic Acid

Azelaic acid is a naturally occurring aliphatic dicarboxylic acid that is a competitive inhibitor of tyrosinase. Azelaic acid is a reversible inhibitor of cytochrome P450 reductase and 5a-reductase in microsomes and a reversible inhibitor of some enzymes in the respiratory chain. [3] Its efficacy is attributed to activity against *Propionibacterium acnes,* normalization of keratinization, and a direct anti-inflammatory effect. [4] A beneficial effect may not be observed until 4 weeks after initiation of treatment, which may need to be continued for several months.

Benzoyl Peroxide

Benzoyl peroxide rapidly improves both inflammatory and noninflammatory acne lesions. It can be used effectively as monotherapy for mild disease. Benzoyl peroxide has antibacterial activity, reducing the population of *P. acnes* by generating reactive oxygen species. Benzoyl peroxide can initially irritate skin, and bleaching of skin and hair have been reported. It is available in a variety of formulations, including gels, lotions, creams, and washes with a concentration of 2.5% to 10%, or by prescription in a variety of formulations.

Clindamycin

Clindamycin 1% is available in several topical formulations (gel, solution, lotion). Two recent clinical trials showed that the combination of 5% benzoyl peroxide and 1% clindamycin gel was superior in acne improvement than clindamycin alone. [5] Antibiotic therapy may be discontinued for 1 month then resumed or an alternative agent substituted if resistance develops.

Erythromycin

Topical erythromycin reportedly reduces acne lesions by 50 to 60 percent. It decreases comedogenic free fatty acids and exerts an anti-inflammatory effect by suppressing neutrophil chemotaxis. Topical erythromycin has a low potential for sensitization. A recent study suggests that erythromycin acts as a catalyst to increase benzoyl peroxide radical activity. [6]

Tazarotene

Tazarotene is a topical acetylenic retinoid that normalizes keratinization of the follicular epithelium, preventing the formation of microcomedones, thereby helping to reduce the proliferation of *P. acnes.* [7] A recent multicenter, double-blind, randomized, trial showed comparable efficacy of alternate day tazarotene 0.1% gel and once-daily adapalene 0.1% gel. [8]

Tretinoin (Vitamin A Acid) (See also Chap. 244)

The actions of tretinoin include influencing desquamation of abnormal epithelium, altering the microclimate of the microcomedo, resolving mature comedones, preventing new lesions, and enhancing the penetration of other drugs. [9] By increasing mitotic activity and turnover of follicular epithelial cells and regulating maturation of epidermal cells, tretinoin induces thickening of the granular layer and normalization of parakeratosis. Tretinoin treatment in acne enhances epithelial turnover, loosening keratin debris; it promotes the drainage of preexisting comedones and inhibits formation of new ones.

Initially, tretinoin may cause erythema and tenderness of the skin, but the comedones then start to extrude and do not usually reform if therapy is continued. The irritation can be minimized by using the mildest formulation (0.025% cream) first and initiating its use on alternate days. Maximal therapeutic results take up to 6 weeks, and maintenance therapy may be required to prevent exacerbations. Tretinoin is available in cream, gel, and solution formulations in an assortment of concentrations.

ANALGESICS

Capsaicin

Capsaicin is an active ingredient of cayenne peppers and other plants of the Capsicum family. The mechanism of pain relief is not known; however, it may be a result of reduction in afferent input following depletion of substance P. Consequently, pain impulses cannot be transmitted to the brain. When applied topically, capsaicin causes vasodilatation and a burning sensation. After repeated exposures, the burning sensation may diminish. Capsaicin is applied four or five times per day for 4 to 6 weeks. Patients should be instructed to wash their hands after each application and to avoid inadvertent eye contact. Capsaicin has been used to treat postherpetic neuralgia, painful diabetic neuropathy, postmastectomy pain syndrome, nostalgia paresthetica, meralgia paresthetica, and cluster headaches. Its effect appears to be modest, but it is quite safe.

Eutectic Mixture of Local Anesthetic (EMLA)

EMLA cream contains a eutectic mixture of 50 percent lidocaine and 50 percent prilocaine in an oil-in-water emulsion. EMLA is applied to intact skin and covered with an occlusive dressing. Anesthesia develops in hours at a depth in the skin proportional to the duration of application. Maximal penetration occurs 30 min after the removal of EMLA, and analgesia persists for several hours. EMLA is safe and particularly useful in children.

Topical Anesthetics

Topical anesthetics, such as benzocaine, are sensitizers that should be avoided. Lidocaine (United States) or lignocaine (United Kingdom) and other “amide” type agents are rare sensitizers and may be used.

ANTIFUNGALS (See also Chap. 246)

Allylamines

This group of topical antifungals includes terbinafine and naftifine. The fungicidal allylamines inhibit ergosterol synthesis, specifically squalene epoxidase, and thus alter the cell wall. They are lipophilic, allowing binding to the stratum corneum layer. Terbinafine is at least as effective as miconazole 2% cream and naftifine 1% gel in tinea pedis. [10] The side effects of both terbinafine and naftifine include a low incidence of local burning, pruritus, dryness, and erythema.

Azoles

The first- and second-generation imidazoles include clotrimazole, econazole, ketoconazole, miconazole, and sulconazole as topical therapies; they have similar spectrums of efficacy and activity. They function by blocking synthesis of ergosterol, which plays an integral role in cell membrane structure and function. Ketoconazole is available in a shampoo formulation, which leads to more rapid clearing of lesions in tinea versicolor.

Castellani's Paint

Named after Sir Aldo Castellani, this mixture contains resorcinol (8 g), acetone (4 mL), magenta (0.4 g), phenol (4.0 g), boric acid (0.8 g), industrial methylated spirit 90% (8.5 mL), and water (to 100 mL). It is fungicidal and bactericidal with local anesthetic effects, [11] and stains the skin red. Castellani's paint, usually applied to the intertriginous areas of the skin, is particularly effective in inflammatory ntertriginous tinea and acute *Candida paronychia*. It has also been used to treat seborrheic eczema and tinea pedis. It has drying ability, which makes it useful in treating leg ulcers. It is applied daily for 2 weeks, usually at bedtime.

Ciclopirox

Ciclopirox acts by interfering with the uptake and availability of components required for membrane synthesis. Ciclopirox is fungicidal and fungistatic with anti-inflammatory properties. It is also effective against certain gram-positive and gram-negative aerobic bacteria, including resistant strains of *Staphylococcus aureus,* yeasts, dermatophytes, and nondermatophyte molds. [12]

Haloprogin

Haloprogin exhibits activity against a variety of organisms, including dermatophytes and Candida, and against pityriasis versicolor and erythrasma. In yeast infections, it interferes with respiration and disrupts cell membranes. However, its mode of action in dermatophytic infections is not clearly elucidated. The side effects associated with its use include local irritation, pruritus, and contact dermatitis.

Polyenes

The polyenes, such as nystatin, act by increasing fungal cell membrane permeability by binding to membrane sterol. Nystatin is both fungicidal and fungistatic. It has been the standard therapy for candidiasis, especially oral thrush. Topical nystatin has limited systemic absorption but can rarely cause nausea, vomiting, and diarrhea.

Selenium Sulfide

Selenium sulfide is reported to increase fungal shedding by decreasing corneocyte production through its cytostatic effect on cells. It also has sporicidal activity. It is commonly used as adjunctive therapy in tinea capitis to reduce the period of infectivity and in the treatment of pityriasis versicolor and seborrheic dermatitis. For the treatment of tinea versicolor the solution is applied and left on for 10 min before thoroughly rinsing. This is done on a daily basis for 7 days. There are many other effective regimens for using selenium sulfide in tinea versicolor. Associated side effects include skin irritation and increased hair loss and discoloration.

Tolnaftate

Tolnaftate inhibits squalene epoxidation, and is fungicidal. It is not as effective as other antifungals in treating dry trichophyton rubrum infections and candidiasis. Uncommon side effects of tolnaftate include contact dermatitis, urticaria, pruritus, and erythema. Stevens-Johnson syndrome and toxic epidermal necrolysis have also been reported.

Undecylenic Acid

When combined with zinc, calcium, and sodium, undecylenic acid has fungistatic activity.

Whitfield's Ointment

Whitfield's ointment, composed of 12% benzoic acid and 6% salicylic acid, is the least-expensive preparation to treat dermatophytoses. Effective only against dermatophytes, it is fungistatic and keratolytic. Whitfield's ointment has the ability to kill spores and remove infected debris, although many patients discontinue use because of its local irritant effect. [13]

Zinc Pyrithione

Zinc pyrithione is a general inhibitor of membrane transport in fungi. It has fungistatic and antimicrobial activity, [14] but its exact mode of action is unknown. Zinc pyrithione has been used to treat dandruff and psoriasis with variable effectiveness. It has been reported to cause allergic contact dermatitis.

ANTI-HAIR LOSS

Minoxidil

Minoxidil was originally developed as an oral antihypertensive agent. It is a potent vasodilator that acts directly on peripheral arterioles, decreasing blood pressure with resultant tachycardia. It was serendipitously observed that patients on minoxidil developed hypertrichosis. Subsequently, it has been reformulated into a topical solution, which lacks the systemic effects, to treat alopecia. The exact mode of action of minoxidil is unknown, although it has been postulated that minoxidil increases cutaneous blood flow to the scalp. It is available in 2% and 5% formulations. Approximately 30 percent of patients with male pattern baldness achieve some beneficial results. Currently, only 2% minoxidil is approved by the FDA for treatment of androgenetic alopecia in women. [15]

ANTI-INFLAMMATORY AGENTS

Coal Tar

Coal tar is manufactured as the by-product of processing coke and gas from bituminous coal (coal tars). It contains at least 10,000 different chemicals, including aromatic hydrocarbons such as benzenes, naphthalenes, creosols, and phenols. The cruder the coal tar, the more therapeutically effective it is. The method by which coal tar exerts its influence is still not well understood. Studies suggest that tars depress DNA synthesis and have an antimitotic effect. Coal tar applied to normal skin produces early suppression of epidermal DNA synthesis followed by a proliferative response. [16] Tars have phototoxic or photodynamic activity, with an action spectrum in the UVA and visible range. Tar is known to be carcinogenic in animals. However, there are very few reports of squamous epithelioma resulting from the therapeutic use of crude coal tar. The most common adverse effects of tar are folliculitis and irritation. Other side effects include tar acne, phototoxicity, and allergic contact sensitivity. Tar application is messy and can stain clothing. Therapeutic results in chronic eczema, especially atopic dermatitis, are gratifying. Coal tars are frequently formulated as gels, shampoos, and

tar baths.

Shale Tar

Shale tar (ichthammol) originates from shale oil that undergoes chemical degradation with ammonia and sulfuric acid to form a sulfur-rich substance. It is most often formulated with glycerin and is thought to have both anti-inflammatory and vasoactive properties. Ichthammol is a safe, time-honored standard in the treatment of eczema, seborrheic dermatitis, and rosacea, and has also been used in the treatment of otitis externa when mixed with glycerol. The effects of shale tar on neutrophils include inhibiting the release of leukotriene B_4 (LTB_4) and blocking migration. [17] In contrast to coal tar, shale tars are less irritating, not photosensitizing, and less effective.

Wood Tar

Wood tars are obtained by distilling wood under controlled conditions. Oil of cade from juniper is the most common wood tar and has a strong and distinctive odor. Other wood tars include oil of beech, birch, and pine. They can be added to arachis oil (peanut oil) or simple bases as an application to the scalp in seborrheic dermatitis and psoriasis. Oil of cade is also a major ingredient in the 20-10-5 ointment, which consists of 20 percent oil of cade, 10 percent sulfur, and 5 percent salicylic acid. Like shale tars, wood tars are not photosensitizers. [18]

ANTIMICROBIAL AGENTS

Chlorhexidine

Chlorhexidine is a bisbiguanide that has bactericidal and fungicidal activity. However, it does not kill bacterial spores or mycobacteria, although it does inhibit their growth. Because it does not lose its effectiveness in the presence of whole blood, it is an important antiseptic, disinfectant, and preservative.

Dyes

Dyes are useful as topical treatment because they are inexpensive and chemically and physically stable. The two dyes, gentian violet (methylrosaniline chloride) and brilliant green (*p*-diethylamine triphenylmethanol) are both derivatives of triphenylmethane. Gentian violet has been used as a dye for fabrics, wood, and cosmetics, and in food. It is also used as a biologic stain (Gram stain, nucleic acid stain), mycostatic agent in poultry feed, antiseptic, astringent, and anthelminthic, and as a blood additive to prevent the transmission of Chagas' disease by transfusion. [19] The dyes are effective against *Candida* species, streptococci, and staphylococci, including methicillin-resistant *Staphylococcus aureus*. Several hypotheses exist as to gentian violet's mode of antimicrobial activity, including (1) inhibition of bacterial cell wall formation, (2) protein synthesis inhibition, (3) redox potential alteration, (4) inhibition of glutamine synthesis, and (5) formation of a dye-bacteria un-ionized complex. [19]

Hydrogen Peroxide

Hydrogen peroxide has been used for a number of years as a cleansing agent and for the removal of debris. It has antibacterial properties against both gram-positive and -negative bacteria, and its effervescent quality helps to débride wounds. Hydrogen peroxide does not induce bacterial resistance.

Iodinated Compounds

Iodine solution is bactericidal, sporicidal, and viricidal. Iodophors are complexes of iodine with a carrier that slowly liberates inorganic iodine on contact with reducing substances. This preserves the antimicrobial activities of iodine without the irritant effects of the free tincture. Iodophors may be inactivated after contact with whole blood, and have a slower onset of action than iodine solution.

POVIDONE-IODINE Povidone-iodine has a wide spectrum of in vitro activity against gram-negative and -positive bacteria, fungi, and viruses. Wound exudate, however, inactivates povidone. Systemic absorption can occur with resultant renal and thyroid dysfunction.
CLIOQUINOL Clioquinol, 5-chloro-8-hydroxy-7-lodoquinolinol, is weakly antifungal and antibacterial. It is a yellowish-white to brownish-yellow powder available in 1% and 3% cream and ointment bases. It is effective alone or combined with a topical steroid to treat inflammatory dermatoses, especially in intertriginous areas. Adverse reactions include a yellowish discoloration on clothing or skin, delayed contact hypersensitivity, and primary contact dermatitis.

Metronidazole

Metronidazole is an imidazole with the ability to inhibit fungi and *Trichomonas,* and is most useful in rosacea. Its mode of action involves the impedance of leukocyte chemotaxis and selective suppression of cellular immunity.

Mupirocin

Formerly known as pseudomonic acid A, mupirocin is obtained from the fermentation of *Pseudomonas fluorescens*. It is bactericidal at the concentration achieved with topical application to the skin and mucous membranes. Mupirocin prevents the incorporation of isoleucine into proteins by inhibiting bacterial isoleucyl-t-RNA synthetase. Its unique mechanism of action prevents cross-resistance. [20] It has activity against staphylococci, streptococci, and certain gram-negative bacteria (*Haemophilus influenzae, Neisseria* species , *Pasteurella multocida*), but is inactive against

normal skin flora (*Micrococcus, Corynebacterium, Propionibacterium* species).

Silver Sulfadiazine

This compound was originally synthesized in 1968 from silver nitrate and sodium sulfadiazine. It is available as a 1% cream and is effective against a wide spectrum of microbial pathogens. Its antimicrobial activity is thought to occur by inhibiting DNA replication and modifying the cell membrane. It is largely used to treat burn patients, but has been used to treat a variety of other skin conditions including Stevens-Johnson syndrome. Side effects are very few. Of these, transient leukopenia is a side effect encountered with clinical use. Early postburn leukopenia is mild and self-limited. After 2 to 4 days of use, silver sulfadiazine can cause formation of a “pseudoeschar” which is caused by the interaction of proteinaceous exudate in the wound with the drug.

ANTIPARASITIC AGENTS (See also Chap. 238)

Crotamiton

Crotamiton (crotonyl- *N*-ethyl- *O*-toluidine) is a colorless or pale yellow oil used in the treatment of scabies and pediculosis capitis. Other antiparasitic formulations, such as lindane 1% and permethrin cream 5%, are more effective than crotamiton, [21] which is rarely a sensitizer. Its mode of action is unknown. It has some antipruritic activity and is safe. [22]

Gamma Benzene Hexachloride

Gamma benzene hexachloride, a chlorinated hydrocarbon pesticide, is very effective against lice and fleas as a 1% solution. It is amongst the slowest acting ovicides of several antiparasitic agents. Scabies resistant to gamma benzene hexachloride has been reported. Side effects of topical application include central nervous system toxicity, seizures, and aplastic anemia. [23]

Malathion

Malathion is a moderately toxic organophosphate insecticide and is the fastest acting ovicide in comparison with other antiparasitic agents. It acts by irreversibly binding to acetylcholinesterase, [24] and is used for the treatment of head lice. Contact dermatitis has been reported with its use.

Permethrin

Permethrin is a synthetic pyrethroid modeled after the natural insecticide found in the pyrethrum flower, *Chrysanthemum cinerariaefolium,* which has been used for centuries in Iran as an insecticide. It acts on parasitic nerve cell membranes, causing paralysis and death. It is available as a 1% cream rinse, which is left on for 10 min. A single application is effective against head lice and nits, with activity detectable at least 10 days after use. Permethrin is the treatment of choice for treatment of scabies and lice. [25] There is a lack of safety data for its use in children younger than 2 months of age, and in pregnant and breast-feeding women. Permethrin is also effective against pediculosis pubis, and mites infestations including cheyletiella. [25] It was recently used in combination with oral ivermectin in the treatment of rosacea-like demodicidosis. [26]

Pyrethrin

Pyrethrin is the naturally occurring ester of chrysanthemumic acid. In combination with piperonyl butoxide, it is available as a liquid, gel, and shampoo. For the treatment of head lice, it is as cosmetically acceptable as permethrin, but does not kill all unhatched eggs and has no residual activity. [22] Pyrethrin is a neurotoxin, and piperonyl butoxide inhibits its metabolism, potentiating its effects. It is also effective against fleas, mosquitoes, and houseflies.

ANTIPERSPIRANTS

Aluminum Compounds

Aluminum chloride, in solution in anhydrous ethyl alcohol (6 to 20%), has been used to treat hyperhidrosis. The solution is applied to the axillae or the palms and soles for at least 6 to 8 h. Shaving of the axillae should be avoided for 24 to 48 h before application of aluminum chloride. Occlusion, used to increase efficacy, increases the likelihood of irritation. Once excessive sweating is under control, use may be decreased to once or twice a week as maintenance therapy. The mechanism of action is controversial and may occur by blockage of the sweat duct or by atrophy of the secretory cells. [27]

Aldehydes

Glutaraldehyde solution applied to palms or soles has been used to control hyperhidrosis. It may be used on alternate days until desired results are achieved and then decreased to once a week or as needed. Glutaraldehyde as a 10% solution may leave brown pigmentation on the skin. A 2% solution will not produce this discoloration, but is less effective. Formaldehyde is a sensitizer and is not commonly used.

Methenamine

Methenamine is a six-carbon, four-nitrogen compound that has been used for a number of years to treat bacterial infections of the urinary bladder. At acid pH, it releases ammonia and formaldehyde. A 10% solution is effective in mild to

moderate hyperhidrosis, rarely producing allergic reactions. As a 5% firm gel stick, it is effective in reducing palmoplantar hyperhidrosis after 1 month of use, and the effect continues for up to 3 weeks after discontinuation of the product. [28]

ANTIPRURITIC AGENTS

Antihistamines

Topical antihistamines, such as diphenhydramine, are associated with a high incidence of contact sensitization [29] and cross-reactivity, and rarely with photoallergic reactions. [30] Given the availability of other effective topical agents, topical antihistamines should be avoided.

Doxepin

Tricyclic compounds, particularly doxepin hydrochloride, given orally are known to have antipruritic properties. Doxepin cream 5% may be used to treat pruritus, although the mechanism of its effect is uncertain. However, doxepin has an affinity for H_1 and H_2 receptors and may also exert its antipruritic effect through the antagonism of a-adrenergic, muscarinic, and serotonergic receptors and through inhibition of norepinephrine and serotonin neuronal reuptake and the inhibition of platelet-activating factor production. Topical doxepin has a potential for sensitization. It is effective for atopic dermatitis, chronic urticarias, prurigos, and neurodermatitis. [31] Doxepin cream may also be used as an adjuvant to glucocorticoids in treatment of pruritus.

Menthol

Menthol is a highly lipid-soluble cyclic terpene alcohol, often used interchangeably with or in addition to camphor. It is a naturally occurring plant oil obtained from the Mentha species. Menthol is a known chemical activator of cold-sensitive A delta fibers. Menthol does not decrease the duration or magnitude of histamine-induced pruritus. [32]

Phenol

Phenol in low concentrations acts as an antipruritic agent through its anesthetic effect. It may be percutaneously absorbed and should be avoided in pregnant women and infants. [33] It is a common ingredient in over-the-counter preparations for pruritus.

Pramoxine Hydrochloride

Pramoxine hydrochloride, a topical anesthetic, is effective in cases of mild to moderate pruritus. It is available in combination with menthol, petrolatum, and hydrocortisone. It is a sensitizer less frequently than other topical anesthetics.

ANTIVIRALS

Acyclovir

Acyclovir, 9-(2-hydroxyethoxymethyl) guanine, has specific antiviral activity against herpes simplex virus (HSV), varicella, Epstein-Barr virus, and cytomegalovirus. Acyclovir completely inhibits viral DNA synthesis by inactivating viral DNA polymerase. [34] It is more active against HSV-1 than HSV-2. Because frequent application of acyclovir 5% ointment has lower efficacy than systemic formulations, it is only topically indicated in initial genital HSV infections and limited mucocutaneous HSV infection of immunocompromised patients. [35] Some patients with ulceration may experience pain with application of acyclovir. A recent clinical trial showed comparable clinical efficacy between topical acyclovir 3% cream and penciclovir 1% cream when used for up to 7 days of treatment. [36] Penciclovir is a novel acyclic nucleoside analogue that has shown efficacy against HSV types 1 and 2 and VZV in cell culture. [36]

ASTRINGENTS

Aluminum Salts

Aluminum acetate tablets diluted 1:10 to 1:40 (Burow's solution) are an effective astringent. Over-the-counter aluminum sulfate and calcium acetate (Domeboro) are available and, when dissolved in water, make a modified Burow's solution. These solutions may be used as wet dressings, compresses, or soaks.

Potassium Permanganate

Potassium permanganate is a strong oxidizing agent and has non-specific activity against *Candida* species. Solutions of 1:4,000 to 1:16,000 may be used as wet compresses to reduce weeping. Alternatively, a 1:25,000 solution may be used as a medicated bath. Undissolved crystals can burn the skin. The use of this agent is limited because of bright purple staining, which may be removed with a weak solution of oxalic acid or sodium thiosulfate.

Silver Nitrate

Silver nitrate in 0.5% aqueous solution is an astringent and antimicrobial that is valuable in the treatment of infected eczema, gravitational ulcers, and other weeping and/or infected skin lesions. It is effective against *S. aureus, S. epidermidis,* and *P. aeruginosa*. At low concentration (0.5% formulation, used clinically) it is bacteriostatic, while bactericidal at higher concentrations (10%). The precise mode of its action is unknown. It is applied as a wet dressing

and stains the skin black. Its cosmetic disadvantage is often outweighed by the rapid resolution of weeping and superficial infection, often by resistant organisms. A 40% silver nitrate solution in alcohol is helpful in the management of severe folliculitis, and in solid form it may be used as a hemostat. In its concentrated form, it is extremely toxic to tissues, and methemoglobinemia has been noted secondary to topical treatment. [37]

BLEACHING AGENTS

Retinoic Acid

Retinoic acid is an effective acne therapy that has also been used successfully to treat melasma. Retinoic acid combined with 2% to 3% hydroquinone has synergistic effects and causes a rapid decrease in skin pigmentation. It has also been used to treat melasma in black patients effectively.

Azelaic Acid

This agent originally was intended for use in disorders of hyperpigmentation, and was later extended to acne treatment. Azelaic acid exhibits antityrosinase activity and is effective in melanosis caused by hyperfunction or proliferation of melanocytes. It has been used to treat melasma, lentigo maligna, [38] and melanoma. [39] Local irritation with azelaic acid is more common than with hydroquinone. Azelaic acid does not affect normal melanocytes and fibroblasts, and leukoderma and ochronosis are not associated with its use.

Hydroquinone

A hydroxyphenolic compound, hydroquinone is used extensively as a skin bleaching agent. It targets tyrosinase, inhibiting conversion of dopa to melanin. It is an effective depigmenting agent in many disorders of hyperpigmentation, including melasma, ephelides, and postinflammatory hyperpigmentation. Hydroquinone has been combined with retinoic acid and/or dexamethasone to enhance efficacy. The most serious side effect of hydroquinone use is development of ochronosis, seen with prolonged use of strong concentrations (6%). Other adverse events seen with hydroquinone use are development of irritant and allergic contact dermatitis, nail discoloration, and postinflammatory hyperpigmentation. Hydroquinone is available over the counter at concentrations less than 2%.

KERATOLYTIC AGENTS (See also Chap. 248)

a-Hydroxy Acids

a-Hydroxy acids (lactic acid, glycolic acid, citric acid, glucuronic acid, and pyruvic acid) are found in a variety of natural products including cane sugar, fruits, and yogurt. They are extremely effective keratolytics. a-Hydroxy acids reduce the thickness of hyperkeratotic stratum corneum by reducing corneocyte adhesion in the lower levels. These agents are effective in the treatment of disorders of keratinization (e.g., ichthyosis, hyperkeratotic eczema) and photoaging, and have also been used in acne and hyperpigmentation. The pHs of the various a-hydroxy acid preparations, including cleansers, moisturizers, and chemical peeling agents, are important in determining their efficacy.

Propylene Glycol

Propylene glycol and lactic acid have been used for hyperkeratotic conditions since the 1970s. A recent study showed that a combination of 20% propylene glycol with 5% lactic acid in a semiocclusive cream base was both highly effective and well tolerated in patients with lamellar ichthyosis. [40] This drug combination may be very effective in other types of nonbullous ichthyosis, as well as hyperkeratotic forms of eczema and psoriasis. [40] Propylene glycol is also available as a gel containing 6% salicylic acid.

Salicylic Acid

Salicylic acid may be used in concentrations ranging from 0.5% to 60% in almost any base. In concentrations of 3% to 6%, it causes shedding of scales by softening the horny layers. In concentrations higher than 6%, salicylic acid is destructive to tissue. It is for this reason that it is employed in wart therapy. Salicylism has been reported with widespread and prolonged use, especially in children. Sensitization is rare, and irritation can be minimized if introduced at lower concentrations. Salicylic acid's keratolytic effect occurs by dissolving the intracellular matrix and softening the stratum corneum, causing scale shedding. A loss of connectivity between corneocytes causes skin desquamation. [41]

Urea

Urea is proteolytic at high concentrations. It has been indicated for use in dry skin and the associated pruritus, ichthyosis vulgaris, atopic dermatitis, hand dermatitis, and nonsurgical avulsion of nails. [42] Urea has been added to some topical glucocorticoid preparations. In various bases, 5 to 10% urea is used in the management of ichthyosis. However, some patients experience burning with this therapy.

PSORIASIS THERAPIES

Anthralin

Anthralin (USP) or dithranol (BP) is a synthetic derivative of chrysarobin derived from chrysarophanic acid. Anthralin's exact mode of action is unknown. It may affect DNA synthesis (probably mitochondrial DNA), reducing cell turnover, or affect various enzyme systems (e.g., leukotriene synthesis, polyamines, respiratory function). [43] The most common

adverse events seen with anthralin use are erythema, irritancy, and contact dermatitis. Anthralin stains normal skin dark brown or black. Consequently, it is usually prepared in a paraffin base so that it does not spread to normal skin. Anthralin is available in pastes, ointments, and creams.

Calcipotriol

Calcipotriol is a vitamin D analogue. A recent review of treatment for mild to moderate chronic plaque psoriasis noted that topical calcipotriol 0.005% cream or ointment was more effective than calcitriol, coal tar, allantoin 2%, hydrocortisone 0.5%, short-contact dithranol, and tacalcitol. [44] It possesses the same therapeutic properties as vitamin D_3, including inhibition of epidermal proliferation, induction of differentiation, and anti-inflammatory effects. Hypercalcemia may occur if more than 100 g is used per week. It is applied initially twice daily, and maximal improvement can be expected within 6 to 8 weeks. Cutaneous irritation may occur in up to 20 percent of patients. This agent should be used cautiously on the face, groin, or intertriginous areas. In view of the risk of hypercalcemia and high cost, this preparation is not recommended for patients with extensive psoriasis.

Tazarotene

Tazarotene is useful in treatment of mild to moderate plaque psoriasis. Tazarotene normalizes abnormal keratinocyte differentiation, has antihyperproliferative activity, and is anti-inflammatory. [45] It is nonsensitizing, nonphototoxic, and nonphotoallergenic. Tazarotene is available in a 0.05% and 0.1% gel. It is effective as a once-daily application, and clearing can occur in 12 weeks. The most common side effect is local skin irritation.

WART THERAPIES

Dinitrochlorobenzene (DNCB)

DNCB is a potent sensitizer. The mechanism of action of topical DNCB may be to systemically stimulate T_H1 cell responses. [46] DNCB is mutagenic and potentially carcinogenic.

Diphenylcyclopropenone

Diphenylcyclopropenone is also used in contact immunotherapy in much the same way as DNCB. However, it is not mutagenic.

5-Fluorouracil

5-Fluorouracil is a pyrimidine analogue that inhibits thymidine synthetase, thereby inhibiting DNA synthesis. In addition to its use in actinic keratosis, it has been used successfully in the treatment of flat, mosaic, and genital warts. Its effectiveness may be heightened by an occlusive dressing or in combination with salicylic acid.

Formaldehyde

Formaldehyde acts similarly to glutaraldehyde. It is useful in the treatment of mosaic plantar warts, which are especially resistant to therapy. A 3% solution is used to soak the infected area for 15 to 20 min daily. The solution can be reused.

Glutaraldehyde

Glutaraldehyde is viricidal. It hardens the wart surface, thereby facilitating paring. It stains skin brown, making it less cosmetically appealing. The benefit to using this agent is that it reduces viral shedding from the wart surface, thus reducing the infectious risk.

Imiquimod

Imiquimod belongs to a class of imidazoquinolinamines that has antitumor and antiviral activity. The mechanism of action is uncertain. It exerts no direct antiviral effect within the mammalian cell in vitro, but does activate the immune system via cytokine induction. [47] Imiquimod is available in a 5% cream (see also Chap. 250).

Mono-, Di-, Trichloroacetic Acids

Eighty percent monochloroacetic acid penetrates the skin and may produce necrosis of the epidermis by blister formation. Saturated dichloroacetic acid or trichloroacetic acid in concentrations of 50% to 80% are less powerful but still effective in the management of warts. [48] Occlusive dressings enhance effectiveness. The application needs to be repeated at 1- to 2-week intervals until complete resolution.

Podophyllin Resin

Podophyllin is an extract from the dried roots of either *Podophyllum peltatum* or *P. emodi*. It acts as an antimitotic agent by preventing the formation of mitotic spindles. It is available in a range of concentrations in various vehicles, such as tincture of benzoin, alcohol, or flexible collodion, and is used as a treatment for genital warts.

Podofilox

Podofilox is the active ingredient obtained upon purification of the podophyllin resin. It does not contain any of the ingredients responsible for the toxicity of podophyllin.

Salicylic Acid

The use of salicylic acid in treating warts lies in the destruction of the epidermis in which the virus is present. Salicylic acid is more irritating than some other over-the-counter preparations.

Consulting with patients and the public about cosmetics is part of the dermatologist's role as the skin care expert. The increasing application of biophysical measurement techniques to study skin allows more accurate assessment of the safety and efficacy of cosmetics. Notwithstanding this advance, published evidenced-based clinical data on which dermatologists can support this advice are limited, and advertising and press reports create unrealistic public expectations. Information technology allows international experts to communicate easily about the dermatotoxicology of cosmetics, and manufacturers frequently sell products internationally; this situation enables global market forces and regulations to determine the nature of available products.

EFFICACY AND SAFETY OF COSMETICS

In response to scientific, economic, and social influences, the definition of cosmetics varies. In the United States, the 1938 Food, Drug, and Cosmetic Act defines cosmetics as "articles intended to be rubbed, poured, sprinkled, or sprayed on, introduced into, or otherwise applied to the human body or any part thereof for cleansing, beautifying, promoting attractiveness, or altering the appearance." Drugs in part are defined as "articles…intended to affect the structure or any function of the body." [1] These definitions are not mutually exclusive, and products such as antiperspirants and whitening agents are regulated both as over-the-counter drugs and as cosmetics. Hutt details not only the law and regulations but also their ambiguities. In Japan, these ambiguities are managed by the classification of "quasi-drug."

In the United States, drugs must meet strict premarket safety and efficacy requirements. Regulatory penalties make cosmetic scientists reluctant to explore the physiologic effects of topical compounds or the nature of their placebo effects. To deal with these contradictory forces, Kligman [2] proposed a separate category—cosmeceuticals—for products that have cosmetic purposes but also affect skin structure and function. This term could describe topical minoxidil used to treat physiologic balding, some topical retinoids that might reverse signs of aging, and some moisturizers applied to treat xerosis. In the last two decades, dermatologic studies have established that the stratum corneum—the "playground" for cosmetics—has a modifiable metabolic activity that influences the structure and function of viable epidermis, [3] making the 1938 definition of a cosmetic outdated and irrational. The advancing field of cutaneous biometrics [4] can bring efficacy claims from fanciful to provable, and consumers' desire for readily available cosmeceuticals will ensure their development.

Physical attractiveness is deemed socially advantageous and results in perceptions of "goodness" and success as well as a sense of well-being. [5] Improvement in attractiveness and consequent psychological benefit promoted by effective cosmetic use extend to the elderly and should be recognized by physicians.

An important consideration in cosmetic innovation and toxicology is the growing concern about animal testing. Some manufacturers have voluntarily abandoned testing final products on animals. The European Union's Sixth Amendment to the Cosmetic Directive proposal that animal testing of ingredients cease was activated on June 30, 2002. [6] Complete, timely compliance with this ban is unfeasible because development validation of alternative testing methods has been

slow and problematic.

In the United States, manufacturers' reporting of adverse cosmetic reactions to the Food and Drug Administration (FDA) is a voluntary program. The Cosmetic, Toiletries, and Fragrance Association (CTFA), the manufacturers' trade organization, sponsors the Cosmetic Ingredient Review (CIR) to review the safety of cosmetic ingredients and publishes its final reports in the *International Journal of Toxicology*. In the United States, ingredient labeling has been mandated for retail cosmetics since 1978. Ingredients are listed in descending order of amount, using nomenclature published in the *International Cosmetic Ingredient Dictionary*. [7] Fragrances (complex mixtures) are described simply as fragrance. Voluntary compliance with these regulations for cosmetics used or sold in beauty spas and salons was adopted in 1989. Beginning in 1998, European cosmetics were also required to have ingredient labeling. Listing of two dozen fragrance allergens may shortly be mandated on European labels. In cooperation with the American Contact Dermatitis Society, the CTFA publishes *Cosmetic Industry On Call,* a list of industry scientists who will aid dermatologists in evaluating patients who may have reactions to cosmetics. [8] Irritant, urticarial, allergic, or photosensitive eruptions, as well as pigmentary, hair, and nail disorders, or systemic reactions, can result from cosmetic use. To diagnose affected patients, dermatologists must appreciate the diversity of these reactions.

ADVERSE REACTIONS TO COSMETICS (See also Chap. 120)

Irritation Syndrome

Previously considered monomorphous, the irritation syndrome (Table 252-1) is a heterogeneous process. It often has an eczematous appearance, notwithstanding disparate mechanisms. Several clinical and biologic entities have been described, and others await clinical or basic science definition.

Objective Irritation	Subjective Irritation
Acute or corrosive reaction	Sensory irritation
Irritant dermatitis	
Irritant reaction	
Cumulative irritation	
Mechanical irritation	
Acneiform and pustular eruption	
Phototoxic reaction (photoirritation)	

TABLE 252-1 **Irritation Syndrome Related to Use of Cosmetics**

OBJECTIVE IRRITATION Skin irritation is defined as localized inflammation that is not mediated through the immune system and is caused by endogenous and environmental factors. Hair straighteners, permanents, and depilatories can cause *acute reactions* if directions for their safe use are not strictly followed. Cleansers are frequently responsible for causing *irritant dermatitis*. Moisturizers or emollient creams, in which water and oleacous materials are blended, contain surfactants and emulsifiers that are often mild irritants. When these cosmetics are applied to the face or to dry or eczematous skin, where the stratum corneum is a less-efficient barrier, *irritant reactions* may result. Morphologic features include scaling, which may rapidly clear with avoidance of exposure but becomes erythematous with recurrent dosing and may evolve into chronic irritant dermatitis. Some cosmetics produce irritation only after repeated application; this phenomenon is termed *cumulative irritation*. Friction, injury, and *mechanical irritation* can be caused by popular cosmetics containing granules or by devices (e.g., synthetic sponges) used to exfoliate the skin. Sensitive bioengineering techniques used to evaluate the pathophysiology of irritation include transepidermal water loss, skin impedance, conductance resistance, and blood flow velocity. [9] By using predictive testing in animals and humans, manufacturers can recognize strong or moderate irritant ingredients or products. In premarket testing, mild irritants are more difficult to detect and quantify. Some skin and hair care cosmetics cause acneiform eruptions. *Acnegenicity* encompasses both comedogenicity, which refers to follicular keratin impaction [10] and papulopustular formation. [11] The time course for the appearance of facial papulopustules and comedones is different: papulopustules may appear in just a few days, whereas the appearance of comedones is delayed. Considerable confusion derives from the testing techniques: for example, isopropyl myristate in concentrations as low as 10% in petrolatum rapidly induces comedones in the rabbit ear but yields papulopustules in humans. Even common emulsifiers such as sodium lauryl sulfate produce pustules in a dose-related manner. The mechanisms appear to be related in spite of varied morphology. The European Community's proposed ban on animal testing of final products will result in stronger reliance on human testing, whether this takes the form of use tests or application of a cosmetic under occlusion to the back for 4 weeks and subsequent cyanoacrylate or cationic polymer biopsies (to identify microcomedones), or both. [11] The clinical significance of cosmetics in precipitating postadolescent acne in women was recently called into question by one of the authors of the original paper on “acne cosmetica.” [10], [12] To avoid total confusion in light of this development, it seems prudent to advise female acne patients to keep their cosmetic regimen of care simple and gentle, using products from manufacturers who test for acnegenicity. Bergamot oil (5-methoxypsoralen) is a *phototoxic* fragrance ingredient that was used in cosmetics but has been removed. As interest in “natural” ingredients increases, [13] new phototoxins may be inadvertently introduced and have serious consequences when they are not recognized clinically.

SUBJECTIVE IRRITATION Burning, stinging, or itching caused by application of a cosmetic or topical medicament without detectable visible or microscopic change is termed *sensory irritation*. The afferent limb of this reaction is carried by C nerve fibers that are present throughout the dermis and viable epidermis. The stinging occurs on the face within an hour of application in susceptible individuals. In a segment of the population, this sensory response is caused by many ingredients at dosages that do not produce clinical objective irritation. Examples of such ingredients are propylene glycol, benzoic acid, hydroxy acids, and ethanol. To identify susceptible persons (“stingers”), Frosch and Kligman [14] applied 5% lactic acid to the nasolabial fold when the subject was sweating profusely; about 20 percent of the population experiences an unpleasant sensation under these circumstances. “Stingers” do not have a higher incidence of atopy or dry skin, but do report frequent adverse reactions to cosmetics. Strontium nitrate and chloride inhibit sensory irritation caused by a-hydroxy acids, ascorbic acid, and aluminum salts. [15] These blockers are being incorporated into skin care products such as those containing a-hydroxy acids.

Contact Urticaria Syndrome

Contact urticaria syndrome typically consists of a wheal-and-flare response developing within 30 to 60 min after the skin is exposed to certain agents. Symptoms range from the mildest manifestations (e.g., itching, tingling, burning, and erythema) to the most severe (e.g., anaphylaxis and death). Diagnosis of immediate contact urticaria is based on a thorough medical history (including notation of burn, sting, or itch resulting from skin contact; urticaria; or respiratory symptoms) and skin testing using suspected substances as summarized by Amin and Maibach. [16]

Contact urticaria syndrome is divided into two subtypes—nonimmunologic and immunologic—based on proposed pathophysiologic mechanisms. [16] Nonimmunologic contact urticaria, the most common form, occurs in the absence of previous exposure and remains localized, causing no systemic symptoms. Typically, the strength of the reaction varies by ingredient concentration and location of use. The mechanism is not completely delineated. Benzoic acid, cinnamic acid, and cinnamal are commonly used in cosmetics and are potent substances capable of eliciting this response.

Immunologic contact urticaria is an immediate type I allergic reaction that occurs in sensitized individuals and is induced more frequently in atopic individuals. The eliciting chemicals react with specific IgE molecules on mast cell membranes. Localized urticaria can extend beyond the site of contact, or may be accompanied by other symptoms such as rhinitis, conjunctivitis, asthma, and anaphylaxis. In this manner, methylparaben, ethylparaben, henna, and ammonium persulfate have been associated with systemic reactions. [16], [17]

Delayed Hypersensitivity Reactions

Adverse reactions to cosmetics constitute a small but significant portion of contact dermatitis cases treated by dermatologists. In a study conducted by the North American Contact Dermatitis Group (NACDG), patch testing showed contact dermatitis related to cosmetics in 5 percent of more than 13,000 patients evaluated; [18] similar percentages have been reported from Europe. [19] These figures underestimate the total number of cases, because most mild reactions are not investigated by dermatologists. In the NACDG study, 59 percent of the cosmetic-induced reactions occurred on the face and 79 percent were seen in women, but a relation to cosmetics was suspected by the dermatologist or patient initially in fewer than half the cases. Diagnosis of allergic contact dermatitis is based on a compatible history and examination supported by results of patch testing. Most cosmetics are not strong irritants and can be patch tested closed in the usual manner; however, notable exceptions exist (Table 252-2). Weakly positive reactions should be confirmed by medical history, test repetition, and patch testing of ingredients. Ingredient testing is a problem in the United States because of the limited number of chemicals available on the T.R.U.E. (thin-layer rapid use epicutaneous) test screening tray. It is important to recognize which of these allergens are found in cosmetics (Table 252-3). Cosmetic Industry on Call [8] provides information for contacting manufacturers who may provide ingredients for patch testing. De Groot et al. [19] provide reference information on chemical concentrations and vehicles to use in testing cosmetic ingredients.

*Patch for mercury sensitivity.

TABLE 252-3 **Ingredients Found in Cosmetics Included on T.R.U.E.* Test**

The provocative use test (PUT), also called the repeat open application test (ROAT), [20] is a practical way to screen for allergy to cosmetics including fragrances [21] or to confirm the clinical significance of weak positive reactions. The cosmetic is applied twice daily for up to 4 weeks to an approximately 5-cm area on the flexor surface of the forearm near the cubital fossa.

Most photoallergic ingredients in cosmetics are sunscreening agents or fragrances. To test for photoallergy, the patch site is exposed to between 5 and 10 J of ultraviolet A (UVA) 24 h after application; after 48 h, the photopatch site is compared with a nonirradiated site similarly patch tested.

Most allergic reactions to cosmetics are caused by fragrances, preservatives, and a small number of miscellaneous ingredients. [18], [19] Familiarity with these allergens will enable clinicians to diagnose many of these cases accurately.

FRAGRANCES

Fragrance allergy is common, affecting approximately 1 percent of the general population; dermatitis may develop on the

face, neck, hands, and axillae, or it may be generalized. [22]

Fragrances are ubiquitous: in addition to cosmetics and toiletries, they are added to household goods or cleansers in the workplace, and some are used as flavorings. Paradoxically, “unscented” cosmetics may contain a masking fragrance. A new method of promoting fragrances is to claim that scents have mood-altering effects—so-called aromatherapy. Inevitably, troublesome sensitization has occurred in consumers who have doused themselves and their surroundings with fragrance. Since 1966, toxicologic information related to fragrance ingredients has been assembled and assessed by the industry-sponsored Research Institute for Fragrance Materials (RIFM). [22], [23] Based on this information, the International Fragrance Association (IFRA) publishes guidelines that industry members generally agree to follow.

Photosensitization occurred more commonly before methyl coumarin and musk ambrette were eliminated from fragrances. Sensitization to musk ambrette left an extensive legacy of so-called persistent light eruptions. Because fragrance allergy is frequently not suspected by either the patient or the physician, patch testing is an important tool for reaching this diagnosis. Balsam of Peru, cinnamal, fragrance mix, and colophony are recognized markers for fragrance allergy on patch-test screening series. At present, the fragrance mix (marketed by Hermal and by Chemotechnique and also marketed in the T.R.U.E. test) contains eight ingredients: eugenol, isoeugenol, oak moss absolute, geraniol, cinnamal, a-amyl cinnamic aldehyde, hydroxycitronellal, and cinnamic alcohol. In an international study of 165 patients with probable fragrance allergy, the fragrance mix detected 86 percent of positive reactions. [24] Addition of ylang-ylang oil, narcissus oil, sandalwood oil, and balsam of Peru raised this percentage to 96 percent. Racial and geographic distinctions exist; for instance, Japanese patients tested were more frequently reactive to benzyl salicylate. Such racial differences were highlighted by the epidemic of bizarre facial hyperpigmentation seen in Japanese women in the 1960s and 1970s caused by allergy to fragrances and coal-tar dyes used in some cosmetics; elimination of these allergens solved the problem. [25]

Allergy to fragrance can be tested by using ROAT for up to 4 weeks. [21] Balsams, cinnamic alcohol, cinnamaldehyde, benzyl alcohol, and benzaldehyde are among the fragrance ingredients that can evoke contact urticaria not detected by closed patch testing. [17]

PRESERVATIVES

Preservatives are added to prevent contamination of cosmetics by microorganisms, which degrade the product or cause infection in consumers; but the term *preservative* may encompass agents that prevent degradation induced by oxidation or ultraviolet light. Approximately 60 chemicals are commonly used as preservatives in cosmetics. Preservatives may consist of a single ingredient or a mixture of ingredients (e.g., Euxyl 400 is a mixture of methyldibromoglutaronitrile and phenoxyethanol). Use of specific preservatives varies among American, European, and Asian markets; consequently, the incidence of allergic reactions to individual agents also varies. Adverse reactions have prompted development of preservative-free cosmetics. Strategies for developing such products include modification of the manufacturing and packaging processes as well as use of botanicals, which have antimicrobial activity. The increasing complexity of cosmetics and their vehicles makes this goal even more difficult to achieve.

Paraben esters, the most popular group of preservatives, are effective against fungi and gram-positive (but not gram-negative) bacteria. Parabens rarely sensitize but may do so when applied to eczematous skin. Sensitized patients frequently tolerate parabens in cosmetics applied to normal skin.

Propylene glycol, a popular solvent and humectant, has antimicrobial properties but is used in some “preservative-free” cosmetics. Review of the literature and observations in patch tested patients suggest that propylene glycol is a mild irritant that only occasionally sensitizes. [26]

Formaldehyde and formaldehyde releasers are widely used. [27] Formaldehyde is formulated in wash-off products such as shampoos. Quarternium-15, imidazolidinyl urea, diazolidinyl urea, DMDM hydantoin, and 3-bromo-2-nitropropane-1-3-diol are commonly used preservatives that release formaldehyde. They may sensitize themselves or cause reactions secondary to formaldehyde release in formaldehyde sensitive patients, and cross-reactions in the group are reported. Patients' tolerance of products containing preservatives to which they are sensitive is modified by the site of application and their degree of sensitivity. For example, some formaldehyde sensitive individuals can tolerate low levels of formaldehyde releasers on normal skin.

When introduced into Europe as a preservative, methylchloroisothiazolinone/methylisothiazolinone was used extensively in concentrations, that frequently caused sensitization. [19] Benefiting from the European experience and in an effort to diminish the problem, CIR set guidelines restricting concentration to =15 ppm in wash-off products and to =7.5 ppm in leave-on products.

A mixture of methyldibromoglutaronitrile and phenoxyethanol (Euxoyl 400) used initially in Europe has gained popularity and is being reported more frequently as an allergen. [28] Butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), tocopherol, propyl gallate, and t-butyl hydroquinone used as antioxidants are sometimes reported as allergens. Other ingredients reported frequently as allergens in cosmetics include paraphenylenediamine, toluene sulfonamide/formaldehyde resin (tolysamide/formaldehyde resin), acrylates, lanolin, glyceryl thioglycolate, and UV light-absorbing agents. These will be discussed below in reviewing cosmetic categories.

Cosmetic Intolerance Syndrome and “Sensitive Skin”

Cosmetic intolerance syndrome is not a single entity but rather a symptom complex of multiple exogenous and endogenous factors (Table 252-4). The syndrome is an uncommon clinical entity in which patients complain bitterly of facial burning and discomfort associated with application of most skin care products. Their skin may show overt inflammatory changes, or symptoms may be only subjective. These patients seriously challenge practitioners' empathy

and diagnostic skills because the severity of symptoms does not match objective signs of disease. Many patients affected with this syndrome have tried numerous cosmetics and topical medications. Gradually, over the past two decades, most of these individuals have been recognized to have an organic rather than a functional basis for their complaints.

Exogenous Causes	Endogenous Causes
Subjective irritation	Seborrhea/psoriasis
Objective irritation	Rosacea and perioral dermatitis
Contact urticaria	Atopic dermatitis
Allergic contact dermatitis	Dysmorphobia
Photoallergic contact dermatitis	

Source: Adapted and reproduced by permission of the publisher from Malbach and Engasser[29]

TABLE 252-4 **Types and Causes of Facial Skin Intolerance to Cosmetics**

Fisher [29] coined the term *status cosmeticus* for the condition in which patients no longer tolerate use of any facial cosmetic product. Some of these patients initially experience subjective or objective irritation in response to use of cosmetics and become intolerant to many other topical agents during the evolution of this disorder. Other patients have occult allergic contact dermatitis, allergic photocontact dermatitis, contact urticarial reaction, or a combination of these conditions. In this group, causal agents can be documented by careful clinical review and patch testing. Other patients have a seborrheic-rosacea diathesis which flares and is accompanied by facial erythema and scaling when use of soap and water is abandoned and cleansing creams and emollients are overused. Atopic dermatitis and dry skin are other factors that predispose patients to this condition.

Strictly observing a prolonged program of eliminating cosmetics is an important therapeutic intervention (Table 252-5). Some patients are able to return gradually to using other cosmetics after 6 to 12 months. Subsequent additions to the skin care regimen can be made one at a time every 2 weeks. For the final regimen, the number of cosmetics and frequency of their use should remain limited.

Examine every cosmetic and skin care product
Administer patch and photo patch test to rule out occult allergic and photoallergic dermatitis
Test for contact urticaria
Do careful repeat open application testing (ROAT)
Treat endogenous inflammatory disease
Limit skin care to
Water washing without soap or detergent
Lip cosmetics as desired if lips are clear
Eye cosmetics as desired if eyelids are asymptomatic
Face powder
Glycerin and rose water as a moisturizer if necessary
Avoiding other cosmetics for 6 to 12 months

TABLE 252-5 **Diagnosis and Treatment of Patients Whose Skin Is Intolerant to Cosmetics**

Other patients experience facial burning continuously, without showing objective signs. Cotterill [30] described these patients as having “dermatologic nondisease.” Many of these patients have a disturbed body image or dysmorphobia—that is, they complain of physical defects that lack objective evidence. Many are depressed and need psychiatric help, which they frequently reject.

Sensitive skin covers the same range of pathophysiology as the cosmetic intolerance syndrome, but it is generally less severe. Sensitive skin is a lay term coined to describe the condition of consumers who believe their skin is less tolerant than that of the average person's to environmental conditions and topical preparations. This is a common perception. In a recent British survey, 51 percent of the women and 38 percent of the men believed that they have sensitive skin, and 19 percent of this population reported an adverse reaction to a cosmetic product in the last year. [31] The largest segment of these consumers manifests sensory skin irritation.

SKIN CARE COSMETICS

Cleansing Agents

Cleansing the skin removes environmental contaminants, sweat, sebum, desquamated cells, and microorganisms. Soap bars are manufactured by saponification of fat and alkali, and “syndet” bars contain synthetic detergents to emulsify lipids, which will then be rinsed off with water. Originally, wipe-off cleansing creams containing mineral oil and borax were commonly used as cleansing agents. Detergents are often used in rinse-off foaming lotions. Lipid-free cleansing lotions contain fatty alcohols and may be wiped or rinsed off. In the 1950s, liquid soaps were developed for cleansing workers' hands and were perceived as harsh; liquid cleansers and gels evolved in the 1970s and 1980s to become popular as gentle hand, face, or body washes using blends of surfactants (including nonionics), which are claimed to be less irritating. Fatty acids and polymers are added to enhance mildness. Antimicrobial agents such as chloroxylenol (PCMX) or triclosan are used in cleansers whose manufacturers make antibacterial claims.

Use of cleansers may cause irritation, to which subsets of the population (such as persons who are elderly or who have atopic eczema) are susceptible. The irritant potential of cleansers is gauged by soap-chamber tests or by use tests, which may be exaggerated. Visually or with instrumentation, these tests indicate barrier injury, inflammation, dryness, or skin roughness. Testing is refined to detect subclinical damage and define the depth of injury in the stratum corneum using squamometry. [32] Factors that influence irritancy are the structure and quantity of surfactant, mechanical trauma, water temperature, and duration and frequency of cleansing.

Because wash-off products contact the skin briefly, they infrequently cause allergic contact dermatitis; however, some surfactants (cocamidopropyl betaine), preservatives (methylchloroisothiazolinone/methylisothiazolinone), antimicrobials (PCMX), and fragrances have been reported as allergens in these products. Cocamidopropyl betaine is the most

commonly used amphoteric surfactant in cosmetics, and some of the allergic reactions are caused by impurities. Purification of this surfactant may lead to reduced incidence of sensitization. [33]

Shaving Products

Foaming shaving creams or gels are designed to wet and soften the beard hair in order to reduce the friction caused by a metal blade cutting the hair. Lubricants are added to these fatty acid soaps to decrease frictional forces as the blade traverses the skin. Preshave cosmetics for use with electric razors are fragranced alcohol products that dry the skin and reduce friction. Aftershaves are fragranced cosmetics applied to freshly shaven skin with a compromised barrier, which partially accounts for the frequency of allergic and photoallergic reactions reported in the past when photosensitizers such as musk ambrette were present. [22]

Hair Removers

Superfluous hair may be disguised by bleaching or removed by shaving, waxing, plucking, chemical dissolution, or electrolysis. Laser hair removal is becoming an increasingly popular alternative. For some patients who have curly beard hair and who are susceptible to pseudofolliculitis barbae, use of barium sulfide depilatories is a helpful but malodorous and irritating alternative to shaving.

Most modern depilatories contain substituted thiols. Calcium thioglycolates are the least irritating. They act more slowly than sulfides but are safer. Thioglycolates attack keratin and may injure the epidermis; manufacturers' directions should be followed closely.

Eflornithine hydrochloride cream has been approved by the FDA for the reduction of unwanted facial hair in women by inhibiting the enzyme ornithine decarboxylase. This drug may be used to complement facial hair removal, and its effect is reversed when the drug is discontinued.

Deodorants/Antiperspirants

These popular cosmetics are designed for use in the axillae, whose apocrine sweat glands produce organic chemicals metabolized by bacteria to produce an odor generally considered undesirable. [34] Eccrine sweat distributes these chemicals more broadly. Deodorants contain antimicrobial agents (e.g., triclosan) as well as fragrance to mask odor. Antiperspirants use aluminum salts, which theoretically cause temporary plugging of the eccrine sweat glands to reduce their output and decrease the bacterial population. Aluminum salts may cause irritant reactions, but the allergic reactions associated with these products are caused by fragrance or other ingredients.

Moisturizers

Most dermatologists are conversant with the promotional faces of moisturization, as detailed by dermatologic, cosmetic, and occupational specialty firms. The word is beguilingly simple; the mechanism of action and biology are highly complex and incompletely understood.

It is probable that branded moisturizers appreciated by the consumer vary depending on the anatomic site intended for use. Materials for the face may be highly regarded when they produce a slight swelling and improve cosmetic feel and appearance. Hand care presents a different situation; the consumer does not need or desire swelling and instead, appreciates the healing effects of certain lipid-rich moisturizers that are formulated to avoid greasiness that interferes with the consumer's tasks. Legs present another clinical situation—the consumer/patient desiring a diminution in itch and scaling is more tolerant of increasing lipid content, and in some moisturizers, keratolytics are incorporated successfully.

The chemistry—in spite of a century of extensive development by various industries involved—remains incompletely understood, in terms of both formulation and mechanism of action. Lipids provide the underpinnings of most moisturizing products. These (see below) depend highly at one extreme on the greasiness of petrolatum and on the other extreme, the more esthetic qualities of the lanolins. Glycerin, highly popular in the nineteenth century, has regained its prominence in recent years in consumer acceptance studies and the marketplace. Other formulating materials include urea (shown to be effective in controlled consumer studies but far less so in the marketplace) and a mixture named *natural moisturizing factor.* In most formulations, water constitutes the major component.

Moisturizers improve the appearance and tactile properties of dry and aging skin by acting on the stratum corneum to diminish scaling and to enhance suppleness, presumably by increasing its water content. [35] Traditionally, moisturizers inhibit transepidermal water loss by occlusion. The “bricks and mortar” model illuminates the stratum corneum's role as an active membrane [36] (see Chap. 9). Loss of intercellular lipids (i.e., ceramides, cholesterol, and fatty acids that form bilayers) damages the water-barrier function and calls into play repair mechanisms signaled into action by the stratum corneum. In this way, treating dry skin has consequences in the viable epidermis.

Usually containing mixtures of water and fatty substances such as petrolatum, lanolin, lanolin derivatives, and fatty alcohols, moisturizers decrease scale and transiently increase water content in the stratum corneum. Several putative mechanisms are popular: (1) occlusion, that is, allowing water to percolate up from the viable epidermis; (2) replacement or assisted synthesis of lipid mixtures in the intercellular spaces; [3], [37] and (3) use of humectants, which bind water in the stratum corneum. Success of these maneuvers is determined in the laboratory by measuring transepidermal water loss, impedance, and conductance, [38] as well as by epidermal capacitance and regression testing. But discerning consumers judge by the feel and appearance of their skin, which introduces the criterion of esthetics. In recent years, several experiments confirm conventional wisdom—moisturizers decrease irritant dermatitis, [39], [40] and their efficacy is related to

their lipid mass. [41] It is likely that moisturizers are equal or more important than glucocorticoids in this regard.

What is not clear is the prophylactic value of moisturizers in preventing irritant dermatitis. Several studies on acute exposure in highly controlled environments demonstrate their value; however, in the one chronic administration study, [42] this benefit was not only not confirmed, but showed an exacerbation of surfactant-induced irritant dermatitis. The clinical experience and literature on barrier creams is beyond the province of this brief chapter. Zhai summarizes much of this information. [43]

Petrolatum, a semisolid mixture of hydrocarbons obtained from dewaxed heavy mineral oils, is a uniquely effective moisturizer as a result of mechanisms not fully understood. Petrolatum delays water evaporation from the stratum corneum. In contrast to a vapor-impermeable membrane (e.g., latex), petrolatum does not impede barrier lipid repair in acetone-stripped stratum corneum and enhances immediate repair. [3], [44] Petrolatum is not a primary or cumulative irritant and can protect against irritant effects of detergents. Kligman [12] has questioned the acnegenicity and comedogenicity of petrolatum, and high-quality, cosmetic-grade petrolatum appears to be safe in this regard. Unfortunately, large amounts impart a tacky feel, which consumers do not like.

Lanolin and its derivatives are more esthetically acceptable and are good emulsifiers. Lanolin is a mixture of esters and polyesters of high-molecular-weight alcohols and fatty acids. Analysis of tape strippings shows that lanolin penetrates the entire stratum corneum and appears to emulsify intercellular water. [45] Although lanolin has been reported to be an allergen in 2 to 5 percent of patients who received patch tests, [46], [47] it infrequently causes reactions on normal skin but can sensitize when applied to eczematous skin, especially in stasis dermatitis. Cronin [47] reported 26 cases of lanolin-cosmetic facial dermatitis in women, for half of whom the eyelids were affected to a striking degree. Wool alcohols (30% in petrolatum) and Amerchol L-101 (50% in petrolatum) are used in patch tests to screen for allergy.

Three types of lipid—cholesterol, free fatty acids, and ceramides—are required for maintaining the epidermal permeability barrier. All three lipids in proper molar proportions are alleged to be necessary. These data are being used to formulate moisturizers. [37]

Glycerin and propylene glycol function as humectants. Studies of moisturizers containing glycerin showed formation of a glycerin reservoir in the stratum corneum, suggesting a role in barrier repair and in preventing transition of stratum corneum lipids to a solid crystalline state. [48]

The hygroscopic properties of urea allow it to bind water quickly in the stratum corneum, especially at high humidity. [38] Incorporating urea in hydrophilic ointment enhances the water binding capacity for at least several hours, but this function is lost at lowered humidity.

Smoothing rough skin and minimizing signs of aging fit the consumer's broad definition of moisturizing. Consequently, keratolytic agents (i.e., hydroxy acids and salicylic acid) are extremely popular ingredients in skin care products (see also Chap. 248). In 1974, a-hydroxy acids were proposed for treatment of keratinizing disorders, [49] and lactic acid was noted to improve dry skin; however, no major launch of a cosmetic containing a-hydroxy acid occurred until 1992. Hydroxy acids at low concentrations diminish corneocyte adhesion at the lower level of the stratum corneum, stimulate epidermal cell proliferation, and increase the thickness of viable epidermis. The thinner stratum corneum they create is more flexible. The a-hydroxy acids can stimulate glycosaminoglycan and perhaps collagen synthesis. Consumers perceive improved skin texture, brightness, and firmness, as well as less wrinkling and pigmentation. [50] Like the drug tretinoin, hydroxy acids modify some of the adverse effects of sun exposure, photoaging. Topical retinoids, which two decades ago revolutionized dermatologic therapy of photoaging, are discussed in Chap. 244. If formulated properly, a-hydroxy acids may be useful for treating acne, and salicylic acid, which is lipid soluble, has been used for decades for this purpose.

Improved formulations reduced the irritation and unpleasant odor of skin care products. In general, lower pH and higher concentration increases penetration of these ingredients. The CIR concluded that glycolic acid, lactic acid, and their common salts and esters are safe for use in cosmetics at concentrations =10 percent when the product is at pH =3.5 and formulated to avoid increasing sun sensitivity or when directions for use specify daily use of sun protection. [51] The FDA has proposed further toxicologic study.

Reactive oxygen species (e.g., free radicals) arise from UV light and from other insults that damage cells. Theoretically these chemical species are partly responsible for aging. Antioxidants such as vitamins A, C, and E and their derivatives are added to cosmetics in an attempt to block this injury, and mixtures of antioxidants may have a synergistic benefit improving efficacy. [52] To prove that this can be accomplished by using any of these agents as currently administered, the complex chemistry of these oxidative processes must be further studied.

Sun-screening agents are added to many cosmetics to prevent photodamage to skin. In the United States, sunscreens are regulated as over-the-counter drugs when a sun protection factor (SPF) is tested. The list of permitted ingredients, methods of efficacy testing, and labeling standards are published as regulations in the Federal Register. [53]

Many so-called antiaging and photoprotective products have vehicles that are, in fact, identical to moisturizers. Many of the studies provided to dermatologists only show a before and after difference, rather than demonstrating a difference between an active and a placebo. It is unclear how much of the value comes from the active agent and how much comes from the moisturizer-like composition.

Self-Tanning Agents

“Sunless” or “self-tanning” lotions containing dihydroxyacetone are regulated as cosmetics, although they do provide some protection from longwave UVA light. [54] Dihydroxyacetone binds to the skin's surface keratin, producing a brown

stain that fades only as corneocytes desquamate. These products have become popular because they can give the illusion of a tan. Allergic contact dermatitis may occur rarely from dihydroxyacetone or other ingredients in the formulation. A system called Turbo-PUVA, which uses dihydroxyacetone to photoprotect noninvolved psoriatic skin during PUVA therapy, allows higher UVA exposure and faster clearing. [54]

Whitening Agents

There is wide consumer interest in agents that lighten skin tone and improve irregular pigmentation. In vivo and in vitro investigation of potential whitening agents have been conducted, and some are available in the nonprescription market. [55] Hydroquinone inhibits the tyrosinase conversion of tyrosine to melanin. Nonprescription bleaching creams containing up to 2.0% hydroquinone are modestly effective in treating postinflammatory hyperpigmentation, lentigines, and melasma. In 2002, the FDA approved for the first time a skin whitening prescription agent. It contains fluocinolone acetonide 0.01%, hydroquinone 4%, and tretinoin 0.05%. Successful treatment of melasma requires strict protection from UV light. Adverse effects associated with the use of hydroquinone include irritant and allergic reactions, hypopigmentation, hyperpigmentation, exogenous ochronosis, and staining of nails.

Hydroxyacids have been used to enhance hydroquinone, and there is evidence in a double-blind study that 5.0% lactic acid or greater acts as a whitening agent alone. [56] Kojic acid, a fungal metabolic product, suppresses tyrosinase by chelating copper. First marketed in Japan at a 1% concentration in nonprescription preparations in 1988, it remains popular there and is now used in United States. [55] Stable derivatives of vitamin C, vitamin E, and linoleic acid are being studied for their effectiveness in suppressing pigment production. Also, “natural” agents have been sought. Arbutin, extracted from pear tree leaves, is a source of hydroquinone, and glycyrrhizinate from licorice root can lighten pigment in clinical studies. [56] These cosmetic ingredients, as well as the prescription combination products, offer the consumer a wider choice for treating pigment disorders.

Makeup

Makeup has been used since ancient times to normalize, glamorize, and accentuate features, or to create a stylized appearance. Camouflage techniques using specially designed opaque cosmetics have been developed by skilled makeup artists and can be taught to patients with disfiguring disorders, greatly benefiting these patients' psychological well-being. [34], [57]

Sales of ethnic cosmetics burgeoned in the 1990s, and jet-milled and coated pigments enabled the development of darker makeup shades, which require more pigment. An important trend in mass-market color cosmetics is the use of silicone technology to produce long-lasting formulations for lipsticks, foundations, and related products. To be permitted in makeup, colors must be government-certified for use; they seldom cause adverse reactions. The United States has certified 34 colors, but only 13 of these are certified in all three major markets (Japan, Europe, and the United States). Most makeup can be tested for contact allergy in the standard manner by using a closed patch test. Waterproof mascara is an important exception: it contains volatile solvents and must be dried thoroughly to avoid severe irritant reactions. Upper-eyelid dermatitis syndrome is related to multiple endogenous and exogenous causes. Irritant and allergic contact dermatitis caused by cosmetics accounts for a small percentage of these cases. Mercury preservatives are permitted only in cosmetics designed for use in the eye area owing to the danger of *Pseudomonas* infection. Eye infections are rarely traced to use of eye cosmetics that have not been adequately preserved.

HAIR CARE COSMETICS

Shampoos and Conditioners

Shampoos are cleansing agents designed to remove sebum, scale, microorganisms, and environmental debris. Thorough cleansing can leave hair dry, statically charged, and without luster. Modern shampoos contain single or combined anionic, amphoteric, cationic, or nonionic surfactants that vary in their ability to clean as well as to leave hair manageable. Products designed for use on dry, normal, or oily hair inform consumers regarding cleansing intensity, which is determined by type and concentration of surfactants. Baby shampoos contain amphoteric surfactants that do not sting the eyes and which cleanse moderately well.

Conditioning agents are used in hair care products for many purposes—to enhance combability of wet and dry hair, to neutralize static charges, and to promote the appearance, feel, fullness, luster, and general manageability of hair. Long hair, hair that is frequently shampooed, chemically exposed and treated hair, and dry hair require conditioners to aid grooming, prevent damage, and enhance appearance. Quaternium compounds, hydrolyzed proteins, cationic surfactants, polymers, lipids, glycols, and silicones are the most commonly used conditioners. Some recently marketed shampoos simultaneously cleanse and deposit conditioning agents on the hair shaft. [58] Conditioning can be modified to enhance volume of fine, straight hair without causing buildup. For hair damaged extensively by chemicals, application of conditioner separately after shampooing allows deposition of more material. Shampoos also contain thickeners, foam boosters, colors, and preservatives.

Shampoos and conditioners are only briefly in contact with the skin and infrequently cause adverse contact reactions. Allergic reactions have been reported to occur both in consumers and in beauticians using the “mild” amphoteric surfactant cocamidopropyl betaine. [33] Formaldehyde and a combination of methylchloroisothiazolone and methylisothiazolone also are preservatives that have caused allergic contact dermatitis. [19]

Hair Dyes

Hair coloring is increasingly popular worldwide; in the United States alone, an estimated 50 million consumers color their hair. These versatile cosmetics allow men and women to add highlights, change color, or disguise gray hair. In addition

to bleaches, hair dyes are classified as temporary, progressive, semipermanent, or permanent.

Temporary colors are deposited on the surface of the hair and are removed by shampooing. They make minor changes in shade or blend gray hair. Dyestuffs used can include basic dyes, indolamine, indophenols, and azo, azine, or thiazine derivatives, and are generally harmless. Progressive lead acetate dyes deposit lead oxides and sulfides, which build on the hair shaft when applied repeatedly. Used almost exclusively by men to conceal graying, these dyes preclude successful perming or use of other color systems. Use of metallic dyes is not considered to put consumers at risk for acute toxicity except when such dyes are accidentally ingested by children. [59] In 1980, the FDA approved these dyes after reviewing available data on human absorption of lead during simulated use. Concerns about lead in the environment remain.

Color from semipermanent dyes lasts through about a dozen shampoos. When used on unbleached hair, these dyes can add new tones to natural hair, cover as much as 50 percent of gray hair, and occasionally improve the appearance of permanently tinted hair. Semipermanent hair-coloring products use low-molecular-weight dyes that penetrate the hair cuticle. These dyes are mostly derivatives of nitroanilines, nitrophenylenediamines, and nitroaminophenols. Recently, some of these products were modified by blending in oxidative precursors and adding a low percentage of peroxide for a more lasting effect. These formulations are called tone on tone.

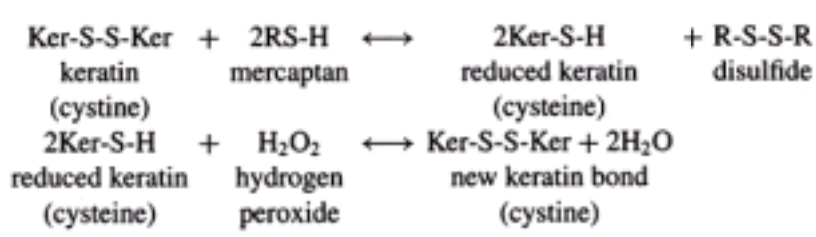
Permanent hair dyes contain colorless precursors that react with hydrogen peroxide inside the hair shaft to produce permanent hair colors. Primary intermediates such as *p*-phenylenediamine or *p*-aminophenol are oxidized by hydrogen peroxide and react with many different couplers (e.g., resorcin) to produce a range of shades. Owing to their esthetic appeal, coal-tar hair dyes are popular; however, they can cause allergic reactions (mostly to *p*-phenylenediamine) and satisfactory substitutes are often unavailable. Semipermanent dyes often do not induce a cross-reaction, but they do not cover gray nearly as successfully as permanent dyes. Adverse reactions to *p*-phenylenediamine include type IV acute and chronic dermatitis rarely leading to depigmentation, and rare type I urticaria and anaphylaxis.

Bleaches

Hair bleaches—hydrogen peroxide solutions that oxidize melanin to a lighter color—may be supplemented with persulfate boosters. Ammonium persulfate does cause types I and IV allergic contact reactions. [16], [17] The type I reaction has rarely progressed to systemic reaction in consumers, whereas type IV can result in hand dermatitis for frequent users such as hairdressers.

Permanents

Permanents allow reconfiguration of the hair fiber while it remains wound around a curling rod. In this process, mercaptans cleave the disulfide bonds in hair so that they can later be reformed in a new configuration when neutralized: [58]



Neutralizers contain hydrogen peroxide, potassium or sodium bromate, perbromates, percarbonates, or sodium borate perhydrate. Curled hair appears more voluminous, so women with fine, thin hair often use permanents to give the illusion of a fuller head of hair.

Ammonium thioglycolate applied improperly can cause extensive hair damage and acute irritant dermatitis; dithiodiglycollic acid is added to “self-timing” permanents to prevent over processing. [58] Glyceryl thioglycolate used in “acid” permanents initiates allergic contact dermatitis. [60] Sodium sulfite is used in some home permanent kits, and cystine waving solutions have become popular in Japan.

Ethnic Hair Products

Extremely curly hair may be straightened temporarily, mechanically by pressing, or permanently by using chemical relaxers. After the pressing oils are applied, heated metal combs or round tongs are used to straighten the hair. In the early 1900s, pressing oils consisted of heavy waxes in a petrolatum base; lanolin, phenyldimethicone, and dimethicone now allow production of lighter preparations that leave hair silkier and less greasy.

In the 1940s, sodium and potassium hydroxide-containing preparations were introduced as chemical straighteners that permanently changed the configuration of kinky hair, and a petrolatum “base” was applied to the scalp for protection. Gentler to the scalp are “no-lye” relaxers: lithium hydroxide and guanidine hydroxide (made by mixing calcium hydroxide and guanidine carbonate). Neutralizing acid shampoos are applied after the hair has been relaxed; these shampoos contain mixtures of anionic and amphoteric surfactants combined with cationic polymers for conditioning. Relaxing damages the hair; therefore, particular care must be taken when relaxing new growth not to overlap and double-process the hair, causing breakage. Alkaline thioglycolates formulated in viscous emulsions and neutralized with an oxidative step are used as straighteners also. [58] Grooming—combing, brushing, heat setting, coloring, bleaching, waving, and straightening—all damage the hair shaft to a varying degree. True repair or reversal of this damage is not feasible at present, which is why prevention by gentle care is important.

NAIL COSMETICS

Used judiciously, nail cosmetics can protect and enhance the esthetic appearance of nails. Professional manicures are complex procedures involving many products; most adverse reactions (aside from mechanical trauma) are caused by nail polish or by acrylates used for nail enhancement.

Nail Polish

Nail polishes, including base and top coats, are of a similar composition, containing the following types of ingredients: (1) a film former of nitrocellulose; (2) resins to improve adhesion and gloss; (3) plasticizers to increase flexibility; (4) solvents and diluents to modify viscosity; (5) colors; and (6) suspending agents to prevent pigments from settling. Most reported allergic reactions to nail enamel have been caused by tolysamide/formaldehyde resin [toluene sulfonamide/formaldehyde resin (TSFR)]. In a study of approximately 3500 patients patch-tested between 1996 and 1998, 1.5 percent of the positive reactions were caused by this resin and 68 percent of these reactions were clinically relevant. [61] Allergic contact dermatitis to nail polish can be misdiagnosed because it frequently affects the face, eyelids, sides of the neck, or mouth, and may spare the hands and fingers. In a study of TSFR-allergic patients referred to an occupational dermatology clinic, the allergen had not previously been detected; instead the cause was mistakenly attributed to work conditions. [62] The consequences of this mistake were dramatic: 11 of the 18 patients in the study erroneously took sick leave or modified or changed their jobs. Results of patch tests using 10% TSFR in petrolatum established the diagnosis, and closed patch tests of dry nail polish were positive in 17 of the 18 patients. [62] California legislation has prohibited the use of the solvent toluene, and cosmetic manufacturers in a legal settlement agreed to reformulate nail polish, in most cases eliminating toluene and TSFR. Salon-distributed products may still contain TSFR. [63] New formulations of nail enamels use other resins, so different allergens may emerge, for example, methyl acrylate and phthalic anhydride/trimellite/glycol copolymer. [64], [65] and [66]

Nail Elongation Materials

Manicurists enhance natural nails by gluing on preformed prostheses, wrapping and gluing nails with strips of fine cloth, molding acrylic extensions, or adding layers of photodeveloped plastic gels.

Prostheses may consist of plastic nails that cover the entire nail plate, but using cyanoacrylate glue to attach plastic tips to the distal portion of the nail has become popular because their application requires less skill than creating sculptured acrylic extensions. Allergy to instant cyanoacrylate glue can cause nail dystrophy and periungual dermatitis. Acrylics, gels, or wraps are used to smooth and strengthen this form.

Sculptured nails are molded (by using liquid acrylic monomers mixed with powdered polymers) onto templates that surround the nail; the sculptured nails are then filed to the desired shape. The liquid may contain a stabilizer such as hydroquinone, plasticizers, and solvents, and the powder contains an initiator (e.g., benzoyl peroxide). Before application, the nail plate is prepared by abrading it with a file and/or by painting it with methacrylic acid. As the nail grows out, the base must be filled with new applications of the resin. Infections, paresthesia, nail dystrophies, and allergic dermatitis surrounding the nail and at distant sites have all been reported as a consequence of this procedure. [67] Most patients who have inflammatory reactions to sculptured nails are never patch tested, and their reactions are not reported. The chemistry is complex, patterns of cross-reaction are common, and labeling of ingredients in salon products is voluntary and often inadequate. Patch-test data from patients sensitized by the use of acrylic nails suggests that five chemicals may be used as screening patch-test materials: ethyl acrylate, 2-hydroxy ethyl acrylate, ethylene glycol dimethacrylate, ethyl cyanoacrylate, and triethylene glycol diacrylate. In a series of 11 patients, 0.1% ethyl acrylate in petrolatum detected 91 percent of the patients sensitized to these nails. [68]

Ultraviolet light–cured acrylates, known as gels, are also popular for nail enhancement. In studying women sensitized to photobonded acrylic nails, 2-hydroxyethyl methacrylate and ethylene glycol dimethacrylate are useful screening materials for patch testing. [69] Professionals applying these gels had reactions to 15 of the 31 acrylates tested. [70] Complex occupational cases are best evaluated at centers prepared for extended patch testing.

The CIR published a final report on ethyl methacrylate, a frequent ingredient of sculptured nails, and declared it safe as used by professionals; however, it advised against retail sale of products containing ethyl methacrylate because they can sensitize when contacting the skin. [71] However, in a Finnish study, 6 of 23 acrylate-sensitive patients were sensitive to ethyl methacrylate, demonstrating its considerable sensitizing potential. [72]

Despite the adverse reactions seen by dermatologists, the popularity of these cosmetics is great: myriad of nail salons have opened in the United States during the past decade, supporting the $8-billion-per-year nail care industry.

OCCUPATIONAL HAZARDS

Occupational hand eczema frequently develops in hairdressers. Novice beauticians' hands become dry and chapped from shampooing many clients. A history of atopic hand eczema heightens the risk for irritant contact dermatitis. Educating hairdressers on safe practices and having them apply low irritancy moisturizing creams before and after work mitigates this condition. Hairdressers are constantly exposed to sensitizers such as hair dyes, ammonium persulfate, preservatives, surfactants, fragrances, and glyceryl thioglycolate. Glyceryl thioglycolate penetrates most protective gloves and remains on customers' hair despite shampooing, making avoidance difficult for the sensitized hairdresser. [60] Rubber gloves worn for protection may prove to be sensitizing. When chronic hand eczema interferes with a beautician's career, patch testing is mandatory to determine whether a relevant allergen is causing or aggravating the dermatitis. Many epidemiologic studies of hairdressers working with hair dyes have looked for a relation between exposure to health

hazards and carcinogenesis, but the findings have been equivocal or contradictory. [59], [73]

A recent epidemiologic study of 897 bladder cancer patients in Los Angeles County showed women who used permanent hair dyes monthly had a 2.1-fold risk as compared to nonusers. Subjects who worked as hairdressers for 10 years or more experienced a fivefold risk of bladder cancer. [74] Manicurists are at risk for developing contact allergy to acrylates but proper training in protection and “no touch” techniques enhanced their safety. [63], [66]

There is evidence that artificial fingernails worn by health care workers harbor pathogens and may pose a risk to their patients. [75] In response, a major HMO has banned their use by health care workers at all their medical centers in California.

CONCLUSION

Consumers consider cosmetics useful, industry introduces innovation to enhance their efficacy, and physicians should recognize their functional and psychological importance for patients. Safety considerations must also not be forgotten. We are alerted to this fact by a report of mercury poisonings in the United States resulting from use of a mercury-containing cosmetic manufactured in Mexico. [76] Except for small amounts permitted as eye cosmetic preservatives, mercury has long been banned from use in cosmetics sold in major markets. International trade and less-stringent laws in some countries can lead unsuspecting consumers to disaster. Skin is not an impermeable membrane, and substances applied for beautification must be monitored carefully.

REFERENCES

Glucocorticoids are a mainstay of dermatologic therapy because of their potent immunosuppressive and anti-inflammatory properties. In 1949, Hench and co-workers [1] described the beneficial effects of cortisone in patients with rheumatoid arthritis. By understanding the properties and mechanisms of action of glucocorticoids, one can maximize their efficacy and safety as therapeutic agents.

BIOLOGY

The major naturally occurring glucocorticoid is cortisol (hydrocortisone). It is synthesized from cholesterol by the adrenal cortex. Normally, less than 5 percent of circulating cortisol is unbound; this free cortisol is the active therapeutic molecule. The remainder is inactive because it is bound to cortisol-binding globulin (CBG, also called transcortin) (95 percent) or to albumin (5 percent). The daily secretion of cortisol ranges between 10 and 20 mg, with a diurnal peak around 8 A.M. [2] Cortisol has a plasma half-life of 90 min. It is metabolized primarily by the liver, although it exerts hormonal effects on virtually every tissue in the body. The metabolites are excreted by the kidney and the liver.

The mechanism of glucocorticoid action involves passive diffusion of the glucocorticoids through the cell membrane, followed by binding to soluble receptor proteins in the cytoplasm. [3] This hormone-receptor complex then moves to the nucleus and regulates the transcription of a limited number of target genes; some of the most important appear to be inhibitory effects on the transcription factors AP-1 and NF-?B, coupled with increased I?Ba, an inhibitor of NF-?B. [4] Glucocorticoids decrease the synthesis of a number of proinflammatory molecules, including cytokines, interleukins, adhesion molecules, and proteases, largely through their effects on transcription. [4] Similarly, other mediators of inflammation, such as cyclooxygenase-2 and the inducible form of nitric oxide synthase, are inhibited.

Glucocorticoids increase the synthesis of other important molecules, such as annexins 1 and 2. Annexins reduce phospholipase A_2 activity, which reduces the release of arachidonic acid from membrane phospholipids, [5], [6] limiting the formation of prostaglandins and leukotrienes. [7], [8] There is usually a delay in the onset of pharmacologic activity of glucocorticoids relative to their peak blood concentrations, which is probably consequent to altering the transcription of genes, [4] although some actions appear to be independent of transcription. [9] Glucocorticoids may also exert their effects by nongenomic mechanisms such as membrane-bound receptors and/or physicochemical interactions with cellular membranes. [10] Some effects of glucocorticoids are too rapid to be mediated by genomic glucocorticoid action. [11] This mechanism might explain additive benefits of very high-pulse glucocorticoids.

Glucocorticoids profoundly affect the replication and movement of cells. They induce monocytopenia, eosinopenia, and lymphocytopenia and have a greater effect on T cells than on B cells. [12] The lymphocytopenia appears to be caused by a redistribution of cells as they migrate from the circulation to other lymphoid tissues, and it has been suggested that glucocorticoids induce apoptosis. [13] The increase in circulating polymorphonuclear leukocytes is related to demargination of cells from the bone marrow and a diminished rate of removal from the circulation, at least partially mediated by the increase in annexin 1 [14]; there also appears to be inhibition of neutrophil apoptosis. [15]

Glucocorticoids affect cell activation, proliferation, and differentiation. They modulate the levels of mediators of inflammation and immune reactions, as seen with the inhibition of interleukin (IL)-1, IL-2, IL-6, and tumor necrosis factor synthesis (or release). [16], [17] Macrophage functions—including phagocytosis, antigen processing, and cell killing—are decreased by cortisol, [18], [19] and this decrease affects immediate and delayed hypersensitivity.

Glucocorticoids suppress monocyte and lymphocyte function (both T_H1 and T_H2 cells) more than polymorphonuclear leukocyte function. [20] This effect is clinically important because granulomatous infectious diseases, such as tuberculosis, are prone to exacerbation and relapse during prolonged glucocorticoid therapy. The antibody-forming cells, B lymphocytes and plasma cells, are relatively resistant to the suppressive effects of glucocorticoids. Very high doses of glucocorticoids are needed to suppress antibody production. [21]

The multiplicity of biologic effects produced by glucocorticoids emphasizes that currently there is no unifying hypothesis to explain the therapeutic efficacy of these extremely potent anti-inflammatory and immunosuppressive agents.

PHARMACOLOGY

When hydrocortisone is given in moderate to high doses, its mineralocorticoid effects can be deleterious, and thus synthetic analogues of cortisol have been developed that have greater anti-inflammatory properties and less sodium retention. Small substitutions on the basic steroid structure of three hexanes and a pentane ring (Fig. 253-1, Table 253-1) account for the differences in plasma half-life and the relative anti-inflammatory and sodium-retaining potencies (Table 253-2). In general, most synthetic analogues bind less efficiently to CBG (about 70 percent binding). This property may explain, in part, their tendency to cause side effects at lower dosages. The 11-betahydroxyl group in cortisol is essential for activity. Because cortisone and prednisone are 11-keto compounds, they are active only after being converted in the liver to the corresponding 11-betahydroxyl compounds (cortisol and prednisolone) (Table 253-1). Patients with severe liver disease generally maintain their ability to convert the 11-keto compounds; nevertheless, some authorities suggest that only the converted active compounds should be administered to these patients. [22]

DISEASES TREATED WITH GLUCOCORTICOIDS

Skin diseases commonly treated with oral glucocorticoids include serious blistering diseases (pemphigus, bullous pemphigoid, cicatricial pemphigoid, linear IgA bullous dermatoses, epidermolysis bullosa acquisita, herpes gestationis, erythema multiforme, toxic epidermal necrolysis); connective-tissue diseases (dermatomyositis, systemic lupus erythematosus, mixed connective-tissue disease, eosinophilic fasciitis, relapsing polychondritis); vasculitis; neutrophilic dermatoses (pyoderma gangrenosum, acute febrile neutrophilic dermatosis, Behçet's disease); sarcoidosis; type I reactive leprosy; capillary hemangiomas; panniculitis; and urticaria/angioedema. Short courses of glucocorticoids, under appropriate conditions, may be used for severe dermatitis (contact dermatitis, atopic dermatitis, photodermatitis, exfoliative dermatitis, erythrodermas). Acne and hirsutism consequent to adrenogenital syndromes can be treated with low doses of glucocorticoids at bedtime if these conditions are unresponsive to more conservative therapy. The use of glucocorticoids is controversial in the treatment of erythema nodosum, lichen planus, cutaneous T cell lymphoma, and discoid lupus erythematosus.

COMPLICATIONS OF SYSTEMIC GLUCOCORTICOID THERAPY

Complications associated with systemic glucocorticoid therapy (Table 253-3) [23], [24] increase with higher doses, longer duration of therapy, and more frequent administration. However, osteoporosis and cataracts develop with alternate-day dosing, and avascular necrosis can be seen after only short courses of glucocorticoids.

Central nervous system	Endocrinologic
Pseudotumor cerebri and psychiatric disorders	Suppression of HPA*
Musculoskeletal	Growth failure
Osteoporosis with spontaneous fracture	Secondary amenorrhea
Aseptic necrosis of bone	Metabolic
Myopathy	Hyperglycemia and unmasking genetic predisposition to diabetes mellitus
Ocular	Nonketotic hyperosmolar states
Glaucoma and cataracts	Hyperlipidemia
Gastrointestinal	Alterations of fat distribution (typical cushingoid appearance)
Peptic ulceration	Fatty infiltration of the liver
Intestinal perforation	Drug interactions (decreased anticoagulant effect of ethyl biscoumacetate)
Pancreatitis	Fibrinolytic inhibition
Cardiovascular and fluid retention	Inhibition of wound healing
Hypertension	Subcutaneous tissue atrophy (striae, purpura, ecchymosis)
Sodium and fluid retention	Suppression of host defenses
Hypokalemic alkalosis	Immunosuppression, allergy
Atherosclerosis	Effects on phagocyte kinetics and function
Hypersensitivity reactions	Increased incidence of infections
Urticaria	
Anaphylaxis	

*HPA, hypothalamic-pituitary-adrenal axis.

TABLE 253-3 **Complications of Glucocorticoid Therapy**

Osteoporosis

Osteoporosis occurs in 40 percent of individuals treated with systemic glucocorticoids; it is especially prominent in children, adolescents, and postmenopausal women. [25] Approximately one-third of patients have evidence of vertebral fractures after 5 to 10 years of glucocorticoid treatment, but this proportion is higher in postmenopausal women. [26], [27] Bone loss occurs most rapidly in the first 6 months of glucocorticoid use, but continues at a slower rate after that, with loss of 3 to 10 percent of bone per year in many patients. [25], [28] Some of the bone loss may be reversible after glucocorticoids are stopped, at least in the young. [29]

Glucocorticoids inhibit osteoblasts, increase calcium excretion by the kidney, decrease intestinal calcium absorption, and, concomitantly, increase bone resorption by osteoclasts. [30] They also reduce estrogen and testosterone levels, which is likely to be an important factor in the pathogenesis of osteoporosis. Serum osteocalcin, a measure of osteoblast function, decreases within a day after a dosage regimen of as little as 10 mg of prednisone a day is begun; a dosage regimen of 7.5 mg of prednisone a day or more often causes significant bone loss and an increased fracture rate. [31], [32] and [33] Trabecular bone is primarily affected, leading to painful vertebral fractures.

Avascular Necrosis

Avascular necrosis (AVN) is manifest by pain and limitation of motion in one or more joints. There is intraosseous hypertension, leading to bone ischemia and necrosis. [34] It is likely that intraosseous lipocyte hypertrophy causes this intraosseous hypertension in persons taking glucocorticoids. In addition, glucocorticoids induce apoptosis of osteoblasts, likely contributing to AVN. Underlying diseases, such as systemic lupus erythematosus (SLE), increase the likelihood of steroid-induced AVN. [35] Studies suggest that many patients who develop AVN have either thrombophilia or hypofibrinolysis, which leads to thrombotic occlusion of venous outflow from the bone, decreased arterial perfusion, and subsequent infarction of bone. [36]

Atherosclerosis

Glucocorticoids enhance many risk factors that are associated with atherosclerosis, including arterial hypertension, insulin resistance, glucose intolerance, hyperlipidemia, and central obesity. It is thus not surprising that patients taking glucocorticoids have an increased risk of atherosclerosis. [37] Patients with untreated Cushing's disease have a four times higher mortality rate from cardiovascular complications, including coronary artery disease, congestive heart failure, and cardiac stroke. [38] The risk factors for atherosclerosis persist for at least 5 years after normalization of the serum cortisol level in Cushing's disease, and similar findings may be true in those treated with chronic glucocorticoids. [39]

Suppression of the Hypothalamic-Pituitary-Adrenal Axis

The hypothalamic-pituitary-adrenal (HPA) axis is rapidly suppressed after the onset of glucocorticoid therapy. However, if therapy is limited to 1 to 3 weeks, the recovery of the HPA axis is rapid. Longer daily glucocorticoid therapy is associated with suppression of the HPA axis for up to 1 year after therapy is terminated. [40] Symptoms of adrenal suppression include lethargy, weakness, nausea, anorexia, fever, orthostatic hypotension, hypoglycemia, and weight loss.

There also exists a steroid withdrawal syndrome, in which patients experience symptoms of adrenal insufficiency despite having an apparently normal cortisol response to adrenocorticotropic hormone (ACTH). Symptoms most commonly include anorexia, lethargy, malaise, nausea, weight loss, desquamation of the skin, headache, and fever. Less commonly, vomiting, myalgias, and arthralgias occur. These patients have adjusted to high levels of glucocorticoids, and symptoms disappear after the glucocorticoids are restarted. This problem can be treated by slower tapering of the glucocorticoids, often by 1 mg of prednisone every few weeks. [41]

Drug Interactions

Glucocorticoids are associated with a number of important drug interactions. Drugs such as barbiturates, phenytoin, and rifampin, which induce hepatic microsomal enzymes, may accelerate the metabolism of glucocorticoids. [42] Drugs such as

cholestyramine, colestipol, and antacids, impair absorption of glucocorticoids. Glucocorticoids reduce the serum salicylate level and necessitate a higher dose of warfarin (Coumadin) for anticoagulation.

Immunologic Side Effects

Glucocorticoids impair delayed-type hypersensitivity reactions because of their inhibition of lymphocytes and monocytes. Prednisone at daily doses of 15 mg or more suppresses the response to tuberculin, although it takes an average of 13.6 days for oral prednisone at 40 mg/day to inhibit the response to tuberculin. [43] Thus, even in situations requiring immediate use of prednisone, it is possible to perform simultaneously a purified protein derivative of tuberculin (PPD) test and an anergy panel. Overall, there is an increased incidence of infections attributable to both the glucocorticoids and the immunologic changes related to the underlying disease. [44]

Concerns during Pregnancy and Lactation

Glucocorticoids cross the placenta, but they are not teratogenic. Exposed infants as well as breast-fed infants of mothers receiving glucocorticoids should be monitored for adrenal suppression and growth suppression.

THERAPEUTIC USE OF GLUCOCORTICOIDS

Fundamental Principles

Before therapy with glucocorticoids is begun, the benefit that can realistically be expected should be weighed against the potential side effects. Alternative or adjunctive therapies should be considered, especially if long-term treatment is contemplated. Coexisting illnesses such as diabetes, hypertension, or osteoporosis need to be considered. The predisposition of the patient to side effects should be included in an assessment of risk.

Choosing among Glucocorticoids

A number of considerations bear on the choice of glucocorticoids. First, a preparation with minimal mineralocorticoid effect is usually picked to decrease sodium retention. Second, the long-term oral use of prednisone or a similar drug, with an intermediate half-life and relatively weak steroid-receptor affinity, may reduce side effects. Long-term use of drugs like dexamethasone, which has a longer half-life and high glucocorticoid-receptor affinity, may produce more side effects without any better therapeutic effects. Third, if a patient does not respond to cortisone or prednisone, the substitution of the biologically active form, cortisol or prednisolone, should be considered. In general, even in severe liver disease, substitution has not proved to be very important. Fourth, methylprednisolone is used for pulse therapy because of its low sodium-retaining characteristics and high potency.

Route of Administration and Dosage Schedules

Systemic glucocorticoids can be administered intralesionally, orally, intramuscularly, and intravenously. The route and regimen are determined by the nature and extent of the disease being treated.

Intralesional glucocorticoid administration allows direct access to either a relatively few lesions or a particularly resistant lesion. The concentration depends on the site of injection and the nature of the lesion. Lower concentrations (2 to 3 mg/mL) are used on the face to prevent atrophy of the skin, whereas keloids may require concentrations of 40 mg/mL. In conditions requiring sustained effects, such as keloids and alopecia areata, longer-acting glucocorticoids, such as Aristospan, can be administered alone or mixed with the more typically used Kenalog. It is best to limit the total monthly dose of Kenalog to 20 mg to assure that the HPA axis will not be suppressed. [45]

There are serious drawbacks to intramuscular administration because of erratic absorption and lack of daily control of the dose. Because Kenalog is longer-acting than prednisone, there are more potential side effects, including increased HPA suppression and myopathy.

When oral glucocorticoids are prescribed, prednisone is most commonly selected. Glucocorticoids are usually administered daily or every other day, although for acute disease split daily doses can be administered. The initial dose is most often daily to control the disease process and can range from 2.5 mg to several hundred milligrams daily. If used for less than 3 to 4 weeks, glucocorticoid therapy can be stopped without tapering. The lowest possible dose of a short-acting agent every other morning minimizes side effects. Because cortisol levels peak at around 8 A.M., the HPA axis is least suppressed with this morning dosage, and maximal feedback suppression of ACTH secretion by the pituitary is already occurring. The low levels of glucocorticoids at night allow for normal secretion of ACTH. Low doses of prednisone (2.5 to 5 mg) at bedtime have been used to maximize adrenal suppression in cases of acne or hirsutism of adrenal origin.

Intravenous glucocorticoids are used in two situations. One is for stress coverage for patients who are acutely ill or are undergoing surgery and who have adrenal suppression from daily glucocorticoid therapy. The other is for patients with certain diseases—such as resistant pyoderma gangrenosum, severe pemphigus or bullous pemphigoid, serious SLE, or dermatomyositis—to gain rapid control of the disease and thus minimize the need for long-term, high-dose oral steroid therapy. [46] Methylprednisolone is used at a dose of 500 mg to 1 g daily because of its high potency and low sodium-retaining activity. Serious side effects associated with intravenous administration include anaphylactic reactions, seizures, arrhythmias, and sudden death. Other adverse reactions include hypotension, hypertension, hyperglycemia, electrolyte shifts, and acute psychosis. Slower administration over 2 to 3 h has minimized many of the serious side effects, and as long as vital signs are determined frequently, patients without underlying renal or cardiac disease do not need to be treated in a monitored bed. [47] It is important to monitor serum electrolytes before and after pulse therapy,

particularly when patients are on concomitant diuretic therapy.

STRATEGIES TO REDUCE GLUCOCORTICOID SIDE EFFECTS

Evaluation before Treatment

To minimize potential problems, the baseline evaluation should include a personal and family history, with special attention to predisposition to diabetes, hypertension, hyperlipidemia, glaucoma, and associated diseases that could be affected by steroid therapy. Baseline blood pressure and weight should be measured. If prolonged administration is anticipated, an eye examination and a PPD test should be performed and an anergy panel applied. Examination for other covert infections should be based on history and physical examination. For instance, a stool culture for *Strongyloides* should be performed for immigrants from third-world countries and for Vietnam veterans. [48] If long-term administration of glucocorticoids is anticipated, baseline spinal bone-density measurement should be obtained by quantitative computed tomography (CT), dual-photon absorptiometry, or dual-energy x-ray absorptiometry (DEXA). [49]

Evaluation during Treatment

At follow-up visits, patients receiving chronic glucocorticoid therapy should be questioned about polyuria, polydipsia, abdominal pain, fevers, sleep disturbances, and psychological effects. There may be serious effects on affect and even psychosis in patients with high doses of glucocorticoids. Weight and blood pressure should be monitored. Serum electrolytes, fasting blood sugar, and cholesterol and triglyceride levels should be measured on a regular basis. Stool should be examined for occult blood. Follow-up eye examinations should be performed with careful monitoring for the development of cataracts and glaucoma.

Preventive Measures (Table 253-4)

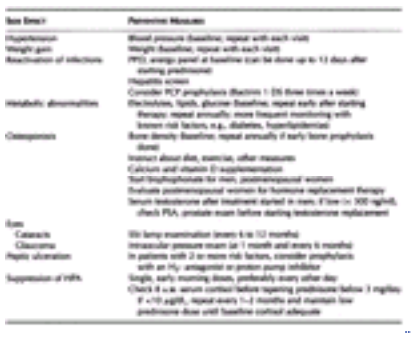

TABLE 253-4 **Prevention of Side Effects with Chronic (= 3 months) Glucocorticoid Use**

DIET Diet should be low in calories, fat, and sodium, and high in protein, potassium, and calcium. Protein intake is important to reduce steroid-induced nitrogen wasting. [50] Use of alcohol, coffee, and nicotine should be minimized. Exercise should be encouraged.

INFECTIONS Patients with a positive PPD should be given prophylaxis with isoniazid. [51] Anergic patients should have a baseline chest x-ray to search for evidence of previous tuberculosis. Fevers or focal findings should be evaluated with appropriate cultures and diagnostic approaches. Some advocate use of Bactrim prophylaxis (1 DS Bactrim 3 days a week) against *Pneumocystic carinii* when patients receive concomitant cytotoxic therapy. [22]

GASTROINTESTINAL COMPLICATIONS Although there is controversy about whether an increase in the incidence of peptic ulcer disease occurs in otherwise unaffected patients receiving glucocorticoids, there is almost a ninefold increase in patients taking both glucocorticoids and nonsteroidal anti-inflammatory agents. [52], [53] In patients with two or more risk factors (such as those taking nonsteroidal anti-inflammatory medications, a previous history of peptic ulceration, advanced malignant disease, or a total dose of glucocorticoids >1000 mg), prophylaxis may be considered. Prophylaxis can include antacids, H_2-receptor blockers (cimetidine, ranitidine, nizatidine, or famotidine with the evening meal), or proton pump inhibitors (Prilosec or Prevacid).

ADRENAL SUPPRESSION Patients receiving daily glucocorticoid therapy for longer than 3 to 4 weeks must be assumed to have adrenal suppression that requires tapering of the glucocorticoids to allow for recovery of the HPA axis. Tapering is best performed by switching from a single daily dose to alternate-day doses, followed by a gradual reduction of the amount of the drug. The daily dose is first gradually tapered to 40 or 50 mg of prednisone. Then either the dose can be kept constant on one day and reduced on the alternate day by 5-mg decrements down to 5 mg/day, or, the steroid dose can be increased on one day and reduced by a similar amount on the alternate day. After the prednisone dose is tapered to 5 mg on alternate days, the need for maintenance therapy must be assessed. The 8 A.M. plasma cortisol level is measured 4 weeks after the 5-mg dose has been reached. The morning dose of prednisone is held until the plasma cortisol level is determined. If the plasma cortisol level is less than 10 µg/dL, the alternate-day prednisone dose should be decreased by 1 mg every 1 to 2 weeks to a maintenance dose of 2 mg/day. Then the 8 A.M. plasma cortisol level should be rechecked every 2 months until it is greater than 10 µg/dL, at which point maintenance glucocorticoids can be terminated. [54] Recovery of the HPA axis can take longer than 9 months. [40] At that point and at any point when the patient is receiving tapering doses of steroids, a stress caused, for example, by trauma, surgery, diarrhea, or fever >38°C (101°F) can precipitate acute adrenal insufficiency related to an inadequate stress response. Patients should wear bracelets or carry cards indicating that they are receiving glucocorticoids. During such stressful situations, it is necessary to give high doses of glucocorticoids, generally 25 to 70 mg/day of prednisone or 100 to 300 mg/day of cortisol in divided doses. [55] Patients must be educated about the need for stress coverage. The amount of glucocorticoids to give for coverage for surgery should probably be individualized to the severity of the operation. Minor operations lasting less than 1 h are associated with, at most, 50 mg/day (12.5 mg prednisone) of cortisol in response to the surgery. Moderate to major surgeries are associated with the production of 75 to 200 mg/day of cortisol. [56], [57] Thus, recent guidelines suggest that adrenally suppressed patients receive 25 mg of hydrocortisone equivalents for minor surgeries, 50 to 75 mg for

moderate surgeries, and 100 to 150 mg for major surgery for 2 to 3 days, beginning when the patient is on call for surgery. [56] No trials have been done, and one recent study suggested even lower doses are adequate. [58] In general, adrenal insufficiency resolves within 1 year of the termination of glucocorticoid therapy. An ACTH (cosyntropin) stimulation test may be performed after maintenance glucocorticoids are terminated to assess adrenal reserve. This test is performed in the office by determining a baseline cortisol level, giving an intramuscular injection of 0.25 mg of cosyntropin, and measuring the serum cortisol level again 1 h later. [54] The adrenal response is suppressed if the serum cortisol level fails to increase by at least 5 µg/dL to a stimulated value 60 min later of more than 20 µg/dL. If adequate adrenal response to stress is demonstrated, there is less concern about the endogenous cortisol response to stress. [22] However, such a response is not a guarantee of adequate adrenal reserves if severe stress occurs, and many physicians would choose routine stress coverage with glucocorticoids without performing an ACTH stimulation test.

OSTEOPOROSIS Attention to the prevention of osteoporosis is becoming increasingly important as newer therapies that may deter bone loss become available. Calcium and vitamin D supplements, sex hormone replacement, a weight-bearing exercise program, and sodium restriction are suitable first-line therapies. [59], [60] Calcium and vitamin D together, but not calcium alone, preserve bone mass in patients receiving long-term treatment with glucocorticoids at an average of 15 mg/day. [59], [61] Patients taking glucocorticoids should be given elemental calcium, 1500 mg/day, and vitamin D_2, 400 units twice daily. Activated forms (alfacalcidiol, 1 µg/day, or calcitriol, 0.5 to 1 µg/day) can be given, but more frequent monitoring is required for hypercalciuria and hypercalcemia. Patients with a history of renal stones should not receive supplemental calcium and vitamin D. For patients receiving calcium and vitamin D_2, calcium levels should be measured in serum and in 24-h urine collections every 3 months or whenever glucocorticoid doses are substantially altered. If the urinary calcium level exceeds 250 to 350 mg/dL, the addition of 12.5 to 25 mg/day of thiazide will reduce the renal excretion of calcium. [62] If thiazide is not added, calcium and vitamin D supplementation should be adjusted. Postmenopausal and premenopausal women who become amenorrheic because of glucocorticoids benefit from hormone replacement therapy (HRT). Such therapy helps to prevent the effects of glucocorticoids on bone. [63], [64] Postmenopausal women should receive oral conjugated estrogen (Premarin), 0.625 mg/day. Women with a uterus should also receive medroxyprogesterone (Provera), 2.5 mg/day, which prevents the increased endometrial carcinoma that occurs in women receiving estrogen alone. [65] Transdermal estradiol is also a common route of drug delivery. Newer selective estrogen receptor modulators, such as Raloxifene, offer the option of HRT to women previously unable to tolerate estrogens, and mimic the effects of estrogen on bone and blood lipid levels without the stimulatory effects on the breast and uterus. Raloxifene has more modest effects than conjugated estrogens on bone resorption and formation parameters, and is less effective in increasing bone mineral density; its role in glucocorticoid-induced osteoporosis has not been specifically studied. [66] Women who are to receive hormonal therapy should not have a history of benign or malignant breast disease or other hormone-sensitive tumors, thrombophlebitis, smoking, gallstones, or a family history of breast cancer. Breast and pelvic examinations should be performed initially and at regular 6- to 12-month intervals during hormone therapy. Glucocorticoids suppress serum testosterone in men. [67] Low serum testosterone is associated with low bone density in hypogonadal men; bone density increases in these men when they receive supplemental testosterone. [68] One study suggests that testosterone partially reverses the effects of glucocorticoids on bone. [69] Men with low serum testosterone levels who are receiving glucocorticoids should have testosterone supplementation. Based on recommendations published by the American Association of Clinical Endocrinologists and the American College of Endocrinology, men with serum testosterone levels below the physiologic range (<300 ng/mL) should receive replacement therapy. [70] Replacement is administered either by the intramuscular route (testosterone enanthate or cypionate, 200 mg IM every 2 weeks or 100 mg every week to avoid cycling) or by testosterone patches (Androderm, 4 or 6 mg applied daily). Serum testosterone should be checked after replacement to assure adequate treatment. The increased osteolysis caused by steroids has led to the use of a number of agents that inhibit bone resorption, such as the bisphosphonates and calcitonin. Inhibition of bone resorption leads to recoupling of the remodeling unit, thereby preventing further bone loss. In addition, because bone formation proceeds at a much slower pace than resorption, antiresorptive drugs produce a period of time up to 2 years where formation is greater than resorption. Several bisphosphonates are now available and have revolutionized the approach to prevention and treatment of steroid-induced osteoporosis. These include alendronate, 70 mg/week or 5 mg/day (10 mg/day for postmenopausal women not on HRT); risedronate, 30 mg/week or 5 mg/day; etidronate, 400 mg/day for 2 weeks every 13 weeks; and pamidronate, 30 to 60 mg intravenously every 6 to 12 months. All four agents increase vertebral bone mineral density and decrease vertebral fractures in patients receiving glucocorticoids, and alendronate and risedronate are currently recommended for prevention and treatment of glucocorticoid-induced osteoporosis. [71], [72] Intranasal calcitonin may increase bone mineral density, but less effectively than the bisphosphonates, and it does not reduce the risk of vertebral fractures. [73], [74] Calcitonin offers a treatment for patients unable to tolerate the bisphosphonates or unwilling to add another pill to their regimen. It is considered a second-line agent for treatment of osteoporosis and is not recommended for prevention of bone loss in early glucocorticoid therapy. [59] It is used as one spray to one nostril daily, alternating nostrils each day to minimize local irritation. Calcitonin is often helpful in relieving the pain of compression fractures. [75] Current recommendations include baseline measurements of bone density and a sequential study to identify early those who are rapidly losing bone density. [24], [59] Bone density is best measured in the lumbar spine in patients younger than 60 years of age and in the femoral neck in patients older than 60 years of age. All men and postmenopausal women in whom long-term glucocorticoid treatment at =5 mg/day is being initiated or who have below normal bone mineral density T-scores should receive bisphosphonates at the time glucocorticoids are prescribed. Premenopausal women treated with bisphosphonates should prevent pregnancy. A decrease in bone mineral density of 5 percent or greater warrants changing or starting additional treatment strategies.

ATHEROSCLEROSIS Blood pressure, serum lipids, and glucose levels should be measured serially. Abnormalities should be treated with dietary manipulation and medication as necessary. Patients who smoke should be encouraged to stop. Female sex hormones protect against the development of atherosclerosis, and thus HRT for postmenopausal women on glucocorticoids makes sense. [76] However, recent data suggest that women with established atherosclerosis actually do worse with HRT, and there was a 58 percent increase in coronary heart disease events in the first year after myocardial infarction in patients treated with an estrogen/progestin combination. [77] If patients develop increased levels of cholesterol or triglycerides while taking glucocorticoids, there are now good approaches to treatment, particularly with some of the newer statins, that impact on the development of atherosclerosis and prevent myocardial infarctions. Patients should be treated or referred for treatment on the basis of guidelines that emphasize the importance of assessing the risk of atherosclerosis. These guidelines recommend treatment when patients have low-density lipoprotein (LDL) cholesterol

levels greater than 160 mg/dL and fewer than two coronary heart disease risk factors (high LDL cholesterol, smoking, hypertension, diabetes, male sex, family history of premature heart disease), LDL cholesterol levels greater than 130 mg/dL with two or more additional risk factors for heart disease, and LDL cholesterol levels greater than 100 mg/dL for patients with established coronary artery disease. [78] High-density lipoprotein (HDL) cholesterol levels lower than 35 mg/dL independently predict increased coronary mortality rates in men and should be taken into account in therapeutic decisions. Several trials have demonstrated reduction in both coronary heart disease and total mortality rates with statin therapy. [79], [80] and [81] Patients should supplement the diet with folate and B_6 to control any elevations in homocysteine.

AVASCULAR NECROSIS Early detection is important because early intervention may prevent progression to degenerative joint disease requiring joint replacement. Twenty percent of patients with AVN have normal x-rays. Bone scan and magnetic resonance imaging (MRI) are more sensitive techniques for evaluating AVN. Patients should be regularly questioned about pain and limitation of motion of joints. If abnormalities develop, an x-ray, bone scan, or MRI should be ordered. If imaging shows AVN, an orthopedic surgeon skilled in early intervention with core decompression may be able to halt progression of the disease. Patients with AVN have an increased risk that other joints will be affected. The progression of AVN to destructive joint disease may require joint replacement surgery. [82]

Sulfones

PHARMACOLOGY
INDICATIONS
ADVERSE EFFECTS
MONITORING OF DAPSONE THERAPY
MECHANISM OF ACTION

REFERENCES

In 1940, Costello [1] first described the dramatic success of sulfapyridine in treating a patient with dermatitis herpetiformis, a disease he believed to be a form of bacterial allergy. Swartz and Lever [2] later reported the regular response of all their patients with dermatitis herpetiformis to sulfapyridine therapy. In the early 1950s, a group of drugs chemically related to sulfapyridine, the sulfones (dapsone and related compounds), were first used in treating patients with this disease. Because dapsone is the most widely used drug among these compounds, there has been an enormous amount of research into its metabolism, mechanisms of action, and toxicity. This chapter focuses on the effect of dapsone on inflammatory skin diseases.

PHARMACOLOGY

Figure 254-1 shows the chemical structure of dapsone [4,4'-diaminodiphenylsulfone (DDS)]. Derivatives of dapsone such as sulfoxone (no longer available in the United States) are thought to be metabolized to the parent dapsone structure. Sulfapyridine resembles dapsone in that it has an aminophenyl group attached to a sulfone (SO_2); however, on the other side of the sulfone, there is a pyridine group (Fig. 254-1). Although other sulfonamides have an aminophenyl group attached to a sulfone, they have different groups on the other side of the sulfone, and none is as effective as sulfapyridine in the treatment of inflammatory diseases. The pyridine group was thought to contribute to the beneficial effect of sulfapyridine, and other compounds, such as pyribenzamine and nicotinamide, were said to be useful in treating patients with dermatitis herpetiformis. After many years, sulfapyridine is still available only under an investigational new drug (IND) application.

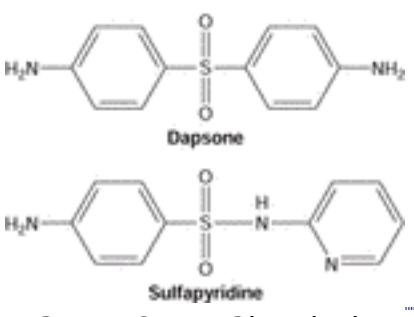

FIGURE 254-1 Chemical structure of dapsone and sulfapyridine.

After oral administration of dapsone, approximately 80 to 85 percent is absorbed, with peak levels being reached 2 to 6 h after a single dose. In patients taking 50 to 300 mg/day of dapsone, the peak levels of dapsone and its major metabolite reach 0.5 to 7 mg/L and 0.2 to 5 mg/L, respectively. [3] The half-life of dapsone in the circulation is approximately 30 h. [4] Its retention in the body, however, is prolonged, perhaps because of its enterohepatic recirculation, since high concentrations have been detected in the bile. Dapsone and its metabolites may be transmitted through human milk [5] and are excreted by the kidneys. [4]

Dapsone is metabolized in the liver. The two major metabolic pathways involve acetylation and *N*-hydroxylation (Fig. 254-2). As with isoniazid and certain hydrazides and sulfonamides, dapsone and its derivatives are acetylated polymorphically, that is, some patients rapidly acetylate dapsone to monoacetyldapsone (MADDS), the major metabolite, whereas in others, this process occurs slowly. However, in humans, MADDS is rapidly deacetylated. Thus, an equilibrium between MADDS and dapsone is rapidly reached and sustained. The half-life in the body seems to be unrelated to the rate of acetylation. From a clinical standpoint, it seems that in dapsone's control of symptoms of dermatitis herpetiformis and even in its efficacy as an antileprosy drug, the dapsone dosage requirement is unrelated to acetylator phenotype. [3], [6]

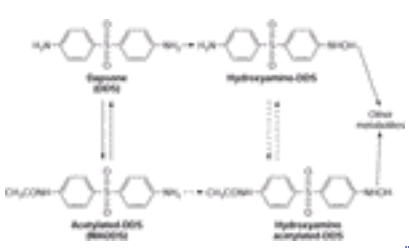

FIGURE 254-2 Dapsone metabolism in humans.

The other major metabolic pathway involves hydroxylation of one of the amino groups to form aminohydroxylaminodiphenylsulfone. This compound is responsible for the methemoglobinemia, hemolysis, and Heinz-body formations that occur regularly when dapsone is administered. [7], [8] and [9] Thus, these pharmacologic side effects must be anticipated.

A number of drugs interfere with the effect of dapsone, including probenecid, [10] rifampicin, [11] cimetidine, [12] omeprazole, [13] and trimethoprim. [14]

INDICATIONS

Since its introduction into clinical medicine, dapsone has had therapeutic trials in a multitude of diseases. Long lists of inflammatory diseases that have responded to dapsone therapy have been generated. [15], [16] Some of the individual reports are difficult to assess critically. Two diseases that invariably respond to dapsone therapy are dermatitis herpetiformis and erythema elevatum diutinum. [17] The dramatic dependence of patients on dapsone is best exemplified by the prompt exacerbations that follow withdrawal of the drug.

Other diseases for which dapsone therapy reportedly has been effective in some patients are rheumatoid arthritis; idiopathic or autoimmune thrombocytopenic purpura; acne conglobata; actinomycetoma; pyoderma gangrenosum; bullous pemphigoid; linear IgA disease; scarring pemphigoid; relapsing polychondritis; the bullous eruption of systemic lupus erythematosus (SLE); granuloma faciale; subcorneal pustular dermatosis; necrotic arachnidism; and certain forms of leukocytoclastic vasculitis. As a unifying feature, most of these diseases have granulocytes (neutrophils or eosinophils) as the predominant infiltrating cell. In most diseases, the neutrophils appear early in the pathologic process. The response to dapsone therapy is not as rapid, regular, or predictable in any of these diseases as it is in dermatitis herpetiformis or erythema elevatum diutinum.

Prospective controlled trials show dapsone therapy to be modestly effective in the treatment of some patients with rheumatoid arthritis. [18] Similarly, 50 percent of patients with thrombocytopenic purpura respond to dapsone therapy. [19] High dosages (up to 400 mg/day) are usually required in the treatment of otherwise unresponsive patients with cystic acne. With the advent of the synthetic retinoids, however, a trial of dapsone therapy may no longer be necessary. A few patients with bullous pemphigoid have responded fairly dramatically to dapsone therapy. [20] Indeed, some authors have advocated its use as a regularly effective treatment for bullous pemphigoid, [21] while others have found its efficacy in bullous pemphigoid to be limited. [22] Dapsone and sulfapyridine are effective in ocular cicatricial pemphigoid, particularly in the early inflammatory phases (reviewed in Ref. [23]), and dapsone is effective in patients with superficial pemphigus who have a low or negative pemphigus antibody titer. [24]

Patients with SLE occasionally have subepidermal vesicular lesions that closely simulate dermatitis herpetiformis histologically. These patients do not have an “admixture” of dermatitis herpetiformis and SLE, although the eruption is extraordinarily responsive to dapsone therapy. [25] Therapeutic responses to dapsone have occurred in occasional patients with subacute cutaneous lupus erythematosus. [26] Granuloma annulare has also been reported to respond to dapsone treatment. [27] Some patients with subcorneal pustular dermatosis respond to and become dependent on dapsone, whereas others are unresponsive. This difference may reflect the heterogeneity of this disease, whose nosologic features have been a source of considerable debate. [28]

Although several reports suggest that dapsone therapy is remarkably effective in the treatment of relapsing polychondritis, my experiences with dapsone therapy in several patients with this condition have been uniformly unsuccessful. Occasionally, there are patients with chronic leukocytoclastic vasculitis in addition to those with erythema elevatum diutinum in whom dapsone therapy induces the prompt cessation of lesions. Because there is no uniformly successful therapy for these patients, many of whom do not seem to have associated internal problems, a short trial of dapsone therapy is warranted. In general, when a pathologic lesion is characterized by a neutrophilic infiltrate and is unassociated with an infectious agent, a trial of dapsone therapy should be considered. Even if a therapeutic trial is successful, the dose of dapsone should be decreased to a point at which lesions recur to be sure that the improvement was indeed due to dapsone and that there is a continuing need for the drug.

In the early 1990s there was considerable enthusiasm for the potential of dapsone as a prophylactic agent for *Pneumocystis carinii* pneumonia (PCP). It is now considered less effective than trimethoprim-sulfamethoxazole (TMP-SMX). However, dapsone is a reasonable choice for PCP prophylaxis in patients who are unable to take TMP-SMX. [29]

ADVERSE EFFECTS

Dapsone therapy produces hemolysis and methemoglobinemia. The metabolite responsible for both these pharmacologic effects of sulfones has been identified as aminohydroxylaminodiphenylsulfone. Patients taking more than 50 mg/day of dapsone probably will have some degree of hemolysis that will be reflected in a lowered hemoglobin level. At 150 mg/day, dapsone may produce a decrease of as much as 2 g of hemoglobin. Patients with glucose-6-dehydrogenase deficiency have a greater decrease in the hemoglobin level. Most patients tolerate a 2-g fall in the level of hemoglobin well, but older patients or those with cardiopulmonary problems should be closely monitored or they should be given sulfapyridine. An increase in the reticulocyte count accompanies the fall in the hemoglobin level. Several months after treatment has begun, the hemoglobin level may rise almost to pretreatment levels but usually remains about 1 g below the original level.

Methemoglobinemia also regularly occurs in patients treated with sulfones but not as often as in patients treated with sulfapyridine. Methemoglobinemia is not a major problem in most patients. Even in patients taking 200 mg/day of

dapsone, the level usually does not exceed 12 percent of the total hemoglobin level and is often less than 5 percent. The methemoglobin level is more pronounced at the onset of treatment and, as with hemolysis, it is dose-dependent. The cyanosis (which may seem more gray than blue) that results from methemoglobinemia may be seen in anyone with a methemoglobin level greater than 3 percent but may not be apparent in some patients with a level as high as 12 percent. Symptoms of methemoglobinemia include weakness, tachycardia, nausea, headache, and abdominal pains, which should not be attributed to methemoglobinemia until levels reach 20 percent or greater. Dapsone-induced methemoglobinemia can be reduced by coadministration of cimetidine. [30]

Other than these pharmacologic side effects, the adverse effects of dapsone may be idiosyncratic or allergic in nature [15], [31], [32] (Table 254-1). Peripheral neuropathy is one such example, and usually occurs at high dosage levels. Loss of motor function is the most common type of neuropathy, and it is reversible by decreasing the dose of dapsone. Sensory neuropathy is rare. Other side effects include the induction of acute psychosis [33], [34] and a potentially fatal mononucleosis-like “dapsone” syndrome that occurs during the induction of dapsone therapy in patients with leprosy, [35] but also in patients with vasculitis and dermatitis herpetiformis. [36], [37] Severe hypoalbuminemia with anasarca has also been reported. [38]

Pharmacologic effects	Morbilliform eruptions
Hemolysis	Erythema nodosum
Methemoglobinemia	Erythema multiforme
Headache	Exfoliative dermatitis
Gastric irritation	Toxic epidermal necrolysis
Nausea	Severe hypoalbuminemia
Anorexia	Psychosis
Fatigue	Leukopenia
Hepatitis, infectious mononucleosis-like with adenopathy	Agranulocytosis
Cholestatic jaundice	Peripheral neuropathy (almost always motor)

SOURCE: Modified from Lang,[15] Klemmer,[31] and Kato et al.[32]

TABLE 254-1 **Adverse Reactions to Sulfones**

Agranulocytosis has been estimated to occur in 0.2 to 0.4 percent of patients treated with dapsone. [39] If agranulocytosis occurs, its onset is almost always during the first 3 months of therapy. [39], [40] Although it is usually reversible when patients stop therapy, it may be fatal. Patients should be warned to seek medical care immediately if an infection develops during the first several months of therapy. Generally, when adverse reactions occur as a result of therapy with dapsone, dapsone derivatives and even sulfapyridine cause the same types of problems.

Information from two independent studies of carcinogenicity suggests that dapsone is a “weak carcinogen” in rats. [41], [42] There is no similar evidence from studies in humans.

A frequently asked question is whether dapsone is safe to use during pregnancy. In one study, 2 of 56 infants born to patients with leprosy who were being treated with dapsone had congenital malformations. [43] There are no controlled studies in animals or humans that address this point. As mentioned earlier, dapsone may be found in breast milk. [5]

MONITORING OF DAPSONE THERAPY

Before therapy with the sulfones or sulfapyridine is started, a complete blood cell (CBC) count should be obtained. In addition, Asians, blacks, or persons of Mediterranean descent should be tested for glucose-6-phosphate dehydrogenase deficiency, because sulfones can cause profound hemolysis in persons lacking this enzyme. After therapy is begun, a leukocyte count with a differential and hemoglobin levels should be obtained weekly for the first month and then twice a month during the next 2 months. Thereafter, CBC counts should be obtained periodically. Liver and renal function also should be tested before therapy starts and periodically thereafter. Once the disease being treated is under control, the dosage of dapsone should be reduced to be sure that the patient is using the minimum amount of drug required. Although in some diseases, such as dermatitis herpetiformis, the patients may alter the drug dosage according to the severity of the disease, they should be reminded not to increase the dosage by large amounts abruptly. Because the blue-gray color of methemoglobinemia may be attributed to other causes by emergency room physicians, patients should be advised to carry a medication card in their wallets.

MECHANISM OF ACTION

The mechanisms of action of dapsone in leprosy and inflammatory diseases have been the subject of considerable study. Dapsone and its derivatives are potent oxidants with a notable influence on glutathione. Interference with the folate biosynthetic pathway of bacteria accounts for their bacteriostatic effect. Less-well-known activities of dapsone involve its inhibition of choline incorporation into the lecithin of the cell membranes, thereby decreasing phospholipid synthesis. [44] Also, dapsone administered in the diet decreases visceral lesions and mortality in chickens infected with Marek's disease, in which a herpesvirus induces a lymphocytic malignant neoplasm in chickens. [45]

Numerous studies have attempted to determine how dapsone exerts its anti-inflammatory effect. Evidence suggests that its antiinflammatory effect is not related to its antibacterial effect. Dapsone inhibits lysosomal enzyme activity, [46] interferes with the myeloperoxidase-H_2O_2-halide-mediated cytotoxic system, [47], [48] and inhibits the generation of 5-lipoxygenase products in polymorphonuclear leukocytes. [49] Dapsone and its analogues also inhibit the zymosan-mediated human neutrophil respiratory burst. [50] Although these findings may account for the effect of the drug on neutrophils or on their lysosomal enzymes at the site of injury, they probably do not account for the lack of influx of neutrophils into the dermis in treated patients. There is little evidence to support suggestions that dapsone interferes with complement activation and deposition. Some in vivo studies have shown that dapsone at doses of 100 to 200 mg/kg

inhibits adjuvant-induced arthritis and carrageenan-induced inflammation in rats. [51]

Several studies suggest that dapsone and its derivatives do not affect the response of neutrophils to chemotactic stimuli. However, other studies suggest that dapsone inhibits leukotriene B_4 binding to and chemotaxis of neutrophils. [52], [53] Yet others demonstrate that dapsone inhibits the neutrophil response to some selected chemotactic stimuli. [54] More extensive studies with chemotactic stimuli in varied concentrations are required to evaluate the possibility that dapsone may interfere with a specific chemotactic factor or with the response of neutrophils to such a factor. Another possibility for the beneficial effect of dapsone on neutrophil-rich dermatoses may be its ability to inhibit (1) interleukin 1–stimulated neutrophil adhesion to endothelial cells, [50] (2) neutrophil adherence to antibodies deposited in skin, [55] (3) integrin-mediated neutrophil adherence functions, [56] or (4) chemoattractant-induced signal transduction. [57] More recent studies suggest that dapsone may inhibit the release of chemotactic stimuli from keratinocytes. [58]

The 4-aminoquinolines are a family of compounds derived from quinine. Chloroquine (CQ) and hydroxychloroquine (HCQ) are the principal members of this class of compounds and are those most often used as therapeutic agents in dermatology. Quinacrine (QE), a quinine derivative classified as an acridine, has also been used in dermatology. Quinine is extracted from the bark of the cinchona tree. It is said that, in 1638, Anna del Chinchon, the wife of the viceroy of Peru, was cured of malaria by the bark from this tree. Although the validity of this claim is debated, the tree from which the bark was taken still bears her name. By 1645, news of the use of cinchona bark to treat intermittent fevers reached Rome via a delegate from Peru who convinced Roman Jesuits of its efficacy. By the 1670s, the bark was being used throughout Europe. In the mid-1700s the French explorer De la Condamine identified the tree and named it quinquina (the word comes from *quina,* which is Peruvian vernacular for cinchona). In 1852, a Dutch expedition succeeded in transplanting cinchona seeds and plants to Java in the Dutch East Indies, and by the end of the nineteenth century, 90 percent of the world's supply of quinine came from Java. (For a more detailed history of quinine, see Hofheinz and Merkli. [1])

The research and development of synthetic antimalarials derived from quinine stemmed from military demand. After World War I, supplies of quinine dwindled. CQ was first synthesized in Germany in 1934. QE and other synthetic quinine derivatives were also produced in the 1930s. During World War II, Japan occupied Java and cut off supplies, again creating a need for alternative sources. More than 17,000 compounds were tested for antimalarial properties in the United States and England, and, as a result of this research, HCQ was synthesized in 1946. These antimalarial drugs were first used for dermatologic conditions in 1894, when Payne reported the treatment of lupus erythematosus (LE) with quinine. [2] In 1951, Page reported that during World War II he had observed that 18 American soldiers taking quinine noted an improvement of their cutaneous lupus and inflammatory arthritis. [3] Since that time antimalarial drugs (primarily CQ, HCQ, and QE) have been studied for dermatologic use. QE was first synthesized as an alternative to quinine for the treatment of malaria and was subsequently found to be much more efficacious, with greater bioavailability and better tolerance. It became an important agent for the treatment of *Giardia* infections. Its production in the United States was discontinued in 1992. These agents, their pharmacology, mechanisms, clinical applications, and side effects are described below.

PHARMACOLOGY, PHARMACOKINETICS, DISTRIBUTION, AND DOSING

CQ, HCQ, and QE are closely related structures (Fig. 255-1). CQ and HCQ are 4-aminoquinolines, whereas QE, with an additional benzene ring, is classified as an acridine. The pharmacology and pharmacokinetics of these antimalarial compounds are similar (Table 255-1). They are bitter, water-soluble, and readily absorbed from the gastrointestinal tract. All have a relatively good bioavailability and achieve peak concentrations within hours. Both CQ and HCQ have large volumes of distribution and prolonged half-lives. [4], [5] QE is extensively bound to plasma proteins, whereas CQ and HCQ are only partially bound. [4], [5] and [6] The half-life of QE is substantially less than that of the other compounds. [6] CQ is metabolized (dealkylated) in the liver by P450 enzymes into desethylchloroquine (DECQ) and bisdesethylchloroquine (BDCQ). [4] CQ and its metabolites are stored in relatively high concentrations in the liver, spleen, lungs, and adrenals, and in melanin-containing cells. [4] Approximately 50 percent of CQ is eliminated by the kidneys unchanged. [4] HCQ is also metabolized in the liver (*N*-de-ethylation) into three chief metabolites: desethylhydroxychloroquine (DHCQ), DECQ, and BDCQ. [5] The parent compound and metabolites are taken up by lysosomes and concentrated in lysosome-rich tissues. Approximately 15 to 25 percent of the total clearance is through the kidneys. [5] As with CQ, renal excretion can be enhanced with acidification of the urine. [4], [5] QE is excreted in urine, bile, sweat, and saliva, [6] with renal excretion accounting for only about 11 percent. The highest tissue concentrations are in the liver and spleen. [6] Equivalent doses of these compounds are 250 mg of CQ, 400 mg of HCQ, and 100 mg of QE. The usual doses used in dermatology are 250 to 500 mg/day for CQ, 400 mg/day for HCQ, and 100 to 200 mg/day for QE. Evidence of efficacy is generally seen after 1 to 3 months of use, after which the dose may be tapered to a minimum effective dose. Because the mechanism of action, metabolism, clearance, and side-effect profile of QE are sufficiently different from those of HCQ and CQ, no crossover reactivity is thought to occur between QE and the 4-aminoquinolines. [7]

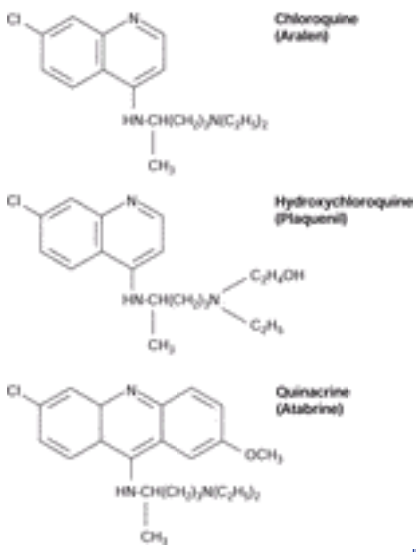

FIGURE 255-1 Antimalarial drugs used in dermatology.

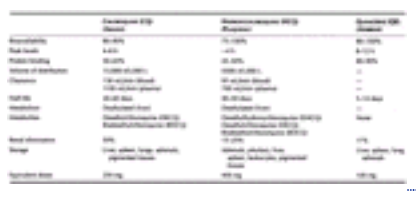

TABLE 255-1 **Pharmacology and Pharmacokinetics of Antimalarial Compounds**

MECHANISMS OF ACTION

The precise mechanism by which antimalarial compounds exert their action is still a subject of debate. However, several discrete mechanisms have been determined and attributed to the drugs' efficacy. Generally, antimalarial drugs are felt to be anti-inflammatory. For the treatment of malaria, the aminoquinolines concentrate in the *Plasmodium* digestive vacuole and prevent polymerization of toxic heme released during proteolysis of hemoglobin. [8] Other important actions of antimalarial compounds are summarized below.

Photodermatologic Properties

The 4-aminoquinolines bind in the epidermis in high concentrations, probably because of their affinity for pigment. However, studies of the photoprotective effects of antimalarials have yielded conflicting data. Both in vitro and in vivo studies indicate that CQ absorbs ultraviolet light in the UVB range. [9], [10] The effect on the minimal erythema dose (MED) is less certain. One study showed that QE prolonged the MED in two patients with lupus. [3] Another study showed that CQ had no effect on the MED in 21 patients with polymorphous light eruption. [11]

Immunologic and Anti-inflammatory Effects

CQ and HCQ are weak diprotic bases that are protonated, become trapped, and accumulate to 100 times concentration inside acidic vesicles such as lysosomes. [12] QE inhibits Na-K ATPase activity, stabilizes cell membranes, and concentrates in lysosomes. The effects are most evident in macrophages and phagocytic cells, where phagocytosis and chemotaxis are impaired. [13] Cellular enzymes and receptors dependent on lysosomes for function or activation are also affected, thus altering the cell's responsiveness to mitogenic stimuli. [12] Decreases in the T cell release of interleukin (IL)-1, IL-6, tumor necrosis factor (TNF), and interferon-? have been observed. [14] The fact that IL-1, IL-6, and TNF play a role in the hepatic production of acute phase reactants may contribute to their anti-inflammatory properties. [15] Inhibition of calcium signaling within the T cell may be involved. [16] Low concentrations of CQ and QE inhibit the pro-IL-6 stimulatory effect of cytosine-phosphorothiolated guanine (CpG)-oligodeoxynucleotides on human peripheral blood mononuclear cells. [17] CQ has also been implicated in the inhibition of natural killer (NK) cell activity, decreased production of IL-2 by activated lymphocytes, and alteration of antigen-antibody complexes. QE also inhibits NK cells and blocks the primary proliferative response of cytotoxic T cells to non-T cell antigens. [15] Lastly, the arachidonic acid pathway is affected by antimalarial compounds. CQ inhibits phospholipases A_2 and C, [15] and QE also inhibits phospholipase A_2. Thus, important mediators of inflammation such as prostaglandins, leukotrienes, bradykinin, and histamine can all be decreased by antimalarial therapy.

Interaction with Cellular DNA

Both QE and CQ bind cellular DNA by intercalation between base pairs, thus stabilizing the DNA. [18], [19] Gene transcription and subsequent translation are inhibited.

Other Effects

Antimalarial compounds exhibit many effects. HCQ improves lipid profiles. Both CQ and HCQ improve glucose profiles and inhibit platelet aggregation. High doses of CQ may produce an antioxidant effect. Through membrane stabilization, antimalarials can produce a local anesthetic effect. In vitro, HCQ induces apoptosis in B-chronic lymphocytic leukemia cells. CQ, HCQ, and QE all interfere with HIV-1 replication and function.

INDICATIONS FOR USE OF ANTIMALARIAL DRUGS

The FDA-approved indications for the use of CQ, HCQ, and QE are limited. Nonetheless, antimalarial drugs have been used to treat a myriad of dermatologic and nondermatologic conditions (Table 255-2). The treatment of malaria is the only indication shared by all three drugs. CQ is approved for the treatment of extraintestinal amebiasis, and QE is approved for the treatment of giardiasis. HCQ, the drug most extensively studied, is indicated for rheumatoid arthritis, discoid lupus and other forms of cutaneous lupus erythematosus, and systemic lupus erythematosus. It has also been found efficacious in a long list of dermatologic conditions. CQ has been used to treat many of these diseases, although not to the same extent. The current difficulty in obtaining QE may account for the relatively fewer indications. The following sections discuss the more accepted uses of these drugs in dermatology.

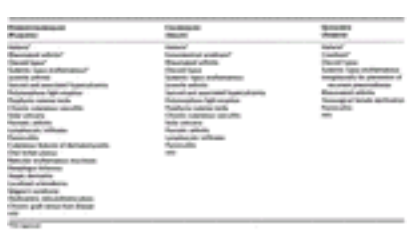

TABLE 255-2 **Medical and Dermatologic Uses of Antimalarial Agents**

Lupus Erythematosus (See also Chap. 171)

Antimalarial drugs have been used for the cutaneous manifestations of lupus for more than a century. During World War II, CQ and QE were also found to be effective as well. [3] Ninety to 95 percent of patients receiving HCQ are thought to benefit. [20] A double-blind trial of HCQ for chronic discoid lupus showed a 70 percent response rate. [21] QE has a 73 percent response rate in 20 clinical trials in patients with LE. [22] Each of the antimalarials is effective as a glucocorticoid-sparing agent in the treatment of LE. [23] Typically, these drugs are used to treat patients whose symptoms cannot be controlled by topical glucocorticoids and sun protection. Widespread cutaneous lesions, hypertrophic and verrucous lesions, and long-standing discoid lesions do not respond as well. Antimalarials are not effective for systemic symptoms of fever or renal and hematologic abnormalities in systemic SLE. The onset of action for antimalarial therapy is 4 to 8 weeks. More rapid response has been achieved with QE. [22] Anecdotal reports suggest that when HCQ is ineffective as a monotherapy, CQ may be efficacious. The use of QE alone or in combination with either HCQ or CQ has also been suggested as eliciting a response in patients with recalcitrant disease. Triquin, a combination of all three drugs, had been used for discoid lupus and cutaneous LE. Although the manufacturers have discontinued making the drug, it can be compounded.

Porphyria Cutanea Tarda (See also Chap. 149)

The first reported case of porphyria cutanea tarda treated with CQ was published in 1957. [24] Since then, mechanisms of action have been suggested, side effects described, and treatment regimens identified. Phlebotomy remains the principal treatment for porphyria cutanea tarda after exacerbating factors are identified and removed. Antimalarial therapy is used with phlebotomy as an adjuvant therapy or when phlebotomy is not possible. CQ inhibits porphyrin synthesis and mobilizes lysosomal stores of porphyrins, allowing for the formation of water-soluble complexes that are then excreted by the kidney. [25] Headache, nausea, fever, elevated transaminase levels, and urinary excretion of porphyrins occur 3 to 4 days after the initiation of therapy with CQ at 250 mg/day. [26] Multiple treatment regimens have been found effective. High doses of HCQ (250 mg tid) for short courses induce a prolonged remission. Marked increases in liver transaminase levels require hospitalization during the initiation of therapy. Low-dose CQ therapy, consisting of 125 mg twice a week for 2 weeks followed by 250 mg twice a week thereafter has been proposed. Alternatively, HCQ, at 100 mg three times a week for a month, then 200 mg three times a week for a month, then advanced to 200 mg daily can be used. These lower dosing schedules appear to alleviate the severe hepatotoxicity. Finally, phlebotomy prior to the initiation of CQ therapy may also reduce the severity of hepatotoxicity. [27] Laboratory monitoring of liver function is recommended during therapy.

Polymorphous Light Eruption (See also Chap. 136)

Polymorphous light eruption is an inflammatory reaction in sun-exposed areas of the skin. IL-1, -6, and -8 may play a role in the inflammatory process. [28] CQ decreases IL-1 and IL-6 production. Additionally, it absorbs UVB light. CQ has been used to treat this reaction for a number years, [11] and placebo-controlled trials have proven its efficacy. [29] HCQ at doses of 200 to 400 mg/day is effective. Topical sunscreens should be used in conjunction with antimalarial therapy. In northern climates, discontinuation of therapy during the winter months may decrease the cumulative side effects of antimalarial therapy.

Sarcoidosis (See also Chap. 183)

Antimalarial therapy for cutaneous manifestations of sarcoidosis was first described nearly 50 years ago. A review concluded that antimalarials were highly effective, with a greater than 70 percent response rate. Two to 3 mg/kg per day of HCQ was reported as being effective in 12 of 17 patients treated. CQ therapy initiated at a dose of 500 mg/day for 2 weeks, then lowered to a maintenance dose of 250 mg/day, has been described as safe and effective. [30] Therapy may also be effective for associated hypercalcemia.

SPECIAL CONSIDERATIONS

CQ and HCQ have been used to treat children. However, reports of fatal toxicity suggested that antimalarial drugs were contraindicated in the pediatric population. [31] It was later determined that, milligram per kilogram, antimalarials are generally safe in the treatment of children with connective tissue diseases, juvenile rheumatoid arthritis, morphea, panniculitis, and porphyria cutanea tarda. [32] The risk for toxicity in children is felt to be no greater than in adults.

The use of antimalarial drugs in pregnancy is controversial, but is now generally accepted as safe. The 4-aminoquinolines cross the placenta and accumulate in fetal tissues. [4], [5] Congenital defects are rarely reported in newborn children of women with malaria who were taking antimalarial drugs. [33] However, the extended half-life of these drugs does suggest significant fetal exposure, even if the drug is discontinued once pregnancy is detected. One study of 24 women exposed to CQ or HCQ during 27 pregnancies uncovered no congenital anomalies. [34] Another retrospective review of 33 women with lupus exposed to HCQ during 36 pregnancies reported no evidence of teratogenic effects. [35] Larger reviews of the British and North American experiences with antimalarial drugs also support the use of 4-aminoquinolines during pregnancy. [36], [37] Conversely, discontinuation of antimalarial therapy for the treatment of lupus may cause a significant flare, which can be associated with prematurity, growth retardation, and increased fetal loss. The safety of QE is less well documented.

The use of antimalarials during breast-feeding is relatively contraindicated. CQ and HCQ are both excreted in breast milk. [38] Infants are exposed to 2 percent of the maternal dose of HCQ per kilogram per day and 1 percent of the maternal dose of CQ. [7] As the half-life is long and elimination is slow, the potential exists for the accumulation of drug in the infant.

SIDE EFFECTS AND DRUG INTERACTIONS

Antimalarial drugs are safe and effective when used responsibly. Without proper monitoring, however, they have the potential for serious side effects, most of which are reversible with decreased doses or drug withdrawal. Retinopathy is the most severe side effect and may be permanent even after therapy is discontinued (Table 255-3).

Organ System	Toxic Reaction
Gastrointestinal	Anorexia, nausea, vomiting, diarrhea, weight loss, hepatotoxicity
Hematologic	Hemolytic anemia (G6PD deficiency), aplastic anemia, agranulocytosis, pancytopenia
Mucocutaneous	Pigmentation-blue gray, yellow (QE), rashes (urticaria, morbilliform, lichenoid, exfoliative dermatitis, AGEP) pruritus, worsening psoriasis
Ophthalmologic	Neuromuscular eye toxicity (diplopia, blurred vision, loss of accommodation), corneal deposits (halos around lights, photophobia), retinopathy (premaculopathy-reversible and true retinopathy-irreversible; not seen with QE therapy)
Neuromuscular	Nightmares, vertigo, tinnitus, nervousness, irritability, toxic psychosis, seizures, neuromyotoxicity, myasthenia-like syndrome, ototoxicity
High doses	Cardiovascular toxicities, hypotension, neurotoxicity, respiratory or cardiac arrest, death

NOTE: AGEP, acute generalized exanthematous pustulosis; G6PD, glucose-6-phosphate dehydrogenase.

TABLE 255-3 **Possible Side Effects from Antimalarial Compounds**

At therapeutic doses gastrointestinal complaints of anorexia, nausea, vomiting, diarrhea, and weight loss are most commonly encountered (10 percent for HCQ; 20 percent for CQ; 30 percent for QE). [39] Nightmares are also reported. Acute symptoms from high doses of CQ and HCQ include blurred vision, cardiovascular toxicities, hypotension, neurotoxicity, and respiratory or cardiac arrest. [4], [5] As little as 0.75 g in children and 2.25 to 3.0 g in adults of CQ can be fatal, with a direct action on the myocardium as the cause of death. Lethal doses of HCQ are considered to be in the similar range. [4], [5] Management of overdose consists of gastric lavage, ventilation, and inotropic support. [4], [5] A lethal dose of QE has not been determined.

Hematologic effects can be seen with antimalarial therapy. Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiencies are susceptible to CQ- and HCQ-induced hemolytic anemia, although rarely when the drugs are used in therapeutic ranges. Aplastic anemia, agranulocytosis, neutropenia, and thrombocytopenia are rare, potentially fatal, adverse reactions. [4], [5]

Cutaneous adverse effects occur with antimalarial therapy, including the exacerbation of preexisting psoriasis. It is estimated that up to 18 percent of patients with psoriasis develop an exacerbation of their disease while on antimalarial therapy. [40] One review of the literature suggested that CQ was responsible for most psoriatic flare-ups, QE was more likely to induce exfoliative erythroderma, and HCQ was much less likely to exacerbate psoriasis. [41] These same authors concluded that the use of antimalarial drugs in patients with psoriasis was associated with a 31 percent risk of severe cutaneous reaction. In the general population, the incidence of pruritus and rashes secondary to antimalarial use is reported to be 10 to 20 percent, [42] although this rate may be an overestimate. Dose-related QE-induced drug eruptions were reported during World War II. One in 2000 soldiers taking QE, 100 mg qd, reported a reaction, whereas 1 in 600 soldiers taking 200 mg qd had a cutaneous reaction. Lichenoid reactions accounted for approximately 20 percent of the reactions in this series. CQ has an affinity for melanin and thus concentrates in the skin. The binding of drug molecules to melanin may cause a blue-black discoloration of the skin in 10 to 25 percent of patients treated with these compounds

for a prolonged course. The shins, face, hard palate, and nail beds are commonly affected. [43] The discoloration may fade slowly over months after the drug is discontinued. QE also binds melanin and may cause hyperpigmentation similar to that seen with CQ. More commonly, a dose-related yellowish staining occurs and affects the skin, sclera, and bodily secretions. This discoloration also tends to fade over time after drug withdrawal.

Ocular toxicity is the most worrisome side effect of antimalarial therapy. Neuromuscular eye toxicity, corneal deposits, and potentially irreversible retinopathy can all occur. During the initial weeks of therapy blurred vision and reduction in accommodation power can occur from the depressive effect on ocular muscles; this effect is transient and typically self-limited. CQ is deposited in the basal epithelium of the cornea. Deposition of HCQ can also occur, but is less likely at therapeutic doses. [44] These depositions can be responsible for patient complaints of blurred vision, halos around lights, and photophobia. [45] The corneal deposits are dose related, reversible with cessation of therapy, and not a contraindication for continued therapy. CQ has an affinity for retinal pigment epithelium and can be stored there for years, even after discontinuation of therapy. Retinopathy induced by antimalarial therapy can be reversible (premaculopathy) or irreversible (true retinopathy). Premaculopathy includes changes of visual fields or funduscopic exam not associated with visual loss, but with potential to progress to irreversible disease if the offending drug is not discontinued. True retinopathy is associated with bilateral, permanent visual field abnormalities. The risk of true retinopathy from antimalarial therapy has been studied and debated, but it is generally accepted that the risk of retinopathy is greater for CQ than HCQ. [44] Doses considered to be safe for preventing retinopathy are less than 4.0 mg/kg per day for CQ and less than 6.5 mg/kg per day for HCQ. [46] Higher doses and impaired renal function may contribute to the risk of retinopathy. As HCQ-induced retinopathy is felt to be quite rare, screening as a cost-effective measure is questioned. Current American guidelines include a baseline slit lamp, funduscopic, visual field, and acuity examination by an ophthalmologist every 6 months for a year, and then yearly. The patient should also self-administer the Amsler grid test each month and report changes. [47] More recent Canadian and British guidelines are less stringent. [48], [49] QE does not appear to cause retinal toxicity. Other less likely side effects of antimalarial therapy include neuromyotoxicity [50] and myasthenia-like syndrome, [51] ototoxicity, [52] and acute generalized exanthematous pustulosis (AGEP). [53]

Drug interactions with antimalarial agents are few. Penicillamine or digoxin levels may be increased with concurrent use of CQ or HCQ. [4], [5] Cyclosporine levels may be increased by CQ, [4] and metoprolol levels by HCQ. [54] CQ may reduce the bioavailability of ampicillin. [4] Antacids and kaolin may decrease the gastrointestinal absorption of CQ, and their administration should be separated by at least 4 h. [4] Cimetidine may increase CQ levels, [4] raising the potential for other side effects. The concurrent use of CQ and mefloquine may increase the risk of seizures. Hepatotoxic drugs taken with CQ increase the risk of hepatotoxicity. [4] Finally, smoking may alter the bioavailability of antimalarial therapy by inducing the cytochrome P450 enzyme system; a report of decreased efficacy of antimalarial therapy in smokers has been published. [55]

In conclusion, antimalarial drugs are useful therapeutic anti-inflammatory agents that are well established in the dermatologic armamentarium. Although these drugs are typically well tolerated, the risk of ocular toxicity and irreversible retinopathy warrant judicious monitoring and use. For many dermatologic conditions, the benefits of therapy significantly outweigh the risks.

Cytotoxic and Antimetabolic Agents

ANTIMETABOLIC AGENTS

Methotrexate

Thiopurines

ALKYLATING AGENTS

Cyclophosphamide

Chlorambucil

Anthracyclines

REFERENCES

Cytotoxic and antimetabolic agents can often control skin disease that is otherwise refractory to topical therapy. Discussion in this chapter focuses on the agents clinically relevant to practicing dermatologists. Most of the drugs discussed in this chapter are used by dermatologists at immunomodulatory rather than cytotoxic doses. Despite widespread use of these drugs to treat dermatologic disease, none of the drugs discussed here, except methotrexate, is approved by the FDA for the treatment of inflammatory dermatoses.

Systemic cytotoxic and antimetabolic drugs can be used to modulate the behavior of inflammatory cells. These agents exert their effects primarily through the inhibition of cell proliferation. Depending on the dose, their action can range from modulation of cellular activity to induction of apoptosis or cell death. An understanding of the mechanisms of action, toxicities, and clinical effects of these drugs is essential for optimal use.

The cell cycle is the sequence of growth phases on which all cells of the body depend. The cycle begins with the G_1 phase, in which cell metabolism is directed toward preparing for DNA synthesis. The S phase, which follows G_1, is devoted to DNA synthesis. At the end of DNA synthesis, the G_2 phase occurs. The G_2 phase is followed by the M phase, cell division. Cells may also enter a resting state of variable length, termed G_0, from either the G_1 or the G_2 phase (Fig. 256-1; see Chap. 7). Cytotoxic drugs are effective at specific stages of the cell cycle (e.g., methotrexate in the S phase).

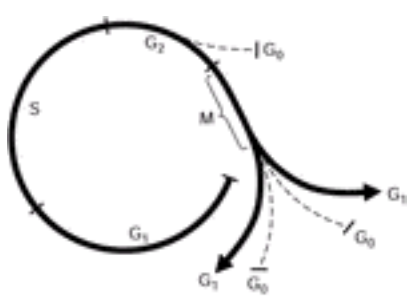

FIGURE 256-1 Diagram of the cell cycle.

Most systemic cytotoxic drugs that are useful in dermatology fall into two broad groups, the antimetabolites and the alkylating agents. Antimetabolites mimic natural molecules and are most active while DNA is being synthesized in the S phase. [1] These drugs require a target cell population that is proliferating in order to exert their effect. A corollary of this principle is that side effects of this class of drugs are most prominent in cells of the body that have an innately high proliferative index, such as visceral epithelium and bone marrow. Alkylating agents exert their effects through an actual physicochemical interaction with preformed DNA molecules. [1] These interactions include alkylation, cross-linking, and carbamylation. Alkylating agents affect not only proliferating populations of cells but also cells that are not actively synthesizing DNA. Their adverse effects are not limited to proliferating cell populations, and they have a greater potential for mutagenicity.

The immunosuppressive potency of cytotoxic drugs has benefits and risks. Dramatic clinical improvement is a major benefit, but infections of lethal proportion may arise quickly and quietly in immunosuppressed patients. Patients should be assessed at each visit for symptoms of infection, including fever, chills, sweats, shortness of breath, cough, headache, dysuria, and arthritis; and they should be instructed to report any new symptoms promptly.

ANTIMETABOLIC AGENTS

Methotrexate

Aminopterin, a folate antagonist, was introduced in 1948. It was followed by methotrexate (amethopterin), which remains one of the most commonly used antimetabolic agents. [2] Methotrexate was initially used to treat hematologic malignancies and various epithelial-derived tumors, but it has been used subsequently to treat nonmalignant diseases, including rheumatoid arthritis, asthma, graft-versus-host disease, and cutaneous conditions such as psoriasis, cutaneous T cell lymphoma, and cutaneous sarcoidosis. Dermatologists have used this drug since the early 1960s and have generated an

impressive record of safety with careful monitoring. Despite this safety record, some dermatologists are reluctant to initiate methotrexate therapy. Many concerns can be alleviated through drug awareness, careful patient selection, laboratory monitoring, and the use of folic acid supplementation.

PHARMACOLOGY Methotrexate is a synthetic analogue of folic acid that differs structurally from folate in two regions (Fig. 256-2). The folate vitamins function as 1-carbon carriers and are essential for the synthesis of purines and thymidylic acid, which are required for the production of RNA and DNA, as well as for gene synthesis and cell division (Fig. 256-3). Of the two forms of folate, the polyglutamated form is preferentially retained within cells and is a more efficient cofactor than the monoglutamated form. To be active, these folate cofactors must be reduced to tetrahydrofolate by the enzyme dihydrofolate reductase (DHFR). Methotrexate is a competitive inhibitor of DHFR.

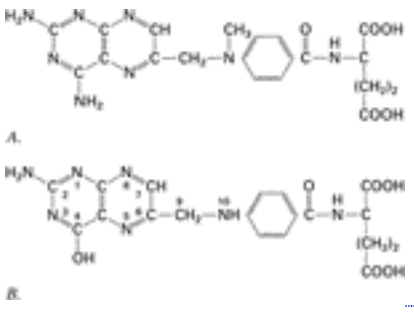

FIGURE 256-2 Chemical structure of methotrexate and folic acid. *A.* Methotrexate. *B.* Folic acid.

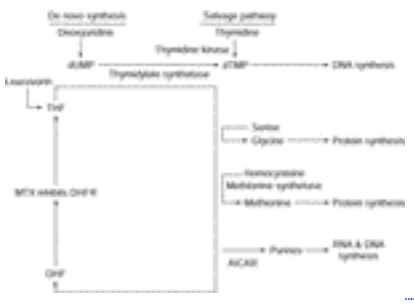

FIGURE 256-3 Contribution of folate to pathways for DNA synthesis. AICAR, 5-aminoimidazole-4-carboxamide ribonucleotide transformylase; DHF, dihydrofolate; DHFR, dihydrofolate reductase; dTMP, deoxythymidine-5-monophosphate; dUMP, deoxyuridine-5-monophosphate; MTX, methotrexate; THF, tetrahydrofolate. (*Modified from Said et al.,* [5] *used by permission of Elsevier Science Inc.*)

Oral methotrexate is variably absorbed at higher dose concentrations, and its absorption is influenced by food and milk in children, but not in adults. [3], [4] In adults, mean bioavailability is 67 percent of the administered dose with plasma peaks between 1 and 3 h after the administration of 10 mg/m ^{2}. Divided oral doses of methotrexate (for example, three 5-mg doses separated by 12 h) result in blood levels ranging from 0.17 to 0.5 µg/mL. For doses higher than 25 mg per week, intramuscular administration may be preferable because of erratic oral absorption above this level. [5] Methotrexate blood levels peak approximately 1 to 1.5 h after absorption, and there is low central nervous system penetration. [5] The mean half-life of the drug is approximately 4 to 5 h. [5] The weak organic acid property of methotrexate contributes to its renal elimination; it is excreted 60 to 95 percent unchanged. [6], [7] A decrease in glomerular filtration or tubular secretion can rapidly lead to toxic levels of methotrexate. Various weak organic acids, including aspirin, other nonsteroidal agents, and probenecid, interfere with methotrexate excretion caused by displacement from serum proteins and changes in renal function. Decreased excretion leads to increased drug concentration and increased cytotoxic properties such as leukopenia. Therefore, it is important to follow markers of renal function as toxicity can develop quickly. Biliary excretion accounts for less than 10 percent of methotrexate elimination. [6] Liver metabolism largely contributes to polyglutamated forms of methotrexate that remain in the body longer and may contribute to overall toxicity.
MECHANISM OF ACTION Methotrexate binds to dihydrofolate reductase and competitively and irreversibly inactivates the enzyme. Methotrexate also partially inhibits thymidylate synthetase. [7] Inhibiting these enzymes decreases the available reduced folate and thymidylate necessary for RNA and DNA synthesis during the S phase of the cell cycle (Table 256-1).

Folate antagonisms/decreased cell proliferation
Suppression of inflammatory cell chemotaxis
Inhibition of monocyte/macrophage activation
Inhibition of histamine release from basophils (and mast cells?)
Inhibition of lymphocyte function

TABLE 256-1 **Potential Mechanisms of Methotrexate Activity in Skin Disease**

In psoriasis, the efficacy of methotrexate was initially related to its effect on epidermal cell proliferation. However, in vitro studies demonstrating that methotrexate has a more significant effect on cells of lymphoid origin [8] followed the findings that psoriasis is a T cell–mediated immunologic disease. The activity of methotrexate is enhanced by polyglutamylation, as is the activity of the natural substrate folic acid. These polyglutamated derivatives form rapidly within cells, increase with the concentration of the drug and the duration of exposure, and bind more tightly to dihydrofolate reductase than does unaltered methotrexate. Glutamylation also broadens the spectrum of enzyme inhibition, shown by studies suggesting that methotrexate has other anti-inflammatory properties. [9] First, by inhibiting aminoimidazole carboxamide ribonucleoside (AICAR) transformylase, methotrexate-polyglutamate increases the local tissue concentration of adenosine, which has potent anti-inflammatory properties. Inflammatory exudates from methotrexate-treated mice were found to have higher concentrations of adenosine than inflammatory exudates from saline-treated mice. [9] Second, methotrexate decreases the production of S-adenyl methionine (SAM) by decreasing available tetrahydrofolate and thereby inhibiting methionine synthetase. The enzyme methionine synthetase converts homocysteine to methionine, which is later converted to SAM. The decreased SAM results in decreased inflammation. [9] Consequently, methotrexate produces a greater anti-inflammatory effect than was previously understood. This fact is an important consideration in the design of treatment regimens, adjustment of dosages, and minimization of adverse effects.

CLINICAL USES The largest and most widely accepted dermatologic use for methotrexate in nonneoplastic disease is in the treatment of psoriasis. In 1987, Peckham and colleagues [10] reported that more than half of the dermatologists in the United States use methotrexate to treat severe psoriasis. Methotrexate was second only to ultraviolet (UV) radiation as a treatment modality for severe disease. The use of methotrexate dates from 1951, when it was reported that a patient's psoriasis unexpectedly cleared during treatment with the drug. [2] The 12-h dosing regimen used today was originally based on the cell cycle kinetics of the psoriatic keratinocyte, which runs 36 h versus 311 h in the normal keratinocyte. [11] Although dosing variations of methotrexate were based on response of disease, tolerability of side effects may better explain the use of the divided-dose regimen. [5] Current use of methotrexate to treat psoriasis is most common in patients with severe or refractory plaque-type disease that requires systemic treatment. It is also very useful for erythrodermic and pustular psoriasis, as well as psoriatic arthritis. [12] Other diseases for which methotrexate is beneficial include pityriasis lichenoides et varioliformis acuta, lymphomatoid papulosis, pityriasis rubra pilaris, granulomatous vasculitis, rheumatoid vasculitis, polymyositis, pemphigus vulgaris, lupus erythematosus, pyoderma gangrenosum, Reiter's syndrome, and sarcoidosis. [7] In severe steroid-responsive cutaneous diseases, the concomitant use of a cytotoxic agent such as methotrexate may allow reduction of the systemic dose of the glucocorticoid. The dermatologist must use caution when administering methotrexate to patients with diseases known to affect the kidney, liver, bone marrow, and lungs, as toxicity may be potentiated in these patients.

PATIENT SELECTION Excluding inappropriate patients by careful selection is a priority for the dermatologist initiating methotrexate therapy. The ideal patient has severe skin disease but is otherwise healthy and compliant. Methotrexate is relatively contraindicated for patients with histories of renal or hepatic disease; excessive alcohol use or hepatitis; evidence of laboratory abnormalities in renal, hepatic, or hematologic function; and those wishing to conceive children. [13] Geriatric patients are less than optimal because of the decrement in renal function that occurs as part of the aging process. Administration of the drug to pregnant women or nursing mothers is absolutely contraindicated. [13] Conception should be avoided during treatment and afterward for at least 3 months in males and one ovulatory cycle in females. [13] The question of whether HIV+ individuals with psoriasis can be safely treated with methotrexate is still unsettled. Published reports reveal varying rates of opportunistic infection in HIV+ patients treated with a range of doses of methotrexate for psoriasis. [14] Methotrexate in low doses may be tolerated by some HIV+ individuals for whom other psoriasis therapies have failed. Careful laboratory monitoring for HIV status and methotrexate toxicity is mandatory as is avoidance of concomitant medications, such as trimethoprim-sulfamethoxazole, that alter methotrexate metabolism. However, with the theoretical possibility of added immunosuppression by methotrexate in HIV+ patients, the authors recommend that first-line systemic treatment for these patients should be a nonimmunosuppressive agent such as a retinoid (e.g., acitretin). Attention to detail is critical when caring for patients receiving methotrexate. Such attention includes regular follow-up, detailed review of systems at each visit, monitoring of appropriate laboratory parameters (Table 256-2), tracking of cumulative methotrexate dosing, and communication with the patient's general physician when appropriate. Laboratory examinations should be performed 5 to 7 days after each dose to ensure normalization of expected increases in liver transaminases before the administration of the next dose. Optimal patient compliance should be promoted by detailed instructions (Table 256-3).

TABLE 256-2 **Premethotrexate Tests**

1. Follow instructions faithfully.
2. Take methotrexate weekly, not daily.
3. Call your physician immediately if overdose is suspected.
4. Notify your physician if fever, cough, or shortness of breath develops.
5. Tell your physician about all side effects.
6. Inform all of your physicians that you are taking methotrexate.
7. Drink no alcoholic beverages and take no other medications without physician approval.
8. Do not take methotrexate while pregnant or while trying to conceive.
9. Do not take methotrexate if you have an active infection (including but not limited to cold/flu, urinary tract infection, pneumonia) without notifying your physician.
10. Allow no one else to take this medication.

TABLE 256-3 **Instructions for Patients Receiving Methotrexate**

DOSAGE SCHEDULE The effects of methotrexate vary with the dose. Higher doses are more directly cytotoxic. High oncologic doses of methotrexate (for example, 100 to 250 mg/m ^{2} per week) depress the antibody response to common antigens, whereas lower doses suppress rheumatoid factor production. Low immunomodulating doses of methotrexate (for example, 7.5 to 15 mg/week) also suppress the division of mononuclear cells, inhibit the cellular response to interleukin-1, suppress neutrophil and monocyte chemotaxis in vitro and in vivo, and depress Langerhans cell activity and leukotriene B_4 synthesis by neutrophils. [9], [15] Dosages in dermatologic use are usually less than 30 mg per week. Dermatologists most often prescribe methotrexate for oral dosing in one of two regimens: a single dose weekly or a weekly dose divided into three portions, each separated by 12 h. Beginning therapy with the administration of a small test dose is a common practice that is included in the most recent guidelines. [13] Patients deemed to be appropriate candidates on the basis of disease severity, general health, and personal habits, and whose baseline laboratory results are acceptable may be started on a test dose of 5 to 10 mg orally. The patient should return in 1 week for repeat laboratory tests [complete blood count (CBC), plus differential, blood urea nitrogen (BUN)/creatinine (Cr), liver enzymes], a skin examination, and a review of systems. Weekly therapy may be continued at a therapeutic dose of 7.5 to 15 mg per week in a single dose or in divided doses. If a patient does not achieve a sufficient clinical response, the dose can be increased slowly by 2.5 to 5 mg per week until adequate control is achieved. Concomitant topical therapy is usually helpful and can minimize the methotrexate dose needed to provide satisfactory disease control. Patients continue periodic visits until their disease is quiescent and their drug dosage is stable (usually 2 to 3 months). Patients are followed monthly for laboratory safety monitoring and drug effectiveness, unless dose increases require more frequent monitoring. When improvement has stabilized, the dose can be tapered to the point where the disease activity increases slightly. The goal of therapy should allow some mild disease activity to avoid using a dose that is too high. In some

cases, the drug may be discontinued entirely and mild recurrences treated with topical medications. If a patient does not demonstrate acceptable improvement on a dose of 20 to 25 mg per week, consideration should be given to switching to another drug. Occasional patients with refractory disease respond better to parenteral methotrexate, usually intramuscular. In refractory cases, combining methotrexate with UVB phototherapy can enhance therapeutic efficacy without significantly increasing toxicity.

ADVERSE EFFECTS There is a large collected experience in the rheumatologic and dermatologic literature regarding the toxicity of low-dose methotrexate. [13], [16] Adverse reactions (Table 256-4) may be life-threatening or trivial. Several principles regarding the side effects of methotrexate are generally applicable. First, as with many drugs, higher doses cause more side effects. Second, patients who experience side effects early in therapy will probably continue to do so, whereas patients who are free of early complaints may be more likely to remain so during long-term treatment. Third, sicker, older, or more debilitated patients seem to experience more problems than do patients who are in good health. Finally, the use of divided drug dosing is often helpful in reducing side effects (e.g., nausea), likely a result of decreased peak levels. Toxicity can develop with either the single- or the three-dose regimens.

Gastrointestinal: nausea, vomiting, stomatitis, diarrhea, ulceration
Hepatic: abnormal transaminase levels, hepatitis, fibrosis, cirrhosis
Hematopoietic: anemia, thrombocytopenia, leukopenia, pancytopenia
Pulmonary: acute hypersensitivity, fibrosis
Systemic: anaphylaxis

TABLE 256-4 **Adverse Reactions to Methotrexate**

The most common complaints of patients being treated with methotrexate involve the gastrointestinal tract, particularly nausea and vomiting, and these are largely dose related. [13], [16] These side effects can also occur with intramuscular injection. Indeed, 10 to 30 percent of all patients experience some difficulty taking methotrexate. Because some patients experience symptoms before a dose, or even 24 to 36 h after a dose, it has been suggested that these symptoms may have a psychological or centrally active basis. [17], [18] Mucocutaneous complaints are not uncommon. Oral ulcerations and soreness are most often noted. Skin ulcerations are much less frequent and may herald bone marrow toxicity. The authors recommend laboratory evaluations (e.g., CBC, BUN/Cr, liver enzymes) and dosage reduction or discontinuation with mucocutaneous ulcerations. A major limitation of methotrexate therapy is the induction of liver fibrosis. [6], [16], [19], [20] and [21] Methotrexate is a hepatotoxic drug, and elevations in liver enzymes commonly occur in patients taking the drug. Although disquieting, these elevations are of limited value in predicting which patients will develop cirrhosis. For unknown reasons, patients with psoriasis seem to have a higher incidence of liver fibrosis than do patients with rheumatoid arthritis who are treated with similar methotrexate regimens. [13] Fibrosis relates to the duration of therapy, total dose, patient age, and comorbid risk factors. Between 0 and 26 percent of patients receiving methotrexate have demonstrated cirrhotic changes on liver biopsy. [6] A somewhat larger number may show fatty infiltration and a clinically less significant or insignificant fibrosis. [6] The course of methotrexate-induced liver disease is thought to be relatively nonaggressive and, depending on the normalization of liver enzyme levels in the blood, can be continued in some patients. [20] Low-risk patients receiving total doses of less than 1.5 g have a negligible incidence of fibrosis. [6] Patients with prior liver disease, diabetes, obesity, significant alcohol intake, and intravenous drug use are all at increased risk for hepatic fibrosis and cirrhosis. [6] The only acceptable method for verifying methotrexate-induced cirrhosis is percutaneous needle biopsy of the liver. [19] This procedure is usually safe, especially when ultrasound guided. The approximate risk of minor bleeding is 1 in 1000, and the risk of death is estimated as 1 in 10,000. [22] Biopsy results are classified according to liver architecture, degree of inflammation and fibrosis, and the presence of fat, and are graded on a scale of I to IV (Table 256-5). Roenigk and colleagues [13] recommend that patients with grades I and II histology may continue methotrexate therapy, those with grade IIIA histology may continue therapy with a repeat liver biopsy in 6 months, and those with grades IIIB and IV histology should discontinue therapy. According to a study published by Newman and colleagues, [23] 8 of 11 patients with fibrosis or cirrhosis secondary to methotrexate therapy showed meaningful improvement in liver histologic findings after methotrexate treatment had been discontinued for 6 months or more; none had progression of abnormalities.

Grade I	Normal to mild fatty infiltration, portal inflammation, and nuclear variability
Grade II	Moderate to severe fatty infiltration, nuclear variability, portal tract expansion and inflammation, and necrosis
Grade IIIA	Mild fibrosis
Grade IIIB	Moderate to severe fibrosis
Grade IV	Cirrhosis

TABLE 256-5 **Liver Histology Grading Scale**

Perhaps the most important acute adverse effect of methotrexate is the induction of bone marrow suppression. [24], [25] Marrow cells are rapidly proliferating, and they are particularly susceptible to methotrexate. Severe bone marrow suppression caused by low-dose oral methotrexate has been reported. [24] Anemia, neutropenia, and thrombocytopenia, with sepsis and severe bleeding disorders can result. Factors that appear to put patients at increased risk for marrow toxicity include advanced age, low creatinine clearance, and concurrent administration of certain drugs (see " Drug Interactions"). Methotrexate can cause mutations in laboratory animals. However, there has been no associated increase in cancer in patients treated with dermatologic doses of methotrexate. [26], [27] and [28] There was a report of Epstein-Barr virus-associated lymphoma in a patient with psoriasis treated with methotrexate. [29] Because methotrexate is teratogenic and may act as an abortifacient, administration during pregnancy is absolutely contraindicated. [13] There is no apparent effect on the outcome of pregnancies that occur after the discontinuation of methotrexate therapy. [5] There are no reports of abnormal children fathered by men receiving methotrexate therapy, although sperm motility may be abnormal during treatment. [30] However, men treated with methotrexate should wait 3 months after therapy is stopped before attempting conception, and women treated with methotrexate should wait one full menstrual cycle. [13] Pulmonary toxicity (acute pneumonitis and subtle pulmonary fibrosis) has been reported in patients receiving methotrexate therapy for psoriasis. [31] It does not appear to be directly associated with any one risk factor and may be an idiosyncratic reaction. Normal chest radiographs should still be followed up with pulmonary function tests in patients with pulmonary complaints during therapy. Pulmonary toxicity may be related to high-dose regimens more than to cumulative exposure. Withdrawal of therapy is recommended for these patients. [31] Opportunistic infections (pneumocystis pneumonia, cryptococcosis, and histoplasmosis) have been reported in otherwise healthy individuals who are receiving low-dose methotrexate. However,

these patients were often taking a concomitant immunosuppressive medication (e.g., prednisone). [14]

OVERDOSAGE Overdosage is a dangerous side effect that can present in patients with decreased renal function, daily ingestion of methotrexate, or concomitant use of another folate antagonist such as trimethoprim-sulfamethoxazole. Overdosage with methotrexate should be treated promptly with leucovorin (folinic acid). [13] Leucovorin is metabolized in vivo directly to tetrahydrofolate in the absence of dihydrofolate reductase and acts as an antidote to methotrexate overdose by providing a continued supply of thymidine until the methotrexate is cleared from the body. Thymidine is converted to thymidylate by thymidine kinase and thus bypasses the enzyme thymidylate synthetase. This provides the necessary precursors for the synthesis of RNA and DNA. The optimal timing of leucovorin rescue for low-dose methotrexate therapy is critical. [32] An initial dose of 10 mg of folinic acid per square meter (about 20 mg) should be given immediately, either orally or parenterally. An initial oral dose of leucovorin is more beneficial than waiting for intravenous administration. The blood level of methotrexate should be determined every 12 to 24 h, and repeat doses of leucovorin should be given every 6 h on the basis of drug level (Table 256-6). If creatinine clearance decreases by 50 percent, then 100 mg/m ^{2} should be given every 3 h. Leucovorin administration should continue until the level of serum methotrexate falls below 10 $^{-8}$ M. [13]

Serum Methotrexate Level	Leucovorin Dosage*
0.5×10^{-8} M	20 mg q6h
0.1×10^{-7} M	100 mg q6h
0.2×10^{-7} M	200 mg q6h

*Increase proportionately for higher methotrexate levels.

TABLE 256-6 **Potential Drug Interactions with Methotrexate**

Cases of systemic anaphylaxis caused by low-dose methotrexate have been reported, but anaphylaxis usually occurs in patients on high doses. [33] Many of these patients had previously received uneventful methotrexate treatments at comparable doses.

DRUG INTERACTIONS There are three major groups of drug interactions: the first results from alterations in protein binding, the second from altered renal excretion, and the third from hepatotoxicity. [34] Although any drug that may enhance methotrexate toxicity should be avoided, there are several near-absolute contraindications (Table 256-7).

Mechanism	Drugs
Decreased renal elimination of methotrexate	Nephrotoxins (e.g., aminoglycosides, cyclosporine)
	Many nonsteroidal anti-inflammatory agents
	Sulfonamides*
	Probenecid
	Salicylates
	Penicillins
	Colchicine
	Cisplatin and all renal-toxic drugs*
Additive or synergistic toxicity	Trimethoprim-sulfamethoxazole*
	Ethanol
	Pyrimethamine
Displacement of methotrexate from protein binding	Salicylates
	Probenecid
	Barbiturates
	Phenytoin
	Retinoids
	Sulfonamides*
	Sulfonylureas
	Tetracyclines
Intracellular accumulation of methotrexate	Thyroid hormones
Hepatotoxicity	Retinoids
	Ethanol*
Other	Allopurinol

*Other absolute contraindications.

TABLE 256-7 **Leucovorin Treatment of Methotrexate Overdosage**

EVIDENCE-BASED MEDICINE Two questions continue to arise about methotrexate use. First, when should liver biopsies be performed? Second, should folic acid supplementation be given routinely to patients on methotrexate? Roenigk and associates, [13] in a consensus conference, recommend that a liver biopsy be performed after administration of the first 1 to 1.5 g of methotrexate in patients with no risk factors, and at or near the beginning of treatment in patients with risk factors. Waiting 2 to 4 months after initiating therapy may decrease the need for liver biopsy in patients who may not require or tolerate long-term therapy. It is recommended that once patients reach 1.5 g of methotrexate, a liver biopsy should be performed with a repeat biopsy at 3 g, and then every 1 to 1.5 g thereafter. Because normal liver function tests and routine ultrasound may not indicate the presence of liver changes, Zachariae [35] proposes the use of newer techniques to identify those patients who would benefit from liver biopsy to identify hepatotoxicity. One method is radioimmunoassay of the amino-terminal propeptide of type III procollagen (PIIINP). PIIINP is produced by the liver during fibrogenesis, but it is also found in other tissues and is increased in patients with psoriatic arthritis. The proposed use is for serial testing at 3-month intervals to detect active fibrogenesis. Another method is dynamic hepatic scintigraphy (DHS), which monitors the portal contribution of blood flow to the liver. Combining these tests with patient history and appropriate laboratory monitoring may lead eventually to a decreased number of liver biopsies. [35] However, these tests are not currently accepted as substitutes for liver biopsy. Folic acid supplementation in patients on methotrexate has received much attention recently, mostly as it relates to use in patients with rheumatoid arthritis. Folic acid enters cells by active transport, without competing with methotrexate, but methotrexate does compete with folinic acid. [17] Folic acid supplementation from 1 mg per day up to a weekly ratio of 3:1 to methotrexate reduced side effects such as nausea, vomiting, stomatitis, elevated liver transaminase levels, and mild myelosuppression without reducing efficacy of methotrexate. Although folinic acid appeared to reduce these side effects, it also decreased the efficacy of methotrexate. [17] Side effects such as liver fibrosis, cirrhosis, pneumonitis, and moderate myelosuppression did not seem affected by folate supplementation. However, folic acid supplementation also decreased the associated increase in homocysteine levels found in patients taking methotrexate. [36] Homocysteine is elevated when folate levels are decreased, because folate is needed to convert homocysteine to methionine. Elevated homocysteine levels are independent risk factors for cardiovascular disease. [36] A drawback to folate supplementation is the potential masking of vitamin B_{12} deficiency macrocytosis in red blood cells. Some patients tolerate methotrexate without supplementation. Other patients may benefit from a trial of folic acid supplementation, if side effects result in the consideration of discontinuation of treatment. Clear guidelines for folate supplementation have not been established.

Thiopurines

AZATHIOPRINE The thiopurine drugs are synthetic analogues of the natural purine bases. They were first synthesized in the 1950s, and many derivatives have subsequently been produced. Azathioprine is the derivative most commonly used in dermatology.

Pharmacology Azathioprine was first developed as a prodrug of 6-mercaptopurine with better bioavailability than that of 6-mercaptopurine alone (Fig. 256-4). Azathioprine and 6-mercaptopurine are equally potent when administered

parenterally, but 6-mercaptopurine is much-less effective when given by mouth. Azathioprine absorption after oral administration is fairly complete. [37]

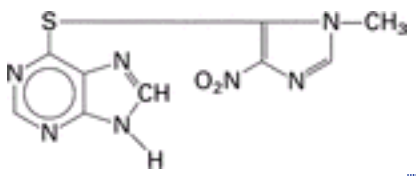

FIGURE 256-4 Chemical structure of azathioprine.

Mechanism of action The clinical activity of all the thiopurine drugs is believed to stem from the inhibition of RNA and DNA synthesis and function. Three specific enzymes are involved in the metabolism of azathioprine: hypoxanthine-guanine phosphoribosyl transferase (HGPRT); xanthine oxidase (XO); and thiopurine methyltransferase (TPMT). [38] Azathioprine is a prodrug that is metabolized to 6-mercaptopurine, which is then converted to active analogues by HGPRT. These monophosphate nucleotide analogues, including 6-thioguanine, block purine synthesis at the initial step. Triphosphorylated 6-mercaptopurine is also incorporated into DNA, rendering the molecule susceptible to strand breaks and point mutations. Patients with Lesch-Nyhan syndrome (HGPRT deficiency) and certain tumor cells that lack HGPRT are resistant to the cytotoxic effects of azathioprine. [39] 6-Mercaptopurine also undergoes oxidations to inactive metabolites by XO. Concomitant administration of allopurinol should be avoided as it may lead to the accumulation of toxic metabolites through the inhibition of XO. Through S-methylation, TPMT is another enzyme involved in the catabolism of 6-mercaptopurine to inactive metabolites. Variations among patients in the activity of TPMT affect the efficacy of drug administration, therapeutic dosage, and amount of toxicity experienced. The TPMT gene is autosomal codominant in inheritance with high activity in approximately 89 percent of individuals, intermediate activity in 11 percent, and low activity in less than 1 percent (1 in 300). [40] TPMT is essential in the metabolism of the active metabolite 6-thioguanine. Thus, genetic polymorphism may contribute to excessive myelosuppression in some patients treated with azathioprine.

Clinical uses The immunopathology of the pemphigus group of diseases makes immunosuppressive drugs a logical therapeutic choice. In 1969, Wolff and Schriener [41] reported the successful treatment of pemphigus with azathioprine. Although the drug may be used as a monotherapy, it is most commonly used as an adjunct to steroid treatment. In a prospective long-term study of patients with pemphigus who were treated with glucocorticoids and azathioprine, 45 percent achieved apparent remission. [42] The starting dose of azathioprine was 2 to 3 mg/kg per day combined with 80 to 200 mg per day of methylprednisolone. The glucocorticoid was maintained for several months, then tapered, and eventually discontinued. The onset of therapeutic effect of azathioprine in pemphigus is delayed by up to several weeks. Other bullous diseases respond to azathioprine. Case reports endorse the use of the drug for steroid-resistant bullous pemphigoid. [43] Treatment regimens are similar to those used for patients with pemphigus. The addition of cytotoxic drugs to glucocorticoid therapy has greatly increased the survival of patients with systemic vasculitis. [44] Cyclophosphamide is the cytotoxic drug of choice for this application because azathioprine seems more able to maintain a remission than to induce one. [44] Azathioprine does not appear to induce gonadal dysfunction, and therefore it is sometimes used in patients who wish to conceive after treatment for their disease. Other inflammatory diseases that have been targets for azathioprine therapy include lupus erythematosus, [45] polymyositis, [46] and various photodermatoses. [47] Because of the differences in azathioprine metabolism among individuals, it may be necessary for researchers and clinicians to consider the genetic polymorphism when evaluating the success or failure of the drug. Any episode of leukopenia in an azathioprine-treated patient may indicate a genetically determined sensitivity to the drug. This occurrence may require a new, lower maintenance dose of azathioprine, or alternatively, the substitution of a different oral agent.

Dosage schedule Azathioprine is supplied as 50-mg tablets and in injectable form. Before therapy begins, baseline blood count, BUN, creatinine, and liver function tests should be performed. Impaired renal function may be associated with greater toxicity even though mercaptopurine metabolites have less activity than the parent drug. During therapy, blood counts and liver function tests should be obtained weekly during the first month, and every 2 or 3 weeks thereafter. Dosage increases require more frequent testing. Azathioprine therapy (1 to 2 mg/kg per day) can be initiated early in the course of disease treatment, usually after the first week or two, if 60 to 80 mg of prednisone has failed to control new blister formation. The addition of azathioprine speeds glucocorticoid tapering without exacerbating the disease.

Adverse effects Azathioprine is generally a safe drug when used with careful monitoring. A comparison of adverse reactions in patients with rheumatoid arthritis treated with methotrexate and those treated with azathioprine failed to reveal significant differences. [48] Adverse effects tend to occur in patients with lower TPMT activity, higher doses of azathioprine, or concomitant use of allopurinol (Table 256-8).

Myelosuppression
Infection
Drug fever
Gastrointestinal
Nausea, vomiting, diarrhea
Hepatitis
Pancreatitis
Induction of malignancy
Shock

TABLE 256-8 **Adverse Reactions to Azathioprine**

Myelosuppression is the major toxic side effect of azathioprine administration. A generalized depression of leukocytes is the most common type of myelosuppression, but any cell line may be exclusively suppressed. Because platelets have the shortest life span of all the formed elements, thrombocytopenia is the most common presentation of toxic marrow suppression. Bone marrow suppression usually occurs only at the higher dosage ranges of dermatologic azathioprine therapy and with lower TPMT activity. [49] Most patients treated with this drug also receive large doses of glucocorticoids as part of their treatment regimen, and therefore it is difficult to assess the exact role of azathioprine in predisposing them to infection. [49] Unlike cyclophosphamide-mediated immune suppression, suppression mediated by azathioprine is not proportional to the peripheral leukocyte count. Rather, the actual function of T cell–mediated immunity and B-cell antibody production is decreased. [39] Thus, infection may occur at normal white blood cell levels. Most commonly, patients receiving high doses of azathioprine may experience nausea, vomiting, and diarrhea. [49], [50] The symptoms are usually not severe and may be minimized by using a divided dose or taking the medication with food. Toxic hepatitis developed in about 1 percent of patients with rheumatoid arthritis who received azathioprine. This hepatitis is characterized by

extremely high alkaline phosphatase levels and is usually reversible. Other reported adverse effects include hepatic venoocclusive disease, pancreatitis, and, infrequently, drug fever. [51], [52] and [53] Discontinuation of therapy is indicated. Azathioprine-induced shock and hypersensitivity-like reactions have also been reported in dermatology patients. [54], [55] In most cases of azathioprine-induced shock, the hypotensive collapse occurred within hours of the first dose. The most recent analysis of patients with rheumatoid arthritis suggests that hematologic malignancies, particularly non-Hodgkin's lymphoma, may be promoted by azathioprine. The relative risk is roughly ten- to thirteenfold, or one lymphoma per 1000 patient years of azathioprine treatment. [56] There is an increased incidence of azathioprine-related lymphoma in renal transplant, Sjögren's syndrome, and rheumatoid populations. [50] In general, dermatologic doses are lower than those used to treat patients with renal or rheumatologic disease. Likewise, the duration of therapy for skin disease is usually shorter. It is the opinion of the authors that the risk of lymphoma is probably significantly less in azathioprine-treated patients with dermatologic disease than in transplant patients or patients with arthritis. Skin cancers were increased in transplant patients. The skin cancers were thought to be related to metabolites of azathioprine imidazoles, which sensitize skin to light and thioguanine. [57] Squamous cell skin cancers were noted in three patients receiving long-term azathioprine therapy for dermatologic disorders. [58] Roubenoff and associates [59] reviewed the incidence of azathioprine-associated birth defects. The rate of congenital malformation is only 4.3 percent. The prevalence of neonatal immunosuppression may be significant. There appears to be no adverse effect on fertility. Azathioprine and its active metabolites readily cross the placenta, and newborns frequently have hematologic abnormalities. [49] Some believe that patients who previously received alkylating agents may have a greatly increased risk for subsequent malignancy after thiopurine therapy. The thiopurines should be avoided in these patients when possible.

Drug interactions The major drug interaction is with allopurinol through the inhibition of xanthine oxidase. This allows toxic metabolites to accumulate and leaves TPMT as the only catabolic reaction for azathioprine metabolism.

Evidence-based medicine Providing the proper dose of azathioprine to treat the disease effectively, while minimizing side effects is often difficult. Armstrong and Oellerich [60] note that a polymerase chain reaction test can screen for all eight of the known TPMT mutations. They report that 6-thioguanine levels measured in erythrocytes correlate well with TPMT activity. However, measuring TPMT activity directly through assays with 6-thioguanine was shown to have flaws as a consequence of contaminants in the thioguanine substrate lots. [61] With this finding, many clinicians will likely delay TPMT testing until patients develop adverse reactions or demonstrate sub-therapeutic responses.

MYCOPHENOLIC ACID AND MYCOPHENOLATE MOFETIL Originally named by Alsberg and Black in 1913, mycophenolic acid (MPA) is a lipid-soluble, weak organic acid that is antifungal, antibacterial, antiviral, and immunosuppressive. [62] MPA was used as an oral agent for the treatment of moderate to severe psoriasis since the early 1970s, but was discontinued because of unwanted side effects. Mycophenolate mofetil (MMF) is a morpholinoester derivative of MPA, with greater bioavailability and immunosuppressive capability. It is also tolerated better than MPA.

Pharmacology MMF is well absorbed after oral ingestion and is quickly converted to MPA, which is then converted to its inactive glucuronide in the liver. The inactive glucuronide lacks the ability to penetrate the cell membranes of most tissue types and is subsequently excreted by the kidneys. Certain tissue types, such as the lining of the gastrointestinal tract and the epidermis, have ß-glucuronidase activity that converts the inactive MPA glucuronide into its active form. MPA can then readily penetrate the eukaryotic cell membrane. [62], [63]

Mechanism of action MPA acts as a noncompetitive inhibitor of the eukaryotic inosine monophosphate dehydrogenases by blocking the conversion of inosine-5-phosphate and xanthine-5-phosphate to guanosine-5-phosphate. By blocking the production of the necessary precursors of DNA and RNA synthesis, MPA interferes with de novo purine biosynthesis. MPA therefore is cytotoxic for cell types that rely predominantly on de novo purine biosynthesis (lymphocytes) rather than the purine salvage pathway. MPA blocks the proliferative responses of T and B lymphocytes and inhibits antibody formation and the generation of cytotoxic T cells. [64] The mechanism by which MPA successfully controls psoriasis is unknown. MPA may act selectively on lymphocytes, the predominant inflammatory cell type in psoriatic lesions. Lymphocytes rely on de novo purine biosynthesis and are susceptible to the action of MPA. Alternatively, MPA may act via direct antiproliferative effects on keratinocytes. A third possibility is that MPA may exert an antiproliferative effect indirectly through the inhibition of cytokine production.

Clinical uses MMF is currently marketed for the prevention of renal allograft rejection but is used off-label as a therapy for psoriasis. MPA has been investigated as an oral agent for the treatment of moderate to severe psoriasis. In a pilot study of MPA in psoriasis, Jones and colleagues [65] demonstrated that it is an effective mode of treatment. This study was then followed by a multicenter, double-blind, placebo-controlled study and by a long-term, follow-up study. These investigations found that MPA was safe and effective at doses ranging from 3000 to 4800 mg/day. Another potential application of MPA is as a steroid-sparing agent, in lieu of azathioprine, in the treatment of dermatologic diseases. Numerous reports suggest MMF improves autoimmune blistering diseases when used in conjunction with oral glucocorticoids, and may act as a steroid-sparing agent. Its anecdotal use has also been reported in pyoderma gangrenosum and systemic vasculitis. [66] MMF has been used to treat rheumatoid arthritis. [67] Topical MPA improved experimental allergic contact dermatitis. [68]

Dosage schedule An MMF dose of 1.3 g to 2 g/day is the presumed effective dose range based on the bioavailability of MMF, which is 43 percent greater than that of MPA (whose dose range was typically 3 to 4.8 g). [62] A recent study with 11 patients found that MMF in doses of 1 g bid was more effective than in doses of 0.5 g bid for treatment of severe psoriasis. [69] Daily doses of 2 g or less of MMF appear to be better tolerated. [69], [70] Monitoring guidelines have not been formally established, but cautious laboratory observation is recommended.

Adverse effects There is a large collection of information detailing the known side effects of MPA. [62], [71] Briefly, MPA has dose-dependent side effects on the gastrointestinal system that decrease dramatically after the first year. There are reports of reversible dose-related bone marrow toxicity, although this complication did not contraindicate therapy. Genitourinary complaints with MPA were common, dose and time-dependent, and without significant nephrotoxicity. [72] Opportunistic infections have not been associated with MPA, and there was not an increased age-adjusted rate of cancer development. [71] MPA is pregnancy category C and its potential teratogenic effect is unknown. MMF is better tolerated and has fewer side effects than MPA. In comparison to azathioprine, MMF acts as a noncompetitive inhibitor of guanine nucleotide synthesis and has not been shown to cause chromosome breaks. Conversely, azathioprine is metabolized into a purine analogue, with the potential of becoming incorporated into DNA, thus causing chromosome breaks with a potential mutagenic risk. [72] MMF is safe for long-term therapy, has no clinically significant hepatotoxicity, and causes less bone marrow toxicity than azathioprine. [73]

Drug interactions Several drug interactions have been studied for MMF and MPA. [66] Antacids containing magnesium and aluminum hydroxide decrease the absorption of MMF, while acyclovir and ganciclovir increase drug levels by competing with MMF for renal tubular secretion. Cholestyramine decreases levels of MPA, possibly through the interruption of enterohepatic recirculation. [66]

THIOGUANINE Elion and Hitchings first described thioguanine, a structural analogue of guanine, in 1955. [74] It is another member of the thiopurine family of drugs, and has a metabolism and mechanism of action similar to those of azathioprine.

Pharmacology Thioguanine is administered orally and has incomplete and unpredictable absorption; there may be more than a tenfold variation in plasma concentrations. Peak levels occur 2 to 4 h after ingestion. Unlike azathioprine and mercaptopurine, thioguanine may be administered concurrently with allopurinol without a dosage reduction.

Mechanism of action Thioguanine is a nucleoside analogue and acts as a prodrug. It generates guanine analogues in the tissues via the action of purine nucleoside phosphorylase. The guanine analogues must undergo enzymatic conversion to the nucleotide to display cytotoxic activity by incorporating thioguanine into cellular DNA. According to one study, the mechanism of action appears to be the induction of apoptosis in activated T lymphocytes. [75] The number of T lymphocytes in skin lesions is decreased, while levels of overall circulating leukocytes remain near normal. Contrary to previous theories about the association of clinical response with decreased total leukocytes counts, Murphy and colleagues [75] found that clinical response was more closely related to decreased T lymphocyte counts in psoriatic skin lesions.

Clinical uses The predominant dermatologic use of thioguanine is for the treatment of psoriasis, particularly in patients who have failed other systemic therapies or who have a contraindication to other systemic therapies such as liver disease. [75], [76] In a recent retrospective study of patients with recalcitrant psoriasis, 14 of 18 patients had greater than 90 percent improvement with thioguanine, including patients with psoriatic arthritis, as well as palm, sole, and scalp involvement. [77] When Zackheim and colleagues [76] treated 81 patients with psoriasis with thioguanine, they found that 49 percent of the patients with plaques were effectively maintained with 6-thioguanine for a median of 33 months and that 4 of 5 patients with palmoplantar pustular psoriasis experienced a substantial benefit. Thioguanine is also used to treat acute granulocytic leukemia, acute lymphocytic leukemia, and chronic granulocytic leukemia.

Dosage schedule Thioguanine is supplied in 40-mg tablets. Treatment can be initiated at a dose of 40 mg/day, with close monitoring for signs of bone marrow depression. After 1 month, if the clinical response is inadequate, the dose may be increased to 80 to 120 mg/day. At the higher doses, significant bone marrow suppression often occurs. Pulse dosing is another reportedly effective treatment option, beginning at doses of 80 mg to 100 mg twice weekly, and increasing as necessary up to 160 mg three times per week. [78]

Adverse effects Adverse effects of thioguanine include bone marrow depression and gastrointestinal disturbances. A toxic hepatic venoocclusive disease also has been described in association with 6-thioguanine therapy for psoriasis. [75], [79] Frequent hematologic monitoring is important in patients treated with thioguanine. Pulse dosing of thioguanine may be a way to decrease side effects.

HYDROXYUREA Hydroxyurea was discovered in 1869, but its effectiveness in the treatment of psoriasis was not appreciated until 100 years later. [80] Outside of dermatology, it is primarily used in the treatment of hematologic malignancies.

Pharmacology Hydroxyurea is well absorbed after oral administration. Its serum level peaks within 2 h, and its cerebrospinal fluid level peaks within 3 h. [81] Eighty percent of an oral dose can be recovered in the urine after 12 h, and at 24 h levels are negligible.

Mechanism of action Hydroxyurea is a low-molecular-weight drug that causes immediate inhibition of DNA synthesis (Fig. 256-5). The drug inhibits ribonucleotide diphosphate reductase, which converts ribonucleotides to their deoxy form. Inhibiting this enzyme limits the supply of DNA bases and thereby decreases the rate of DNA synthesis. Strand breakage and cell death result. Hydroxyurea also prevents cells from repairing damage from ultraviolet and ionizing radiation, thereby acting as a radiosensitizer. [82] Finally, hydroxyurea causes hypomethylation of the fetal hemoglobin gene, a benefit to patients with sickle cell disease. This hypomethylation is also thought to lead to normalization of psoriatic skin by inducing differentiation. Hydroxyurea is most active in cells with a high proliferative index, and exists in higher concentrations in leukocytes than in erythrocytes. [81], [83], [84]

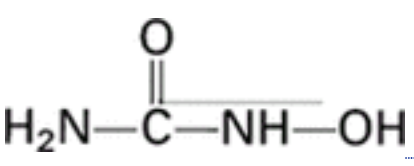

FIGURE 256-5 Chemical structure of hydroxyurea.

Clinical uses The major dermatologic use of hydroxyurea is for the treatment of psoriasis. In 1970, Leavell and Yarbro [83] found in a double-blind study that 9 of 10 patients with severe psoriasis demonstrated clinical and histopathologic responses to hydroxyurea. When Moschella and Greenwald [84] treated 60 patients with psoriasis with hydroxyurea, they achieved a 50 to 60 percent response rate. The authors note that clinical improvement of psoriasis is apparent only if the total white blood cell count is reduced below 4000. Initial response can be expected within 2 to 3 weeks and maximum response by 6 to 8 weeks. [80] Patients should have a baseline chemistry profile, CBC, and urinalysis, with repetition of the CBC at regular intervals. Because hydroxyurea has relatively little hepatic toxicity, it may be a good choice for patients who are excluded from methotrexate therapy because of liver disease. Hydroxyurea seems to be neither as effective nor as rapid in onset of action as methotrexate or azathioprine; however, it is clearly beneficial in some patients.

Dosage schedule Smith [80] recommends that patients should initially receive a dose of 1 g once daily, and the total dose should not exceed 2000 mg/day. Older patients and patients with renal impairment are more susceptible to hydroxyurea and should receive starting doses of 500 mg/day. [80] Hydroxyurea should be taken with food, and patients should add milk or antacids if gastric discomfort occurs. Hydroxyurea is usually well tolerated.

Adverse effects Layton and colleagues [85] found that 57 percent of patients who received 1.5 g/day of the drug experienced no adverse effects and that only 18 percent stopped hydroxyurea therapy because of side effects. The most significant adverse effects of hydroxyurea are bone marrow suppression and teratogenesis. Bone marrow suppression occurs in nearly all patients who are treated with therapeutic levels of the drug and reflects the susceptibility of proliferating cell populations to hydroxyurea. Bone marrow suppression usually resolves rapidly after hydroxyurea is discontinued. Patients taking hydroxyurea may experience adverse cutaneous effects, including but not limited to a

lichen planus-like eruption, a benign dermatomyositis-like eruption, and hyperpigmentation of the skin and nails. Other reported effects include lupus erythematosus, leg ulcers, mild gastrointestinal effects, and the development of secondary malignancies when used in patients being treated for primary malignancies such as polycythemia vera. [80], [86] A rare but important adverse effect of hydroxyurea is fever and a flulike illness. [87] In patients treated for myeloproliferative disorders, nonmelanoma skin cancers were reported. [82] Conception should be avoided when either partner is taking hydroxyurea.
Drug interactions Hydroxyurea appears to have few significant drug interactions, with the exception of other myelosuppressive agents and cytarabine. [80] This caution is because of the potential for additive bone marrow toxicity.

ALKYLATING AGENTS

Cyclophosphamide

Cyclophosphamide is a derivative of nitrogen mustard (Fig. 256-6). As with other nitrogen mustards, cyclophosphamide acts primarily as a DNA cross-linker. [88] It is used as an antineoplastic agent in oncology. However, in certain diseases, especially the autoimmune blistering disorders and systemic vasculitis diseases, it can be used as a steroid-sparing agent or for its inherent efficacy.

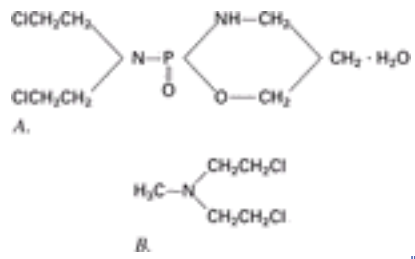

FIGURE 256-6 Chemical structure of the alkylating agents. *A*. Cyclophosphamide *B.* Mechlorethamine (nitrogen mustard).

PHARMACOLOGY Cyclophosphamide is a prodrug that undergoes hepatic conversion by the cytochrome P450 system. It has good oral bioavailability and reaches peak plasma levels within 2 h; its half-life is between 3 and 12 h. Important metabolites are 4-hydroxycyclophosphamide and phosphoramide mustard, both of which are active, and acrolein, an inactive metabolite. [1] Aldehyde dehydrogenase is responsible for the production of another inactive metabolite.
MECHANISM OF ACTION Because cyclophosphamide interacts with preformed DNA and RNA (cell-cycle nonspecific), the drug is active against cells with a low proliferative index. Results from alkylation include DNA cross-linking, abnormal base-pair formation, imidazole ring cleavage with depurination, and chain scission. These mutations can lead to cell death or mutagenesis and carcinogenesis. [81] Cyclophosphamide is more active on B lymphocytes than on T lymphocytes. [81]
CLINICAL USES The major dermatologic use of cyclophosphamide is for the treatment of severe life-threatening diseases resistant to other forms of therapy. Cyclophosphamide is used either to maintain remission after withdrawal of systemic steroids, or as a steroid-sparing agent. The latter usage in patients who have not responded to azathioprine therapy is based on a single report. [89] Pemphigus vulgaris in particular may be treated with cyclophosphamide in combination with prednisone. [89], [90] Recent reports on intravenous pulse therapy of cyclophosphamide and combined pulse dexamethasone-cyclophosphamide therapy in the treatment of pemphigus vulgaris described a curative effect. [90], [91] The survival of patients with systemic vasculitis was enhanced with the introduction of combined steroid/cytotoxic therapy. [44] Diseases that were once lethal are now controllable with such therapy. Wegener's granulomatosis and lymphomatoid granulomatosis often require cyclophosphamide therapy for sustained remission. [92], [93] Other diseases may also respond to cyclophosphamide, including Behçet's disease, pyoderma gangrenosum, lichen planus, and lichen myxedematosus. [81] With the availability of cyclosporine and related drugs, however, cyclophosphamide may not be the drug of choice for steroid-resistant but nonlethal inflammatory diseases. However, in a recent controlled trial, cyclosporine was ineffective as an adjuvant to glucocorticoids for the treatment of pemphigus. [94]
DOSAGE Cyclophosphamide can be given orally or parenterally through intravenous administration. Oral dosages are usually 1 to 3 mg/kg per day either in divided doses or as a single morning dose for nonmalignant diseases. Intravenous pulse dosing of 0.5 to 1 g/m ^{2} monthly may be associated with fewer side effects than daily oral dosing. [90], [95] Vigorous hydration 24 h before and continuing through therapy is strongly recommended to prevent serious bladder toxicity.
ADVERSE EVENTS The side effects of cyclophosphamide are significant. [95] Nausea and vomiting are the most common gastrointestinal side effects associated with cyclophosphamide administration, but ondansetron combined with dexamethasone can significantly reduce these effects. Alopecia, mucosal ulcerations, cardiotoxicity, syndrome of inappropriate antidiuretic hormone secretion (SIADH), squamous cell skin cancer, and hematologic malignancies are associated with cyclophosphamide use. [88], [95] As teratogenicity is of concern with cyclophosphamide, avoidance of pregnancy is stressed and males may consider banking sperm before initiation of therapy. Infertility is another major risk of cyclophosphamide therapy. [90] Hematologic disturbances are frequent, especially leukopenia and thrombocytopenia. [88] The leukocyte nadir is usually around 8 to 12 days after initiation of therapy, with a goal for the absolute neutrophil count to remain above 2000/mm ^{3}. It is not necessary to induce myelosuppression to induce immunosuppression. [81] In some cases with immunoablation through high-dose cyclophosphamide, hematopoietic stem cells appear resistant to the cytotoxic effects of cyclophosphamide through the enzyme aldehyde dehydrogenase. [96] Many forms of bladder toxicity exist in association with cyclophosphamide. Hemorrhagic cystitis occurs in 5 to 40 percent of patients treated with oral cyclophosphamide. [81], [95] This cystitis occurs during therapy and is believed to be caused by the metabolite acrolein. [97] A scavenging agent, mesna (sodium 2-mercaptoethane sulfonate), binds acrolein in the bladder and prevents severe bladder irritation. It is used primarily with high-dose cyclophosphamide regimens and is administered orally or intravenously. Chronic hemorrhagic cystitis and untreated bladder toxicity are thought to be responsible for the development of transitional cell carcinoma of the bladder, which is associated with a thirty-one– to thirty-threefold increase with chronic daily oral cyclophosphamide. [90] Stein and colleagues [98] reported two rare cases of

cyclophosphamide-induced squamous cell carcinoma of the bladder. Cancers may arise many years after therapy, and therefore continued monitoring of the lower urinary tract is indicated. The importance of vigorous hydration and frequent bladder clearance during cyclophosphamide therapy cannot be overemphasized.
DRUG INTERACTIONS Because the microsomal enzyme systems responsible for cyclophosphamide activation are involved in the metabolism of other drugs, there is great potential for drug interaction during cyclophosphamide therapy. Allopurinol, cimetidine, and chloramphenicol increase cyclophosphamide toxicity. Cyclophosphamide has other important drug interactions with succinylcholine, halothane, nitrous oxide, doxorubicin, digoxin, and barbiturates. [81]

Chlorambucil

Chlorambucil is another cell-cycle nonspecific alkylating agent derived from nitrogen mustard that interferes with DNA synthesis and cellular proliferation with effects similar to cyclophosphamide. It is well absorbed orally and undergoes hepatic metabolism with a plasma half-life of approximately 1.5 h. [1] Commonly used in the treatment of chronic lymphocytic leukemia, Waldenström's macroglobulinemia, and lymphomas, it is rarely used in dermatology. However, there are recent reports of treatment of pemphigus and erythrodermic cutaneous T cell lymphoma with various regimens of chlorambucil as a steroid-sparing agent. [99], [100] Although chlorambucil is considered the least toxic nitrogen mustard, its side effects include induction of other malignancies, nausea and vomiting, azoospermia, amenorrhea, pulmonary fibrosis, seizures, dermatitis, and, rarely, hepatotoxicity. [1], [100] Because of infrequent use, dosage schedules of chlorambucil for the treatment of dermatologic disease have not been standardized and must be determined on an individual basis.

Anthracyclines

Anthracyclines are antibiotic molecules with antineoplastic properties that are cell-cycle specific for the S phase of cell division. The mechanism of antineoplastic activity is thought to involve intercalation with DNA and inhibition of DNA and RNA synthesis by template disordering and steric obstruction. This usually results in cell death, but also leads to mutagenesis and carcinogenesis. [1] Pegylated (methoxypolyethylene glycol) liposomal doxorubicin hydrochloride (Doxil) is approved for the treatment of AIDS-related Kaposi's sarcoma. The encapsulating liposomes avoid detection by the reticuloendothelial system and increase the blood circulation time of doxorubicin. [101] These protected liposomes result in a 55-h half-life and allow improved penetration of the compromised vasculature of the Kaposi's sarcoma, thus accumulating within the tumors. [101], [102] Doxorubicin is administered intravenously at a recommended dose of 20 mg/m ^{2} over 30 min once every 3 weeks, as tolerated by the individual patient.

Liposomal doxorubicin has toxicities similar to those of nonliposomal doxorubicin, but it generally is considered to be better tolerated. Careful hematologic monitoring is required, as a transient myelosuppression is expected during the second week of therapy. [1] A small percentage of patients may experience an initial infusion reaction, which typically resolves and does not occur in later infusions if not present initially. Palmar–plantar erythrodysesthesia is not unusual, and hepatotoxicity has also been reported. [101], [102] Doxorubicin is embryotoxic and abortifacient and should be avoided in women who plan to conceive. It should be assumed that liposomal doxorubicin may have myocardial toxicity similar to that of other preparations of doxorubicin. In addition, a history of the use of other anthracyclines or anthracenediones will lower the total dose of doxorubicin required to cause cardiotoxicity. Also reported was recurrence of postradiation skin reaction in patients receiving this drug. Other minor side effects occurred in more than 5 percent of the patients with AIDS-related Kaposi's sarcoma receiving doxorubicin therapy.

Cytotoxic agents are associated with important risks and benefits in the treatment of severe dermatologic disease. Meanwhile, the use of steroids to induce disease remission is also often complicated by serious side effects during prolonged therapy. Many of the discussed cytotoxic agents demonstrate steroid-sparing benefit and may be used successfully with careful attention to laboratory and clinical monitoring. However, with the continued introduction of newer, targeted, immunomodulatory agents, many of the cytotoxic drugs discussed in this chapter will likely be used less often to treat dermatologic disease.

FACTORS IN THE DECISION TO USE RETINOIDS

REFERENCES

Retinoids is a generic term for both naturally occurring molecules and synthetic compounds with specific biologic activities that resemble those of vitamin A. Since the early twentieth century, animal experiments in conditions of vitamin A deficiency have revealed alterations of epithelia such as epidermal hyperkeratosis, squamous metaplasia of mucous membranes, various keratinization disorders, and certain precancerous conditions. [1] In view of the “antikeratinizing properties” of vitamin A, the profound clinical impact of synthetic retinoids was first observed and described in patients with dermatologic disease. In initial clinical investigations, synthetic vitamin A was either ineffective at well-tolerated doses or too toxic. Because of this narrow therapeutic index, a large program of chemical synthesis of derivatives was launched to engineer synthetic retinoids that would offer the highest therapeutic activity with the lowest toxicity.

All- *trans*-retinoic acid (tretinoin, ATRA), a naturally occurring metabolite of retinol, was the first retinoid to be synthesized. Its systemic use provided no significant advantages over vitamin A, [2] and hence its dermatologic use is as a topical treatment for disorders of keratinization such as acne vulgaris, ichthyosis, actinic keratosis, and basal cell carcinoma, as well as pityriasis rubra pilaris. ATRA has been used widely as a differentiation-inducing agent for acute promyelocytic leukemia, leading to renewed interest in its effects. [3]

Isotretinoin (13- *cis*-retinoic acid), first synthesized in 1955, was tested only later in clinical trials that were hampered initially by concern about the thalidomide tragedy and about its teratogenicity. Initially, Orfanos and coworkers [4] obtained equivocal results in treating psoriasis with isotretinoin. Subsequently, etretinate, either alone [5] or in combination with topical dithranol, [6] was found to be very effective in treating psoriasis. These findings led to the temporary abandonment of isotretinoin. Interest in isotretinoin was rekindled after the discovery that it was effective in the treatment of lamellar ichthyosis and other cutaneous disorders of keratinization [7] and in producing complete responses with prolonged remissions in patients with previously treatment-resistant cystic and conglobata acne. [8] It also was found to be partially effective in the treatment and prevention of basal cell carcinoma. [9]

In 1972, Bollag, in his chemical program directed at finding retinoids with better therapeutic margins, developed two aromatic retinoids, etretinate and acitretin. These compounds showed a therapeutic index 10 times more favorable than that of ATRA in the chemically induced rodent papilloma test model. Etretinate and its free acid metabolite, acitretin, the second generation of retinoids, achieved a real breakthrough in the treatment of psoriasis.

The recent discovery of retinoic acid receptors (RARs) [10], [11] allows research directed toward third-generation retinoids with a safer therapeutic index and a selective action. Bexarotene for systemic use and adapalene and tazarotene for topical use are at the forefront of this research.

This chapter summarizes the pharmocokinetics, mechanisms of action, efficacy, and toxicity of oral synthetic retinoids in dermatology, with emphasis on acne, psoriasis, and other off-labeled indications.

MECHANISMS OF ACTION

Retinoids are involved in the regulation of diverse biologic functions. They affect cell growth and differentiation, morphogenesis, tumor promotion, and malignant cell growth; exert immunomodulatory action; and alter cellular adhesiveness.

A major breakthrough in the understanding of retinoid action came from the discovery of nuclear receptors for retinoids. [10], [11] Retinoids exert their physiologic effects through two distinct families of nuclear receptors, RARs and retinoid X receptors (RXRs). RARs and RXRs belong to a superfamily of nuclear receptors that act as ligand-activated transcription factors and include the steroid, vitamin D, and thyroid hormone receptors and peroxisome proliferator–activated receptors. Each family contains three receptor isotypes—a,ß, and ?—encoded by different genes. Whereas ATRA binds only to RARs, 9- *cis*-retinoic acid binds to both RARs and RXRs. RARs function as heterodimers with RXRs, whereas RXRs may act as homodimers, as well as participate in the formation of heterodimers, with various other nuclear receptors, including vitamin D, thyroid hormone, and peroxisome proliferator– activated receptors. Such heterodimers can provide a mechanism for cross-talk between nuclear hormone-signaling pathways. Dimers of retinoid receptors (RAR/RXR or RXR/RXR) are localized in the nucleus and bind even in the unliganded state to specific DNA regulatory sequences called *hormone response elements* in the promoters of retinoid-responsive genes. The unliganded receptors bind to corepressor molecules and repress transcription. However, when the receptor binds its ligand, it undergoes a conformational change that results in the release of corepressors and in the recruitment of coactivators. These molecules include histone acetylases that change the conformation of the chromatin and allow access to the DNA by transcriptional machinery. Finally, the retinoid-receptor complex modulates the transcription of specific sets of genes. Retinoids have both direct and indirect effects on gene transcription. Their direct effects are mediated through binding to their hormone response element (retinoid hormone response element, or RARE) in the promoter region of target genes. In contrast, the indirect effects of retinoids result from the downregulation of genes that do not contain RARE in their promoter region. The retinoid-receptor complex probably antagonizes various transcription factors involved in proliferative and inflammatory responses such as activator protein 1 (AP-1) or nuclear factor–interleukin 6 (NF–IL-6) by competing for commonly required coactivator proteins, resulting in a nonproductive complex. [12] Synthetic “dissociating retinoids” have been synthesized that induce the indirect anti-AP-1 function but not the direct gene transactivation function. Finally, the nongenomic effect of retinoids and the reversible phosphorylation of retinoid receptors are still a matter of investigation.

The existence of several types and distribution of receptors, dimers, hormone response elements, mechanisms of action, and regulatory proteins means that retinoid action is mediated by multiple pathways and results in the complex activation or inhibition of a large set of coordinately regulated genes.

PHARMACOLOGY

ATRA, isotretinoin, etretinate, acitretin, and bexarotene, the oral retinoids (Fig. 257-1) that are or have been available commercially, differ not only in their spectra of clinical efficacy but also in their toxicities and pharmacokinetics. Thus each retinoid should be studied as a unique drug, and the lack of a disease response to one retinoid does not equate with unresponsiveness to the others. Three generations of synthetic retinoids have been developed. Members of the first generation of monoaromatic retinoids (isotretinoin, ATRA) are produced by chemically modifying the polar end group and the polyene side chain of vitamin A. Those in the second generation of monoaromatic retinoids are formed by replacing the cyclic end group of vitamin A with diverse substituted and nonsubstituted ring systems (etretinate, acitretin). The third-generation polyaromatic retinoids (also called *arotinoids*) are synthesized through cyclization of the polyene side chain and include bexarotene, adapalene, and tazarotene.

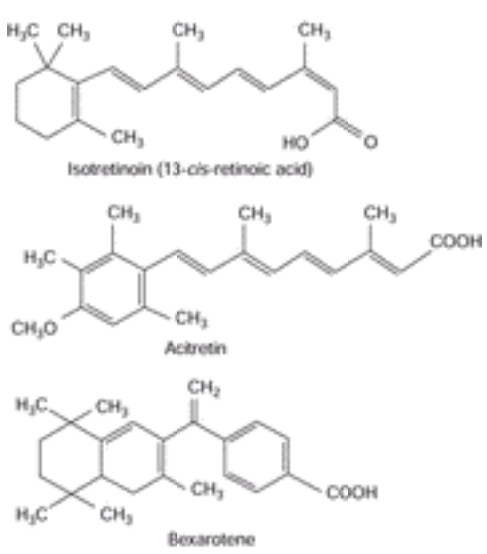

FIGURE 257-1 Chemical structures of systemic retinoids.

Due to their lipophilicity, the oral bioavailability of all retinoids is enhanced when administrated with food, especially with fatty meals. Retinoids are metabolized mainly in the liver. Metabolism involves oxidation and chain shortening to biologically inactive and hydrophilic metabolites, facilitating biliary and/or renal elimination. The oxidative metabolism is induced primarily by the retinoids themselves and possibly also by other agents that induce hepatic cytochrome P-450 isoforms. [13]

Vitamin A

Vitamin A (retinol), one of the fat-soluble vitamins, is required for the visual cycle of dark adaptation, physiologic growth, reproduction, regulation of embryonic development, morphogenesis, and immunomodulation. Most vitamin A must be

acquired through the diet from ingested retinyl esters and provitamin A carotenoids, of which beta-carotene is the most active. In the intestinal lumen, these esters are hydrolyzed to retinol, which is absorbed and stored in the liver in the ester form (especially retinol palmitate). Retinol represents the main dietary source, transport, and storage form of vitamin A. Once in the bloodstream, after the retinol ester/storage form is released, retinol is transported bound to a complex of retinol-binding protein (RBP) and transthyretin. The basic cellular pathway leading to the conversion of retinol to ATRA, the biologically active ligand that binds to nuclear receptors, consists of two steps. In a reversible process, retinol (vitamin A alcohol) is oxidized to retinal (vitamin A aldehyde) and is irreversibly converted to retinoic acid (vitamin A acid). A binding protein, designated *cellular RBP* (CRBP-I), facilitates these enzymatic reactions by delivering retinol to the appropriate enzymes. Two additional intracellular carriers, cellular retinoic acid–binding proteins (CRABP-I and CRABP-II), are thought to act to transport retinoic acid to the nucleus and to buffer the level of free ATRA in the cell. CRABP-I enhances retinoic acid metabolism to inactive derivatives, thereby dampening a cell's ability to respond to retinoic acid; in contrast, CRABP-II sensitizes cells to retinoic acid by channeling it to RARs through protein-protein interactions and enhances retinoic acid–induced transcriptional activity. [14] Retinoic acid is found in both all- *trans* and 9-*cis* configurations. Physiologically, ATRA is the predominant retinoic acid form; only a small fraction is transported as 13-*cis*-retinoic acid. ATRA is the active ligand that binds to the three known nuclear RARs that mediate, at least in part, the molecular and cellular effects of retinoic acid. Retinoic acid can substitute for retinol in growth, morphogenesis, and epithelial differentiation. However, it cannot substitute completely for retinol in reproductive function, nor can it replace retinal in the visual cycle.

Etretinate and Acitretrin

Etretinate is an ethylester that undergoes extensive hydrolysis in the body to yield the corresponding acid metabolite (acitretin). It appears from cellular and molecular pharmacology studies that the pharmacologically active compound of etretinate is acitretin, and therefore, etretinate may be considered as a prodrug. In animal studies and in clinical studies in patients with severe keratinizing disorders, [15] acitretin is as effective as etretinate. However, acitretin has a profound pharmacokinetic advantage because it is eliminated more rapidly than etretinate. [16] Etretinate is approximately 50 times more lipophilic than acitretin and binds strongly to plasma proteins, particularly lipoproteins and albumin. This fact has a profound influence on the respective pharmacokinetic properties of the two drugs.

When etretinate or acitretin is taken with a meal, the absorption of the drug is increased two- to fivefold, and the amount absorbed is more consistent. [16] It is therefore recommended that etretinate or acitretin be taken with the main meal of the day. However, even when the drugs are taken with food, their absorption varies. Marked interindividual variations in plasma retinoid concentration occur and appear not to depend on body weight. [17] The main adverse effect associated with synthetic retinoids is teratogenicity, and the length of time that these drugs are present in the body is thus of great interest. Etretinate is stored in adipose tissue, including subcutaneous fat, from which it is released slowly. It has a long terminal half-life of up to 120 days. In contrast, under identical conditions, acitretin carries a negatively charged group and, not being as lipophilic as etretinate, does not accumulate in adipose tissue and is eliminated from the body more rapidly. Acitretin has an elimination half-life of 2 days. [18] With etretinate, there is a significant first-pass hepatic metabolism by hydrolysis to the active metabolite. Acitretin metabolism involves isomerization instead of oxidation. The major metabolite of acitretin is its *cis* isomer. Paradoxically, acitretin activates all three RAR subtypes but binds poorly to them. [19]

The initial publication of data indicating that etretinate can be formed in patients receiving acitretin [20] has been confirmed by others. This esterification seems to occur when acitretin is taken simultaneously with alcohol. [21] This finding prompted the manufacturer to extend the time of compulsory contraception in patients taking acitretin to 2 years, as it is for etretinate. [22] Indeed, the Food and Drug Administration (FDA) approved the required contraceptive period of at least 3 years for acitretin, based on the pharmacokinetics of acitretin and etretinate in clinical trials and on previous safety experience with etretinate. The pharmacokinetic advantage of acitretin over etretinate still holds true, however, for all women who strictly avoid alcohol during treatment and for 2 months thereafter. [18] For all these reasons, acitretin represents a therapeutic alternative with greater clinical potential than etretinate. In June 1997, acitretin was approved by the FDA as a substitute for etretinate for similar indications. [18]

Isotretinoin (13- *cis*-Retinoic Acid)

Isotretinoin is a naturally occurring physiologic compound that results from the metabolism of vitamin A. Isotretinoin and ATRA are two interconvertable isomers that differ in their elimination half-lives—approximately 20 h for isotretinoin and 1 h for ATRA. Absorption of isotretinoin is increased considerably with food intake. Isotretinoin undergoes first-pass metabolism in the liver and subsequent enterohepatic recycling. In plasma, isotretinoin is more than 99 percent bound to plasma protein, mainly albumin. There is neither liver storage nor adipose tissue storage, in sharp contrast to vitamin A. The major metabolite of isotretinoin is produced by oxidation, which forms 4-oxoisotretinoin. Isotretinoin and its major metabolites are excreted in urine and feces. After the end of treatment, endogenous concentrations of isotretinoin and its major metabolite are reached within 2 weeks, ranging from 2 days for ATRA to 10 days for 4-oxoisotretinoin. Therefore, a 1-month posttherapy contraceptive period provides an adequate safety margin. [23] No clear affinity for any retinoid receptors has been identified with isotretinoin.

Bexarotene

Bexarotene, a specific RXR-selective retinoid (rexinoid), was approved in 1999 in the United States for the treatment of cutaneous T cell lymphoma. This compound is about 100-fold more potent for RXR relative to RAR. Its absorption is particularly increased by fatty meals. In plasma, bexarotene is highly bound (>99 percent) to proteins that have not yet been characterized, and the ability of bexarotene to displace drugs bound to plasma proteins and the ability of drugs to displace bexarotene is unknown. Bexarotene probably has a clearance profile similar to that of isotretinoin with a terminal half-life of between 7 and 9 h. [24] Bexarotene is metabolized by cytochrome P-450 3A4 (CYP 3A4) and generates its own oxidative metabolites via hepatic CYP 3A4 induction. 6/7-Hydroxybexarotene and, to a lesser extent, 6/7-oxobexarotene

appear to be the major metabolites, which exhibit insignificant in vitro receptor retinoid affinity and transactivation. [25] Neither bexarotene nor its metabolites are excreted in urine; elimination is thought to occur primarily via the hepatobiliary system. [24]

CLINICAL USES (Table 257-1)

TABLE 257-1 **Use of Systemic Retinoids in Dermatologic Disease States***

Psoriasis

The retinoids of first choice for the treatment of psoriasis are etretinate and subsequently acitretin. Several randomized multicenter trials have been performed to ascertain the efficacy of acitretin on plaque-type [26], [27], [28], [29] and [30] and pustular psoriasis and to compare its efficacy with that of etretinate. [26] Acitretin appears to be as effective as etretinate and can be used in the same combination regimens. Adverse effects appear to be similar in quality and incidence. The best results have been obtained in palmoplantar or generalized (von Zumbusch) type pustular psoriasis, in which etretinate and acitretin are considered to be the treatments of first choice. [31], [32] Both localized and generalized pustular psoriatic lesions as well as those of erythrodermic psoriasis cleared more rapidly with etretinate or acitretin monotherapy than with most other therapies. [31], [32] and [33] Rebound does not usually occur after acitretin or etretinate treatment is stopped, [34] and reintroduction of the drug when it does occur produces a beneficial response. [34] The most common form of psoriasis, plaque-type psoriasis, responds variably to both drugs. Although complete clearing of the lesions is achieved in only about 30 percent of treated patients, significant improvement is obtained in a further 50 percent. [35], [36] The decrease in the psoriasis area and severity index (PASI) score is approximately 60 to 70 percent, depending on the dosage. [15] Approximately 20 percent of patients may be considered treatment failures. [15], [36]

One of the main reasons for treatment interruption is initial worsening of the disease with increased erythema. Another is an increase in the extent of the lesions, which may occur within a few days of the start of treatment at doses of 0.5 to 1 mg/kg per day (30–70 mg/day). A therapeutic dosage scheme with an initially low dose (10 mg/day) of etretinate or acitretin, followed by progressively increasing doses, seems to avoid this initial worsening. [17] To define the efficacy of acitretin as monotherapy, different doses (10–75 mg/day) were compared in a double-blind fashion with placebo in patients with psoriasis. At the end of an 8-week treatment period, acitretin at doses of 25 and 50 mg/day [37] and 50 and 75 mg/day [38] was superior to placebo in two studies. The efficacy of a dose of 10 mg/day was not significantly different from that of placebo in either study. [17]

Total clearing of the lesions usually requires a combination of treatment such as retinoids plus topical glucocorticoids, topical vitamin D derivatives, dithranol (anthralin), or photochemotherapy (psoralen plus ultraviolet A, or PUVA).

COMBINATION WITH ULTRAVIOLET THERAPY One of the major developments for the treatment of widespread plaque-type psoriasis in recent years has been the combined use of PUVA photochemotherapy with the retinoids etretinate or acitretin (Re-PUVA therapy), in which retinoids are given 14 days before PUVA is started. The effects of etretinate and PUVA appear to be additive. [39] Studies with acitretin have demonstrated the superiority of Re-PUVA. In a double-blind comparative trial, [40] patients with psoriasis received either retinoid (acitretin or etretinate, 50 mg/day) or placebo without PUVA for 2 weeks. This monotherapy phase was followed by a combined-therapy phase of retinoid (acitretin or etretinate, 25 mg/day) or placebo plus PUVA three times a week until remission occurred. Although etretinate plus PUVA was more effective than placebo plus PUVA, statistically significant differences in the number of PUVA exposures and total dose of ultraviolet A (UVA) until remission were shown only between acitretin plus PUVA and placebo plus PUVA. The efficacy of acitretin was confirmed in another study that showed that the mean cumulative UVA dose was 42 percent less in the acitretin plus PUVA group than in the placebo plus PUVA group. [41] The main advantages of the Re-PUVA combination are the acceleration of the response rate of psoriatic lesions and the clearing of lesions that could not be cleared with retinoid or PUVA alone. A further advantage is that the ultraviolet exposure necessary to produce remission is significantly lower with Re-PUVA. The lower dosage is likely to diminish the risk of PUVA-induced carcinogenic effects, which are clearly UVA-dose-dependent. Oral retinoids also can be combined with bath PUVA (psoralen bath plus UVA), which also allows a reduction in the effective dose of UVA. The combination of etretinate or acitretin with ultraviolet B (UVB) phototherapy also has been shown to be more effective in patients with psoriasis than retinoid or UVB phototherapy alone. [40], [42], [43]

TREATMENT OF PATIENTS WITH HIV INFECTIONS The frequency of psoriasis in patients with HIV infection does not differ significantly from that in persons who do not have HIV infection. However, the psoriasis in HIV-infected patients tends to be more aggressive, and treatment poses a unique challenge. Topical agents are usually not sufficient to control the disease process. Potentially immunosuppressive treatments for psoriasis, including phototherapy and the use of glucocorticoids, methotrexate, and cyclosporine, are contraindicated. Eleven patients with psoriasis associated with HIV infection were enrolled in a 20-week treatment protocol. Six (54 percent) of the 11 achieved good to excellent responses with acitretin monotherapy. Both skin and joint manifestations responded to acitretin therapy in most patients. Optimal results were achieved with a dosage of 75 mg/day. The adverse effects were moderate and well tolerated, and

parameters of immunosupression were not exacerbated in most patients. Thus acitretin does not appear to have immunosuppressive properties. Its mode of action in psoriasis is unknown, regardless of HIV status. [44]
ISOTRETINOIN Isotretinoin has a lesser effect on psoriasis than acitretin or etretinate, although some efficacy has been shown in combination with PUVA. [22] Nevertheless, some dermatologists use isotretinoin to treat women with psoriasis who need systemic retinoids in order to avoid the long postacitretin contraception period.

Acne

The retinoid of first choice for the treatment of acne is isotretinoin. The introduction of isotretinoin was a key step in the history of dermatologic treatment. It is still the only compound that really cures acne because it is the only one that affects, albeit not to the same degree, all etiologic factors implicated in the pathogenesis of acne: sebum production, comedogenesis, and colonization with *Propionobacterium acnes.* [45] Among the natural and synthetic retinoids used in humans, only isotretinoin suppresses sebum excretion and significantly improves acne. The “sebospecificity” of oral isotretinoin cannot be explained on the basis of the molecular biology of retinoid nuclear receptors because it has no special affinity to any of the identified retinoid nuclear receptors. Attempts have been made to relate the sebosuppressive effect to a metabolite; 4-oxoisotretinoin has been considered as a candidate, but little supporting evidence has been presented so far. The antiacne effect of isotretinoin relates mainly to its potential to inhibit the production of sebum by inhibition of sebaceous gland differentiation and proliferation, reduction of sebaceous gland size, decrease of skin dihydrotestosterone, and downregulation of skin androgen receptors. Other mechanisms include desquamative effects on poral occlusion, antibacterial action, and anti-inflammatory effects. In the early 1980s, isotretinoin treatment was restricted to patients suffering from severe nodulocystic acne. With increasing experience, however, its use has been extended to patients with less severe disease who respond unsatisfactorily to conventional therapies such as long-term antibiotics because of the increased resistance of *P. acnes* to many antibiotics, in particular erythromycin and tetracycline. [46] Patients with moderate acne that may induce scars also have been treated. Current isotretinoin usage policies and treatment recommendations are being reviewed by expert panels to provide treatment guidelines based on clinical experience. [47]

Acne morbidity is related to more than physical appearance. The significant psychosocial impact of acne includes depression, anxiety, interpersonal and work-related difficulties, and attempted suicide. Studies with quality-of-life instruments have shown that isotretinoin treatment significantly improves mental health, social function, and self-esteem.

It initially had been considered that optimal benefit would be achieved with a high daily dose, about 1 mg/kg of body weight per day. [45] This high dose induces undesirable side effects, and similar short-term therapeutic results are obtained with a dose below 0.5 mg/kg of body weight per day. This approach implies that the treatment is maintained over a longer period of time in order to reach the threshold of the cumulative dose, a concept introduced in 1989. [48] The cumulative dose (mg/kg of body weight) is the total amount of oral isotretinoin taken by the patient during treatment divided by body weight. Thus a patient weighing 50 kg and receiving 25 mg/day of isotretinoin for 100 days would receive a cumulative dose of 50 mg/kg (25 mg × 100 days divided by 50 kg). Data from several centers indicate that posttherapy relapse is minimized by a treatment course amounting to a cumulative dose of at least 120 mg/kg [49] with no further therapeutic gain beyond about 150 mg/kg. [47] A lag period of 1 to 3 months may exist before the onset of the therapeutic effect. Continued healing after the discontinuation of therapy regularly occurs. Consequently, treatment need not be maintained until total clearance is achieved. Approximately one-third of patients with acne require a second course of therapy for either persistent disease or relapse. The only predictive factors of resistance to isotretinoin treatment are closed comedonal acne and microcystic acne. [50] A flareup of disease during the first few weeks of treatment and the evolution of acne cysts into lesions resembling pyogenic granuloma may be observed with isotretinoin treatment; these reactions may be due to the cessation of previous systemic antibiotics in association with impaired cutaneous barrier function leading to *Staphylococcus aureus* colonization and formation of granulation tissue. Furthermore, retinoids may alter directly or indirectly the expression of pro- or antiangiogenic growth factors such as vascular endothelial growth factor/vascular permeability factor (VEGF/VPF). Women with a history of acne refractory to isotretinoin or repeated relapses should be examined for hirsutism, questioned about abnormal patterns of menstruation, and considered for an endocrinologic workup for evaluation of ovarian or adrenal dysfunction. Adrenal dysfunction and 5a-reductase hyperactivity have been reported in such cases. [51]

Women of childbearing potential must have a negative pregnancy test and must practice effective contraception during and for 1 month after the completion of therapy. A 1-month posttherapy contraceptive period affords a sufficient safety margin because plasma concentrations of isotretinoin return to physiologic levels within 10 days of therapy completion. [52] The SMART (System to Manage Accutane Related Teratogenicity) has been put into effect by the FDA and the manufacturer of isotretinoin.

Isotretinoin has limited effect on hidradenitis suppurativa; surgical treatment is the first choice for all intertriginous lesions. Some investigators recommend oral isotretinoin during the weeks or months preceding the surgery and perhaps also during the postoperative period. [53]

Cutaneous T Cell Lymphoma (CTCL)

Etretinate may induce clinical improvement in patients with CTCL (e.g., mycosis fungoides or Sézary syndrome) with no internal involvement; better results were obtained when etretinate was combined with PUVA treatment or interferon-a. The combination of acitretin or isotretinoin with oral vitamin D_3 calcitriol to obtain synergistic effects for the treatment of CTCL has been reported. [54], [55]

Both oral and topical bexarotene have produced improvement in patients with CTCL; the topical formulation also has shown efficacy in Kaposi's sarcoma. In early (IA-IIA) and advanced (IIB-IVB) stages of CTCL, oral bexarotene monotherapy produced about 60 and 50 percent response rates, respectively, at a dose of 300 mg/m^2 or higher per day

within the first 2 months in most patients. [56], [57] The FDA approved bexarotene in December 1999 as oral therapy for the treatment of CTCL that is refractory to at least one systemic therapy and in June 2000 as a gel formulation for cutaneous manifestations of early-stage refractory or persistent CTCL. [57] The recommended initial dose is 300 mg/m ^{2} per day, administered as a single oral dose with meals. Based on the severity of adverse effects, the dose may be adjusted down to 100 or 200 mg/m ^{2} per day or may be suspended temporarily. If the tumor does not respond after 8 weeks of therapy, the dose may be increased to 400 mg/m ^{2} per day with careful monitoring.

FDA-Unapproved Clinical Uses

The pleomorphic effects of the retinoids, as well as the relatively selective targeting of skin structures, explain their broad potential benefit for patients with skin disease. Multiple other skin disorders respond to retinoids (see Table 257-1), but only for a few of them is the effect established in controlled studies. [58] In many skin conditions, reports were confined to etretinate before acitretin was developed, and the choice of etretinate/acitretin rather than isotretinoin was based not on pharmacologic considerations but on availability of the product.

Ichthyosis

Among the different types of ichthyoses, the best results are obtained with acitretin in nonbullous congenital ichthyosis such as erythrodermic and nonerythrodermic lamellar ichthyosis. Treatment of bullous ichthyosiform erythroderma may lead to an initial increase in bullae. Good results also have been achieved in recessive X-linked ichthyosis and ichthyosis vulgaris; however, in contrast to lamellar ichthyosis, the limited severity of the disease often does not require retinoid therapy.

Darier's Disease

Severe forms of Darier's disease are good indications, and care should be taken to initiate therapy with a very low dose, such as 10 mg/day of acitretin, to prevent initial exacerbation of the disease; usually 20 mg/day is sufficient for significant improvement.

Pityriasis Rubra Pilaris (PRP)

Early treatment with retinoids appears to offer the best chance for clearing of PRP. In extensive cases, concomitant use of methotrexate may be advantageous. Etretinate is considered to be superior to isotretinoin in the treatment of adult-onset PRP. [59]

Rosacea

In severe forms or treatment-resistant rosacea, isotretinoin may be more effective on inflammatory lesions than on vascular lesions. [60] A low daily dose (10 mg) is often sufficient. The best indications are severe cases of rosacea associated with significant seborrhea.

Premalignant and Malignant Skin Lesions

Etretinate and acitretin are effective in the treatment of premalignant skin lesions, including human papillomavirus–induced tumors and actinic keratoses. In the basal cell nevus syndrome and in xeroderma pigmentosum, these drugs reduce dramatically the incidence of malignant degeneration of the skin lesions. A double-blind study demonstrated that acitretin at a dose of 30 mg/day for 6 months prevented the development of premalignant and malignant skin lesions in renal transplant recipients. [61]

Graft-Versus-Host Disease (GVHD)

In an open study, 3 months of therapy with etretinate produced an encouraging response among patients with refractory sclerodermatous chronic GVHD resulting from allogeneic bone marrow transplantation. [62]

Lichen Sclerosus et Atrophicus

Acitretin is an effective treatment for severe lichen sclerosus et atrophicus of the vulva and may be recommended intermittently for patients who are intolerant of or resistant to local therapies.

Lupus Erythematosus

Both isotretinoin and acitretin have been used successfully by patients with various forms of lupus erythematosus. However, the lesions recurred after completion of the treatment as quickly as the initial improvement had appeared. Acitretin and hydroxychloroquine are equally effective in the treatment of chronic discoid lupus erythematosus and subacute cutaneous lupus erythematosus.

ADVERSE EFFECTS

Teratogenicity is the most troublesome adverse effect of oral retinoids. The side-effects profile of systemic retinoids (Table 257-2) resembles qualitatively that of the clinical toxic effects of vitamin A or hypervitaminosis A syndrome, although important differences exist. These effects can be globally divided into two types: skin and mucous membrane adverse effects (Type I) and systemic toxic effects (Type II) (Table 257-3). The acute retinoid toxicities include

mucocutaneous lesions (most patients) and laboratory abnormalities (less common but may be severe), whereas the chronic retinoid toxicities involve bony changes (rare).

TABLE 257-2 **Adverse Effects of Systemic Retinoids**

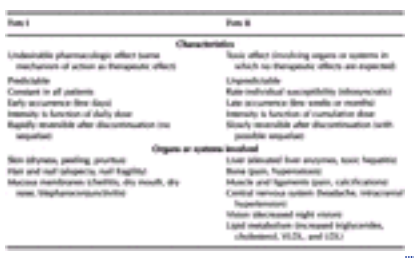

TABLE 257-3 **Types of Side Effects with Oral Retinoids**

Teratogenicity

Isotretinoin and etretinate are potent teratogens, and fetal deformities are the major concern in treating fertile women with oral retinoids. The teratogenic threshold has not been established for synthetic retinoids in humans in contrast to vitamin A. [63] Therefore, there is no safe minimal dose during pregnancy. Retinoid-induced birth defects (retinoid acid embryopathy) include auditory, cardiovascular, craniofacial, ocular (microphthalmia), axial and acral skeletal, central nervous system (hydrocephalus, microcephaly), and thymus gland abnormalities. [64] Etretinate is less likely to induce cardiac malformations and more likely to induce acral skeletal malformations. In some instances, the abnormalities may lead to death, spontaneous abortions, and premature birth. The putative mechanism involves toxic effects on neural crest cells, particularly with exposure during the fourth week of gestation. [65]

In men, retinoid therapy does not appear to produce abnormalities in spermatogenesis, sperm morphology, and sperm motility. [66] However, it is not known whether retinoids present in human semen interfere with normal embryogenesis. No typical retinoid embryopathy malformations have been reported in pregnancies where the male partner was taking acitretin at the time of the conception. No conclusions can be drawn from these limited data, and it is usually recommended that men who are actively trying to father children avoid systemic retinoid therapy.

The recommended duration of contraception after discontinuation of oral retinoid therapy varies with the different retinoid compounds, reflecting mainly their pharmacologic profiles (half-life, deposition in adipose tissue).

Skin and Mucous Membrane Adverse Effects (Type I)

MUCOCUTANEOUS Undesirable dose-related effects on the skin and mucous membranes during treatment with systemic retinoids reflect mainly decreased sebum production, reduced stratum corneum thickness, and altered skin barrier function. [67] Most patients receiving retinoids develop dryness and chapping of the lips, skin, and mucous membranes. Cheilitis is the most common toxicity occurring in almost all patients receiving isotretinoin. Cheilitis is the earliest and the most frequent sign appearing after the start of acitretin treatment, followed by blepharoconjunctivitis, dry eyes, dry nose, and dry mouth. [67] Dryness of the mouth with thirst and dryness and fragility of the nasal mucosa, leading to epistaxis, are observed frequently. Xerosis of the skin, associated with pruritus and peeling, especially of the palms and soles, occurs very frequently. Etretinate and acitretin in particular lead to palm, sole, and fingertip peeling and skin fragility. [67] Skin fragility and fissuring of fingertips sometimes create a problem, especially for those who work with their hands. Photosensitivity is particularly observed with isotretinoin and probably reflects the reduction of thickness of the stratum corneum. Bexarotene appears to induce fewer mucocutaneous and ocular side effects than other classes of retinoids; localized or extensive exfoliative dermatitis is the most common cutaneous side effect with bexarotene. [24] *S. aureus* colonization tends to correlate with isotretinoin-induced reduction in sebum production and may lead to overt cutaneous infections. [68] Various ill-defined skin eruptions, called *retinoid dermatitis,* are observed frequently. The erythema is sometimes difficult to differentiate from the underlying psoriasis, which might become erythrodermic. In atopic patients, eczema may be worsened and pruritus exacerbated by oral retinoids.
OCULAR Blepharoconjunctivitis occurs with varying severity in about one-third of patients and may prevent the use of contact lenses. *S. aureus* has been cultured from the eyelids of patients with isotretinoin-induced blepharoconjunctivitis, and *S. aureus* colonization of the conjunctival sac increases significantly during isotretinoin therapy. However, bacterial

conjunctivitis occurs to a lesser extent than *S. aureus* colonization. [69] If artificial tears and topical ophthalmologic antibiotic therapy fail to alleviate the conjunctivitis, ophthalmologic consultation should be sought.

HAIR AND NAILS Diffuse or localized hair loss (telogen effluvium), which is more severe during treatment with etretinate than with isotretinoin, is a common complaint, although objective alopecia tends to occur only at higher dosage levels. Systemic retinoids may induce undesirable effects on the nail apparatus, such as nail thinning, fragility, and shedding; paronychia-like changes; and periungual granulation tissue.

Systemic Toxic Effects (Type II)

BONE Bone toxicity was first observed in retinoid-treated patients maintained on a high dose and after an extended period of continuous treatment for disorders of keratinization. Bone pain without objective evidence of any abnormalities and without sequelae is frequent in retinoid-treated patients. Although these minor complaints appear to have no long-term pathologic effects on the skeleton, several reports with conflicting results have implicated synthetic retinoids, including etretinate and isotretinoin, in the formation of diffuse hyperostoses of the spine [diffuse idiopathic skeletal hyperostosis (DISH) syndrome–like bone changes] and in calcification of tendons and ligaments, particularly involving the ankles. [70] Specific findings include anterior spinal ligament calcification, osteophytes, extraspinal calcifications, and bony bridges but no narrowing of the disk space. Rarely, ossification of the spinal posterior longitudinal ligament has been reported; this change, if progressive, may lead to spinal cord compression with signs of partial spastic paraplegia. [71] Based on data from retrospective studies, it was concluded that although many of the bone changes could not be positively attributed to etretinate or acitretin therapy, spurs and interosseous membrane and tendon calcifications probably were treatment-related. [72] Subsequent prospective studies have shown that the effects of retinoids on bone, if present at all, likely involve worsening of preexisting skeletal overgrowth rather than de novo changes. [73] The long-term use of isotretinoin by patients with acne does not usually cause clinically significant radiologic abnormalities, and most hyperostoses are asymptomatic and clinically insignificant. [74] Osteoporosis has been observed with hypervitaminosis A and after long-term therapy with etretinate but not with isotretinoin. [75] However, recently, a loss of bone density of 4.4 percent without measurable alterations of calcium metabolism was identified in patients after 6 months of isotretinoin use compared with control subjects. [76] In children, only a few cases of skeletal abnormalities including osteoporosis, periostal thickening, slender long bones, and premature epiphyseal closure [67], [77], [78] and [79] have been reported. No baseline x-rays are required, although monitoring high-risk patients receiving prolonged high-dose retinoid treatment may be useful.

MUSCLE Muscle pain and cramps occur in patients taking etretinate or acitretin; however, these muscle effects are associated mostly with isotretinoin, particularly in individuals involved in vigorous physical activity. Sometimes myalgias are accompanied by elevations in creatine phosphokinase levels. Increased muscle tone and axial muscle rigidity and myopathy were reported to be related to etretinate and acitretin therapy, respectively. [80]

CENTRAL NERVOUS SYSTEM (CNS) AND PSYCHIATRIC CNS side effects are rare. Although individual signs of increased intracranial pressure such as headache, nausea, and vomiting are observed occasionally, the complete syndrome with papilledema (pseudotumor cerebri) and impaired vision is exceptional. [81] Concomitant use in isotretinoin-treated patients of tetracycline, doxycycline, or minocycline, which rarely produce increased intracranial hypertension, is the major risk factor for developing pseudotumor cerebri. Combined therapy with isotretinoin and these antibiotics should be avoided. Examination for papilledema should be performed immediately when a patient receiving retinoid therapy complains of headache, visual changes, nausea, or vomiting or if pseudotumor cerebri is otherwise suspected. There have been anecdotal reports suggesting a causal association between isotretinoin therapy in acne patients and severe depression, psychosis, and suicide attempts. [82] However, large-scale epidemiologic studies provide no evidence that isotretinoin exposure compared with antibiotics is associated with increased risk of newly diagnosed depression, suicidal behavior, psychosis, or other psychiatric disorders. [83] Two patients have been reported to undergo a definite change in their dream patterns with a story-like script 2 to 3 weeks after starting treatment with isotretinoin. [84]

OCULAR The most common retinoid effects on eyes are dryness and irritation. Alterations in visual function, mainly poor night vision, excessive glare sensitivity, and changes in color perception, also have been reported. [85]

PANCREATITIS In contrast to first- or second-generation retinoids, acute hemorrhagic pancreatitis has been encountered with a high incidence in patients taking bexarotene. One case of fatal fulminant pancreatitis with acitretin treatment has been reported. [86] Pancreatitis occured in three patients treated with oral bexarotene, 300 mg/m ^{2} or more per day, in association with marked elevations of fasting serum triglycerides. [56] For safety reasons, an initial dose of 300 mg/m ^{2} or less per day is recommended.

HYPOTHYROIDISM Clinical and biochemical central hypothyroidism occurred in 40 percent of patients in the CTCL trials with bexarotene. It was rapidly and completely reversible with cessation of therapy without any clinical sequelae. [56], [87] This effect probably is mediated through suppression of thyrotropin ß subunit (TSHß) secretion by the thyrotrope cells of the anterior pituitary, which express RXR?.

RENAL Renal toxicity has not been a characteristic consequence of retinoid administration. Isotretinoin has been administered safely to patients with end-stage kidney disease who were undergoing hemodialysis. However, case reports describing reversible renal function impairment with elevated creatinine levels during etretinate therapy advise monitoring renal function during retinoid therapy, particularly in patients with a history of renal disorders. [88]

INFLAMMATORY BOWEL DISEASE Isotretinoin rarely has been linked to inflammatory bowel disease (IBD). Four cases of IBD that were induced or exacerbated by isotretinoin have been reported. There was a history of IBD in most of these patients prior to the introduction of isotretinoin. Thus isotretinoin may be used with caution in the presence of IBD. A 5-year prospective study did not demonstrate an increased risk of IBD or of cancer, diabetes, and cardiovascular disease in association with long-term etretinate use for psoriasis. [86] Similar safety with long-term acitretin therapy has not been established.

Laboratory Abnormalities

HYPERLIPIDEMIA Serum lipid changes are the most frequent laboratory abnormalities of retinoid therapy. Isotretinoin and etretinate/acitretin elevate triglycerides in 50 percent and cholesterol in 30 percent of treated patients, [66], [89] whereas bexarotene elevates triglycerides and cholesterol in approximately 79 and 48 percent of patients, respectively. [56]

Disturbance of blood lipids is generally higher with isotretinoin. In cases of severe retinoid-induced hypertriglyceridemia, eruptive xanthomas and acute hemorrhagic pancreatitis may occur. Obtaining baseline serum lipids before initiating retinoid therapy and additional values every 1 to 2 weeks until they are stable (generally in 4 to 8 weeks) may be desirable. In practice, however, monitoring levels monthly for the first 2 months and then at 2- to 3-month intervals is adequate in patients with normal baseline lipid levels and absence of risk factors (obesity, high alcohol intake, diabetes). Discontinuation of therapy is required if the triglyceride level reaches 800 mg/dL. A less severe increase may be treated by dose reduction, therapy withdrawal until normalization of serum lipids, or reduction in alcohol and tobacco consumption. In some instances, lipid-lowering agents may be indicated. [90] Coadministration of atorvastatin with bexarotene is recommended to lower the risk of hyperlipidemia and pancreatitis. [24] The effects of retinoid-induced hyperlipidemia and its management during long-term therapy on the development of atherosclerotic cardiovascular disease are unknown. Retinoids probably cause hyperlipidemia by interfering with lipid clearance. Transactivation of RXRs increases the expression of apolipoprotein C-III, which prevents the uptake of lipids from very low density lipoproteins (VLDL) into cells. [91]

LIVER TOXICITIES Transitory abnormal elevations in serum transaminases have been reported in approximately 20 percent of patients treated with either etretinate or acitretin and occur much less frequently with isotretinoin and bexarotene. Alkaline phosphatase, lactate dehydrogenase, and bilirubin also may be abnormal. Liver function test changes usually occur between 2 and 8 weeks after therapy is begun. Severe or persistent hepatotoxic reactions appear in less than 1 percent of patients. Acitretin therapy elicited no biopsy-proven hepatotoxicity in a 2-year prospective study, suggesting that periodic liver biopsy should not be necessary. [92] No specific studies evaluate the use of retinoids in patients with hepatic insufficiency. However, because retinoids are metabolized by hepatic cytochrome P-450 isoenzymes (CYP 3A4) and undergo partial biliary elimination, significant hepatic insufficiency may interfere with drug elimination. Transaminase elevations greater than three times the upper normal range should lead to discontinuation of retinoid therapy. With two- to threefold transaminase elevations, therapy should be withdrawn until liver function tests are normalized. [24]

HEMATOLOGIC TOXICITIES A high incidence (28 percent) of dose-related leukopenia has been reported with bexarotene in the CTCL studies, occuring as early as 2 to 4 weeks, and due to a decrease in neutrophils rather than lymphocytes. [56] Hematologic abnormalities are much less common with other retinoids. However, careful hematologic monitoring in HIV-infected patients is warranted. Most adverse effects associated with retinoids are preventable and manageable with proper patient selection, dose adjustments, discontinuation of treatment, and routine monitoring for potential toxicity. Absolute contraindications are pregnancy or women contemplating becoming pregnant, noncompliance with contraception, breast-feeding, and hypersensitivity to parabens (preservatives present in acitretin's capsule). Relative contraindications are leukopenia, cholesterol or triglyceride elevations, significant hepatic (especially bexarotene) or renal dysfunction, and hypothyroidism (bexarotene). Patients should be advised not to take other vitamin A supplements.

DRUG INTERACTIONS

The concurrent use of retinoids with other therapies having similar side effects may increase the risk of these adverse events. Tretracycline, minocycline, and doxycycline (increased intracranial pressure and increased phototoxicity), alcohol (increased conversion to etretinate, hepatoxicity), metothrexate (synergistic liver toxicity with retinoids), and vitamin A supplements (hypervitaminosis A) should be avoided. [86] The concomitant administration of bexarotene and gemfibrozil results in a substantial increase in plasma concentrations of bexarotene and its potential toxicity, probably at least partially related to CYP450 3A4 inhibition by gemfibrozil. The concomitant administration of atorvastatin does not affect bexarotene plasma levels and is the recommended concomitant antilipemic therapy. In rare instances, patients with diabetes may have more difficulty controlling glucose while taking a retinoid; however, a causal relationship is uncertain. In addition, acitretin may possibly reduce the efficacy of progestin-only contraceptives. Retinoid drug levels and resultant potential for toxicity may increase with CYP 3A4 inhibitors such as azole and macrolides. In contrast, antituberculosis drugs (rifampicin) and anticonvulsants (phenytoin and carbamazepine) may decrease the drug levels of retinoids via CYP 3A4 induction. Retinoids may also increase the drug levels of cyclosporine via competition for CYP 3A4 metabolism. [24] Neomycin induces malabsorption syndrome, especially with regard to the absorption of vitamin A.

FACTORS IN THE DECISION TO USE RETINOIDS

As with other medications, the risk-benefit ratio should be used to determine whether or not to treat a dermatologic patient with synthetic retinoids. Factors to be considered include the following:

1. *Responsiveness of the disorder to retinoids.* The treatment of severe acne vulgaris with isotretinoin is optimal, with short-term exposure leading to long-term remission.
2. *Dose of retinoid required.* The use of retinoids in combination with other effective treatments, such as RePUVA (combination photochemotherapy) for psoriasis, may enhance efficacy and allow dose reduction with fewer side effects.
3. *Availability of alternative treatments.* In some diseases (severe Darier's disease, pustular psoriasis, pityriasis rubra pilaris, epidermolytic hyperkeratosis), synthetic retinoids may be the only effective treatment.
4. *Acute and chronic toxicity of retinoid therapy.* Major systemic adverse effects, such as teratogenicity, and ocular, bone, lipid, and liver adverse effects make careful patient selection and ongoing laboratory surveillance critical. Diseases that relapse rapidly on withdrawal of synthetic retinoids require continuous retinoid administration and, therefore, are associated with increased risk of chronic skeletal toxicity, particularly in children.
5. *Severity of the disease.* Disease-induced limitations on educational, psychological, or physical development should be considered. For example, early retinoid treatment of lamellar ichthyosis may prevent the development of ectropion.
6. *Age of the patient.* Children with disorders of cornification requiring chronic moderate- to high-dose retinoid therapy are at highest risk of developing bone toxicity. They are at risk of premature epiphyseal closure, and because of longer lifetime exposure to the drug, they are at higher risk for future development of the vertebral changes resembling DISH syndrome–like bone changes.
7. *Sex of the patient.* Retinoid teratogenicity entails special risks for the female patient of childbearing potential.

Current guidelines are that adequate contraception should be used for at least 1 month before therapy with all systemic retinoids. Isotretinoin and bexarotene require contraception for 1 month after cessation of therapy, whereas acitretin and etretinate require contraception for 3 years after cessation of therapy in the United States and 2 years in Europe.

8. *Presence of other disorders that may be aggravated by retinoid use.* Renal or hepatic compromise, preexisting hyperlipidemia, or a family history of hyperlipidemia or premature atherosclerotic cardiovascular disease should be considered in the therapeutic assessment.
9. *Concomitant use of other drugs.* Drugs interacting with hepatic CYP 3A4 metabolism should be administered carefully in association with systemic retinoids. Other drugs that are hepatotoxic (methotrexate), elevate serum lipids (estrogens, glucocorticoids), or rarely produce benign intracranial hypertension (tetracycline, doxycycline) should be avoided, if possible, or the patient must be monitored carefully during the clinical course.

After more than two decades of experience with isotretinoin and etretinate/acitretin in the treatment of dermatologic diseases, synthetic retinoids are firmly established as efficacious therapeutic agents. New retinoids (agonists, inverse agonists, or neutral antagonists) are being designed to interact with selected nuclear retinoic acid receptors (RARs, RXRs) to focus on a specific therapeutic goal and to improve the therapeutic index.

REFERENCES

In 1937, Bovet and Staub demonstrated that some of the effects of histamine in experimental animals could be antagonized by amines containing a phenolic ether moiety. Subsequent research led to the development of histamine-receptor antagonists, or antihistamines, that became available for clinical use as therapeutic agents in the 1940s. The fact that these antihistamines were unable to block the effects of histamine on the gastric mucosa suggested that histamine might exert its effects via different receptors, which were designated H_1 and H_2. This observation led to the synthesis of compounds that selectively blocked histamine at the H_2-receptor site. H_3 receptors have been recognized in the brain and lung, but not in the skin, in humans [1]; intracellular histamine receptors and H_4 receptors have been described in certain cells and tissues, but, again, not in the skin.

TRADITIONAL, CLASSIC, OR FIRST-GENERATION H_1-TYPE ANTIHISTAMINES

The traditional, classic, or first-generation H_1-type antihistamines have a substituted ethylamine moiety as an integral part of the molecule (Fig. 258-1). The activity of an H_1-type antihistamine is increased by the substitution of a halogen in the *para* position of the phenyl or benzyl group of R^1. For maximum activity, the terminal nitrogen of the ethylamine group should be a tertiary amine with methyl groups or a cyclic moiety in R^2 and R^3. The dextro isomers are more active than are the levo isomers. In addition, H_1-type antihistamines have a tertiary amino group linked by a two- or three-atom chain to two aromatic substituents. Traditional H_1-type antihistamines have been divided into six groups (Table 258-1) on the basis of substitution at the X position with nitrogen, oxygen, or carbon. The presence of multiple aromatic or heterocyclic rings and alkyl substituents results in their lipophilic properties. Evidence that with prolonged use H_1-type antihistamines may produce tachyphylaxis or lose their efficacy appears to reflect decreased compliance rather than an increased rate of metabolism.

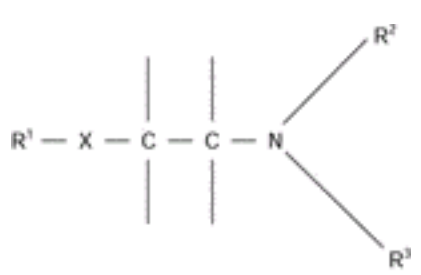

FIGURE 258-1 Ethylamine moiety present in H_1-type antihistamines. R^1, aromatic and/or heterocyclic groups; X, linkage such as nitrogen, oxygen, or carbon.

Chemical Class	Generic Name
Alkylamine (propylamine)	Brompheniramine maleate
	Chlorpheniramine maleate and tannate
	Dexbrompheniramine maleate
	Dexchlorpheniramine maleate
	Dimethindene maleate
	Triprolidine hydrochloride
Ethanolamine (aminoalkyl ether)	Carbinoxamine maleate
	Clemastine fumarate
	Diphenhydramine citrate and hydrochloride
	Doxylamine succinate
	Embramine hydrochloride
	Melenditamium methylsulfate
	Trimethobenzamine citrate
Ethylenediamine	Mepyramine maleate
	Pyrilamine maleate
	Tripelennamine citrate and hydrochloride
Phenothiazine	Dimethothiazine mesylate
	Methdilazine
	Methdilazine and methdilazine hydrochloride
	Promethazine hydrochloride and theoclate
	Trimeprazine tartrate
Piperidine	Azatadine maleate
	Cyproheptadine hydrochloride
	Diphenylpyraline hydrochloride
	Phenindamine tartrate
Piperazine	Hydroxyzine hydrochloride and pamoate

TABLE 258-1 **Traditional, Classic, or First-Generation H_1-Type Antihistamines**

Pharmacology

H_1-type antihistamines are absorbed from the gastrointestinal tract after oral administration. Their effects can be observed within 30 min, are maximal within 1 to 2 h, and persist for 4 to 6 h; however, some of these therapeutic agents may have a longer duration of action. For example, after the oral administration of a single dose, the serum half-lives of brompheniramine, chlorpheniramine, and hydroxyzine exceeded 20 h in adults. The serum half-lives of brompheniramine, [2] chlorpheniramine, diphenhydramine, and hydroxyzine are shorter in children and longer in elderly individuals. H_1-type antihistamines are metabolized by the hepatic cytochrome P450 (CYP) enzyme system CYP3A4, in which they are conjugated to form glucuronides. Excretion of these compounds in the urine is almost complete 24 h after administration.

The H_1-type antihistamines suppress wheal-and-erythema reactions induced by the intracutaneous injection of histamine for various time intervals depending on the agent studied. Their potency can be compared by their inhibition of the cutaneous wheal-and-erythema response. Clemastine, diphenhydramine, promethazine, and triprolidine are excreted in breast milk.

Mechanism of Action

H_1-type antihistamines are competitive inhibitors of the actions of histamine at tissue receptor sites. Their binding is reversible and they can be displaced by high levels of histamine. In addition to their antihistamine actions, H_1-type antihistamines also have sedative effects, anticholinergic activity, local anesthetic effects, antiemetic activity, and anti–motion-sickness effects. Some H_1-type antihistamines possess a-adrenergic receptor or cholinergic muscarinic receptor blocking properties, while others possess antiserotonin effects. Some H_1-type antihistamines may have additional antiallergic properties. For example, azatadine inhibits IgE-mediated histamine release and cysteinyl leukotriene generation and release in vitro from mast cells and basophils.

Clinical Uses

H_1-type antihistamines have been used for the relief of pruritus and for the treatment of urticaria, angioedema, and physical urticaria. In double-blind, placebo-controlled studies, H_1-type antihistamines were statistically superior to placebos in the treatment of urticaria and angioedema. However, comparative studies of the groups of H_1-type antihistamines have shown them to be of equal efficacy. If an agent from one therapeutic group of H_1-type antihistamine proves ineffective, then an agent from another group should be administered. H_1-type antihistamines from different groups may be combined. H_1-type antihistamines are of benefit to patients with a history of reactions to radiocontrast media and transfusion reactions.

H_1-type antihistamines are used to treat pruritus in patients with atopic dermatitis. Their efficacy may in part be related to the suppression of anxiety and to their sedative effect. Pruritus associated with other conditions, such as allergic contact dermatitis and other forms of eczematous dermatitis, lichen planus, mosquito bites, infestations, and pruritus secondary to underlying medical disorders or of an idiopathic nature, also may be relieved by H_1-type antihistamines, although controlled trials do not exist.

There are limited guidelines for the use of H_1-type antihistamines to treat pregnant women. Most H_1-type antihistamines are classified as United States Food and Drug Administration (FDA) pregnancy category B or category C. Although it is recommended that all H_1-type antihistamines be avoided in the first trimester of pregnancy, [3] a meta-analysis of malformations caused by H_1-type antihistamine use in pregnancy showed an odds ratio of 0.76, which suggested that the risk of fetal malformations in early pregnancy was less than that of controls. [4]

Dosage Schedules and Formulations

H_1-type antihistamines are conventionally administered in divided doses at intervals between 4 and 6 h. However, the observation that one oral dose of certain of these agents is associated with longer serum half-lives suggests that some H_1-type antihistamines may not require administration so frequently as was previously indicated. H_1-type antihistamines of the ethylenediamine group are no longer available in the United States.

Adverse Effects

Approximately 25 percent of patients receiving H_1-type antihistamines experience an adverse reaction. Sedation is the most common problem because H_1-type antihistamines cross the blood-brain barrier. This sedative effect is pronounced with the ethanolamine and the phenothiazine groups and is less marked with the alkylamine group. The sedative effect ameliorates in most individuals within a few days of continual administration of H_1-type antihistamines. If tolerance to the sedative manifestations does not occur, an agent from another group should be used.

The use of H_1-type antihistamines has been associated with increased occupational injuries at work, and the risk of injury is enhanced with an odds ratio of 1.5. [5] Other central nervous system (CNS) effects include dizziness, tinnitus, disturbed coordination, inability to concentrate, blurred vision, and diplopia. Stimulatory CNS effects, which occur especially with the alkylamine group, include nervousness, irritability, insomnia, and tremor.

Studies to demonstrate the CNS effects of H_1-type antihistamines include the multiple sleep latency test, critical flicker fusion test, choice reaction time, digit symbol substitution test, tests involving brain stem-evoked potentials, acuity tests, cognitive skill tests, and actual and simulated driving tests. [6] In brain stem-evoked potential studies, the individual's attention and processing speed are impaired by H_1-type antihistamines. In multiple studies, driving skills were impaired after the use of H_1-type antihistamines. Fatal automobile accidents have been reported.

Gastrointestinal complaints, which are the second most frequent side effect and are noted especially with the ethylenediamine group, include anorexia, nausea, vomiting, epigastric distress, diarrhea, and constipation. The administration of these agents with food may eliminate some of these manifestations.

H_1-type antihistamines have anticholinergic effects, which include dry mucous membranes, difficulty in micturition, urinary retention, dysuria, urinary frequency, and impotence. These clinical manifestations occur with the ethanolamine, the phenothiazine, and the piperazine groups. The anticholinergic effects of H_1-type antihistamines preclude their use in patients with narrow-angle glaucoma and require that they be used with caution in patients with prostatic hypertrophy.

The cardiovascular effects of H_1-type antihistamines are not usually experienced after oral administration. Transient hypotension may develop after intravenous therapy, especially if the drug is administered rapidly.

Cutaneous reactions occurring after the administration of H_1-type antihistamines are uncommon; they include eczematous dermatitis, allergic contact dermatitis, urticaria, petechiae, fixed drug eruptions, and photosensitivity.

In children, acute poisoning may develop; hallucinations, ataxia, incoordination, athetosis, and convulsions are the major features. Anticholinergic effects include flushing, dilated pupils, and hyperthermia.

Drug Interactions

The H_1-type antihistamines diphenhydramine, chlorpheniramine, clemastine, promethazine, hydroxyzine, and tripelennamine inhibit CYP2D6 in vitro. [7] The levels of metoprolol increase with the administration of diphenhydramine in healthy men with high CYP2D6 activity. [8] Diphenhydramine inhibits CYP2D6-mediated metabolism of venlafaxine. [9]

When H_1-type antihistamines are consumed in combination with alcohol or other therapeutic agents with CNS depressant effects, such as diazepam, the central depressive effects may be accentuated. Antihistamines of the phenothiazine group may block and reverse the vasopressor effect of epinephrine. If individuals receiving a phenothiazine require a vasopressor agent, norepinephrine or phenylephrine should be used. H_1-type antihistamines are contraindicated for patients receiving monoamine oxidase inhibitors.

LOW-SEDATING OR SECOND- AND THIRD-GENERATION H_1-TYPE ANTIHISTAMINES

Low-sedating or second- and third-generation H_1-type antihistamines (Table 258-2) are less lipophilic, minimally cross the blood-brain barrier, and preferentially bind to peripheral H_1 receptors. Some of these agents possess membrane-stabilizing or quinidine-like effects on cardiac muscle, and are responsible for a prolongation of the refractory period of the heart and the ventricular arrhythmia torsade de pointes. The administration of low-sedating H_1-type antihistamines has not been associated with the development of tachyphylaxis.

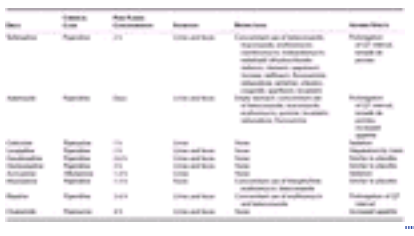

TABLE 258-2 **Low-Sedating, Second- and Third-Generation H_1-Type Antihistamines**

Pharmacology

The low-sedating H_1-type antihistamines are absorbed from the gastrointestinal tract and achieve peak plasma concentrations within 2 h (Table 258-2). They suppress the wheal-and-erythema reaction from 1 to 24 h. [10], [11], [12] and [13] Terfenadine, astemizole, loratadine, acrivastine, mizolastine, ebastine, and oxatomide are metabolized in the liver via the hepatic CYP enzyme system CYP3A4. Cetirizine, the carboxylic acid metabolite of hydroxyzine, fexofenadine, the carboxylic acid metabolite of terfenadine, and desloratadine are not metabolized in the liver.

Astemizole is a long-acting agent with a slow onset of action and with a steady-state concentration reached in 3 to 4 weeks. Its plasma half-life after a single dose is biphasic, with an initial phase of 1.1 days and a second phase of 9.5 days, owing to its metabolite desmethylastemizole. The effects of astemizole are long lasting, and the drug should be discontinued 4 to 6 weeks before diagnostic prick skin tests are performed. Cetirizine and fexofenadine have similar elimination half-life values in children and adults. The plasma half-life of fexofenadine is greater in individuals older than 65 years of age and in those individuals with renal impairment; however, the pharmacokinetics in patients with hepatic disease do not differ from those in healthy individuals. Desloratadine has a half-life of 27 h with steady-state serum concentrations achieved within 7 days. [14] In pharmacokinetic studies, approximately 7 percent of all subjects and 20 percent of African Americans were slow metabolizers of desloratadine. There are no restrictions on the use of desloratadine in patients with renal or hepatic failure. Food and grapefruit juice have no effect on its bioavailability and absorption. Pharmacokinetics of mizolastine in elderly individuals were similar to those in healthy volunteers. Ebastine, which is metabolized to form its carboxylic acid metabolite, carebastine, [15] has a half-life of 15 h. Impaired renal function alters the pharmacokinetics of emedastine, and the dose should be adjusted in such patients. [16] Terfenadine, cetirizine, loratadine, fexofenadine, and desloratadine are excreted in breast milk.

Mechanism of Action

Low-sedating H_1-type antihistamines bind in a noncompetitive manner to the H_1 receptor, are not easily displaced by histamine, dissociate slowly, and have a longer duration of action. Some low-sedating H_1-type antihistamines affect the trafficking of cells in the skin and other tissues, the release or generation and release of inflammatory mediators, and the expression of adhesion molecules.

Cetirizine inhibits chemotaxis in a variety of models. After the administration of cetirizine, the challenge of allergic subjects was associated with a decrease in the influx of eosinophils into the skin, as assessed by a skin-window technique in one study. Cetirizine has an inhibitory effect on eosinophil chemotactic responses in vitro to *N*-formyl-methionyl-leucyl-phenylalanine (FMLP) and platelet-activating factor (PAF), and in vivo to the influx of eosinophils induced by PAF. In skin chambers, the migration of eosinophils, neutrophils, and basophils was attenuated with cetirizine, but not with terfenadine, promethazine, chlorpheniramine, and diphenhydramine. Desloratadine and emedastine [17] inhibited PAF-induced eosinophil chemotaxis, TNF-a–induced eosinophil adhesion, and spontaneous and phorbol myristate-induced superoxide generation. [18]

Cetirizine in vitro inhibited the chemotactic responses of monocytes and T lymphocytes of unspecified types to stimulation with FMLP and leukotriene (LT) B_4. [19] After administration of cetirizine to healthy human subjects, peripheral blood monocytes and T lymphocytes showed a diminished chemotactic responses to the aforementioned stimuli.

Cetirizine reduced the wheal-and-flare reaction but not the release of histamine, tryptase, prostaglandin (PG) D_2, and eosinophil cationic protein in a microdialysis study. [20] Oxatomide inhibited the release of histamine and tryptase and the generation and release of PGD_2 and LTC_4 from human basophils and mast cells in vitro [21] and inhibited the synthesis of LTB_4 and PAF in neutrophils in vitro. [21] In other studies, terfenadine, cetirizine, and loratadine decreased expression of intercellular adhesion molecule (ICAM)-1 on human keratinocytes, Langerhans cells, and endothelial cells. Mizolastine inhibited antigen-induced ICAM-1 expression in skin blister aspirates. [22]

Clinical uses

In double-blind, placebo-controlled, or parallel studies, the lowsedating H_1-type antihistamines, terfenadine, astemizole, [23] cetirizine, [23] loratadine, fexofenadine, desloratadine, [24] acrivastine, mizolastine, [25], [26] azelastine, [27] ebastine, [27] and oxatomide, [28] were found to be statistically superior to placebo in the treatment of chronic idiopathic urticaria and angioedema. In studies in which low-sedating H_1-type antihistamines are compared with each other and with traditional H_1-type antihistamines, no single therapeutic agent commands preeminence. No objective evidence exists to support the effectiveness of low-sedating H_1-type antihistamines in the treatment of the pruritus in atopic dermatitis. [29] Azelastine suppressed the pruritus in patients with mastocytosis.

Most low-sedating H_1-type antihistamines are classified as FDA pregnancy category B or category C. In a prospective trial, astemizole administered to pregnant women was not associated with intrauterine growth retardation or perinatal complications. The rate of birth malformations was identical to that of the control group and to that of the general population.

Dosage Schedules and Formulations

Most low-sedating H_1 antihistamines are administered once daily. Those currently available in the United States include cetirizine, loratadine, fexofenadine, and desloratadine. Although azelastine is available as an oral preparation in other countries, it has been approved in the United States only as a nasal spray for allergic rhinitis. In the United States, acrivastine exists only in combination with pseudoephedrine hydrochloride for the treatment of allergic rhinitis. Ebastine, emedastine, mizolastine, and oxatomide are not available in the United States, and terfenadine and astemizole are no

longer available in the United States. Tazifylline, temelastine, noberastine, and setastine are investigational agents and are not discussed in this chapter.

Adverse Effects

The low-sedating H_1-type antihistamines lack both sedative and anticholinergic side effects, and have fewer adverse effects when compared with the traditional H_1-type antihistamines. [30]

With the use of terfenadine and astemizole, a ventricular tachycardia known as torsade de pointes was associated with prolongation of the QT interval and has been reported to occur after drug overdose and as the result of drug interactions. Perhaps individuals with hepatic dysfunction or those susceptible to conditions associated with a prolonged QT interval also may be at risk. Loratadine does not increase the QT interval; however, a prolonged QT interval developed in a single patient with coronary artery disease after the administration of loratadine and quinidine. The QT interval was not affected when fexofenadine was administered with erythromycin or ketoconazole. [31] Desloratadine, acrivastine, mizolastine, [26] and emedastine [32] have no effect on the QT interval. Changes in the QT interval were noted with the administration of ebastine with ketoconazole and with erythromycin, [33] but not with ebastine alone.

Cetirizine is less sedating than its parent compound hydroxyzine. When assessed by actual driving, the critical tracking test, and the divided attention test, cetirizine was more sedating [34] than were placebo, loratadine, and terfenadine. When assessed by tests of cognitive function and psychomotor performance in healthy volunteers, cetirizine at 10 mg was not more sedating than loratadine at 40 mg. One case of cholestasis has been reported after the administration of cetrizine. [35]

In a study of alertness and performance on a flight simulator, the skills of airline pilots who received 10 mg of loratadine were as unaffected as the skills of those who received placebo. In a study of the effects of antihistamines on children's learning, loratadine caused less learning impairment than did diphenhydramine. As assessed by the critical flicker fusion test, choice reaction time, and continuous tracking task test, cetirizine and loratadine were indistinguishable from placebo. [36] The elimination of loratadine is not decreased in individuals with renal impairment. Two cases of hepatotoxicity with liver failure have been reported.

Fexofenadine does not affect actual driving and psychomotor performance, and it attenuated alcohol's adverse effect on driving. [37], [38] Desloratadine has no sedative side effects as assessed by the maintenance of wakefulness test, which measures the ability to stay awake, and the multiple sleep latency test, which measures the time to fall asleep. Desloratadine did not impair driving performance during an over-the-road driving test. [39]

Sedation is a side effect of acrivastine. In a questionnaire study, [40] acrivastine was 2.8 times more likely to result in sedation than were loratadine and fexofenadine. CNS effects are produced by its interactions with alcohol. As assessed by positron emission tomography, ebastine causes brain histamine H_1 receptor occupation of 10 percent, which is consistent with its low incidence of sedative side effects. [41]

Astemizole and oxatomide are associated with increased appetite and weight gain.

Drug Interactions

Prolongation of the QT interval has been reported to occur in patients taking terfenadine and concomitant ketoconazole and itraconazole, but not fluconazole; macrolide antibiotics, such as erythromycin and clarithromycin, but not azithromycin or dirithromycin; troleandomycin; lovastatin; protease inhibitors; and flavonoids, such as naringin in grapefruit juice. There are no interactions between terfenadine and theophylline or between terfenadine and phenytoin. Terfenadine does not enhance the depressant effects of alcohol or benzodiazepines. Astemizole metabolism studied in human liver microsome preparations in vitro is less sensitive to the effects of ketoconazole than is the metabolism of terfenadine. It is recommended, however, that astemizole not be administered with ketoconazole, itraconazole, erythromycin, quinine, lovastatin, nefazodone, and fluvoxamine. There are no restrictions on the ability to take cetirizine with other medications. Electrocardiographic abnormalities and cardiac side effects have not been reported. Although erythromycin and ketoconazole inhibit the metabolism of loratadine, [42] electrocardiographic abnormalities and cardiac side effects have not been reported. Desloratadine has no clinical drug interactions with erythromycin or ketoconazole or with grapefruit juice, [11] and no effect has been demonstrated on the QT interval with these combinations. There is no increased psychomotor impairment with associated alcohol use. [39] Mizolastine is associated with increased levels of theophylline. [43] There are no interactions with lorazepam or ethanol. Ebastine taken with either erythromycin or ketoconazole results in the increased accumulation of ebastine in plasma. [33] Ebastine does not interact with diazepam or alcohol.

H_2-TYPE ANTIHISTAMINES

H_2-type antihistamines possess an imidazole ring and lack the aryl ring of H_1-type antihistamines. These therapeutic agents are lipophobic, which presumably accounts for their lack of CNS effects. Famotidine and nizatidine differ from cimetidine and ranitidine in that they contain a thiol ring.

Pharmacology

H_2-type antihistamines are rapidly absorbed from the gastrointestinal tract with peak levels occurring between 1 and 2 h;

they undergo renal clearance with hepatic metabolism.

Only a small proportion of cimetidine is absorbed from the stomach; most of its absorption occurs in the small intestine. The half-life of cimetidine in plasma is 2 h; approximately 69 percent is excreted unchanged in the urine. The plasma half-life of ranitidine is 2 to 3 h in adults, and it is prolonged in the elderly and in individuals with liver or kidney diseases. The drug and its metabolites are excreted principally in the urine. Famotidine has a plasma half-life of 3 to 8 h. In patients with renal failure, the half-life of famotidine may exceed 20 h. Nizatidine has a plasma half-life of 1 to 2 h, and its duration of action is up to 10 h. Nizatidine is primarily eliminated by the kidneys within 16 h. The oral bioavailability of nizatidine is not affected by food. Cimetidine, ranitidine, famotidine, and nizatidine are present in breast milk.

Mechanism of Action

Although H_2-antihistamines were developed to treat peptic ulcer disease, they have been used in the treatment of dermatologic disorders because of the presence of H_2 receptors on the cutaneous microvasculature. Inasmuch as the skin microvasculature contains both H_1 and H_2 receptors, increased venular permeability depends on the interaction of histamine with both of these receptors.

The presence of an H_2-histamine receptor on CD8 T lymphocytes may partly explain the augmentation of delayed-type hypersensitivity reactions with increased erythema and induration after the intradermal administration of antigens. In healthy volunteers, the oral administration of cimetidine was associated with an increase in the mitogen-induced proliferation of lymphocytes, a decrease in the number of CD8 T lymphocytes, and an increase in the number of CD4 T lymphocytes.

Clinical Uses

The combination of H_1- and H_2-type antihistamines is of benefit to a few patients with acute and chronic idiopathic urticaria and angioedema as well as to those with certain forms of physical urticaria. The combination of H_1- and H_2-type antihistamines should be considered for patients with refractory chronic idiopathic urticaria, in whom H_1-type antihistamines, alone or in combination, are ineffective. The pruritus and whealing in systemic mastocytosis and urticaria pigmentosa were modified in a double-blind trial of chlorpheniramine and cimetidine.

In anecdotal reports, cimetidine was reported to be of value in the treatment of the pruritus resulting from myelofibrosis, polycythemia vera, and carcinoid flush. Anecdotal reports also suggest that the combination of H_1- and H_2-type antihistamines was of value in the treatment of carcinoid flush and alcohol-induced flushing. High doses of cimetidine were successful in the treatment of verruca vulgaris in some individuals.

The H_2-type antihistamines are classified as FDA pregnancy category B.

Dosage Schedules and Formulations

H_2-type antihistamines are administered twice daily, except cimetidine, which is administered four times daily. The H_2-type antihistamines are available without a prescription in the United States and many other countries.

Adverse Effects

Mental confusion may develop in elderly patients with impaired hepatic or renal function who take regular doses of cimetidine, and in younger individuals who take high doses of cimetidine. Other side effects include headache, dizziness, drowsiness, malaise, muscular pain, diarrhea, and constipation. There are rare reports of granulocytopenia.

Uncommon side effects of cimetidine include gynecomastia with or without elevated prolactin levels in men; galactorrhea with elevated prolactin levels in women; and loss of libido, impotence, and reduction of sperm counts in young men. Modest elevations in serum creatinine levels are common and are reversible after the drug is withdrawn. Elevated levels of serum transaminases have been reported and are reversible. Interstitial nephritis, fever, and cutaneous eruptions that include urticaria and erythema multiforme have occurred. Although cimetidine binds to nitrites in the gastrointestinal tract and may yield potential carcinogenic nitroso compounds, the prolonged administration of cimetidine in high doses to rats and dogs failed to result in the development of gastric neoplasms. Cimetidine, however, may mask symptoms associated with gastric carcinoma in humans. Cimetidine increases the concentration of blood alcohol levels due to an inhibitory effect on gastric alcohol dehydrogenase activity.

Ranitidine does not bind to androgen receptors and does not enhance cell-mediated immune responses. Ranitidine may affect physiologic autonomic control of the cardiovascular system by altering indices of parasympathetic and sympathetic control as assessed by power spectral analysis of heart rate variability and calculation of spontaneous baroreflex sensitivity. [44] This altered cardiac sympathovagal balance indicates a shift toward sympathetic predominance and susceptibility to arrhythmias. Ranitidine inhibits gastric alcohol dehydrogenase activity and leads to increased blood alcohol levels. Minor adverse effects include headache, dizziness, malaise, nausea, constipation, and abdominal pain. Serum transaminase and creatinine levels temporarily increase but return to baseline levels with continued treatment.

Adverse reactions to famotidine are infrequent and include headache, dizziness, constipation, and diarrhea. No interference with the hepatic oxidative metabolism of diazepam, phenytoin, theophylline, or warfarin has been observed. Famotidine does not inhibit gastric alcohol dehydrogenase activity; it lacks antiandrogenic side effects.

Minor gastrointestinal side effects occur with nizatidine. Elevations of serum transaminases and uric acid levels, without

adverse clinical consequences, develop, and antiandrogenic effects are absent.

Drug Interactions

Drug interactions have been reported with cimetidine therapy and most importantly include prolonged bleeding and prothrombin times in patients receiving concomitant oral anticoagulants and cimetidine. Cimetidine should be used with caution in patients receiving phenytoin, propanolol, nifedipine, diazepam, and theophylline, because blood levels of these drugs are elevated and their excretion is delayed.

Although ranitidine interacts with other medications less frequently than does cimetidine, interactions with fentanyl, metoprolol, midazolam, nifedipine, theophylline, and warfarin have been observed. Ranitidine may decrease the absorption of diazepam and reduce its plasma concentration by 25 percent.

In healthy volunteers, drug interactions were not reported with the concomitant administration of nizatidine and chlordiazepoxide, diazepam, lidocaine, lorazepam, theophylline, or warfarin.

OTHER THERAPEUTIC AGENTS WITH ANTIHISTAMIC ACTIVITY

Tricyclic Antidepressants

Tricyclic antidepressants act on both H_1 and H_2 receptors. Doxepin was more potent than chlorpheniramine in inhibiting experimental wheals induced by histamine. Doxepin has been used successfully in the treatment of chronic idiopathic urticaria and physical urticaria. In a double-blind, vehicle-controlled trial, topical doxepin cream reduced pruritus in patients with atopic dermatitis. Topical doxepin hydrochloride cream can cause allergic contact dermatitis. Systemic doxepin has been classified as FDA pregnancy category C; topical doxepin is classified as FDA pregnancy category B. Systemic doxepin is contraindicated close to delivery, and systemic and topical doxepin are contraindicated during lactation. Doxepin is present in breast milk.

Ketotifen

Ketotifen, a benzocycloheptathiophene derivative, is an H_1-type antihistamine and calcium channel blocker that prevents histamine release from mast cells induced by IgE and compound 48/80 in vitro and inhibits passive cutaneous anaphylaxis in experimental animals in vivo. Ketotifen has been used successfully in the treatment of chronic idiopathic urticaria, physical urticaria, urticaria pigmentosa in a controlled clinical trial, and the pruritus of neurofibromatosis. Sedation and weight gain are side effects. Ketotifen is available in the United States as an ophthalmic solution.

REFERENCES

Strictly speaking, antibiotics are chemicals produced by various microbes, such as bacteria, actinomycetes, and fungi, that inhibit the growth of other organisms. In common usage, however, *antibiotic* generally refers to a medication with antibacterial action, whether it is a natural or a synthetic substance. Since the late 1930s, when the sulfonamides emerged as therapeutic agents, and the 1940s, when penicillin came into clinical use, the number and variety of these antibacterial agents have multiplied to the point where the amount of information required to prescribe them intelligently is daunting. Because many of these antibiotics are very expensive and have a wide spectrum of antimicrobial activity, their improper use increases the cost of medical care and encourages the emergence of resistant organisms, which has become a widespread and frightening problem throughout the world. Regrettably, office-based clinicians in the United States (and elsewhere) are prescribing more broad-spectrum, expensive antibiotics than ever before, often from the erroneous belief that newer agents are necessarily better than the older, less expensive ones. For nearly all skin conditions requiring antibiotic therapy that a dermatologist is likely to encounter, however, inexpensive, generic preparations from one of four categories will suffice: (1) penicillins—penicillin and dicloxacillin; (2) first-generation cephalosporins; (3) tetracyclines, usually doxycycline; and (4) erythromycin. Penicillins, cephalosporins, and erythromycin are alternative options for treating streptococcal and staphylococcal infections. Doxycycline or erythromycin is appropriate for acne or rosacea; penicillin or doxycycline for the cutaneous manifestations of Lyme disease; and erythromycin for bacillary angiomatosis. Other primary bacterial infections of the skin are rare. This chapter is focused on these agents, which dermatologists should know thoroughly. Table 259-1 delineates the astonishing differences in price between these medications and some of the newer, more expensive antibiotics for which very few dermatologic indications exist. Table 259-2 lists the antibiotic choices for bacterial and rickettsial skin infections.

Medication	Dose	Cost (7 Days)*
Penicillins		
Penicillin V	250 mg qid	$1.49
Dicloxacillin	250 mg qid	$5.32
Amoxicillin-clavulanate	250 mg qid	$53.55
Cephalosporins		
Cephalexin	250 mg qid	$4.48
Cephradine	250 mg qid	$8.40
Tetracyclines		
Doxycycline	100 mg bid	$2.17
Minocycline	100 mg bid	$26.86
Tetracycline	250 mg qid	$1.61
Macrolides		
Azithromycin	250 mg qd (5 days)	$39.19
Clarithromycin	250 mg bid	$52.96
Erythromycin	250 mg qid	$5.04
Fluoroquinolones		
Ciprofloxacin	500 mg bid	$60.48
Ofloxacin	200 mg bid	$57.89
Other		
Clindamycin	150 mg qid	$16.67
Trimethoprim-sulfamethoxazole	1 DS tablet bid	$1.54

*Price to the pharmacist based on average wholesale cost in *Red Book 2001* of lowest-priced manufacturer. Prices vary considerably among different pharmaceutical companies for generic preparations. The amount actually charged to the patient is substantially more.

TABLE 259-1 **Costs of Oral Antibiotics for Dermatologic Use**

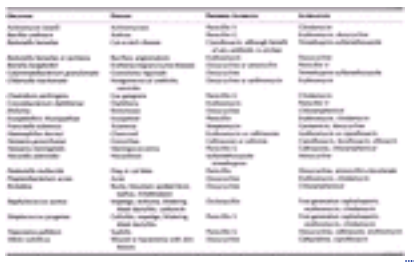

TABLE 259-2 **Antibiotic Choices for Dermatologic Infections**

An understanding of how to prescribe these systemic antimicrobial agents properly requires an acquaintance with some fundamental concepts, such as mechanisms of action, susceptibility testing, drug resistance, and use in special circumstances, such as renal failure and pregnancy.

MECHANISMS OF ACTION AND ANTIMICROBIAL RESISTANCE

Antibacterial agents exert their effects in one of four ways: (1) Some, such as the penicillins and cephalosporins, inhibit cell-wall synthesis, usually leading to the organism's death. (2) Others, by interfering with the 30S or 50S subunit of ribosomes, inhibit protein synthesis. The result may be reversible, temporarily halting growth of the microbe but not killing it—the mechanism for the tetracyclines and erythromycin—or the effect may be lethal, as with the aminoglycosides, such as gentamicin or amikacin. (3) The quinolones (e.g., ciprofloxacin or levofloxacin) affect nucleic acid metabolism, typically killing the bacteria. (4) Sulfonamides and trimethoprim block an essential step in the organism's metabolism by interfering with the folic acid metabolic pathway. The process only inhibits some microbes but kills others.

Microorganisms develop resistance against these antimicrobial effects by the following general mechanisms: (1) The organism may elaborate substances that inactivate the antibiotic. For example, many bacteria, such as penicillin-resistant *Staphylococcus aureus,* produce beta-lactamase that attacks an important ring structure of penicillins and cephalosporins. (2) The microbe may change to prevent the drug from reaching its target or may alter that target. In the former instance, an alteration in the organism's outer membrane may make it impermeable to the drug or the microbe may develop a new membrane transport system that actively extrudes the antibiotic from the cell. In the latter instance, changes occur in the organism's ribosomes, to which the antibiotic ordinarily adheres, thereby preventing the drug from binding to its target and exerting its effect on protein synthesis. Alternatively, by changing its metabolic pathway, the microbe may make the previously effective antimetabolite, such as a sulfonamide, impotent.

These mechanisms of bacterial resistance to antimicrobial agents can arise from random mutations in the organism's chromosomes that are unrelated to drug exposure, with the modified genetic material then passed to its progeny. More commonly, however, resistance comes from extrachromosomal DNA, which other, often unrelated, bacteria transfer to the microbe. This genetic material may reside in plasmids, autonomously replicating pieces of DNA, or transposons, mobile pieces of DNA that can insert themselves into various locations in the bacterial chromosome or plasmids. Some bacteria have numerous plasmids and transposons that confer resistance to several different antibiotics, making treatment of infections caused by these organisms difficult or impossible. This multiresistance typically develops in settings of intensive antibiotic use, such as critical care units. Any indiscriminate prescribing of antimicrobial agents, however, whether in a hospital or an outpatient setting, contributes to the emergence and dissemination of these organisms, because the presence of an antibiotic in a patient allows resistant microbes to flourish while it inhibits the competing susceptible ones. Accordingly, all clinicians must use antibiotics wisely, employing them only when necessary and preferentially prescribing an agent with a narrow spectrum of activity—one that inhibits the pathogen without significantly affecting the rest of the patient's flora.

ANTIMICROBIAL SUSCEPTIBILITY TESTING

After the clinician has submitted an appropriate sample for culture, the laboratory can isolate the infecting organism and determine its susceptibility to a panel of agents with potential activity against the category of bacteria to which the pathogen belongs. The test employs a concentration of 10^5 to 10^6 organisms per milliliter and assesses the effect of various concentrations of the antibiotics on the bacterium's growth after overnight incubation. The minimum inhibitory concentration (MIC) is the lowest amount of the drug that inhibits growth of the organism. The microbe is “sensitive” or “susceptible” when the MIC is less than a concentration (“breakpoint”) of antibiotic ordinarily achievable in the serum of patients given conventional doses of the drug. Because the serum level of antibiotic may differ from its concentration at the site of infection and because the susceptibility test may not reflect local factors that affect drug activity such as pH, the results of the test are potentially misleading, especially in areas such as the cerebrospinal fluid where some antibiotics penetrate poorly. With dermatologic infections, however, the susceptibility results are very reliable.

BACTERICIDAL VERSUS BACTERIOSTATIC ACTION

Laboratory tests can also distinguish between antibiotics that temporarily inhibit the growth of organisms (bacteriostatic) and those that kill (bactericidal). After overnight incubation with the drug, an inoculum of organisms is subcultured onto an antibiotic-free medium for 18 to 24 h. By arbitrary definition, a bactericidal antibiotic has killed 99.9 percent or more of the original bacteria at that time. In general, antibiotics that interfere with cell-wall synthesis, such as penicillins or cephalosporins, are bactericidal. Those that impair protein synthesis or block steps in metabolic pathways may be either bacteriostatic or bactericidal. Furthermore, some agents may kill certain organisms, but only inhibit others. Usually, bactericidal agents have no clinical superiority over bacteriostatic ones, and for almost all infections that a dermatologist is likely to confront the distinction is unimportant. The special circumstances where killing rather than inhibiting growth is significant are infective endocarditis, bacterial meningitis, infections in neutropenic hosts, and, possibly, osteomyelitis.

USE OF ANTIBIOTICS DURING RENAL FAILURE, PREGNANCY, AND LACTATION

For antibiotics eliminated by renal excretion, dose adjustments may be necessary in patients with impaired kidney function to avoid toxic serum levels. Recommended alterations in dose usually depend on an assessment of creatinine clearance. In the absence of a direct measurement, the following formula provides a reasonable estimate for men:

$$\text{Creatinine clearance in men} = \frac{\text{ideal weight in kg} \times (140 - \text{patient's age})}{72 \times \text{serum creatinine in mg/dL}}$$

The value for women is 0.85 of the calculated value for men. These calculations use the ideal body weight, which for men is 50.0 kg + [2.3 kg × (patient's height in inches - 60)] and for women is 45.5 kg + [2.3 kg × (patient's height in inches - 60)]. Patients with creatinine clearances greater than 50 mL/min require no dose adjustments for any antibiotic, but those with lower levels of renal function require either a reduction in the individual dose given of some medications or a greater interval between doses. Because hemodialysis removes a substantial portion of some antibiotics from patients, those undergoing this procedure may require an additional dose afterward. Specific recommendations for these adjustments appear in the discussions of the individual antibiotics.

Because of the risk of affecting the fetus or the newborn (for women near term), clinicians should avoid prescribing antibiotics during pregnancy if possible. Those considered safe include the penicillins, the cephalosporins, and erythromycin (except the estolate form). Clindamycin should be used with caution; and contraindicated drugs include the tetracyclines, the fluoroquinolones, and trimethoprim-sulfamethoxazole. Nursing mothers should avoid taking antibiotics, if possible, but especially the tetracyclines, which stain teeth, and the fluoroquinolones, which may damage joint cartilage in newborns.

INDIVIDUAL ANTIBIOTICS

Penicillins

MECHANISM AND SPECTRUM OF ACTIVITY Penicillins, [1] which exert their antimicrobial action by interfering with bacterial cell-wall synthesis, are active primarily against gram-positive organisms. Those most useful to dermatologists include two oral agents, penicillin V and dicloxacillin, and two parenteral preparations, penicillin G and an intravenous penicillinase-resistant drug such as oxacillin or nafcillin. Penicillin V and penicillin G are effective for skin infections such as cellulitis, blistering distal dactylitis, and impetigo when caused by streptococci and penicillin-sensitive *S. aureus*. As indicated below, however, most strains of *S. aureus* in both the hospital and community settings are penicillin-resistant, and either a penicillinase-resistant penicillin or a cephalosporin is a better choice for infections when *S. aureus* is suspected and its susceptibility to penicillin unknown. Penicillin G and V are appropriate agents to treat *Pasteurella multocida,* an organism often associated with infected cat and dog bites; *Streptobacillus moniliformis* and *Spirillum minus,* the two bacteria responsible for rat-bite fever; *Erysipelothrix rhusiopathiae,* the cause of erysipeloid; *Bacillus anthracis,* which causes anthrax; and *Borrelia burgdorferi,* the pathogen in Lyme disease. Penicillin G, but not V, is the drug of choice for all forms of infection with *Treponema pallidum,* the spirochete responsible for syphilis. Most strains of *S. aureus* produce penicillinase, a beta-lactamase enzyme that splits the beta-lactam ring of some penicillins, including V and G, producing substances with no antibacterial activity. Certain semisynthetic penicillins, however, are penicillinase-resistant, including dicloxacillin, an oral agent, and both nafcillin and oxacillin, which are primarily used as intravenous medications. These penicillins are also effective against *Streptococcus pyogenes* (group A streptococci) and streptococci of other groups, such as F or G, that are responsible for skin infections such as cellulitis. Accordingly, the penicillinase-resistant penicillins are good choices to treat disorders such as impetigo and ecthyma, which either *S. aureus* alone or a mixture of staphylococci and streptococci can cause. Some isolates of *S. aureus* ("methicillin-resistant" strains) are impervious to all penicillins. Alterations of the penicillin molecule have created agents with considerable activity against gram-negative organisms. Such preparations include the aminopenicillins, ampicillin and amoxicillin, which are effective against many isolates of *Escherichia coli* and *Haemophilus influenzae*. These antibiotics have little use in dermatologic practice, but are common causes of drug-induced eruptions. Organisms that produce beta-lactamase inactivate amoxicillin and ampicillin. To prevent this effect and thereby increase the spectrum of activity of these agents, drug manufacturers have combined them with beta-lactamase inhibitors (which preferentially and irreversibly bind the enzyme) to produce a parenteral preparation, ampicillin-sulbactam (Unasyn) and an oral formulation, amoxicillin-clavulanic acid (Augmentin). [2] These drugs are active against beta-lactamase–producing stains of *S. aureus, H. influenzae, Neisseria gonorrhoeae, E. coli, Klebsiella* species, and some other gram-negative bacilli. They are also effective against anaerobes that produce beta-lactamase, such as *Bacteroides fragilis*. Despite this increased spectrum of activity, these agents have little application in dermatologic infections. One exception is in the treatment of bite wounds, for these drugs are active against the likely pathogens—oral anaerobes, *Eikenella corrodens, H. influenzae,* and *S. aureus* in human bites, and *P. multocida,* streptococci, anaerobes, and staphylococci in dog and cat bites. [3] Another use is for serious skin and soft-tissue infections with a complex flora of both aerobic and anaerobic organisms, such as severe diabetic foot infections. Modifications of the ampicillin molecule have created the carboxypenicillins (carbenicillin and ticarcillin) and the ureidopenicillins (mezlocillin, piperacillin, and azlocillin). These "extended-spectrum" parenteral penicillins have much greater activity against many gram-negative bacilli, including *Pseudomonas aeruginosa,* than other penicillins. Two preparations include beta-lactamase inhibitors: ticarcillin-clavulanic acid and piperacillin-tazobactam. Rarely is any of these agents appropriate for treating dermatologic infections, but they commonly cause drug-induced rashes in hospitalized patients.

DOSAGE AND DRUG INTERACTIONS The adult dose of penicillin V is 250 to 500 mg by mouth four times a day. No adjustment is necessary for patients in renal failure, but those undergoing dialysis should receive an extra dose after the procedure. The doses of penicillin G vary according to the infection treated; the reader should refer to the appropriate chapter for details. Patients with creatinine clearance rates between 10 and 50 mL/min should receive 75 percent of the recommended dose, and those with rates of less than 10 mL/min should receive 50 percent of the recommended dose. Patients undergoing hemodialysis should receive an extra dose after the procedure. The intramuscular injection of 1.2 to 2.4 million units of benzathine penicillin provides effective serum levels for 2 to 4 weeks and represents a particularly attractive and dependable approach for the therapy or prophylaxis of streptococcal infections in patients who take medicines unreliably. The adult dose of dicloxacillin is 250 to 500 mg orally four times a day. For infections requiring intravenous treatment of infection from penicillinase-producing *S. aureus,* the adult dose of nafcillin or oxacillin is 1 to 2 g four times a day. No adjustment for renal failure is necessary for any of these agents, and they are not significantly removed by hemodialysis. Amoxicillin-clavulanic acid is available in tablets containing 125 mg potassium clavulanate plus either 250 or 500 mg amoxicillin. The usual adult dose is one of the tablets containing 250 mg of amoxicillin three times a day. Patients with creatinine clearances of 10 to 50 mL/min should receive one tablet twice a day, and those with clearances less than 10 mL/min should receive one tablet a day. Patients undergoing hemodialysis should receive a supplemental dose after the procedure. The parenteral agent ampicillin-sulbactam contains a 2:1 ratio of the two

constituents, respectively. The usual dose is 1.5 g (1 g ampicillin, 0.5 g sulbactam) or 3 g of the combination every 6 h. For patients with a creatinine clearance of 10 to 50 mL/min, the interval should be 12 h; for those with a creatinine clearance less than that, the interval should be every 24 h. Patients undergoing hemodialysis should receive a supplemental dose after the procedure.

ADVERSE EFFECTS The most serious complication of penicillin use is anaphylaxis, which occurs about 10 times in every 100,000 treatment courses, with about a 10 percent fatality rate. [4] Anaphylaxis is not more frequent in atopic patients than in the general population. It begins within the first hour, usually within the first 30 min, after drug administration, and is much less common with oral than with parenteral therapy. Clinical features may include hypotension, wheezing, laryngeal edema, and urticaria or angioedema. As opposed to this immediate response, some patients have an “accelerated” allergic reaction from 1 to 72 h after the dose; the characteristics include urticaria or angioedema, wheezing, and laryngeal edema. These are IgE-mediated events in which the antigens are breakdown products of penicillin (not the intact molecule) bound covalently to proteins. One of these is benzylpenicilloyl, also called the major determinant because it is the most abundant of the penicillin derivatives; it is the antigen involved in accelerated reactions. Several other breakdown products of penicillin, called minor determinants, form in small quantities and are the antigens responsible for anaphylaxis. Penicilloyl polylysine, a manufactured skin-test reagent, tests for IgE against the major determinant; a negative test means that the patient can receive penicillin without developing an accelerated allergic reaction, but it does not exclude the possibility of anaphylaxis. Unfortunately, no commercial preparation of the minor determinants is available in the United States. Studies with noncommercial minor determinant mixtures indicate that a negative skin test predicts that the patient can receive penicillin without developing anaphylaxis. Such skin testing is very safe and quite valuable in assessing the risks of penicillin therapy, because about 80 percent of patients with a history of adverse reactions to penicillin have negative skin tests and can receive the drug without developing anaphylaxis or accelerated reactions. [5] Unless such material is available and the skin testing is negative, however, patients with a history of immediate or accelerated reactions should not receive any kind of penicillin, because the allergic cross-reactivity among all the penicillins appears to be quite high. Skin testing has no predictive value in reactions not mediated by IgE, which include the remaining major adverse effects. Drug fever tends to occur after the first week of therapy in patients without previous exposure, but it can begin earlier in those who have received penicillin in the past. No characteristic pattern of temperature elevation occurs, and the patient's response may range from an unawareness of fever to rigors, hypotension, and delirium. Eosinophilia or a rash accompanies the fever in a minority of cases. The temperature should return to normal within 72 h of discontinuing the medication. Only recurrence of the fever, usually within a few hours, after reexposure to the drug definitively identifies penicillin as the cause, as no reliable laboratory test exists. Such a challenge is safe unless the patient has suffered organ damage, such as nephritis or hepatitis. Rare reactions include hemolytic anemia, usually only with high-dose intravenous therapy; neutropenia; and interstitial nephritis, which typically causes fever, worsening renal function, a morbilliform rash, and the presence of protein, neutrophils, red cells, and eosinophils in the urine. More frequent are gastrointestinal complaints of nausea, vomiting, and diarrhea; but the last is much more likely with ampicillin or amoxicillin than with penicillin or dicloxacillin. Diarrhea is even more frequent with amoxicillin-clavulanic acid. Occasionally, primarily in hospitalized patients, diarrhea related to amoxicillin or ampicillin arises from colitis caused by *Clostridium difficile*. The mechanism of most of the dermatologic reactions to the penicillins is unknown. Because they are not mediated by IgE, skin tests cannot predict their occurrence, indicate definitively that they are drug-related, or confirm that they arise specifically from penicillins in patients concurrently receiving other medications. The most common type of cutaneous reaction to the penicillins by far is a diffuse erythematous eruption with both macules and papules that usually begins on the trunk and spreads to involve the extremities but typically spares the palms, soles, and mucous membranes. It can begin within hours after the first dose, but most commonly develops about 7 to 10 days later. Occasionally, it starts several days after the drug is discontinued; irrespective of when it begins, however, it usually resolves within 7 days. This kind of eruption is most common and has been most extensively studied in patients receiving amoxicillin and ampicillin. With these agents, the eruptions are especially likely to occur in patients with chronic lymphocytic leukemia, those receiving concurrent allopurinol, and those with infectious mononucleosis and cytomegalovirus infections, in whom the incidence is nearly 100 percent. [6] It commonly fails to recur when the patient receives the medication again, and its development is not an indication that the patient is “allergic” to penicillin in the sense of being at greater risk for developing life-threatening adverse reactions. Other skin rashes are distinctly unusual with the penicillins. Serum sickness-like reactions—characterized by fever, arthralgias, lymph node enlargement, and cutaneous eruptions that are morbilliform or urticarial—tend to occur 7 to 10 days after the medication is begun. Other rare skin complications include erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, fixed drug eruption, vasculitis, erythroderma, pemphigus, and acute generalized pustulosis.

Cephalosporins

MECHANISM AND SPECTRUM OF ACTIVITY Like the penicillins, the cephalosporins impair cell-wall synthesis and kill susceptible organisms. These agents have been grouped into four “generations” according to the spectrum of their antibacterial activity. [7] First-generation cephalosporins, which include the parenteral agents cephalothin and cefazolin and the oral preparations cephalexin and cephradine, are active against streptococci (but not enterococci), methicillin-sensitive *S. aureus,* and some gram-negative bacilli, including most *E. coli, Proteus mirabilis,* and *K. pneumoniae*. Second-generation cephalosporins have increased activity against many gram-negative bacilli. Cefamandole, cefaclor, and cefuroxime are effective against *H. influenzae,* and cefoxitin and cefotetan against anaerobic gram-negative bacilli. The third-generation cephalosporins are less active than first- and second-generation agents against gram-positive cocci, but are effective against a larger number of gram-negative bacilli, including some that are resistant to many other agents. The fourth-generation cephalosporin, cefepime, has an extended spectrum of activity against both gram-positive cocci and gram-negative bacilli, including *Pseudomonas aeruginosa*. It has poor activity against anaerobes. Like all other cephalosporins, it is not effective for treating infections caused by *Listeria monocytogenes* or *Enterococcus* species.

DOSAGE AND DRUG INTERACTIONS For dermatologists, cephalosporins are primarily useful for treating streptococcal and staphylococcal infections, especially in patients with previous reactions to the penicillins that are not life-threatening. The preferable parenteral agent is cefazolin, 0.5 to 1 g IM or IV q8h, and the preferable oral preparation is cephalexin administered as 250 to 500 mg qid. In patients with renal failure, the appropriate interval between doses of cefazolin is 12 h for those with creatinine clearances between 10 and 50 mL/min, and 24 h for those with values less than 10 mL/min. For cephalexin, the interval should be 12 h when the value is less than 10 mL/min. For both agents, a supplemental dose

after hemodialysis is advisable. Two third-generation cephalosporins are useful in treating sexually transmitted diseases. Ceftriaxone given as a single intramuscular dose of 125 mg is effective against urethral, cervical, rectal, and pharyngeal gonorrhea; a single dose of 400 mg of the oral agent cefixime is another option. Ceftriaxone, 1 g IV daily, is the agent of choice for gonococcal bacteremia, arthritis, or disseminated disease. A single intramuscular dose of 250 mg is one option for treating chancroid.

ADVERSE EFFECTS Patients with a history of penicillin reactions have a higher incidence of adverse reactions with cephalosporins than do patients without such a history, but the frequency is only about 5 percent, and the manifestations are usually mild, even in patients with positive skin tests to the major and minor determinants of penicillin. [8] Most importantly, the risk of anaphylaxis or accelerated reaction is extremely low except in patients with a history of such an allergy to penicillin, who should not receive cephalosporins. Cephalosporins are generally well tolerated. Gastrointestinal symptoms of nausea, vomiting, abdominal cramps, and diarrhea may occur. Sometimes, primarily in hospitalized patients, the diarrhea may arise from *C. difficile* colitis. Candidal vulvovaginitis and pruritus ani are occasional complications, as is blood eosinophilia, which is usually unattended by any other significant findings. Anaphylaxis and urticaria are rare. Macular and papular eruptions, which occur in 1 to 3 percent of patients, resemble those of penicillin, typically beginning on the trunk and extending to the extremities. Reactions resembling serum sickness have developed primarily with cefaclor. Other rare cutaneous complications include toxic epidermal necrolysis, erythema multiforme, Stevens-Johnson syndrome, fixed drug reaction, erythroderma, pemphigus, and acute generalized exanthematous pustulosis. H4>Tetracyclines

MECHANISM AND SPECTRUM OF ACTIVITY Tetracyclines [9] are bacteriostatic antibiotics that impair protein synthesis by interfering with the 30S subunit of bacterial ribosomes. The most commonly used agents in dermatology are tetracycline, doxycycline, and minocycline. They are active against *Propionibacterium acnes,* considered the most important bacterial species in the pathogenesis of acne. They are also useful in treating rosacea and perioral dermatitis, although the microbial etiology, if any, of those disorders is unknown. Tetracyclines are important in the therapy of certain sexually transmitted diseases. Because of their activity against *Chlamydia trachomatis,* they are useful for urethritis, cervicitis, epididymitis, and pelvic inflammatory disease caused by this organism and for lymphogranuloma venereum. They are the drugs of choice in treating syphilis for adults (except pregnant or nursing women) unable to tolerate penicillin and for granuloma inguinale, which is caused by *Calymmatobacterium granulomatis*. They are active in primary skin infections caused by *Bacillus anthracis* (anthrax), *P. multocida* (infected dog or cat bites), *Vibrio vulnificus* (from wounds contaminated with saltwater), *B. burgdorferi* (the cause of Lyme disease), *Spirillum minus* and *S. moniliformis* (the causes of rat-bite fever), and *Mycobacterium marinum* (the cause of fish-tank granuloma). Tetracyclines are also effective in certain systemic infections that may have cutaneous manifestations, including tularemia, plague, brucellosis, bacillary angiomatosis, psittacosis, ehrlichiosis, *Mycoplasma pneumoniae* infection causing Stevens-Johnson syndrome, and rickettsial diseases (Rocky Mountain spotted fever, typhoid fever, and rickettsialpox).

DOSAGE AND DRUG INTERACTIONS The usual adult dose of tetracycline is 250 to 500 mg qid. Because of its less frequent dosage, approximately equivalent cost, and fewer side effects, especially diarrhea, doxycycline at 100 mg bid is the tetracycline of choice for most infections. The same dose is used intravenously for patients requiring parenteral therapy. Some dermatologists prefer minocycline for treating difficult acne, but little objective evidence demonstrates any superiority to doxycycline [10] and it is much more expensive. Its usual dose is 100 mg qd or bid. Because they increase azotemia by inhibiting protein synthesis and are eliminated by renal mechanisms, most tetracyclines are not recommended for patients in renal failure, but doxycycline, which is metabolized in the liver, can be given in its usual dose to patients with all levels of kidney function, and no supplemental dose is required after hemodialysis. Metals chelate the tetracyclines, impairing their absorption; patients, therefore, should avoid concurrent ingestion of medicinal iron or compounds, primarily antacids, containing aluminum, calcium, and/or magnesium. Sodium bicarbonate, milk, and milk products also decrease absorption of the tetracyclines. Phenytoin, carbamazepine, barbiturates, and alcohol use increase the metabolism of doxycycline; standard, twice-daily dosing, however, is satisfactory for patients receiving these substances.

ADVERSE EFFECTS Because they can stain the teeth and impair bone growth in fetuses and in young children, tetracyclines are contraindicated in pregnant women, nursing mothers, and children younger than 12 years of age. Otherwise, they are generally quite safe. Tetracyclines may cause nausea, vomiting, and diarrhea, and *C. difficile* colitis may be a complication, primarily in hospitalized patients. For some, oral or vulvovaginal candidiasis is a problem. Idiopathic intracranial hypertension, pulmonary eosinophilia, and pancreatitis are rare adverse effects. Esophageal ulcerations and strictures occasionally occur from prolonged exposure of the esophageal mucosa to the drug; taking the medication with copious amounts of water and avoiding its ingestion just before the patient is likely to be recumbent, as at bedtime, should prevent these problems. Minocycline can cause neurologic complications—consisting of dizziness, vertigo, light-headedness, tinnitus, and imbalance—that usually begin within a few days of treatment. These occur more frequently in women and subside several days after the drug is discontinued. Minocycline also can cause a syndrome that includes autoimmune hepatitis and features of systemic lupus erythematosus. All the tetracyclines can cause phototoxic eruptions that resemble severe sunburn, and onycholysis may occur in sun-exposed nails of the fingers and toes. Long-term minocycline therapy can result in various forms of pigmentation. Blue-black macules may develop in areas of previous inflammation or in scars, especially those due to acne. Hyperpigmentation, either macular or diffuse, may occur on sun-exposed areas, particularly the extensor surfaces of the legs and forearms as well as on the hard palate. These forms generally abate over a few months after discontinuation of the minocycline. A more persistent type is a brown-gray discoloration, especially in sun-exposed areas, that may also affect the nails, sclera, and teeth. Other cutaneous reactions to tetracycline are uncommon. Erythema multiforme, erythroderma, Stevens-Johnson syndrome, erythema nodosum, and toxic epidermal necrolysis have been reported, and tetracyclines can cause fixed drug eruptions.

Macrolides

MECHANISM AND SPECTRUM OF ACTIVITY Macrolides—consisting of erythromycin, azithromycin (which belongs to a subclass called azalides), and clarithromycin—interfere with protein synthesis by binding to the 50S ribosomal subunit of susceptible organisms. They are generally bacteriostatic. Clarithromycin and azithromycin are structurally similar to erythromycin, but small alterations have created three major differences. [11] They are more stable in gastric acid, promoting better oral absorption and decreasing the degradation of the drugs into inactive metabolites that cause gastrointestinal side effects. Their penetration into cells is superior to that of erythromycin, achieving concentrations in most tissues, but not the brain or cerebrospinal fluid, that considerably exceed those in the blood. They also have longer serum half-lives, which allows less frequent dosage. These agents are considerably more expensive than erythromycin,

however, and their apparent advantages have little relevance to the treatment of most cutaneous infections. The macrolides are active against most streptococci and *S. aureus* but not methicillin-resistant strains. Unfortunately, azithromycin and clarithromycin are ineffective against erythromycin-resistant *S. aureus,* which is common in some areas. Because of its action against *P. acnes,* topical or systemic erythromycin is an option for treating acne, and it is effective in rosacea and perioral dermatitis as well. It is useful for erythrasma, an infection caused by *Corynebacterium minutissimum,* and is an option for anthrax, erysipeloid (which is caused by I>E. rhusiopathiae), and Lyme disease (which is caused by *B. burgdorferi*). Erythromycin is also useful in sexually transmitted diseases, including chancroid and infections caused by *C. trachomatis,* such as nongonococcal urethritis, cervicitis, epididymitis, conjunctivitis, proctitis, and lymphogranuloma venereum. It is the drug of choice for these infections during pregnancy. Clarithromycin and azithromycin have advantages for two special circumstances of potential relevance to dermatologists. In sexually transmitted diseases, single-dose therapy is ideal, because it can be observed and compliance assured, unlike with regimens requiring further doses. Azithromycin as a single 1 g dose is effective for chancroid and for infections caused by *C. trachomatis,* except lymphogranuloma venereum, which requires protracted therapy (21 days) with erythromycin or doxycycline. These macrolides are also active against various mycobacteria, including both rapidly growing (*M. chelonae, M. abscessus*) and slow-growing species (*M. gordonae, M. szulgai, M. scrofulaceum, M. marinum, M. nonchromogenicum*). Azithromycin and clarithromycin, therefore, may be useful in treating cutaneous mycobacterial infections caused by susceptible organisms.
DOSAGE AND DRUG INTERACTIONS The usual adult dose of erythromycin is 250 to 500 mg qid. No changes are necessary in renal failure, and no supplemental doses are required in hemodialysis. Erythromycin increases the levels of several medications, including theophylline, warfarin, carbamazepine, and cyclosporine. Clarithromycin may increase the blood levels of several drugs, including theophylline, cyclosporine, warfarin, and carbamazepine. The usual adult regimen for azithromycin is 500 mg the first day followed by 250 mg daily thereafter. For clarithromycin, the usual adult dose is 250 to 500 mg twice daily. No adjustment is necessary for renal disease.
ADVERSE EFFECTS The most common adverse effects of the macrolides are gastrointestinal, including abdominal cramps, nausea, vomiting, and diarrhea. Occasionally, *C. difficile* colitis occurs, primarily in hospitalized patients. Cholestatic hepatitis rarely develops with erythromycin, almost exclusively with the estolate preparation. Patients typically have nausea, vomiting, and abdominal pain, followed by jaundice and fever. Laboratory findings include abnormal liver function tests consistent with cholestatic changes and occasionally eosinophilia. Angioedema and photosensitivity are rare dermatologic complications of azithromycin.

Fluoroquinolones

MECHANISM AND SPECTRUM OF ACTIVITY Fluoroquinolones [12] inhibit enzymes involved in the coiling of the DNA helix and are usually bactericidal. Agents in this rapidly expanding class of antibiotics include ciprofloxacin, ofloxacin, sparfloxacin, gatifloxacin, grepafloxacin, moxifloxacin, and levofloxacin. Clinicians extravagantly (and very often inappropriately) prescribe them for diverse infections, but they have few potential uses in dermatology. They are active against *S. aureus,* including some methicillin-resistant strains, but resistance of this organism has emerged from widespread use of these agents. Except for ciprofloxacin and ofloxacin, the fluoroquinolones are active against streptococci. They are effective against many gram-negative organisms, including *N. gonorrhoeae,* and against several mycobacteria, such as *M. tuberculosis, M. fortuitum,* and *M. xenopi*. Most fluoroquinolones are also active against *C. trachomatis*. The dermatologic use of the fluoroquinolones is primarily as treatment options for sexually transmitted diseases. Some of these agents are efficacious, but very expensive alternatives to doxycycline for urethritis, cervicitis, conjunctivitis, and proctitis caused by *C. trachomatis*. Several of these agents are effective in single doses for urethral, rectal, cervical, or pharyngeal gonorrhea; 3-day courses are alternatives for treating chancroid.
DOSAGE AND DRUG INTERACTIONS Patients should avoid the concurrent use of sucralfate, supplements containing zinc or iron, and antacids with aluminum, calcium, or magnesium, all of which inhibit the absorption of the fluoroquinolones. Some fluoroquinolones can increase the serum levels of warfarin, theophylline, and cyclosporine, and they can alter the blood glucose level, causing either hyper- or hypoglycemia in some patients taking oral antidiabetic agents or insulin. The proper adjustment in renal dysfunction varies among the fluoroquinolones, and clinicians should consult appropriate sources to determine the recommended approach.
ADVERSE EFFECTS The most frequent adverse effects are nausea, diarrhea, insomnia, headache, and dizziness. Uncommon complications include serum sickness, a morbilliform eruption, anaphylaxis, and vasculitis. Phototoxic reactions can occur, even when patients use a sunscreen. Occasional abnormal laboratory tests include eosinophilia, increased levels of liver enzymes, and leukopenia. Because studies demonstrate cartilage erosions in the joints of young animals given high doses, the fluoroquinolones are not recommended for children. They should not be used in pregnant women or nursing mothers.

Clindamycin

MECHANISM AND SPECTRUM OF ACTIVITY Clindamycin, [13] a bacteriostatic drug, inhibits protein synthesis by binding to the 50S portion of the ribosome. It is active against streptococci, most *S. aureus,* and most anaerobic bacteria, including *P. acnes*. Its major use in dermatology is as an alternative in treating streptococcal and staphylococcal infections in penicillin-allergic patients and in treating acne. It achieves high levels in the nasal secretions and is one of the most effective agents in eradicating nasal carriage of *S. aureus* and in preventing further episodes in those with recurrent staphylococcal skin infections.
DOSAGE AND DRUG INTERACTIONS The usual adult dose is 150 to 300 mg qid. No adjustment is necessary for renal failure, and no supplemental dose is required for patients receiving hemodialysis. Since clindamycin primarily undergoes hepatic metabolism, it accumulates in patients with severe liver disease, a situation that warrants cautious use, although no specific dose adjustments are available. [14] For the prevention of recurrent staphylococcal skin infection, a reasonable program is 150 mg qd for 3 months. [15]
ADVERSE EFFECTS Morbilliform rashes are frequent, but anaphylaxis, urticaria, and erythema multiforme are rare. Hepatotoxicity is also very uncommon. The most notorious adverse effect is diarrhea, which may occur in up to 20 percent of recipients. In nearly all outpatients and most inpatients, the cause seems related to the antibiotic itself, and the diarrhea abates after the clindamycin is discontinued. In patients in the hospital or recently hospitalized, however, clindamycin, like many other antibiotics, predisposes to colitis due to *C. difficile*. This organism is not part of the normal bowel flora, but it commonly colonizes hospitalized patients, especially those who have received broad-spectrum

antibiotics that eradicate the normal intestinal bacteria. The diarrhea ranges from mild to very severe, when fever, leukocytosis, and intravascular volume depletion may occur. It usually begins during clindamycin administration but may start days or even weeks after the course has ended. The diagnosis is established by finding *C. difficile* or its toxin in the stools of symptomatic patients. Mild cases respond to discontinuation of the clindamycin; more severe ones warrant therapy with oral metronidazole. In general, because of the tendency of this drug to cause diarrhea, either as a direct effect of the antibiotic or through predisposing to *C. difficile* colitis, patients with inflammatory bowel disease should not receive clindamycin.

Trimethoprim-Sulfamethoxazole

MECHANISM AND SPECTRUM OF ACTIVITY This combination of antimicrobial agents, [16] also called co-trimoxazole, blocks two separate steps in the folic acid metabolism of susceptible organisms. It is active against a wide variety of gram-negative bacteria and against most *S. aureus,* including many methicillin-resistant strains. Its main use is for urinary tract and respiratory infections, including sinusitis, otitis media, and pneumonia. Because of its activity against *Pneumocystis carinii,* it is effective in treating and preventing pneumonia and other infections due to that organism, and it is widely used for that purpose in patients infected with HIV. It has few indications in dermatology; it may be useful for acne refractory to tetracycline, and it is effective in treating some patients with mild or moderately severe Wegener's granulomatosis and in preventing recurrent episodes in that disorder. Other agents have generally replaced it in the therapy of sexually transmitted diseases.
DOSAGE AND DRUG INTERACTIONS The usual adult dose is one double-strength tablet (containing 800 mg of sulfamethoxazole and 160 mg of trimethoprim) bid. It may increase the serum levels of phenytoin and enhance the hypoglycemic effects of chlorpropamide and tolbutamide. It displaces warfarin and methotrexate from their albumin-binding sites, potentiating the effects of these drugs, and it decreases the serum levels of cyclosporine.
ADVERSE EFFECTS Gastrointestinal side effects—including nausea, vomiting, and abdominal discomfort—occur in approximately 3 percent of patients. Diarrhea develops in fewer than 1 percent of patients, and *C. difficile* colitis is rare. Trimethoprim-sulfamethoxazole can cause mild nephrotoxicity in patients with underlying renal insufficiency, and the drug is not recommended in this circumstance. Hematologic complications include neutropenia, which is more likely in those undergoing hemodialysis and in patients with preexisting folate or vitamin B_{12} deficiency, concurrent phenytoin administration, malnutrition, and alcoholism. Hemolytic anemia can develop in those with glucose-6-phosphate dehydrogenase (G6PD) deficiency. In patients with HIV infection, neutropenia and thrombocytopenia are frequent. Patients with HIV infection frequently develop rashes with this medication. Morbilliform eruptions occur in 30 to 85 percent of those who receive the drug, commonly during the second week of therapy. [17] The findings are itchy or asymptomatic macules and papules that become generalized and usually resolve quickly after the agent is discontinued. A similar rash occurs in about 3 percent of the general population. More severe eruptions develop in about 13 percent of HIV-infected patients, as compared to approximately 1/100,000 of others receiving the drug. These eruptions include erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. Indeed, trimethoprim-sulfamethoxazole is one of the most common causes of these drug reactions. Other occasional cutaneous complications include vasculitis, erythema nodosum, erythroderma, fixed drug eruption, and serum sickness.

SYSTEMIC ANTIMICROBIAL PROPHYLAXIS IN DERMATOLOGY

Clinicians use antibiotics primarily to treat infections, but a considerable amount of antimicrobial administration is devoted to preventing them. Much of this prophylactic use is unnecessary, and in dermatology only a few indications exist, primarily in patients with recurrent bacterial skin infections. [18] Prophylactic antibiotics are rarely indicated to prevent postoperative infections in cutaneous surgery, which seldom imposes a risk for hematogenous infection of implanted prosthetic material in patients with such devices as artificial heart valves and joints. [18]

Recurrent Bacterial Skin Infections

One study of patients with recurrent staphylococcal skin infections demonstrated that oral clindamycin, 150 mg qd for 3 months, impressively decreased the incidence of further episodes. [15] Among the placebo recipients, 64 percent of patients had a recurrent skin abscess in the 3 months, compared to 18 percent of those receiving clindamycin. Of those who were free of infection while taking the antibiotic, 67 percent had no recurrence for at least 9 months after discontinuing the clindamycin. Although the study did not specifically evaluate this issue, this long-term benefit probably came from eradication of staphylococcal nasal carriage, for which clindamycin is one of the few very effective antimicrobials. No patient had gastrointestinal complaints, including diarrhea. Clinicians considering this prophylaxis should perform appropriate cultures of the skin lesions to ensure that the dermatologic lesions are genuinely due to *S. aureus,* because many cutaneous abscesses and other pustular skin diseases are caused by other organisms or have a noninfectious etiology.

Patients with recurrent bouts of cellulitis typically have predisposing factors including tinea pedis, chronic lymphedema, persistent swelling from other causes, poor hygiene, and trauma. When repeated infections occur despite therapy of these underlying conditions, penicillin or erythromycin (250 mg bid) is very effective in preventing further episodes. In one study, for example, the recurrence rate over 18 months was 50 percent among patients who received no systemic antibiotics, compared with zero percent among those taking twice-daily erythromycin. [19] Monthly or twice-monthly injections of benzathine penicillin represent another option, particularly in patients who do not take medications reliably.

Prevention of Wound Infections after Dermatologic Surgery

To justify the expense and potential complications of antimicrobials prescribed to prevent postoperative wound infections, such infections should be either quite frequent or very severe. Most dermatologic procedures are “clean” surgery, which involves incisions through uninfected skin without transecting mucosal surfaces. The expected infection rate without antimicrobial prophylaxis is less than 5 percent, and in most centers, it is less than 1 percent. Because such infections are rarely severe, preventive antibiotics are unjustified. Even in surgery that is “clean-contaminated”—involving the

transection of mucosal surfaces, such as removing a deep basal cell carcinoma from the nose—the infection rate is low and the infections relatively mild. The 10 percent infection rate quoted for this type of operation derives from studies primarily involving major surgery, such as laryngectomies or gastrointestinal resections, not dermatologic procedures. This kind of skin surgery does not warrant antibiotic prophylaxis. Similarly, in patients with acute nonpurulent inflammation or major breaks in aseptic technique ("contaminated surgery"), where the expected infection rate in major surgery is 20 to 30 percent, the incidence is probably lower in dermatologic procedures, and the infections are usually mild. Even with operations involving purulent lesions ("infected or dirty surgery") in which postoperative infections occur in 30 to 40 percent of patients with major surgery, the risks for patients with cutaneous suppuration are low and the consequences mostly mild. Incision and drainage of skin abscesses, for example, lead to few postoperative infections, and antibiotics seem not only unnecessary but ineffective in this setting. [20], [21]

Some practitioners use prophylactic antibiotics for patients undergoing full-face laser resurfacing for removal of wrinkles, but the available information, which is poor, fails to demonstrate a benefit in this setting. Use of antibiotics, however, does seem to increase the isolation of gram-negative bacilli from the wounds, although these organisms rarely cause clinical problems. [22]

While a procedure with extensive and deep surgery involving a mucosal surface may warrant preoperative antibiotics, such operations are uncommon for most dermatologists. For these unusual dermatologic procedures, one of the most important elements in the use of prophylactic antibiotics is the timing of their administration. Because contamination usually occurs only from the beginning of the incision to the time of wound closure, a single preoperative dose of an antibiotic that sustains good tissue levels throughout this period suffices. Further preoperative or postoperative doses are unnecessary and wasteful. Another important consideration is the choice of the agent; the goal is not to eradicate every microbe potentially present but to reduce the concentration of the most likely contaminating organisms to a level that the host can handle without developing an infection. Most studies on prophylactic antibiotics in surgery have used a parenteral cephalosporin, especially cefazolin, 1 g of which results in good, sustained serum and tissue levels of the antibiotic. Furthermore, it is active against streptococci, staphylococci, and most of the upper respiratory flora that are likely to cause infections in procedures transecting the upper airway mucosa.

Antibiotic Prophylaxis for Patients with Heart Disease or Prosthetic Material

The transient bacteremia that occurs with various dental and surgical procedures can sometimes lead to infections of abnormal cardiac valves, both native and prosthetic ones, and possibly to infections of such implanted devices as artificial joints and vascular grafts. The risk of bacteremia with dermatologic surgery involving incisions through either intact or eroded skin is very low, [18] however, and no prophylaxis is required for patients with either abnormal heart valves or indwelling prosthetic material.

Only with incision and drainage of infected tissue is the frequency of bacteremia likely to be high enough to justify antimicrobial prophylaxis, and even in that or, indeed, any other situation, its efficacy is unknown. A reasonable approach for such an uncommon circumstance is to give a single dose of an agent about 1 h before the procedure in patients with implanted prostheses. An oral antibiotic is usually feasible, but occasionally a parenteral agent may be required—for example, in patients with nausea or with evidence of systemic infection, in whom blood cultures should precede antimicrobial administration. Appropriate choices include a first-generation cephalosporin (cephalexin 1 g PO or cefazolin 1 g IM or IV), a penicillinase-resistant penicillin (dicloxacillin 1 g PO or nafcillin 1 g IV), or clindamycin for patients with serious penicillin allergies (300 mg PO or IV).

Protease Inhibitors
Other Antiretroviral Drugs
REFERENCES

Antiviral drugs have been developed at an extraordinary pace during the past decade. As late as the mid-1980s, only three antiviral drugs were approved for treatment of systemic viral infections. Currently, there are over 30 approved antiviral drugs, and additional ones are likely to be forthcoming. Progress has been accelerated by recent advances in knowledge of the molecular biology and pathogenesis of certain viral infections, of which AIDS has been the most notable. Nonetheless, the field of antiviral drugs still lags considerably behind that of antibacterial antibiotics, both in the numbers of available drugs and in the clinical application of techniques such as pharmacokinetic measurements and in vitro assessment of resistance. These areas are under active development.

This chapter focuses on drugs to treat those viral infections that are most likely to be encountered by dermatologists, such as those caused by herpes simplex virus (HSV) and varicella-zoster virus (VZV). Antiviral drugs used to treat cytomegalovirus (CMV) infections, the interferons, and antiretroviral drugs to combat HIV infection are discussed in less depth, and the reader is referred to reviews of these subjects for more information.

DRUGS FOR THE TREATMENT OF HERPES SIMPLEX VIRUS AND VARICELLA-ZOSTER VIRUS INFECTIONS

Acyclovir

ANTIVIRAL ACTIVITY Acyclovir {9-[(2-hydroxyethoxy) methyl] guanine, Zovirax} (Fig. 260-1) is an antiviral drug widely used for the treatment of HSV and VZV infections. [1] It is highly active against HSV-1, slightly less active against HSV-2, and approximately eightfold less active against VZV in vitro. The activity of acyclovir against CMV is variable, and isolates are frequently resistant. Acyclovir has good activity against Epstein-Barr virus (EBV) in vitro, and at higher concentrations it inhibits human herpesvirus (HHV)-6. The active antiviral moiety of acyclovir is acyclovir triphosphate, which is a potent inhibitor of certain herpesvirus-induced DNA polymerases, but has relatively little effect on host cell DNA polymerase. Acyclovir triphosphate also acts as a terminator of the nascent viral DNA chain because it lacks the 3' hydroxyl group. The initial phosphorylation of acyclovir to acyclovir monophosphate is efficiently carried out by herpesvirus-induced thymidine kinases but not by cellular kinases. Thus, acyclovir monophosphate is concentrated in virus-infected cells, which contributes to its highly selective mechanism of action. [2] Resistance to acyclovir in HSV and VZV isolates occurs most commonly by mutations that result in absent or markedly decreased thymidine kinase activity. Less-frequent mechanisms of resistance are alterations in substrate specificity of the thymidine kinase or changes in the viral DNA polymerase. [3] Resistant viruses have been usually, but not invariably, associated with prolonged use of acyclovir in immunosuppressed patients. Viruses that are resistant to acyclovir on the basis of thymidine kinase mutations are also resistant to ganciclovir and famciclovir, but are generally sensitive to foscarnet and cidofovir (see below). Viruses resistant to acyclovir on the basis of a DNA polymerase mutation are also usually resistant to foscarnet but may retain sensitivity to cidofovir.

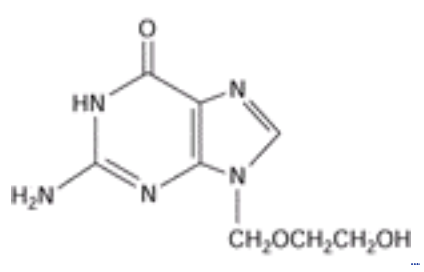

FIGURE 260-1 Acyclovir.

PHARMACOKINETICS Acyclovir is available in oral, intravenous, and topical formulations. The oral bioavailability of acyclovir is low (15 to 30 percent). A 200-mg oral dose of acyclovir results in a peak plasma concentration of 0.4 to 0.8 µg/mL approximately 1.5 h after administration, while an 800-mg oral dose results in a peak plasma concentration of 1.6 µg/mL. [4], [5] Oral absorption may be somewhat less in transplant patients. The plasma half-life of acyclovir is from 2.1 to 3.5 h in patients with normal renal function. Acyclovir is almost entirely eliminated by the renal route, largely

unmetabolized (85 percent), while the remainder is metabolized to a 9-carboxymethoxymethylguanine. Therefore, dosage reductions are required for patients with creatinine clearances of <50 mL/min. [6] Acyclovir is widely distributed in body fluids, including cerebrospinal fluid, vesicle fluids, and vaginal secretions. Acyclovir is available as a 5% ointment in a polyethylene glycol base in the United States, and topical administration results in detectable drug concentrations in lesions but little, if any, systemic absorption.

ADVERSE EFFECTS Acyclovir is generally well tolerated. The major toxicity associated with acyclovir is renal, as a result of crystallization of the drug in renal tubules, which has been reported with high dosage, dehydration, or rapid intravenous administration. Interstitial nephritis associated with acyclovir has also been reported. [7] Central nervous system toxicity has been described, including lethargy, tremors, obtundation, and seizures. [8] These side effects have usually been associated with high plasma levels of acyclovir and with underlying diseases involving the central nervous system. The concomitant use of interferon or other nucleoside analogues may contribute to neurotoxicity.

CLINICAL INDICATIONS The efficacy of acyclovir is well established in the treatment of HSV infections in several clinical settings. These include mucocutaneous HSV infections in immunocompromised patients, which generally respond to either intravenous (5 mg/kg IV q8h) or oral administration (400 mg PO five times per day). These infections are usually treated for 7 to 10 days, but more severe cases may require longer therapy. Acyclovir is also effective as prophylaxis in patients who are seropositive for HSV and who undergo intensive immunosuppression as part of transplantation or chemotherapeutic regimens. Acyclovir administered intravenously or orally to patients with primary genital herpes results in shortened duration of symptoms, acceleration of healing, and reduction of virus shedding. [9] Intravenous and oral therapies have similar efficacies, and the choice between routes of administration should be based on the severity of disease, the need for hospitalization, and the ability of the patient to take oral medications. Acyclovir therapy for primary genital HSV does not reduce the frequency or severity of subsequent recurrences. In recurrent HSV genital infections, oral acyclovir has a modest beneficial effect on the length of time to healing and on the duration of viral shedding, particularly when it is initiated within 24 h of the onset of symptoms. [10] Suppressive therapy with 400 mg of acyclovir PO bid reduces the number of recurrences and is recommended for patients with recurrences that are particularly frequent (more than six times per year) or troublesome. [11] The need for continuation of suppressive therapy should be assessed on an annual basis by stopping the drug to see whether recurrences develop. Chronic suppressive therapy does not eliminate the latent stage of HSV infection, and asymptomatic shedding of virus can occur. Acyclovir therapy for orofacial HSV infections has been less-extensively studied than for genital infections. Oral therapy for herpes labialis produced a modest beneficial clinical effect, particularly if treatment was started early in the recurrence and if higher doses were used (500 mg PO five times per day for 5 days). [12] Primary HSV gingivostomatitis has not been well studied, but anecdotal reports suggest acyclovir may be of some benefit in such cases. The administration of acyclovir prophylactically to patients who experience reactivation of herpes labialis with sunlight may decrease the number of lesions associated with such recurrences but does not appear to have an otherwise beneficial effect. The topical use of acyclovir as a 5% ointment in polyethylene glycol has been largely supplanted in the United States by oral administration of the drug. Acyclovir ointment is beneficial in the treatment of primary genital infections, but less so than oral or intravenous therapy. [13] Topical acyclovir is also modestly beneficial in immunocompromised patients with localized mucocutaneous HSV infections. Topical therapy with acyclovir ointment has not been demonstrated to be of clinical benefit in the treatment of herpes labialis in immunocompetent patients. [14] Intravenous acyclovir is the drug of choice for treatment of life-threatening HSV infections such as encephalitis [15] or neonatal infection. [16] Acyclovir is also effective in the treatment of VZV infection. Because VZV is less sensitive to acyclovir than HSV, higher doses of the drug should be used (10 mg/kg IV q8h or 800 mg PO five times per day for 7 days). In immunocompromised patients with herpes zoster, intravenous acyclovir reduces the frequency of visceral complications and of cutaneous dissemination. [17] Orally administered acyclovir has a modest beneficial effect on the dermatomal lesions of localized herpes zoster in immunocompetent patients. [18] The effect of acyclovir on postherpetic neuralgia is unclear, and a clinical trial suggested that valacyclovir may be more effective in resolution of zoster-associated pain [19] (see below). The use of glucocorticoids along with acyclovir to prevent the development of postherpetic neuralgia remains controversial. One study showed no benefit from the addition of prednisolone to acyclovir in herpes zoster in immunocompetent patients, [20] whereas another showed a beneficial effect of the combination of prednisone and acyclovir in overall quality-of-life measurements, although not on postherpetic neuralgia specifically. [21] Orally administered acyclovir (600 mg five times per day) is effective in the treatment of herpes zoster ophthalmicus. [22] Intravenous acyclovir has been reported to be clinically beneficial in immunosuppressed patients with varicella (chickenpox) and may reduce the rate of visceral complications. [23] Oral acyclovir therapy for varicella in immunocompetent children, adolescents, or adults results in only a modest overall clinical benefit, even if begun within 24 h of onset of lesions. [24], [25] Such therapy has not been demonstrated to reduce the rate of serious complications in these patients. With respect to infections caused by other herpesviruses, acyclovir is not effective in the treatment of CMV infections but has shown efficacy in the prophylaxis of CMV infections in patients undergoing bone marrow, liver, or renal transplantation; it has been used in many transplant centers for that purpose. Acyclovir therapy has no clinical benefit for EBV-induced infectious mononucleosis, although shedding of EBV in the oropharynx was reduced during acyclovir administration. Oral hairy leukoplakia in patients with AIDS frequently responds to acyclovir therapy. Anecdotal reports have described the use of acyclovir to treat EBV-associated posttransplantation lymphoproliferative disorders, but the overall effectiveness of acyclovir in that setting is unclear.

Valacyclovir

Valacyclovir{2-[2-amino-1, 6-dihydro-6-oxo-9 *H*-purin-9-yl-methoxy] ethyl-L-valinate hydrochloride, Valtrex} (Fig. 260-2) is the L-valine ester of acyclovir; it was developed to provide increased oral bioavailability for acyclovir. [26] It is rapidly absorbed from the gastrointestinal tract and is converted almost entirely to acyclovir through intestinal and hepatic esterases. Thus, the mechanism of action and spectrum of activity of valacyclovir is that of acyclovir. After a 1-g oral dose of valacyclovir, peak plasma concentrations of acyclovir of 5.7 µg/mL are achieved in 1.75 h, with area under the curve (AUC) concentrations that are similar to those achieved with 5 mg/kg of acyclovir given intravenously. [27] The pharmacokinetics of acyclovir, once it has been converted from valacyclovir, are those of the parent compound, acyclovir, and adverse effects are those that would be expected with acyclovir. However, severe and even fatal cases of the thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS) have been reported in patients with AIDS and transplant recipients who were taking high doses of valacyclovir. [28] The basis and causal relationship to valacyclovir

of this observation have not been established, and TTP/HUS has not been reported in patients taking conventional doses (up to 3 g/day) of valacyclovir.

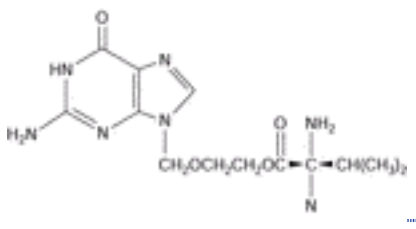

FIGURE 260-2 Valacyclovir.

CLINICAL USEFULNESS Valacyclovir is currently approved for the treatment of initial [29] and recurrent HSV genital infections, [30] for the suppression of frequently recurring genital HSV infections, [31] and for the treatment of herpes zoster in immunocompetent patients. [19] The treatment of initial HSV genital infection with 1 g PO bid for 10 days [29] or recurrent HSV genital infections with 500 mg PO bid for 5 days [30] was as effective and more convenient than when the drug was given at 200 mg five times a day. Clinical episodes of recurrent HSV infections were effectively suppressed with doses of 1 g/day PO in patients with very frequent recurrences (nine or more episodes per year) and with a lower dose (500 mg/day) in those with fewer than nine episodes per year. [31] Suppressive regimes of valacyclovir have been reported to be well tolerated for at least 1 year, and many clinicians have successfully maintained patients on suppressive therapy for even longer periods of times. Valacyclovir is effective in the treatment of herpes zoster in immunocompetent patients if administered within 72 h of the onset of lesions at a dose of 1 g PO tid for 7 days, and it appears to be somewhat superior to acyclovir in the resolution of zoster-associated pain. [19], [32] In a trial comparing valacyclovir with famciclovir (see below) in the treatment of herpes zoster, the two drugs were similarly effective in the resolution of zoster-associated pain. [33] Valacyclovir has been reported to be effective as prophylaxis against recurrences of facial HSV after facial resurfacing. [34] The drug is also being studied as prophylaxis for HSV, VZV, and CMV infections in a variety of immunosuppressed patients, particularly those undergoing transplantation. [35] Because of its favorable pharmokinetic properties and convenience of dosing, many clinicians substitute valacyclovir for acyclovir in the treatment of HSV or VZV infections, even in those in which studies of valacyclovir are not available, such as in immunosuppressed patients or in those with chickenpox.

Famciclovir and Penciclovir

ANTIVIRAL ACTIVITY Famciclovir [9-(4-hydroxy-3 hydroxymethylbut-1-yl) guanine, Famvir] (Fig. 260-3) is a prodrug of penciclovir [9-(4-hydroxy-3-hydroxy-3-hydroxymethylbut-1-yl) guanine]. Penciclovir is phosphorylated to penciclovir triphosphate, which has antiviral activity against HSV-1, HSV-2, VZV, and EBV, and also against hepatitis B virus (HBV). [36], [37] The initial phosphorylation of penciclovir to penciclovir monophosphate is carried out by HSV- or VZV-induced thymidine kinases in a manner analogous to that of the initial phosphorylation of acyclovir. Phosphorylation to di- and triphosphate forms of penciclovir is carried out by cellular kinases. Penciclovir triphosphate inhibits viral DNA polymerases and also inhibits extension of the nascent viral DNA chain. [37] Because of the presence of the hydroxyl group on the acyclic side chain of penciclovir, some DNA chain extension may occur.

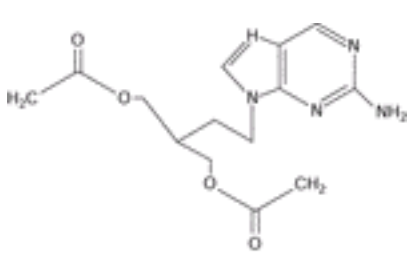

FIGURE 260-3 Famciclovir.

PHARMACOKINETICS Famciclovir is available as an oral formulation, which is converted to penciclovir by deacetylation and oxidation in the liver and intestine. The bioavailability of famciclovir is 77 percent, and a peak penciclovir plasma concentration of 3.3 µg/mL is reached 1 h after oral administration of 500 mg of famciclovir. [38] The plasma half-life of penciclovir is 2 h, and 60 to 70 percent of the drug is excreted unchanged in the urine by both glomerular filtration and tubular secretion. The dose of penciclovir should be reduced in cases of advanced renal dysfunction. [39] Compared to the intracellular half-life of acyclovir triphosphate, that of penciclovir triphosphate is markedly prolonged in HSV-infected cells (10 to 20 h) and VZV-infected cells (9 h). [36], [37] This prolonged intracellular half-life is the rationale for the longer interval of administration of famciclovir (q12h), as compared to that recommended for acyclovir (q4h). HSV and VZV isolates that lack thymidine kinases are resistant to penciclovir just as they are to acyclovir. However, some acyclovir-resistant viruses with altered thymidine kinases remain sensitive to penciclovir.

ADVERSE EFFECTS Famciclovir is well tolerated, and serious clinical and laboratory toxicities are uncommon. Prolonged, high-dose administration of famciclovir to rats was associated with an increased incidence of mammary adenocarcinomas in females, but the clinical significance of this observation is unknown.

CLINICAL USEFULNESS Famciclovir is approved for the treatment of acute herpes zoster, [33], [40] for the treatment or suppression of recurrent genital HSV infections in immunocompetent patients, [41], [42] and [43] and for the treatment of recurrent mucocutaneous herpes simplex infections in HIV-infected patients. [44] Famciclovir is not approved for the treatment of initial genital HSV infections. In immunocompetent patients with herpes zoster treated within 72 h of the onset of lesions, 500 mg of famciclovir PO tid for 7 days had a beneficial effect on the resolution of skin lesions and on the duration of postherpetic neuralgia. In a comparative trial, famciclovir was as effective as valacyclovir for the treatment of herpes zoster in immunocompetent patients. [33] In immunocompromised patients with herpes zoster, famciclovir (500 mg PO tid for 7 days) was as effective as acyclovir (800 mg PO five times day). [40] In studies of recurrent genital HSV infections, famciclovir at a dose of 125 mg PO bid for 5 days reduced the duration of symptoms by 0.6 days, accelerated

healing by 1 day, and reduced the median duration of viral shedding by 2.6 days. [41] Famciclovir appeared to be as effective as acyclovir in the treatment of recurrent genital HSV infection in a comparative trial. [42] Suppression of clinical recurrences of genital HSV infections has been reported with administration of famciclovir, 250 mg PO bid, for up to 1 year. [43] Famciclovir at a dose of 500 mg PO bid for 7 days was as effective as acyclovir at a dose of 400 mg five times per day in the treatment of mucocutaneous HSV infections in HIV infected patients. [44] Famciclovir has also been reported to be efficacious in prophylaxis of HSV recurrences after laser facial resurfacing procedures. [45] Penciclovir is available as a 1% cream in propylene glycol and petrolatum. It is approved for the treatment of recurrent herpes labialis (cold sores) on the face or lips in immunocompetent adults on the basis of two double-blind, placebo-controlled trials involving 3057 patients. In these trials, patients initiated therapy within 1 h of signs or symptoms of lesions and continued to apply the study medication every 2 h while awake, for 4 days. Those patients receiving penciclovir cream experienced a modest benefit, which consisted of a decrease of a half-day in duration of lesions and in pain associated with lesions. [46], [47] Penciclovir cream was well tolerated.

TRIFLURIDINE Trifluridine (5-trifluoromethyl-2'-deoxyuridine, Viroptic) (Fig. 260-4) is a pyrimidine nucleoside analogue with activity against HSV-1, HSV-2, CMV, vaccinia, and, to some degree, certain adenoviruses. [48] Trifluridine monophosphate is an irreversible competitive inhibitor of thymidylate synthetase, and trifluridine triphosphate inhibits HSV DNA polymerase. [48] Trifluridine triphosphate also inhibits cellular DNA polymerases, although to a lesser extent than viral DNA polymerases. Trifluridine shows mutagenesis and teratogenesis in experimental systems.

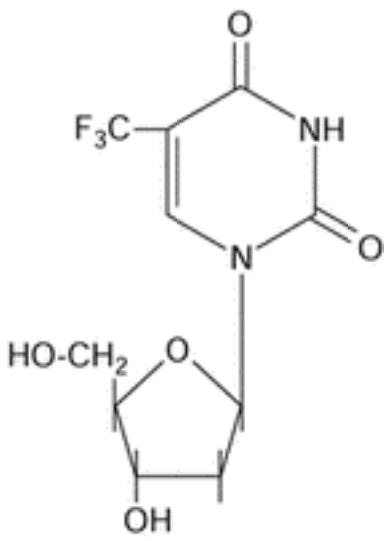

FIGURE 260-4 Trifluridine.

Because of systemic toxicity, trifluridine is approved only for topical application in the form of a 1% ophthalmic aqueous solution for the treatment of primary conjunctivitis and recurrent epithelial keratitis caused by HSV. In comparative trials, it was more effective than topical idoxuridine and similarly effective to topical vidarabine, neither of which is commercially available in the United States. Some patients with herpes simplex keratitis that was unresponsive to idoxuridine or vidarabine have responded to treatment with topical trifluridine. Topical trifluridine, either alone or in combination with interferon (IFN)-a, has been reported to be beneficial in the treatment of acyclovir-resistant mucocutaneous HSV infections in patients with AIDS. [49]

DRUGS FOR THE TREATMENT OF CMV INFECTIONS

Ganciclovir

Ganciclovir [9-(1,3-dihydroxy-2 propoxymethyl) guanine, Cytovene] (Fig. 260-5) is a nucleoside analogue that is similar in structure to acyclovir but is markedly more active than acyclovir against CMV. [50] Ganciclovir has good in vitro activity against HSV-1, HSV-2, VZV, and EBV, and is active against HHV-6 and HBV. The mechanism of action of ganciclovir is similar to that of acyclovir. Ganciclovir is initially phosphorylated by virus-encoded kinases, which, in the case of CMV-infected cells, is a protein kinase encoded by the UL97 gene of CMV. Ganciclovir triphosphate competitively inhibits herpesvirus DNA polymerases and also inhibits elongation of the nascent DNA chain. HSV and VZV viruses may be resistant to ganciclovir through thymidine kinase deficiency and thus would be expected to share cross-resistance with viruses that are resistant to acyclovir on the same basis. Ganciclovir-resistant viruses may also arise through mutations in the viral DNA polymerase, which may be at a different locus than that found with acyclovir-resistant DNA polymerase mutants. Thus, viruses resistant to acyclovir on the basis of DNA polymerase mutation may retain sensitivity to ganciclovir. Ganciclovir-resistant CMV isolates may arise through mutations in the UL97 gene, in which case such viruses remain susceptible to foscarnet or cidofovir (see below). CMV isolates that are resistant to ganciclovir on the basis of DNA polymerase mutations may also be resistant to cidofovir and foscarnet.

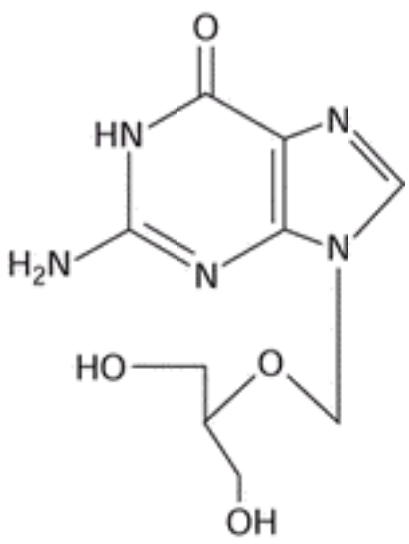

FIGURE 260-5 Ganciclovir.

PHARMACOKINETICS Ganciclovir is available as either an intravenous or an oral preparation. Because of low oral bioavailability (5 to 9 percent), relatively large doses of ganciclovir need to be administered orally (1 g PO three times per day) to achieve an effect. [51] Its use has been largely supplanted by the use of valganciclovir, which is much better absorbed orally (see below). Intravenous administration of ganciclovir at a dose of 5 mg/kg results in a peak plasma concentration of 8 to 11 µg/mL with a serum half-life of 3.5 h. Oral administration of 1 g of ganciclovir results in a peak plasma concentration of 1 µg/mL approximately 4.5 h after administration. [53] Ganciclovir is excreted primarily by the kidney unmetabolized, and the dosage should be reduced in patients with renal dysfunction. Ganciclovir has also been administered intraocularly by intravitreous injection and by the implantation of sustained-release devices in the eye.
ADVERSE EFFECTS The major toxicity associated with ganciclovir is bone marrow suppression, particularly neutropenia and thrombocytopenia. [52] This effect occurs most frequently in patients with underlying bone marrow compromise and is worsened by concomitant administration of other hematotoxic drugs, such as zidovudine. The rates of hematologic toxicity are lower when ganciclovir is administered orally, presumably as a result of poor systemic absorption. Neurotoxicity, fever, liver function abnormalities, and a variety of gastrointestinal symptoms, especially diarrhea, have also been noted. Gastrointestinal intolerance may be a particular problem in patients taking the drug orally. The risk of seizures may be increased when ganciclovir and imipenem are administered concurrently.
CLINICAL USEFULNESS Ganciclovir is widely used for treatment and, in a more limited way, for prophylaxis of CMV infections in immunosuppressed patients. Its most well-established use is for the treatment of CMV retinitis in patients with AIDS, [53] for whom an initial regimen of 5 mg/kg intravenously twice a day for 14 to 21 days is followed by a maintenance regimen of 5 mg/kg intravenously five times per week, indefinitely. Oral ganciclovir (1 g PO tid) and ocular ganciclovir implants have been used as alternative modes for maintenance therapy but are likely to be supplanted by valganciclovir which is under study as maintenance therapy (see below). Ganciclovir is effective for the treatment of gastrointestinal disease caused by CMV in immunosuppressed patients. It is also used for the treatment of CMV-associated pneumonia and neurologic disease, although responses are poor in these cases. Ganciclovir is used for the treatment of CMV infections in patients who are immunosuppressed as a result of organ transplantation. Responses have been variable and, in general, have been etter in patients receiving solid organ transplants than in those receiving bone marrow transplants. Strategies to prevent the development of CMV disease in transplant recipients have included prophylactic administration of ganciclovir during the time of intensive immunosuppression and “preemptive therapy” when CMV virus is detected in the blood by highly sensitive assays but before disease is manifested clinically. The use of ganciclovir in combination with anti-CMV immunoglobulin and in combination with other anti-CMV drugs such as foscarnet (see below) is being evaluated.

Valganciclovir

Valganciclovir or L-valine {2-[(2-amino-1,6 dehydro-6-oxo-9H-purin-9-yl) methoxy]-3-hydroxypropyl ester} (Fig. 260-6) is the L-valyl ester of ganciclovir that acts as a prodrug for ganciclovir in a manner similar to that which valacyclovir serves for acyclovir. After oral administration, valganciclovir is rapidly converted to ganciclovir by intestinal and hepatic esterases. The oral availability of valganciclovir in terms of ganciclovir is approximately 60 percent, and is increased by administration with food. After a 900-mg dose of valganciclovir, the maximum plasma concentration of ganciclovir is 5.61 µg/mL, and the plasma concentration time curve (AUC) is similar to that achieved with ganciclovir given intravenously at a dose of 5mg/kg. [54], [55] The toxicity of valganciclovir is that of its active compound, ganciclovir.

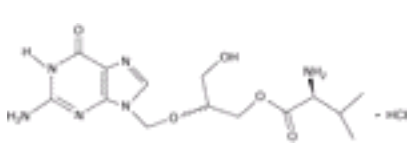

FIGURE 260-6 Valganciclovir.

Valganciclovir is approved for the treatment of CMV retinitis in patients with AIDS. This approval was based on a study of 160 patients in which valganciclovir, initiated at a dose of 900 mg PO bid for 21 days, and then given every day for 7 days, was equivalent in efficacy to standard therapy with intravenous ganciclovir given at 5 mg/kg bid for 21 days and every day for 7 days. After 4 weeks, all patients received valganciclovir for maintenance therapy (900 mg PO qd), thus its efficacy for maintenance therapy was not studied. However, on the basis of pharmacokinetic data, valganciclovir should be at least as effective, if not more so, as oral ganciclovir, which is approved for maintenance therapy of CMV retinitis. [56] Valganciclovir is also currently under study as prophylaxis for CMV infection in immunosuppressed patients in a variety of clinical settings.

Foscarnet

ANTIVIRAL ACTIVITY Foscarnet (trisodium phosphonoformate, Foscavir) (Fig. 260-7) is a pyrophosphate-containing compound that is active in vitro against HSV-1, HSV-2, VZV, CMV, EBV, HHV-6, HBV, and HIV. Foscarnet noncompetitively inhibits viral DNA polymerases at the pyrophosphate-binding site. [57] In contrast to the nucleoside analogues discussed above, foscarnet does not require phosphorylation for its antiviral activity and is therefore active against viruses that are resistant to acyclovir, famciclovir, or ganciclovir on the basis of absent or altered kinase activities. CMV isolates resistant to ganciclovir on the basis of DNA polymerase mutations may also be resistant to foscarnet, although foscarnet-resistant HSV and CMV isolates are variable in their sensitivities to ganciclovir. Some isolates that are resistant to both acyclovir and foscarnet may remain sensitive to cidofovir (see below).

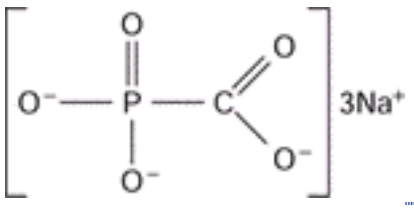

FIGURE 260-7 Foscarnet.

PHARMACOKINETICS Foscarnet is currently available only in an intravenous preparation that has poor solubility and must be administered by an infusion pump in a dilute solution over 1 to 2 h. The plasma half-life of the drug consists of an initial phase of 4 to 8 h and a terminal component of 88 h or more, which reflects a deposition in bone of up to 20 percent of the dose. [58] Eighty percent of the dose is excreted unmetabolized by the kidney, and the dosage should be reduced in patients with renal dysfunction.

ADVERSE EFFECTS The major toxicity associated with foscarnet involves the kidney, and its use requires close monitoring of renal function, particularly during the initial phases of therapy. Saline hydration before administration and slow infusion of the drug appear to reduce nephrotoxicity. Electrolyte abnormalities such as hypo- and hypercalcemia, hypo- and hyperphosphatemia, hypomagnesemia, and hypokalemia have been described. Some of these electrolyte abnormalities appear to be related to the ability of foscarnet to bind divalent cations, whereas the mechanism for others may be related to the interaction of foscarnet with renal function or with bone metabolism. Neurologic toxicities, including tremors, seizures, and altered consciousness, have also been described. Although anemia and, to a lesser extent, neutropenia have been reported with foscarnet administration, hematologic toxicity is less than that with ganciclovir, and foscarnet can often be administered along with myelosuppressive agents. Genital ulcerations have occurred as a result of high concentrations of foscarnet in the urine. [59]

CLINICAL USEFULNESS The major use for foscarnet is in the treatment of CMV retinitis in patients with AIDS. A comparative clinical trial demonstrated that foscarnet was as effective as ganciclovir as first-line treatment of CMV retinitis but was associated with longer survival than ganciclovir, a finding that is perhaps related to the anti-HIV activity of foscarnet. The initial dosage of foscarnet is 60 mg/kg intravenously q8h for 14 to 21 days, followed by a maintenance dose of 120 mg/kg per day. Foscarnet is also used for the treatment of HSV or VZV infection resistant to acyclovir [60] and for ganciclovir-resistant CMV infection. [61] Foscarnet-resistant CMV viruses may emerge on therapy.

Cidofovir

ANTIVIRAL ACTIVITY Cidofovir {(S)-1-[3-hydroxy-2 (phosphonylmethoxy)-propyl] cytosine, Vistide} (Fig. 260-8) is a phosphonate nucleotide analogue with activity against a broad range of herpesviruses, but its major use is against CMV. [62] Cidofovir does not require initial phosphorylation by virus-induced kinases, but is converted by host cell enzymes to cidofovir diphosphate, which is a competitive inhibitor of viral DNA polymerases and, to a lesser extent, of host cell DNA polymerases. Cidofovir is usually active against CMV isolates that are resistant to ganciclovir and foscarnet, although viruses that are resistant to all three drugs have been described. Cidofovir also has antiviral activity against pox viruses, including vaccinia and variola (smallpox), in which there has been renewed interest recently because of bioterrorism concerns. [63]

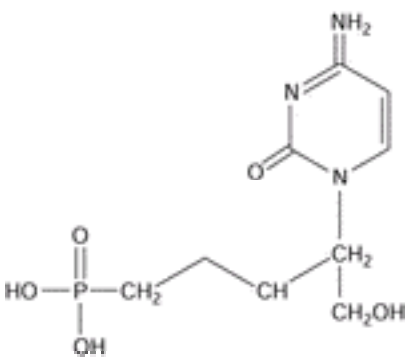

FIGURE 260-8 Cidofovir.

PHARMACOKINETICS Cidofovir is approved for intravenous administration, and a topical formulation and ocular implant have been investigated. An intravenous dose of 5 mg/kg results in a peak plasma concentration of 11.5 µg/mL. The plasma half-life of cidofovir is 2.6 h, and the drug is excreted almost entirely by the kidney. [64] Cidofovir diphosphate has a markedly prolonged intracellular half-life (more than 48 h), which is the basis for the recommended dosing regimen of 5 mg/kg twice a week for the first 2 weeks, followed by one dose every 2 weeks. [65]

ADVERSE EFFECTS The major toxicity associated with cidofovir is renal tubular damage, manifested by proteinuria and elevated serum creatinine levels. [66] Hydration, along with the administration of probenecid before and after administration, appears to protect against nephrotoxicity. Rashes have been reported in patients receiving cidofovir and probenecid.

CLINICAL USEFULNESS Cidofovir is approved for the treatment of CMV retinitis in patients with AIDS who have either failed treatment with ganciclovir and foscarnet or are intolerant of those drugs. Intravitreous administration of cidofovir

has also been used as a maintenance regimen but has been associated with serious toxicities.

INTERFERONS

Interferons are cytokines that have broad antiviral, immunomodulating, and antiproliferative effects. The antiviral activities of interferons are multiple and complex and vary according to the cell type and virus being examined. Interferons have been studied in a variety of viral infections, as well as in a number of diseases of noninfectious etiology. For viral infections, interferon (IFN)-a has been studied most extensively, and four such preparations are currently approved for the treatment of certain viral infections: IFN-a2a (Roferon-A), IFN-a2b (Intron-A), leukocyte-derived IFN-an3 (Alferon N), and IFN alphacon-1 (Infergen). Interferon may be administered intravenously, or, more commonly, subcutaneously or intramuscularly. The plasma half-life after intravenous administration of IFN-a is 2 to 3 h and after subcutaneous or intramuscular administration is 4 to 6 h. [67] A markedly prolonged half-life is seen with the use of "pegylated" interferons, which were recently approved (see below).

The most common adverse effects of interferon are fever, chills, headache, myalgia, arthralgia, and gastrointestinal symptoms. [68] These effects are generally dose-related and are often most prominent with the initial doses of therapy. Granulocytopenia, thrombocytopenia, various neurotoxicities, alopecia, hepatotoxicity, and autoantibody formation have also been noted. [68]

Recombinant IFN-a2b and leukocyte-derived IFN-an3 have been approved for the intralesional treatment of condylomata acuminata, for which purpose they have proved to be modestly effective in placebo-controlled studies. Interferon is most commonly administered in a volume of 0.1 mL through a 30-gauge needle directly into each wart. The recommended dose of IFN-a2b is 1 million units to each wart three times a week for 3 weeks. Significant systemic absorption and associated side effects can result from the intralesional administration of interferon. Systemic (parenteral) administration of interferon has been evaluated as therapy for extensive and refractory warts. In these studies, parenterally administered interferon was associated chiefly with a reduction in the size of warts but not with a decrease in recurrence rates compared to placebo, although there was some variability in findings among the studies. [69], [70]

Interferons have been extensively evaluated in the treatment of chronic HBV and chronic hepatitis C virus (HCV) infection. [68] The administration of recombinant IFN-a2b at a dose of 5 million units per day for 16 weeks resulted in disappearance of HBV DNA in 37 percent of patients and loss of hepatitis B e antigen in 33 percent of patients. [71] Approximately 8 percent of all patients lost hepatitis B surface antigen. In most patients who responded, improvements were sustained for extended periods of time after therapy was discontinued. Predictors of a response to interferon therapy are low HBV DNA levels, high alanine and aspartate aminotransferase levels, short duration of infection, and histopathologic evidence of active hepatitis. [68]

Interferon-a2b, interferon-a2a, and interferon alfacon-1 have been approved for the treatment of chronic HCV infection. [68], [72] Favorable responses were associated with short duration of infection, lower levels of circulating HCV RNA, minimal amounts of hepatic fibrosis, and low hepatic iron stores, as well as with certain HCV genotypes that appear to be more sensitive to interferon. [68] The addition of ribavirin (Rebetol), 1000 to 1200 mg PO daily for 24 to 48 weeks, to interferon therapy increased the rates of responses and was demonstrated to be beneficial for patients with HIV infection who relapsed after interferon therapy had been stopped. [73] The FDA has approved the use of combined IFN-a2b and ribavirin for this purpose. Recently, the FDA approved two "pegylated" interferons, peginterferon-a2b (PEG-Intron) and peginterferon-a2a (PEGASYS), which are covalent conjugates of interferon-a2b or interferon-a2a with monomethoxy polyethylene glycol. This agent reduces the clearance of these interferons markedly and therefore decreases the frequency of administration to once per week. Peginterferon-a2b has been approved for therapy of HCV in combination with ribavirin, as well as by itself. Pegylated interferon-a2a is also currently approved for treatment of chronic HCV. Currently, the optimal regimens for treatment of chronic HCV infection appear to be combinations of pegylated interferon a and ribavirin which result in sustained viral responses of 42–46 percent in patients with genotype 1 infections and 72–82 percent in patients with genotype 2 infections. [74]

DRUGS FOR THE TREATMENT OF HIV INFECTION

The development of antiretroviral drugs to combat HIV infection has been an area of intense preclinical and clinical research activity. Currently there are 16 approved antiretroviral drugs, and it is likely that additional drugs will receive approval in the near future. Strategies for the use of antiretrovirals have emerged from large-scale clinical trials, as well as from advances in the understanding of the pathogenesis of HIV-1 infection. These studies established two important principles on which recommendations for the use of antiretroviral drugs are based: (1) combination therapy with at least three drugs should be used to maximize the clinical and antiviral effects and to minimize the emergence of resistant viruses [75]; and (2) virus load, as well as CD4 counts, should be monitored as an important parameter of the effectiveness of antiviral therapy. The availability of phenotypic and genotypic assays to determine resistance of HIV isolates to antiretroviral drugs also provides increasingly important information for the appropriate use of such drugs. [76]

Recommendations for the use of antiretroviral therapy in various clinical settings, including the optimal time to begin therapy in HIV-infected patients, are still in evolution. For a discussion of those recommendations, and detailed descriptions of individual properties of each antiretroviral drug, itself, the reader is referred to several excellent recent reviews. [75], [77], [78] The major properties of the antiretroviral drugs that are currently available are presented below.

Reverse Transcriptase Inhibitors

Nucleoside analogues that inhibit HIV-1 and HIV-2 reverse transcriptases are the most extensively studied antiretroviral drugs. Six of the currently available drugs—zidovudine, didanosine, zalcitabine, stavudine, lamivudine, and abacavir—are nucleoside analogues, while the seventh, tenofovir, is a nucleotide (nucleoside monophosphate). All

require phosphorylation to the triphosphate form to inhibit viral reverse transcriptases. Resistance to each drug can develop by one or more amino acid substitutions in the HIV reverse transcriptase. Each nucleoside analogue has its own pharmacokinetic profile and characteristic set of toxicities, which determine its suitability for use in individual patients and in combination with other antiretrovirals. The major toxic effects of the nucleoside analogues are as follows: zidovudine, myelosuppression; didanosine, pancreatitis, and peripheral neuropathy; zalcitabine, peripheral neuropathy, mucosal ulcerations, and pancreatitis; stavudine, peripheral neuropathy and pancreatitis in children; and lamivudine, neutropenia at high doses. Abacavir has a hypersensitivity syndrome that consists of fever, usually with a maculopapular or urticarial rash. This syndrome, although uncommon, can be severe; and life-threatening and fatal reactions have been reported when hypersensitive patients are rechallenged with the drug.

Two nucleoside analogues are included in many recommended combination regimens. The most common combinations include zidovudine and lamivudine, zidovudine and didanosine, and stavudine and lamivudine. Zidovudine and stavudine appear to be antagonistic in vitro, and probably in vivo; didanosine and zalcitabine are rarely used together because of overlapping toxicities. The two nucleoside analogue combinations are usually used with at least one other drug from another class of antiretroviral drugs, either a protease inhibitor or a non-nucleoside reverse transcriptase inhibitor (see below). A combination consisting entirely of three nucleoside analogues, zidovudine, lamivudine, and abacavir, is also recommended and is available in a single tablet (Trizivir), which adds to the convenience of such a regimen. A fixed combination of zidovudine and lamivudine (Combivir) is also available as a single capsule.

Nonnucleoside reverse transcriptase inhibitors (NNRTIs) have also demonstrated antiviral efficacy. Of this class of drugs, efavirenz, nevirapine, and delavirdine are approved for use against HIV-1. NNRTIs are compounds of diverse chemical structure that inhibit HIV-1 reverse transcriptase at a characteristic region of the enzyme, generally through noncompetitive allosteric binding. These compounds are active against HIV-1 reverse transcriptases but not against HIV-2 reverse transcriptases. NNRTIs have potent HIV-1 activity in vitro and in vivo, but their use as single agents has resulted in the rapid emergence of resistance across the entire class. Thus, the appropriate use of NNRTIs is as part of combination therapy regimens, with at least two drugs outside of the NNRTI class.

Of this class of drugs, efavirenz, nevirapine, and delavirdine are approved for use against HIV-1. Efavirenz is the most strongly recommended and frequently used member of the class, because of both the convenience of its once-daily dosing schedule and the most extensive clinical experience with the drug. The most common adverse effects associated with the NNRTIs are maculopapular rashes; if they are not severe, they can be managed with antihistamines or glucocorticoids without necessarily discontinuing the drug. Rashes may be particularly frequent with nevirapine, and initiation of therapy with lower doses of nevirapine for two weeks, followed by an escalation to full therapeutic doses has been recommended as a measure to reduce the frequency of skin eruptions.

Protease Inhibitors

The protease inhibitors are an important new class of anti-HIV-1 drugs. [79] These compounds inhibit a virus-specific enzyme that is responsible for the proteolytic cleavage of viral polypeptide precursors. Currently, the protease inhibitors that have been approved for use against HIV-1 infections in the United States are saquinavir, indinavir, ritonavir, nelfinavir, amprenavir, and lopinavir. Each protease inhibitor has a unique pharmacokinetic profile, but all are metabolized through the hepatic cytochrome P450 system. Thus, they have important interactions with the drugs that induce, inhibit, or are, themselves, metabolized by cytochrome P450. Ritonavir has the most profound effect in this regard, and is used frequently at a lower dose in combination with other protease inhibitors to inhibit their metabolism and thus raise their blood levels. A fixed combination of lopinavir and ritonavir (Kaletra) is available as a capsule or a liquid to take advantage of this interaction.

Saquinavir was initially available only as a hard-gel capsule that had poor oral availability. Its use has now largely been supplanted by a soft-gel capsule that gives higher blood levels. Indinavir is poorly soluble and has been associated with both nephrolithiasis and elevated indirect bilirubin levels. The major toxicity associated with ritonavir is gastrointestinal intolerance, although tolerance is improved when lower doses of the drug are used in combination with other protease inhibitors. All of the protease inhibitors can cause disturbances in lipid metabolism, including elevations in serum cholesterol and triglycerides. Diabetes mellitus and fat redistribution syndromes also appear in association with use of protease inhibitors. The molecular basis for resistance to protease inhibitors is complex, but resistance clearly develops when the drugs are used as monotherapy. Therefore, the appropriate use of protease inhibitors is as part of potent multidrug combination regimens.

Other Antiretroviral Drugs

Other steps in the HIV replication pathway have been targeted for the development of antiviral drugs. These include inhibitors of virus-cell fusion, synthesis of virus envelope, nucleocapsid assembly, and integrase activity. Several of these are already in clinical trials, and it is likely that other novel approaches to inhibit virus replication will also be entering clinical evaluation in the coming years.

Oral Antifungal Agents

ALLYLAMINES
Terbinafine
TRIAZOLES
Itraconazole
Fluconazole
IMIDAZOLES
Ketoconazole
Griseofulvin
REFERENCES

Oral antifungal agents are now widely and frequently used for the treatment of superficial fungal infections. [1] The first and the only synthetic agent was griseofulvin. Subsequently, other drugs, including amphotericin B and ketoconazole, were introduced. As a result of recent advances in antifungal chemotherapy, new drugs with a broad spectrum of activity, high efficacy, tolerability, and rare, mild side effects are now available. The three newer, released oral antifungal agents are the first oral allylamine, terbinafine, and the triazoles fluconazole and itraconazole.

ALLYLAMINES

Terbinafine

Terbinafine hydrochloride is a synthetic antimycotic agent that belongs to a new family of compounds known as the allylamines. All allylamine derivatives possess a tertiary allylamine, a structural component crucial for antifungal activity (Fig. 261-1). [2] In vitro the drug is primarily a fungicidal agent and highly active against dermatophytes, but less active against molds, dimorphic fungi, and various yeasts.

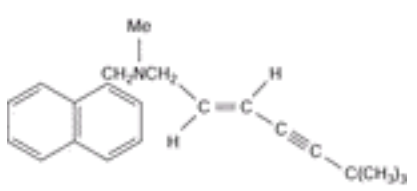

FIGURE 261-1 Terbinafine.

PHARMACOLOGY Terbinafine is well absorbed from the gastrointestinal tract, mostly in chylomicrons. The distribution half-life is 1.5 h, and the elimination half-life is approximately 22 h. [3] Terbinafine is highly lipophilic and keratophilic in nature and, therefore, is widely distributed upon absorption throughout skin and adipose tissue. Terbinafine is extensively biotransformed by the liver, mostly through oxidation by a very small fraction of P450 isoenzymes. More than 80 percent of the drug is excreted in urine; the rest is eliminated with feces. [4]

MECHANISM OF ACTION Terbinafine inhibits the enzyme squalene epoxidase in the fungal membrane, thereby blocking the biosynthesis of ergosterol. [5] Squalene epoxidase, a complex, microsomal, noncytochrome P450 enzyme, catalyzes the first enzymatic step of ergosterol synthesis—the conversion of squalene into squalene epoxide. Consequently, terbinafine causes an abnormal intracellular accumulation of squalene and deficiency in ergosterol. [6] Accumulation of squalene accounts for the drug's fungicidal activity, whereas in vitro deficiency of ergosterol is associated with the drug's fungistatic activity. [6]

CLINICAL USES

Pediatric For the treatment of tinea capitis in children, the dosage guidelines are 3 to 6 mg/kg per day. [7] Children weighing 10 to 20 kg can be given 62.5 mg/day; children weighing 20 to 40 kg can be given 125 mg/day; and those children weighing more than 40 kg can be given 250 mg/day. [8] The treatment course for *Trichophyton* infections is 4 weeks. In a study of tinea capitis in children, comparing a 4-week course of terbinafine with an 8-week course of griseofulvin (10 mg/kg day), oral terbinafine was shown to have efficacy similar to griseofulvin. [9] Other studies suggest that for treatment of *M. canis* with terbinafine, 6 or more weeks may be needed. [8], [10]

Adult Terbinafine is indicated for the treatment of onychomycosis of the toenails and fingernails caused by dermatophytes. [11] In a study comparing continuous terbinafine with intermittent itraconazole in the treatment of toenail onychomycosis, terbinafine was significantly more effective than itraconazole in the treatment of toenail dermatophyte onychomycosis. [12] At week 72, the mycologic cure in those patients treated with a 3-month course of terbinafine was 75.5 percent, compared with a mycologic cure rate of 38.3 percent in those patients treated with a 3-month course of intermittent pulse therapy with itraconazole. Terbinafine is superior to itraconazole in maintaining mycologic and clinical cure for at least 2 years after completion of therapy. [13] In a study of 22 patients with tinea corporis and tinea cruris who used terbinafine 250 mg daily for 1 week, 100 percent clinical and mycologic clearing was observed at 6 weeks. [14] In a study of moccasin tinea pedis and tinea manuum, after a 2-week course of terbinafine 250 mg daily, there was an 86 percent mycologic cure rate at 8 weeks. [15] A placebo-controlled trial demonstrated that a 4-week course of terbinafine 250 mg daily was effective in the treatment of seborrheic dermatitis. [16] Terbinafine is not effective orally for the treatment

of tinea versicolor. [14]

Geriatric Terbinafine is well tolerated by the elderly. [17]

Pregnancy considerations Terbinafine is a pregnancy category B drug and should not be taken by nursing mothers. [11]

DOSAGE SCHEDULES AND FORMULATIONS Terbinafine is supplied as a 250 mg tablet and should be taken once daily for 6 weeks for fingernail onychomycosis and once daily for 12 weeks for toenail onychomycosis. Pretreatment serum transaminase tests are advised for all patients before taking terbinafine, and the drug is not recommended for patients with liver disease. [18] Because of transient lymphopenia observed in patients on terbinafine, complete blood counts should be monitored in patients with immunodeficiency who are receiving terbinafine for longer than 6 weeks. If signs or symptoms of secondary infection occur in patients while on terbinafine, a complete blood count should be performed to rule out neutropenia.

ADVERSE EFFECTS Because of its high selectivity, terbinafine is generally well tolerated with a low incidence of adverse side effects. The most common side effects following oral administration are of a gastrointestinal nature (3.5 to 5 percent). [19] Other rare side effects include headache, exanthematous eruption, acute generalized exanthematous pustulosis (AGEP), pustular psoriasis, subacute cutaneous lupus erythematosus, chest pain, elevated laboratory parameters, loss of taste, tiredness, and malaise. [19], [20], [21], [22], [23] and [24] A few cases of hepatocellular injury (including fulminant hepatic failure), [25] reversible agranulocytosis, [26] and severe skin reactions, including toxic epidermal necrolysis and erythema multiforme, were also reported. [27], [28]

DRUG INTERACTIONS Terbinafine is metabolized by cytochrome P450 enzymes and plasma clearance of terbinafine is increased by the P450-inducer rifampin and decreased by the P450-inhibitor cimetidine. [29] Terbinafine is also reported to decrease cyclosporine levels by increasing cyclosporine clearance. [18], [30] Isolated reports of interactions with warfarin have been reported; however, prospective pharmacokinetic studies have not revealed any clinically significant reactions. [31] It was recently shown that terbinafine inhibits CYP2D6, a cytochrome P450 isoenzyme that metabolizes tricyclic antidepressants and other psychotropic drugs. [32] Other drugs predominantly metabolized by this enzyme include beta-blockers, selective serotonin reuptake inhibitors (SSRIs), and monoamine oxidase inhibitors (MAOIs) type B. [18] In a postmarketing surveillance study of patients on terbinafine, no adverse drug interactions with CYP2D6 substrates were reported. [33] However, there have been two reports of nortriptyline intoxication induced by terbinafine. [34], [35]

TRIAZOLES

Both itraconazole and fluconazole are triazole antimycotic agents sharing a common structural moiety—a triazole ring—not found in azoles of the imidazole family.

Itraconazole

Itraconazole (Fig. 261-2) is a highly lipophilic compound [36] that has a wide spectrum of activity. In vitro it is fungistatic and effective against dermatophytes, yeast, molds, and dimorphic and dematiaceous fungi. [37], [38] and [39]

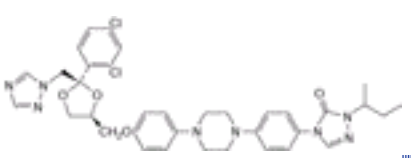

FIGURE 261-2 Itraconazole.

PHARMACOLOGY The serum concentration of itraconazole is influenced by several parameters, including food and gastric acidity. [40], [41] Itraconazole is extensively metabolized, primarily by the cytochrome P450 3A4 isoenzyme system (CYP3A4) to more than 30 metabolites. Hydroxyitraconazole is the main metabolite. Approximately 54 percent of the metabolized drug is excreted in the feces, and 34 percent is excreted in the urine. After single-dose administration, the terminal elimination half-life is 21 h for itraconazole and 12 h for its active metabolite. The pharmacokinetic variables of itraconazole are not affected in patients with renal insufficiency. [42] In patients with liver cirrhosis, the absorption is slightly increased, and the half-life is prolonged, because of a reduced first-pass metabolism. The absorption is decreased in AIDS patients as a result of gastric hypochlorhydria. [42]

MECHANISM OF ACTION Itraconazole inhibits 14-a-demethylase, a microsomal cytochrome P450 enzyme, in the fungal membrane. [43] 14-a-Demethylase is necessary for the conversion of lanosterol to ergosterol, which is the principal structural component of the fungal cell membrane. [38] Consequently, the accumulation of 14-a-methylsterols leads to the impairment of membrane permeability and membrane-bound enzyme activity and to the arrest of fungal cell growth.

CLINICAL USES

Pediatric Recently, itraconazole has been used to treat tinea capitis in children. It is prescribed with food in the capsule formulation because the liquid form of itraconazole contains cyclodextrin, which causes diarrhea and might be carcinogenic in animal models. [37] It is dosed at 5 mg/kg per day for 4 to 6 weeks. [7] Children who weigh between 15 and 30 kg require one 100 mg capsule daily; children weighing 30 to 40 kg require 100 mg one day alternating with 200 mg the next day, to average 150 mg daily. [44] Tinea capitis caused by *T. tonsurans* requires a course lasting 4 weeks; however, a longer treatment course is recommended for *M. canis* [45].

Adult Itraconazole has been approved for the treatment of onychomycosis caused by dermatophytes, [46] and is effective as continuous or pulse therapy. A 2-month course of itraconazole pulse therapy is necessary for fingernail onychomycosis, while toenail onychomycosis requires a 3-month course. A single course consists of 200 mg twice daily for 1 week per month. Itraconazole pulse therapy is at least equal in efficacy, if not superior, in the treatment of toenail onychomycosis, when compared to continuous itraconazole therapy. [47] Itraconazole has been used for the treatment of tinea pedis. A 1-week course of itraconazole 200 mg twice daily is more effective than 200 mg or 100 mg daily for 2 to 4 weeks. [48] Itraconazole at a dose of 200 mg daily is effective in the treatment of tinea versicolor. [49]

Geriatric Itraconazole (pulse) therapy is effective and safe in the elderly. [17]

Pregnancy considerations Itraconazole is a pregnancy category C drug and is not recommended while nursing because it is excreted in human milk.

DOSAGE SCHEDULES AND FORMULATIONS Itraconazole is supplied in 100 mg capsules and can also be given intravenously. Capsules should be taken with a full meal to ensure maximum absorption. [46] Dosage schedules are discussed above. The manufacturers of itraconazole recommend monitoring of hepatic function in patients with preexisting liver disease, or if receiving continuous treatment for more than 1 month. [50]

ADVERSE EFFECTS The most common reported side effects associated with itraconazole therapy are of a gastrointestinal nature. [51] Less-frequent adverse effects are hypertriglyceridemia, edema, [52] urticaria, anaphylaxis, erythema multiforme, [46] headache, neuropathy, impotence, hypertension, leukopenia, nephrotic syndrome, and mildly elevated liver enzymes. [51] Instances of hepatic injury and, rarely, fulminant hepatotoxicity are associated with the administration of itraconazole. There are also rare reports of congestive heart failure and pulmonary edema. When administered intravenously to dogs and healthy human volunteers, negative inotropic effects were noted. [50] Therefore, administration of itraconazole to patients with a history of heart failure is contraindicated, and it is not recommended for patients with a history of liver disease.

DRUG INTERACTIONS Itraconazole inhibits 14-a-demethylase, a fungal P450 enzyme [43] and a member of the same group of enzymes present in the human liver that is responsible for the metabolism of many drugs. Itraconazole specifically inhibits the cytochrome P450 3A4 isoenzyme system (CYP3A4), and, consequently, may increase plasma concentrations of drugs metabolized by this pathway. Itraconazole is also known to increase the levels of digoxin; certain anticonvulsants; antiarrhythmics; antimycobacterials; antihistamines; antipsychotics; benzodiazepines; calcium channel blockers; gastric acid suppressors/neutralizers; gastrointestinal motility agents; 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA)–reductase inhibitors; macrolide antibiotics; nonnucleoside reverse transcriptase inhibitors; protease inhibitors; polyenes; oral hypoglycemic agents; antineoplastic agents; and immunosuppressants [5], [50] (Table 261-1). The concomitant use of itraconazole and sildenafil can lead to a reduction in sildenafil clearance. [53] Cisapride, terfenadine, quinidine, dofetilide, oral midazolam, pimozide, triazolam, and HMG-CoA–reductase inhibitors metabolized by CYP3A4, such as lovastatin and simvastatin, are contraindicated with itraconazole. Because itraconazole is itself metabolized by CYP3A4, any inducers or inhibitors may respectively decrease or elevate itraconazole levels (Table 261-1). Absorption of itraconazole may be decreased by the concomitant administration of antacids, H_2-blockers, and proton pump inhibitors. [5]

TABLE 261-1 **Examples of CYP3A4 Subfamily Substrates, Inducers, and Inhibitors***

Fluconazole

Fluconazole (Fig. 261-3) is fungistatic [37] and is effective against many yeasts (with the exception of *C. krusei*) and dermatophytes. [54]

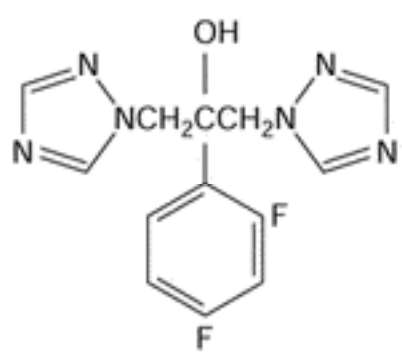

FIGURE 261-3 Fluconazole.

PHARMACOLOGY The pharmacokinetic parameters of fluconazole are similar following either intravenous or oral administration. [54] Extensive absorption (>90 percent) of the triazole appears to be comparable in both postprandial and fasting states and not dependent on stomach acidity. [41], [55] Fluconazole exhibits a long half-life of 25 to 30 h, and a steady-state level is reached after 7 days of once-daily administrations. Fluconazole is only weakly bound to plasma proteins, with about 90 percent of the drug circulating free in the plasma. The drug is resistant to hepatic metabolism, and hence approximately 80 percent of fluconazole is excreted unchanged in urine, with 2 percent in feces and approximately 11 percent as metabolites in urine. [56] The ability to diffuse substantially into the cerebrospinal fluid (CSF) distinguishes this compound from many other antimycotic agents. [57] The levels of fluconazole in cerebrospinal fluid, saliva, vaginal tissue, sputum, skin, and blister fluids are reported to be comparable with or to exceed simultaneous plasma

concentrations. [58] Altered fluconazole pharmacokinetics, including decreased plasma clearance, are detected in patients with cirrhosis [59] and renal impairment. [60]

MECHANISM OF ACTION Fluconazole, like itraconazole, inhibits 14-a-demethylase, a microsomal cytochrome P450 enzyme, in the fungal membrane. [43]

CLINICAL USES

Pediatric In the treatment of tinea capitis, fluconazole has been used successfully at 6 mg/kg per day for 20 days for *T. tonsurans* infection, [61] and at 5 mg/kg per day for 30 days. [44] When *M. canis* is present, a longer treatment course is recommended. [45]

Adult For the treatment of tinea pedis, weekly doses of fluconazole 150 mg were given for a period of 3 to 4 weeks, [62] with a 75 percent mycologic cure rate at 4 weeks. Fluconazole at a dose of 150 mg weekly for 24 weeks is significantly inferior to terbinafine 250 mg daily for 12 weeks in the treatment of onychomycosis. [63] Tinea versicolor can be treated with a single 400 mg dose of fluconazole. [64]

Geriatric Fluconazole is well tolerated in the elderly; [65] however, dose modification is required in elderly patients with renal impairment. [58]

Pregnancy considerations Fluconazole is a pregnancy category C drug and is not recommended in nursing mothers. [66]

DOSAGE SCHEDULES AND FORMULATIONS Fluconazole is available in 50 mg, 100 mg, 150 mg, and 200 mg tablets, and in a liquid form at concentrations of 10 mg/mL and 40 mg/mL. Because it is cleared primarily by renal excretion, dosage should be adjusted in patients with impaired renal function. Fluconazole is indicated for the treatment of vaginal, oropharyngeal, and esophageal candidiasis, cryptococcal meningitis, and for prevention of candidiasis in bone marrow transplant patients. [66] It is approved for use in children age 6 months and older, but not specifically for tinea capitis.

ADVERSE EFFECTS The most common recognized side effects of fluconazole therapy are gastrointestinal. [67] Adverse reactions such as fixed drug eruptions, thrombocytopenia, transient amenorrhea, elevated liver function tests, mild increase in levels of serum creatine phosphokinase, dizziness, anorexia, and alopecia have been observed, and most resolve with continuing fluconazole therapy. [66], [68]

DRUG INTERACTIONS In humans, fluconazole inhibits both CYP3A4 and CYP2C9 in a dose-dependent manner, [5] and consequently may increase plasma concentrations of drugs metabolized by these pathways. Therefore, a number of drugs that are metabolized by CYP3A4 or CYP2C9 are contraindicated or require close monitoring (Table 261-1 and Table 261-2). Coadministration of terfenadine or cisapride with fluconazole is contraindicated. [66]

CYP2C9 Substrates	CYP2C9 Inducers	CYP2C9 Inhibitors
Amitriptyline	Carbamazepine	Amiodarone
Diazepam	Dexamethasone	Disulfiram
Diclofenac	Phenobarbital	Fluconazole
Glipizide	Rifampin	Fluvastatin
Glyburide		Miconazole
Ibuprofen		Omeprazole
Losartan		Ritonavir
Mefenamic acid		Troglitazone
Naproxen		Zafirlukast
Phenytoin		
Piroxicam		
Propranolol		
Terbinafine		
Tolbutamide		
Torsemide		
Zafirlukast

IMIDAZOLES

Ketoconazole

Ketoconazole was introduced in the 1970s as the first effective oral azole antifungal. However, because of the drug's many adverse reactions, it is not used as a first-line agent for the treatment of dermatophyte infections or candida.

Griseofulvin

Griseofulvin has been used since 1958 for the treatment of dermatophyte infections. [45]

PHARMACOLOGY The absorption of griseofulvin is enhanced by several factors, including concurrent intake of a fatty meal and a smaller particle size formulation. Griseofulvin is mainly metabolized by the liver before excretion. [69]

MECHANISM OF ACTION Griseofulvin is fungistatic in vitro, [45] and has a narrow spectrum of antimycotic activity. It disrupts microtubule mitotic spindle formation, thereby causing mitotic arrest at the metaphase stage. [70]

CLINICAL USES

Pediatric Griseofulvin is the drug of choice for the treatment of tinea capitis, but this may alter with new studies emerging about shorter effective courses with the newer antifungal agents. [37] Griseofulvin is recommended at a dosage higher than that suggested by the manufacturers at 20 to 25 mg/kg per day (microsize), or 15 to 20 mg/kg per day (ultramicrosize) to complete a minimum course of 6 to 8 weeks for *T. tonsurans.* [44] However, longer treatment with griseofulvin is recommended for *M. canis* infections. [44]

Adult Although griseofulvin is indicated for the treatment of fingernail and toenail onychomycosis, therapy is prolonged with low cure and high relapse rates, requiring approximately 6 months for the treatment of fingernails and 12 months for toenails. [70]

Geriatric The safety of griseofulvin therapy in the elderly has not been formally evaluated in trials.

Pregnancy considerations Griseofulvin is a pregnancy category C drug. Because griseofulvin interferes with chromosomal distribution during cell division, males should wait at least 6 months after completing griseofulvin therapy before fathering a child. [71]

DOSAGE SCHEDULES AND FORMULATIONS Griseofulvin is indicated for the treatment of dermatophytosis, onychomycosis, and tinea capitis. [71] Griseofulvin is formulated as ultramicrosize tablets in 125 mg, 165 mg, 250 mg, and 330 mg doses. [72] It is also formulated as griseofulvin microsize and is available as 250 mg and 500 mg tablets and in a

125 mg/5 mL suspension. [71] To maximize absorption it should be taken with fatty foods. The manufacturers' recommended dosing is 5 to 10 mg/kg per day (ultramicrosize) or 10 to 20 mg/kg per day (microsize).

ADVERSE EFFECTS The most common side effects are related to the gastrointestinal tract and the central nervous system. [70] The drug is reported to precipitate lupus erythematosus and severe skin reactions. As a result of impaired porphyrin metabolism, griseofulvin therapy is associated with photoallergic reactions. Griseofulvin is contraindicated in patients with porphyria and hepatocellular failure. [45]

DRUG INTERACTIONS Griseofulvin induces CYP3A4, leading to lower plasma levels of drugs metabolized by this pathway (Table 261-1). [5]

EVIDENCE-BASED MEDICINE CONSIDERATIONS Multiple studies looking at the treatment of dermatophytoses have been performed. Criticisms of these studies include the fact that many were open label, leading to investigator bias. [73] Interpretation of competing studies has been difficult as their end points have not been uniform. Such end points may be mycologic cure, clinical cure, complete cure, and effective treatment. Many studies failed to take into account the physiology of nail growth. [13] Toenails can take up to 18 months to grow out fully. Therefore studies at 48 to 52 weeks might not accurately reflect clinical or mycologic cure. Several studies of the treatment of tinea pedis did not always specify the type of tinea pedis, despite known variations amongst forms of tinea pedis in response rate to therapy. Studies of moccasin tinea pedis are preferred as successful treatment usually indicates that the antifungal drug will be effective in the milder forms of tinea pedis as well as tinea corporis and tinea cruris. [73] Finally, the efficacy of antifungal agents depends on the sensitivity of the dermatophyte. For example, in the treatment of tinea capitis, if the causative organism is *M. canis,* longer treatments may be needed than if the organism is *T. tonsurans.* [45] In North America, most tinea capitis is caused by *T. tonsurans,* while surveys in the United Kingdom demonstrate that the predominant dermatophyte is *M. canis.* [45] Consequently, trials assessing the efficacy of a drug may be influenced by the culprit dermatophyte and indirectly by the location of the study.

BASIC PHARMACOLOGIC CONCEPTS IN IMMUNOSUPPRESSIVE THERAPY

Immunosuppressive and immunomodulatory drugs play a crucial role in the management of organ transplantation, as well as in the therapy of autoimmune and inflammatory disorders. The most significant progress in the field of immunosuppression has come from the management of organ transplantation.

The main goal in immunosuppressive therapy is to find the most selective and least toxic regimen. [1] Although, there has been significant progress in the search for selective immunomodulation, the most significant advance in immunosuppressive therapy has been the reduction in the exposure to systemic glucocorticoids. This therapeutic intervention is associated with a significant reduction in morbidity and mortality and is achieved by the avoidance of high doses of systemic glucocorticoids and by the early introduction of steroid-sparing immunosuppressive and immunomodulatory drugs as adjuvant therapy.

The highest level of “safety and effectiveness” in immunosuppressive therapy is currently accomplished by the use of “combination therapy.” [2] Briefly, three major pharmacodynamic effects are obtained by combining these drugs. The first effect is synergistic, whereby the immunologic effect of the drug combination is higher than the one obtained by an individual drug. This allows the use of drugs at lower doses than the ones recommended as sole therapy. Thus, a synergistic combination not only exerts an effective therapeutic dose but also minimizes dose-dependent side effects. The ideal synergistic combination is the one that combines drugs that have different mechanisms of action and have different side effect profiles. Cyclosporine plus mycophenolate mofetil is a commonly used synergistic combination in transplantation and graft-versus-host disease. Certain dermatologic diseases in which this combination may have a synergistic effect include pyoderma gangrenosum, paraneoplastic pemphigus, and lichen planus.

The second major pharmacologic effect obtained with combination therapy is additive, whereby the combination of half of the dosages of individual drugs achieves an immunologic effect that is the similar to the one achieved by the use of a full dose of an individual drug. This is the most common combination used in immunology, especially if only two drugs are combined and one of them is a systemic glucocorticoid. The additive effect in immunosuppressive therapy is the origin of the concept of “steroid sparing agents” in adjuvant therapy. An example of this additive effect is the combination of prednisone and mycophenolate mofetil in organ transplantation and in the treatment of pemphigus.

The third effect of combination therapy is antagonistic, whereby the combining half of the dosages of individual drugs causes a lesser immunologic effect than the one achieved by a full dose of these individual drugs. An example of this effect is the combination of cyclosporine and tacrolimus in transplantation or azathioprine with mycophenolate mofetil in pemphigus. Antagonistic combinations are easy to predict since these drugs usually share similar mechanisms of action and therefore compete for the same intracellular targets.

There are two major obstacles to optimizing immunosuppressive therapy: (1) a low therapeutic index (narrow window between the toxic and the therapeutic range) and (2) intra- and interindividual variation of the pharmacokinetics of these agents. Several concentration-controlled regimens have been developed to overcome these obstacles, including dosing of drugs by ideal (lean) body weight and body surface area. This concept is commonly misinterpreted by some physicians who prescribe these drugs by the actual body weight and not the ideal (lean) body weight of the patient. Another regimen is measurement of drug levels (parent and metabolite serum peak and trough levels). Other more complex methods for prescribing these drugs are less-commonly used, including area under the curve (AUC) and AUC/dosing interval.

The most useful pharmacologic tool that combines the aforementioned pharmacologic concepts is the “median effect formula” of Chou and Talalay (Fig. 262-1). This formula derives from the mass action law and relates dose to biologic effect of drugs. The two major applications of this formula are determination of the therapeutic window of the drug and the type of interactions between agents when used in combination versus individually (i.e., synergistic, antagonistic, or

additive effect). This formula has been used extensively in the design of immunosuppressive regimens. [3]

$$Fa = \frac{D\,m}{Fu\,Dm}$$

D, drug dose; Dm, dose for 50 percent inhibition (median effect); Fa, fraction affected (percent inhibition); Fu, uninhibited fraction (1-Fa); m, slope (Hill) coefficient. *B.* Modified median-effect formula for combined immunosuppressants.

In the scientific design of safe and effective immunosuppressive therapy, it is mandatory to integrate the aforementioned pharmacologic concepts with a full knowledge of the pathogenesis of the disease. Figure 262-2 shows a practical algorithm for the design of immunosuppressive therapy.

MACROLACTAM IMMUNOMODULATORS

This group of immunomodulators is derived from microorganism fermentation products and includes the three classic calcineurin inhibitors (cyclosporine, tacrolimus, and pimecrolimus) and sirolimus. [4] Macrolactams are versatile immunomodulators that have synergistic therapeutic effects when they are combined with virtually any other immunosuppressive drug. The immunomodulatory effects of these drugs are intricate and subject to constant discoveries. The macrolactams selectively suppress T cell response through the inhibition of calcium-dependent signal transduction mechanisms. It is known that the T cell proliferation/stimulation process involves the orchestration of complex interacting mechanisms, most of which are not completely understood. The pharmacodynamic can be summarized as suppression of gene transcription of proinflammatory cytokines and a complex inhibition of the cell cycle of activated cells. These effects are reflected in the primary inhibition of T cell responses. A simplified explanation of the mechanism of action of these drugs is presented in the following sections and is illustrated in Fig. 262-3.

FIGURE 262-3 This diagram outlines the key mechanisms by which calcineurin inhibitors (cyclosporine, tacrolimus, pimecrolimus) and sirolimus inhibit T cell activation triggered by presentation of antigen via the T cell receptor. The first step in antigen presentation involves presentation of a peptide that is bound within the peptide binding groove of the major histocompatibility complex (MHC) class II molecule. This complex is then presented to the T cell receptor (TCR). This causes transmembrane signaling that increases intracellular calcium concentrations. The liberated calcium, bound to calmodulin, interacts with calcineurin, a calcium-dependent serine/threonine phosphatase that dephosphorylates nuclear factor of activated T cells (shown here as NFATc) and this causes NFAT to translocate to the nucleus. There it binds to other nuclear components of NFAT (shown here as NFATn). This complex regulates the transcription of many cytokine genes, shown in the diagram. Cyclosporine, tacrolimus, and pimecrolimus diffuse freely into the cytoplasm of T cells, and bind with their respective immunophilins. This drug/immunophilin complex binds to calcineurin and blocks its ability to dephosphorylate NFAT, and thereby inhibits the production of cytokines that would normally be induced after T cell activation via the TCR. Sirolimus has a more complex intracellular mechanism of action. Although sirolimus binds macrophilin-12, the immunophilin of tacrolimus and pimecrolimus, its mechanism of action does not appear to be

mediated by calcineurin inhibition.

CYCLOSPORINE A

Cyclosporine A (CsA) is a hydrophobic lipophilic undecapeptide extracted from fungi.

Mechanism of Action

CsA and the other calcineurin inhibitors inhibit T cell stimulation initiated by several pathways, of which the T cell receptor (TCR) CD3 is the best understood. Mechanisms involving B-7 and CD28/CTLA-4, and other costimulatory pathways seem not to be affected by CsA or other calcineurin inhibitors. The high-affinity receptor for CsA is a 17-kDa immunophilin called cyclophilin A (CyPA). The other calcineurin inhibitors (tacrolimus and pimecrolimus) and sirolimus bind a structurally unrelated different immunophilin called macrophilin-12. The drug-immunophilin complex binds to calcineurin. Calcineurin is a serine/threonine protease composed of two subunits: calcineurin A (CnA) and calcineurin B (CnB). CnA constitutes the catalytic unit possessing binding sites for CnB and calmodulin. Calcineurin activity strictly correlates with interleukin (IL)-2 production via CD3 activation. Calcineurin is also involved in the induction of apoptosis and degranulation of cytotoxic T lymphocytes. It is well established that calcineurin activation is not only a rate-limiting step but also a crucial propagating factor in calcium-dependent T cell signaling pathways. Although sirolimus binds to macrophilin-12, this drug-immunophilin complex inhibits gene transcription through a complex mechanism that seems to be independent from the one involving calcineurin.

Subsequently, calcineurin regulates the transcription factor NFAT (nuclear factor of activated T cells), which is implicated in the regulation of the cytokine-encoding genes, including the gene regulating IL-2 production. NFAT is a heterodimer complex composed of two molecules: NFATn and NFATc. One of the substrates of calcineurin is the cytoplasmic component of this complex, NFATc. Once NFATc is dephosphorylated by calcineurin, the protein translocates into the nucleus where it binds NFATn, a nuclear AP-1 family member whose synthesis is induced by protein kinase C-dependent signals. Experimental data show that the CsA, tacrolimus, and pimecrolimus/calcineurin complex inhibits the nuclear translocation of the NFATc by blocking its dephosphorylation. This is thought to be the key step by which these drugs uncouple T cell receptor activation from IL-2 transcription. Tacrolimus is 10- to 100-fold more potent than CsA in vitro in the inhibition of calcineurin activity. [5]

Other less-understood mechanisms of action have been postulated for the immunosuppressive and immunomodulatory effects of calcineurin inhibitors, especially in psoriasis. [6] In summary, CsA inhibits the T cell activation mediated by antigen, but it does not inhibit the early phases of lymphocyte signal transduction occurring after antigen-mediated activation. New cellular mechanisms of action of CsA are being explored.

Pharmacokinetics

The microemulsion-based formulation of CsA (Neoral) was developed to improve the bioavailability of the drug. [7] This formulation does no seem to be influenced greatly by food ingestion and is associated with faster, more extensive, and more predictable absorption even in the presence of malabsorption states. CsA can also be administered intravenously as a 50 mg/mL solution made up in an ethanol-polyoxythylated castor oil mixture. The accumulation of CsA in erythrocytes and leukocytes is the reason that whole-blood monitoring of CsA levels is much more accurate than measurement of plasma levels.

It has not been possible to formulate a preparation of CsA in any topical form that has significant penetration of the epidermal barrier. CsA solution does have some penetration of mucosal surfaces, but this is not true of cornified epithelium. Intralesional injections of CsA do provide some local effects in psoriasis, but they are not widely used. The bioavailability of ingested drug ranges from 25 to 35 percent. Peak levels occur from 1.3 to 4 h after oral administration. After gaining access to the circulation, CsA distributes widely and has a large apparent volume of distribution (13 L/kg). CsA is metabolized into greater than 30 cyclic metabolites by the liver cytochrome P450 3A enzyme. It is believed that metabolites retain some biologic and toxic activities.

Because the primary metabolism of the drug is by the hepatic P450 3A enzyme, drugs that compete for binding to P450 3A will increase CsA levels, and drugs that induce P450 will accelerate metabolism and decrease blood levels (Table 262-1). [8] Certain foods rich in bioflavonoids, especially grapefruit, seem to increase the drug's bioavailability through an interaction with cytochromes. [9] Its elimination half-life is 6 to 12 h in the absence of severe hepatic disease, and biliary excretion accounts for more than 90 percent of its elimination.

TABLE 262-1 **Medications that Commonly Alter the Metabolism of Cyclosporine through the Cytochrome P-450 3A Pathway***

Dosages and Monitoring

Unlike organ transplantation, in dermatology, recommended doses rarely exceed 8 mg/kg per day, with no initial loading doses. Dosage increases should not exceed 0.5 to 1 mg/kg per day at 2- to 4-week intervals. Patients who are unable to tolerate the oral formulation, can receive the diluted intravenous formulation, infused slowly over a period of 2 to 6 h at about one-third of the usual oral dose, or about 2 to 3 mg/kg per day.

The National Academy of Clinical Biochemistry/American Association for Clinical Chemistry Task Force on Cyclosporine Monitoring recommends that whole blood be used for CsA assays, that EDTA is the recommended anticoagulant, and that the assay should be specific for the parent drug. Trough levels should be used, with samples obtained before the next dose. The two most common assays for trough levels are high-performance liquid chromatography (HPLC) and radioimmunoassay (RIA), and the recommended range is 200 to 400 ng/mL. It is important to monitor trough CsA blood concentrations, but one must remember that they do not necessarily correlate well with either toxicity or efficacy in individual patients. Children have comparable bioavailability of orally ingested CsA, but have a higher renal drug clearance rate (11.8 mL/min per kg versus 5.7 mL/min per kg in adults), and a correspondingly shorter blood level half-life (7.3 h versus 10.7 h in adults). Children may therefore require somewhat higher dosages and more frequent administration to achieve comparable trough levels to adults. [10]

From a practical standpoint, adequate monitoring of CsA dosage can be achieved by the avoidance of CsA doses higher than 5 mg/kg per day, evaluation of clinical response, and vigilance for signs of toxicity. This requires a detailed physical examination, including blood pressure monitoring with threshold concern triggered by a persistent diastolic blood pressure above 95 to 100 mmHg, a complete history with emphasis on concomitant drug ingestion and medical conditions that may potentiate CsA toxicity, and laboratory evaluations for complete blood count, creatinine and blood urea nitrogen, uric acid, liver enzymes, serum electrolytes and magnesium (because cyclosporin can induce hypomagnesemia), and a urinalysis. In patients receiving long-term CsA therapy (>6 months), the serum creatinine is a poor predictor of altered renal function and potentially irreversible chronic cyclosporine nephrotoxicity may ensue. In such circumstances more reliable studies for the evaluation of renal function may be indicated. [11], [12] and [13]

Side Effects

RENAL Three types of nephrotoxicity have been described with the use of CsA. The first occurs immediately after renal transplantation and occurs in the context of kidneys already damaged by ischemia. Obviously, this type of renal toxicity is not relevant to dermatologic patients. [14] The second type of nephrotoxicity appears during the first 2 to 3 weeks after transplantation and it is usually associated with high CsA blood levels. In this toxicity, there is an insidious decrease in glomerular filtration rate (GFR), along with hypertension, and tubular dysfunction (renal tubular acidosis, hyperkalemia, hyperuricemia, and decreased fractional excretion of sodium) in association with a recovery of renal function upon lowering the CsA dosage. The lack of specific histologic findings for CSA-induced nephrotoxicity poses a challenge in the differentiation from acute organ rejection. This type of nephrotoxicity can also be seen in patients with skin diseases within a few weeks of initiation of therapy. Reduction of CsA dosages or cessation of CsA is generally associated with recovery of renal function. Finally, there is chronic renal toxicity, which is likely a result of cumulative subclinical toxicity. This form of toxicity may occur in the absence of any detectable elevation of creatinine or blood pressure. Histologic changes include interstitial fibrosis, tubular atrophy, and some degree of vasculopathy. Although renal function can improve somewhat after discontinuation of the drug, this type of toxicity is generally irreversible. In the treatment of dermatologic diseases, this is the form of toxicity that is most likely to occur. In psoriatic patients receiving 5 mg/kg per day CsA, elevation of serum creatinine may persist for more than 4 months after discontinuation of the drug. Overall, one in four patients taking CsA develops clinical and laboratory evidence of altered renal function. A crucial mechanism of CsA nephrotoxicity appears to be the failure of downregulation of renal vasoconstriction, caused by both an increase in endothelin (ET)-1–mediated vasoconstriction and a decrease of prostaglandin-mediated vasodilatation. [15] ET-1 decreases the GFR, increases vascular resistance, and possesses mitogenic properties. The inhibition of ET-1 by diltiazem appears to provide renal protection in CSA-treated patients. [16] Nephrotoxicity can be potentiated by nephrotoxic drugs (Table 262-1). Hypertension is another very common adverse effect of CsA and occurs in approximately 30 percent of psoriatic patients. Calcium channel antagonists also exert a beneficial effect on CsA-induced hypertension, presumably through the inhibition of ET-1. On the other hand, angiotensin-converting enzyme inhibitors are not as effective in the therapy of CsA-induced hypertension. Diuretics should be used with caution because of their potential nephrotoxic effects. Another uncommon adverse renal complication is the development of hemolytic-uremic syndrome (HUS), especially in allogenic bone marrow transplant patients receiving CsA for acute graft-versus-host disease (GVHD). [17] Hypomagnesemia and hyperkalemia also reportedly occur.

GASTROINTESTINAL Nausea, vomiting, anorexia, and diarrhea commonly occur with the use of CsA. Hyperbilirubinemia and transient mild elevation of liver enzymes are also reported in CsA-treated patients. Elevations of liver enzymes greater than 100 percent over baseline should be managed by reduction of the CsA dose by 25 percent weekly, until enzyme levels normalize. [18] Avoidance of drugs with potential hepatotoxicity should be emphasized.
NEUROLOGIC Headache is a common complaint, especially in patients with a history of migraines. It tends to resolve spontaneously as therapy continues. CSA-induced seizures appear to be associated with hypomagnesemia and concomitant use of high doses of systemic corticosteroids, Thus, serum magnesium levels should be always monitored and kept above the lower normal range in CsA-treated patients. Cortical blindness, lethargy, confusion, seizures, hemiplegia, tremors, and paresthesias have also been described in patients receiving CsA. [19]
HEMATOLOGIC There is evidence of impaired fibrinolysis and endothelial damage associated with CsA. Hypercoagulability seems to contribute to the progression of atherosclerosis and glomerular damage in CsA-treated patients. Significant cytopenias have rarely been reported with the use of CsA.
METABOLIC Hypercholesterolemia, elevation of low-density lipoproteins (LDL), and hypertriglyceridemia may be seen with CsA, although the precise mechanism of this adverse effect remains unknown. Preventive measures such as weight reduction, avoidance of alcohol, and increased physical activity should be instituted. Caution should be taken with the use of drugs to treat hyperlipidemias because bile acid-binding resins may interfere with CsA absorption and the use of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors such as lovastatin or simvastatin may cause rhabdomyolysis.
NEOPLASTIC There is an increased incidence of neoplasms in transplant patients, but this risk does not seem to be greater in patients treated with CsA when compared to those patients treated with other immunosuppressive drugs. The relative risk for lymphoma in patients treated with CsA is 27.5, versus a relative risk of 33.8 to 58.6 in patients treated with immunosuppressive regimens that do not include the use of CsA. There also are reports of an increased incidence of non-Hodgkin's B cell lymphomas in patients receiving CsA in conjunction with other immunosuppressants. For example, the incidence of lymphoma in transplant patients receiving CsA alone or in combination with corticosteroids is less than 1 percent, whereas the incidence in transplant patients receiving CsA in conjunction with other immunosuppressive drugs is as high as 8 percent. In contrast to the high mortality rate attributed to lymphomas arising in immunosuppressed patients, lymphomas developing in CsA-treated patients seem to carry a better prognosis and the latency period seems to be shorter. [20] In a recent study in a large number of rheumatoid arthritis patients treated with CsA there was no increase in malignancies in comparison with a matched control group of patients with rheumatoid arthritis who were not treated with CsA. [21] The incidence of lymphoma in CsA-treated dermatologic patients is less than 0.2 percent. Most of these are B cell non-Hodgkin's lymphoma, but T cell non-Hodgkin's and Hodgkin's lymphomas have also been reported. An increased incidence of skin cancer is a known complication of immunosuppression, and CsA-treated transplant recipients have a relative risk for all skin cancers of 6.8 versus 2.2 to 5.5 in patients receiving other immunosuppressive therapies. CsA-treated dermatologic patients also have a higher risk of skin cancers, including squamous cell carcinomas (SCCs), basal cell carcinomas, Bowen's disease, and Kaposi sarcoma, and perhaps melanoma. There is a high incidence of squamous cell carcinoma in psoriatic patients treated with CsA, but this could be biased by previous exposures to PUVA or UVB. Kaposi sarcoma with visceral involvement that develops during CsA treatment often fails to respond to therapy, but approximately 25 percent of nonvisceral Kaposi sarcomas can be expected to undergo complete or partial remission following cessation or reduction of immunosuppressive therapy. An increased incidence of carcinoma of the penis, vulva, and anus has also been reported, and some of these carcinomas arise from preexisting viral warts. Cessation or reduction of the immunosuppressive regimen, as well as of retinoid therapy, could be considered as therapeutic strategies for prevention and control of viral induced SCC and dysplastic lesions. Because of the potential carcinogenic potential of viral warts, total eradication of these lesions has been proposed as a way to prevent the future development of SCC, but the validity of this approach is very controversial. Epstein-Barr virus (EBV)–associated posttransplant lymphoproliferative disorder (PTLD) is quite rare in dermatologic patients. PTLD frequently fails to respond to chemotherapy but it may regress spontaneously after reduction and/or cessation of immunosuppression. For PTLD that fails to regress after discontinuation of CsA, therapies include intravenous immunoglobulin, alpha interferon and high doses of IV acyclovir. Other tumors, are also reported in CsA-treated patients, although their true incidence is unknown.
MUCOCUTANEOUS Hypertrichosis is a well-known complication, and probably occurs in 100 percent of patients on long-term CsA therapy. It seems to be more common in dark-skinned patients, is not confined to androgen-dependent hair-bearing areas, and is independent of sex hormone levels. Hypertrichosis tends to worsen with further treatment and shows no tendency to spontaneous remission. Gingival hypertrophy is reported in 8 to 70 percent of patients on CsA therapy. It tends to develop first on the anterior gingival mucosae and the peak incidence occurs within 6 months of the initiation of CsA therapy. This complication is more common in children and is found in individuals with poor oral hygiene. Gingival sensitivity is a common complaint. The underlying histologic finding is fibrous hyperplasia, similar to that seen in patients on phenytoin and calcium channel blockers. This is an important issue because calcium channel drugs are important in the management of CsA-induced hypertension, and the risk for development of this side effect may be much higher with the use of this drug combination. [22] An acneiform eruption, indistinguishable from that seen in steroid-induced acne, is frequently reported. A disseminated comedonal or cystic acneiform eruption can also occur. These side effects can appear at any time during CsA therapy, although they are more commonly described at the time of initiation of CsA therapy. Keratosis pilaris is reported in 21 percent, sebaceous hyperplasia in 15 percent, and epidermal inclusion cysts in 28 percent of CsA-treated patients. Some of the epidermal cysts are small and located on the face, and typically decrease in size and number as time progresses. Flushing, angioedema, urticaria, and anaphylaxis have also been reported with the use of CsA. An increased incidence of keratoacanthomas, sebaceous hyperplasia, and viral warts have been reported.
MUSCULOSKELETAL Osteoporosis occurs in organ transplant patients receiving CsA and seems to result from the drug's action on osteoblasts, and osteoclasts, and by altering lymphokine release. [23] CsA can induce hyperuricemia in up to 15 percent of patients, apparently secondary to decreased urate clearance. [24] Gout appears to be more common in men, in patients with preexisting renal impairment, and in those concomitantly using diuretics. Myopathy has been reported in transplant patients receiving high doses of CsA.
REPRODUCTIVE CsA does not seem to be mutagenic or teratogenic, although there is a high incidence of preterm newborns, fetal growth retardation, abortions, preeclampsia, and hypertension in mothers taking CsA, and these occurrences are magnified in transplant patients. There are no reports of neonatal complications in children born to fathers receiving CsA. Adequate contraceptive measures are recommended in women of childbearing potential. CsA crosses the placenta and is excreted in breast milk. Because preexistent conditions such as hypertension, diabetes, and

renal dysfunction are risk factors in pregnant transplant patients who take CsA, close monitoring during pregnancy, labor, and postpartum is mandatory. [25]
IMMUNOLOGIC There is controversy as to whether there is an increased incidence of life-threatening infections in nontransplant patients receiving low-dose CsA as a sole immunosuppressive therapy. CsA-treated transplant patients seem to have a relative risk for infectious complications that is lower than that seen in patients receiving azathioprine and prednisolone. However, increased vigilance for infectious complications is recommended in CsA-treated patients.

Dermatologic Uses

Vast experience has been gained in the use of CsA in organ transplantation and autoimmune disorders. The usual dosage for these indications ranges from 5 to 8 mg/kg of the microemulsion-based formulation. The medical literature is replete with anecdotal reports of the therapeutic uses of CsA in dermatologic diseases. The most responsive dermatoses are psoriasis, atopic dermatitis, pyoderma gangrenosum, cutaneous and oral lichen planus, GVHD, epidermolysis bullosa acquisita, Behçet's disease, and paraneoplastic pemphigus. Lesser efficacy is reported in dermatomyositis, alopecia areata, recurrent aphthous stomatitis, and others. [26]

CsA is indicated as part of a rotational therapeutic regimen for refractory cases of psoriasis. Although, CsA has been successfully used in all forms of psoriasis with a wide range of success, the vast experience with this drug comes from its use in plaque-type psoriasis. [27], [28] and [29] The FDA has approved CsA for psoriasis in doses up to 4 mg/kg per day. The recommended starting dose is 2.5 mg/kg per day. Dosage increases should be performed after 4 weeks of therapy, and dose reductions are permitted at any time. Doses higher than 5 mg/kg per day are not advisable. In patients going into remission, defined as PASI (psoriasis area and severity index) reduction greater than 75 percent, the CsA dose should be down titrated at 4-week intervals, usually starting at week 16.

Serum creatinine levels should be carefully monitored during CsA therapy. If creatinine levels increase more than 30 percent above baseline, the dosage should be reduced for 1 to 2 weeks. If, after that time, the creatinine levels decrease below the 30 percent elevation mark, continuation at the lower dose is advisable. In cases where the creatinine remains elevated by more than 30 percent, discontinuation of CsA is recommended until the creatinine returns to levels within 10 percent of pretreatment levels. More accurate studies monitoring the GFR clearance are used in individualized cases. Long-term CsA therapy produces significant clinical improvement, although exacerbation was noted in about 50 percent of patients after CsA was withdrawn. Guidelines for the use of CsA in psoriasis have been published. [30], [31]

There is a vast European experience in the use of CsA in atopic dermatitis (AD). Its safety and efficacy in children have been studied and it seems to be a safe alternative short-term therapy for severe atopic dermatitis in children and adults with doses of 3 to 5 mg/kg per day. [32], [33] Relapses within weeks after discontinuation of CsA are common.

Refractory cutaneous lichen planus has been reported to respond to 4 weeks of CsA therapy at a dose of 6 mg/kg per day. Oral lichen planus is the only disease in which the use of topical CsA has been demonstrated to be effective and safe. [34]

Pyoderma gangrenosum usually responds to initial doses of 5 mg/kg per day, with maintenance therapy at 3 mg/kg per day. Significant improvement is expected within 3 months of initiation of therapy. [35] CsA is very effective in the prevention and treatment of graft-versus-host disease. [36] CsA seems to be an effective immunosuppressive drug for the treatment of some cases of paraneoplastic pemphigus, at a dose of 5 to 7 mg/kg per day. It is generally more effective when used in combination with prednisone or other immunosuppressive agents such as mycophenolate mofetil, thalidomide, or azathioprine. [37] CsA doses in the range of 5 to 10 mg/kg per day are superior to conventional therapy in controlling ocular, and also perhaps extraocular, symptoms in Behçet's syndrome. [38]

TACROLIMUS

This immunosuppressant, formerly known as FK506, is a macrolide antibiotic, which was first isolated from the soil microorganism *Streptomyces tsukubaensis*. This drug is also known to inhibit calcium-dependent events mediated by calcineurin. [39] Tacrolimus can be administered intravenously or orally. A topical formulation has also been developed [40] and is discussed in Chap. 250. The usual adult IV dosage is 25 to 50 µg/kg and 50 to 100 µg/kg for pediatric patients. Oral dosages range between 150 and -200 µg/kg for adults and between 200 and 300 µg/kg for children. The topical formulations have a concentration of 0.3% and 0.1% in an ointment vehicle.

The pharmacokinetics of systemic tacrolimus are characterized by a two-compartment model with a rapid initial drop and a long terminal elimination half-life of 12 to 21 h. Tacrolimus is metabolized in the liver with less than 1 percent of the drug excreted intact.

Tacrolimus has not proven to be more effective than CsA as a first-line agent in renal transplantation, but it appears to have a little better bioavailability. Mucocutaneous and metabolic side effects seem to be less frequent with the use of tacrolimus. However, major neurotoxicities and glucose intolerance are somewhat higher than with CsA use. [41] Nephrotoxicity seems to be comparable to that seen with the use of CsA. The histopathology of the renal toxicity is similar to that seen with CsA nephrotoxicity. The dosage of tacrolimus should be reduced in the presence of hepatic dysfunction. The risk for PTLD seems to be particularly high in children with hepatic transplants who received both tacrolimus and anti-OKT3. [42]

There is a good correlation between enzyme-linked immunosorbent assay (ELISA) and HPLC-MS (mass spectrometry) measurements in monitoring of blood concentrations of tacrolimus. However, ELISA assays may also detect metabolites of the drug, which could make this method less accurate in conditions with altered metabolism of tacrolimus, such as hepatic disease. Levels greater than 20 ng/mL in whole blood are associated with toxicity, so that 5 to 15 ng/mL blood

levels are now widely recommended.

Dermatologic Uses

The European Tacrolimus Multicenter Psoriasis Study Group has shown systemic tacrolimus to be effective for recalcitrant plaque-type psoriasis. This was a double-blind, placebo-controlled study in which the efficacy and side effects of tacrolimus in 27 patients were evaluated. An initial dose of 0.05 mg/kg per day for 6 to 9 weeks produced significant improvement in PASI scores, with relatively few side effects—predominantly diarrhea, paresthesia, and insomnia. [43]

Tacrolimus is very effective in the prevention of acute GVHD. (However, a less graft-versus-leukemia effect in comparison to the one seen with CsA was observed in these patients. [44]) There are isolated reports of the effective and safe use of systemic tacrolimus in atopic dermatitis and pyoderma gangrenosum. [45], [46]

In general, systemic tacrolimus can be used in any inflammatory and autoimmune skin disease in which systemic CsA has proven effective.

Topical tacrolimus has shown its consistent effectiveness in the treatment of certain inflammatory skin disorders, namely atopic dermatitis (see Chap. 250). These effects appear to be related to the inhibitory effects on interleukins (IL-2, 4, 5, and 11 a and ß), chemokines, tumor necrosis factor (TNF)-a, granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage inflammatory protein (MIP)-2, and interferon (IFN)-?, as well as modulatory effects of tacrolimus on Langerhans cell IgE receptors and mast cell degranulation. [47], [48]

SIROLIMUS

Sirolimus, also known as rapamycin, is a macrolide that was first isolated from the microorganism *Streptomyces hygroscopicus*. After binding macrophillin-12, the immunophilin–sirolimus complex targets kinases (C-rel, RAFT, and others) that are required for T cell proliferation in the presence of IL-2. Sirolimus also inhibits IL-2–mediated signal transduction pathways, and the calcium-independent mechanisms responsible for the activation of T cells, acting in the late phases in the cell cycle, specifically between the late phase of G1 and S.

This mechanism differs from the mechanism of calcineurin inhibitors as the latter block the cell cycle at earlier phases G0/G1. Other mechanisms of action of sirolimus, including the inhibition of IL-4–driven lymphocyte proliferation, have been described.

Sirolimus has some unique properties that differentiate it from CsA and tacrolimus. In addition to its immunosuppressive effects, it inhibits smooth muscle cell proliferation and migration. This property may be helpful in preventing the intimal hyperplasia that is characteristic of CsA and tacrolimus-induced renal vascular toxicity. [49] The drug is sequestered by erythrocytes. It is metabolized by the same P450 3A enzyme that is involved in the metabolism of CsA and tacrolimus. Its half-life is long, with a 24-h trough concentration, and there is a good correlation between trough levels and administered doses. Further protocols are being explored to delineate its pharmacology and therapeutic uses. [50]

Dermatologic Uses

In vitro sirolimus is very effective in inhibiting the role of Langerhans cells by inhibiting transforming growth factor ß. [51] Sirolimus is effective in preventing GVHD. [52] This drug has a potential use in inflammatory conditions such as atopic dermatitis and psoriasis; however, patients with extensive inflammatory skin disorders treated with sirolimus should be monitored closely for capillary leak syndrome caused by induction of massive apoptosis. [53], [54]

Sirolimus inhibits, in vitro, the proliferation and activation of cells in cutaneous large anaplastic lymphoma and Sézary syndrome. Sirolimus seems to exert this action through the inhibition of the basal activation of the Jak/STAT pathway involved in IL-2R signal transduction in these lymphoma cells. [55]

PIMECROLIMUS

This macrolactam, also known as ASM 981, is a derivative of the parent compound ascomycin. Ascomycin was originally isolated from the fermentation products of *Streptomyces hygroscopicus* var. *ascomyceticus*. [56] Pimecrolimus is a cell-selective inhibitor of inflammatory cytokines, specifically developed for the treatment of inflammatory dermatoses.

Pimecrolimus has a similar mechanism of action as that of other calcineurin inhibitors. [57] Pimecrolimus forms a complex with macrophilin-12 that inhibits calcineurin (Fig. 262-3). Calcineurin inhibition leads to inhibition of synthesis of proinflammatory T_H1 and T_H2 cytokines. [58] Other immunomodulatory effects, including stabilization of mast cells and inhibition of TNF-a and other late-phase cytokines, have also been observed with the use of pimecrolimus. [59]

Pimecrolimus is formulated in vehicle cream at concentrations of 0.2%, 0.6%, and 1%. Early studies showed that pimecrolimus is safe and effective in children with atopic dermatitis. Pimecrolimus also appears to have similar effectiveness to that of tacrolimus in treating psoriasis. [60] It has been reported that pimecrolimus does not induce skin atrophy and the systemic absorption rate appears to be clinically insignificant. [61]

Although, preliminary studies have not shown that pimecrolimus is superior to topical tacrolimus, this ascomycin derivative probably has a role in the topical therapeutic armamentarium of T cell–mediated skin disorders (see Chap.

250). [62]

OTHER IMMUNOSUPPRESSIVE DRUGS

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) is an ethyl ester of mycophenolic acid that is metabolized to the active drug mycophenolic acid (MPA). MPA is a product of several *Penicillium* species. The active metabolite, MPA, had been used in the past for the treatment of severe recalcitrant psoriasis. [63] MMF is the reformulated product of MPA, but with enhanced bioavailability. MPA inhibits the type II isoform of inosine monophosphate dehydrogenase (IMPDH) in the de novo pathway of purine synthesis. Lymphocytes are quite susceptible to this drug effect, because they minimally use the hypoxanthine–guanine phosphoribosyl transferase salvage pathway for purine synthesis. MMF inhibits lymphocyte proliferation, antibody formation, leukocyte recruitment, and glycosylation of lymphocyte glycoproteins involved in adhesion to endothelial cells. The drug is rapidly absorbed after oral administration and antacids and cholestyramine may decrease its absorption. Approximately 5 percent of the drug is bound to albumin. It is nearly completely metabolized by glucuronyl transferase and more than 90 percent of the drug is eliminated by the kidneys. The MMF glucuronide metabolite, which is increased in renal failure, increases MMF clearance by competing for its binding sites on albumin. MMF pharmacokinetics seem not to be affected by the concomitant administration of CsA.

The usual dose is 30 mg/kg per day (1 g every 12 h). Expected toxicities include nausea, upset stomach, vomiting, and diarrhea. There is no increase in nephrotoxicity, hepatotoxicity, hypertension, or neurotoxicity when MMF is used in conjunction with CsA and corticosteroids. The hematologic and gastrointestinal side effects are dose dependent and usually clinically insignificant. An increased incidence of lymphoproliferative diseases and lymphoma is reported with its use, as is some predisposition for infectious complications. Therapeutic drug monitoring measured by IMPDH activity, or by measurement of serum levels of mycophenolic acid, shows inconsistent predictive value to monitor effectiveness and toxicity in MMF-treated patients.

MMF is commonly used in synergistic and safe combination with CsA and glucocorticoids to prevent renal graft rejection. The therapeutic and toxic profiles of MMF make this drug a very attractive substitute for azathioprine in several circumstances. For example, it could be useful in those patients who cannot tolerate azathioprine because of nausea or hepatotoxic reactions, or in those patients who are at risk for azathioprine-induced toxicities as a result of deficiency of the enzyme thiopurine methyl transferase.

MMF is effective and safe in several autoimmune and inflammatory skin disorders including pemphigus, pemphigoid, lupus erythematosus, dermatomyositis, pyoderma gangrenosum, lichen planus, graft-versus-host disease, chronic actinic dermatitis, and cutaneous vasculitis. [64], [65], [66], [67], [68], [69] and [70]

In autoantibody-mediated skin disorders, such as pemphigus vulgaris and foliaceus (antidesmogleins antibodies) and hypocomplementemic urticarial vasculitis syndrome (anti-C1q antibodies), higher doses of MMF (35 to 50 mg/kg per day) are often required to achieve a full corticosteroid-sparing agent effect. [71] and [72] On the other hand, in inflammatory and autoimmune disorders where T cells play a predominant pathogenic role, the standard dose of 30 mg/kg per day is usually effective as adjuvant therapy. The effectiveness, safety, and versatility of MMF in the treatment of a wide range of autoimmune and inflammatory skin disorders, have made this drug an important addition in the therapeutic armamentarium of dermatology within the last 5 years.

LEFLUNOMIDE

Leflunomide (LEF) is an isoxazole derivative that inhibits the proliferation of T and B cell lines, as well as polymorphonuclear cells. The immunosuppressive effects of LEF are mediated by the inhibition of pyrimidine biosynthesis, blocking production of uridine monophosphate by the de novo pathway. The anti-inflammatory effects of LEF are very complex, and tyrosine kinase and STAT 6 inhibition appear to be the most important mechanisms of action. Its efficacy in the prevention of heart, kidney, intestine, lung, and skin allograft rejection has been studied in animal models. Because LEF is activated by the liver, renal failure has fewer effects on its kinetics. Its elimination half-life is approximately 11 days, and the kidneys mainly excrete its metabolite. Toxicities may include the liver, gastrointestinal tract, and morbilliform skin eruptions. Long half-life and the potential teratogenic effect of this drug and its metabolites prompt a comprehensive plan of “washing out” for women as well as for men planning conception. This plan includes, reporting to the pharmaceutical company, cholestyramine oral administration, and measuring serum drug levels. A loading dose of LEF is commonly used for rheumatoid arthritis patients. However, this form of administration does not seem to be necessary for patients with skin diseases. The safety profile, along with its combined immunosuppressive (anti-B and -T cell) and anti-inflammatory effects (anticytokine), makes this drug an important glucocorticoid-sparing agent in the treatment of bullous pemphigoid. [73] The authors have successfully expanded the use of LEF to the management of lichen planus and urticarial vasculitis. LEF is a promising immunomodulator in the treatment of autoimmune and inflammatory skin disorders, especially in elderly patients.

Investigational Drugs

REFERENCES

Immunobiologicals are a diverse set of molecules that can be used to modify normal or pathologic cellular immune reactions. In general, immunobiologicals are rationally designed agonists or antagonists of previously defined pathways that regulate lymphocyte activation, cytokine production, or cytokine actions. Inflammatory skin diseases such as psoriasis or atopic dermatitis and neoplastic infiltrates in cutaneous T cell lymphoma (CTCL) are candidates for treatment with this group of engineered therapeutics. In addition, immunotherapeutics can be used to enhance immune responses to vaccines, virally infected cells, or tumor antigens. At present, most of the agents discussed in this chapter are investigational, but it is expected that some of the agents discussed will become future dermatologic therapeutics. Most immunobiologicals are protein-based molecules and can be categorized as antibodies, antibody-like fusion proteins, cytokines, or immunotoxins (see Table 263-1). These molecules react mainly with cell surface molecules expressed selectively on leukocytes or with molecules secreted by inflammatory cells. Nucleic acid-based molecules, for example, antisense oligonucleotides, can also be considered as immunobiologicals, but they target primarily intracellular biochemical pathways. Small (chemical-based) molecules are not considered in this chapter, although many agents affect biologic responses of immune cells in a specific fashion. The agents listed in Table 263-1 are limited to immunobiologicals that are approved drugs for dermatologic indications and to investigational agents for dermatologic indications. Numerous other immunobiologicals are being studied in organ transplants and in inflammatory diseases of other organs. Hence, it can be anticipated that many other agents will eventually be tested for dermatologic indications.

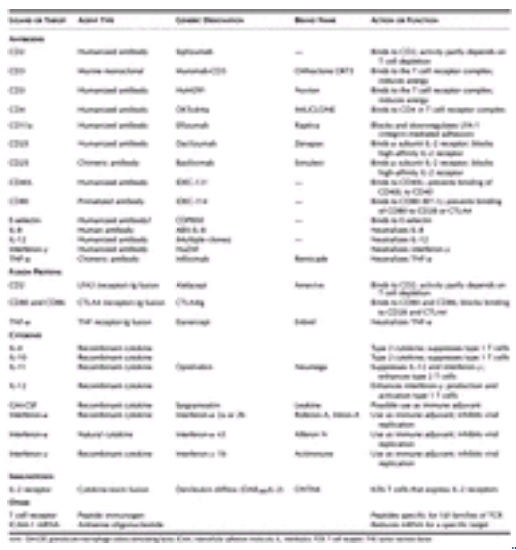

TABLE 263-1 **Immunobiologicals with Potential Use in Dermatology**

PHARMACOLOGY AND MECHANISM OF ACTION

Figure 263-1 shows the general structure of different types of immunobiologicals. Antibodies are currently the most common type of agent in clinical trials. Antibodies can be murine monoclonals, chimeric monoclonals, humanized monoclonals, primatized monoclonals, or human sequence monoclonals. Murine monoclonals are very immunogenic in humans and thus can be used only for short-term treatment. In contrast, humanized and human antibodies are much less immunogenic and better suited for chronic use in humans. [1] However, variation in constant region amino acid sequences between different individuals (allovariation) or glycosylation differences produced by cultured cell lines (all therapeutic antibodies are produced in tissue-culture cell lines) cause all therapeutic antibodies, even fully human sequence antibodies, to be potentially immunogenic in humans. Antibody-like fusion proteins are composed of the ligand-binding domains of human cellular receptors linked to hinge and CH2/CH3 constant region domains of human IgG. The resulting protein is thus composed of a ligand-binding region (like the variable region of an antibody) and a set of immunoglobulin sequences that confer solubility in the plasma and stability similar to antibodies. While protein sequences are fully human, these molecules also have immunogenic potential due to non-natural domain junctions, allovariation, and glycosylation in cell lines. Cytokines are relatively small proteins synthesized based upon human gene sequences. The immunotoxin DAB $_{389}$IL-2 is a fusion protein composed of human interleukin (IL)-2 sequences linked to domains of bacteria-derived diphtheria toxin sequences. This combination protein is highly immunogenic as a consequence of its associated bacterial sequences. Peptides that are homologous to short sequence segments (20 to 40 amino acids) of specific T cell receptor families, for example, Vß 3 or Vß 13, have been constructed as immune “regulatory” immunogens. Antisense oligonucleotides are constructed so that sequences are complementary to coding nucleotides in mRNA for

specific genes.

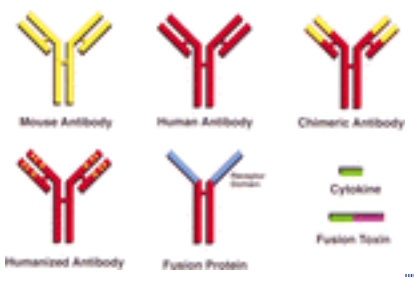

FIGURE 263-1 Structure diagrams of protein-based immunotherapeutics: antibodies, fusion proteins, cytokines, and fusion toxins. For antibodies, mouse sequences are shown in yellow, whereas human sequences are shown in red. The fusion protein contains human immunoglobulin sequences (red) fused to a human sequence receptor domain (blue). The fusion toxin shown combines a human sequence cytokine (green) with a bacterial sequence toxin domain (cyan).

The use of immunobiologicals is predicated on a prior understanding of the role of specific immune receptors, adhesion proteins, and cytokines or chemokines in regulating the immune response or in producing “inflammatory” tissue reactions. A comprehensive discussion of these molecular control points is beyond the scope of this chapter, but Fig. 263-2 presents a simplified view. In addition, a recent review provides a more detailed introduction to cutaneous immunology with a focus on therapeutic ligands or cellular targets that are listed in Table 263-1.[2] Immunobiologicals affect one or more of the six stages of a cutaneous immune response that are diagrammed in Fig. 263-2. These stages are (1) antigen uptake and maturation (activation) of Langerhans cells or other professional antigen-presenting dendritic cells (DCs); (2) activation of T cells through the T cell receptor (TCR) complex; (3) activation of T cells though accessory signals (costimulation); (4) mitotic and differentiation signals delivered by regulatory cytokines; (5) migration of differentiated T cells to skin tissue; and (6) effector actions of T cells in skin tissue, including release of inflammatory cytokines.

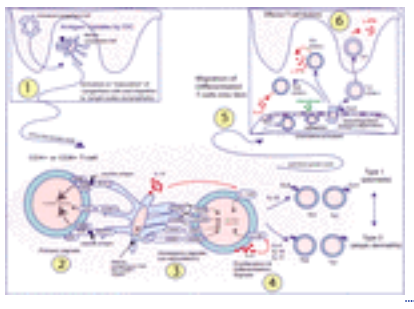

FIGURE 263-2 Cellular processes in the generation of a cutaneous T cell dependent immune response are diagrammed in 6 steps. These steps are (1) antigen capture and processing by Langerhans cells followed by migration of antigen-containing Langerhans cells to a skin-draining lymph node; (2) formation of immune synapes between a T cell and an activated Langerhans cell that initiates T cell activation; (3) enhancement of T cell activation by interactions of coreceptors on T cells and Langerhans cells; (4) proliferative activation of T cells by cytokine mitogens and differentiation of T cells into Type 1 versus Type 2 cells; (5) migration/homing of effector T cells to sites of cutaneous inflammation and transmigration of cells into the dermis; (6) effector immune responses, including release of cytokines, within the cutaneous environment. In general, T cell accumulations in the dermis are CD4-predominant, whereas those in the epidermis are CD8-predominant. The nature of the effector immune response is controlled by the type of antigen encountered and differentiation signals produced within the lymph node.

A cutaneous immune response is initiated by Langerhans cells or other DCs after antigen uptake and processing so that immunogenic peptides reside in major histocompatibility complex (MHC) molecules. Antigen-bearing Langerhans cells migrate to skin-draining lymph nodes upon activation, where naïve T cells are activated and become differentiated memory T cells that have a skin-homing receptor [the cutaneous lymphocyte antigen (CLA) antigen]. The activation of T cells requires physical contact between many different cell surface receptors on DCs and counterreceptors on the T cells, as diagrammed in Fig. 263-2. T cells differentiate into type 1 effectors (which synthesize interferon-?) or type 2 effectors (which make IL-4) in lymph nodes. Differentiated, CLA+ T cells then exit lymph nodes and return to the skin via the blood stream. In postcapillary venules, CLA+ T cells bind to E-selectin or P-selectin, expressing endothelial cells, slowing transit through the vessel. Activation of these “rolling” T cells by various chemokines then stimulates T cells to arrest and attach firmly to endothelial cells via integrins that are expressed on T cells, for example, integrins leukocyte factor antigen (LFA)-1 or very-late antigen (VLA)-1. After firm binding, T cells can migrate through endothelial cells and become extravascular in the dermis. Some T cells, for example, type 1 CD8+ T cells (Tc1 cells), show preferential migration into the epidermis, whereas other T cells remain mostly in the dermis. The relative accumulation of type 1 versus type 2 cells in skin lesions is determined by the nature of the activating antigen, the disease process, and the mixture of chemokines in skin (chemokines stimulate movement of T cell subtypes according to concentration gradients). Once effector T cells have entered the dermis or epidermis, they can recognize activating antigens and release various other “inflammatory” cytokines such as interferon-?, tumor necrosis factor (TNF)-a, or IL-4. In turn, these cytokines induce synthesis of numerous other cytokines and chemokines from skin-resident cells. For example, numerous chemokines induced by interferon-? or TNF-a are upregulated in psoriasis vulgaris skin lesions [this includes IL-8; MIG; gamma-inducible protein 10(IP-10); macrophage inflammatory protein (MIP)-3a; Gro-a; regulated on activation, normal T cell expressed and secreted (RANTES); and MIP-1a]. “Inflammation” results from the effects of these cytokines and chemokines on vascular structure/adhesion, leukocyte trafficking, and biologic activation of skin-resident cells.

Figure 263-3 diagrams the interaction of different immunobiologic agents with molecular or cellular targets in the immune activation sequence described in Fig. 263-2. In this scheme, molecules that inhibit ligand/receptor interactions or

receptor/coreceptor interactions are drawn in orange color. In contrast, agents that activate receptors on DCs and/or T cells are drawn in blue-colored boxes. From this scheme, it can be seen that all stages of an immune response can be affected—either in a stimulatory or inhibitory fashion—by engineered biologic therapeutics. Agents shown can stimulate recruitment of dendritic cells into skin or boost synthesis of antigen-processing and presenting molecules on DCs [granulocyte-macrophage colony-stimulating factor (GM-CSF), interferon-a] or stimulate the differentiation of type 1 (IL-12) or type 2 (IL-4, IL-10, IL-11) T cells. The use of therapeutic cytokines to influence T cell differentiation in a fashion opposite to that of the underlying disease is a strategy termed *immune deviation*. As inhibitors, engineered biologics can prevent T cell activation by modifying activation signals delivered through the TCR; by blocking adhesive or costimulatory interactions between DCs and T cells; by blocking mitogenic or differentiation signals delivered by cell surface receptors; by reducing T cell migration into skin lesions though adhesion-disrupting effects; and by neutralizing cytokines and chemokines that regulate inflammatory effects in tissues. [2], [3] and [4] Immune antagonists that bind to cellular targets can produce reversible blockade of cellular adhesion/activation (such that inhibited function depends on continued presence of the antagonist), T cell anergy (defined as reduced responsiveness of viable T cells to an antigen), or T cell depletion (by apoptotic or cytotoxic mechanisms). [4] To the extent that many antibody responses require T cell “help,” some of the therapeutics listed in Table 263-1, for example, CTLA4-Ig and anti-CD11a, may be able to diminish pathogenic immune responses in antibody-mediated autoimmune diseases. A humanized antibody to CD40L, a molecule expressed on activated CD4+ T and B cells, may have direct inhibitory effects on immunoglobulin production in autoimmune diseases, and it has recently entered clinical studies in systemic lupus erythematosus. [5]

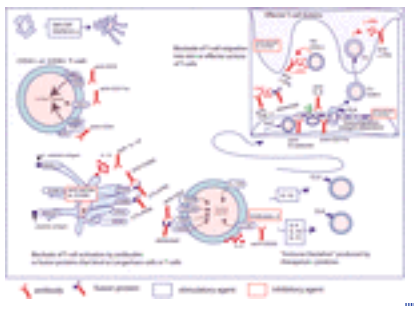

FIGURE 263-3 A diagram of stimulatory and inhibitory biologic agents in the cutaneous immune response according to the activation sequence shown in Fig. 263-2. In this figure, stimulatory agents are shown in blue boxes. Antibodies and fusion proteins can antagonize steps 2–6 of the immune response and their site of action is diagrammed on the figure. A further explanation of the agents shown in this figure can be found in Table 263-1.

Immunobiologicals are mainly proteins that are functionally stable only in neutral pH aqueous buffers. These agents are designed for parenteral administration by SQ., IM, or IV routes. Most agents are large protein molecules that circulate in plasma and have a relatively limited volume of distribution. These agents have variable half-lives that are influenced by the intrinsic nature of the protein, concentrations attained in vivo, and variable human antibody responses to that agent. The half-life of therapeutic antibodies in the circulation is similar to that of naturally occurring human antibodies (however, low concentrations of proteins may be cleared immediately by receptor-mediated uptake). Some agents, for example, the immunotoxin DAB $_{389}$IL-2, have very short circulating half-lives (approximately 1 h), because of receptor-mediated clearance and/or antibody responses to “foreign” or highly immunogenic regions of the fusion protein.

CLINICAL USES

Theoretically, immunobiologicals can be applied to any dermatologic condition where stimulation or inhibition of a cellular immune response might prove beneficial. Commonly considered indications are T cell–mediated inflammatory diseases (psoriasis, atopic dermatitis, alopecia areata), graft-versus-host disease, cutaneous T cell lymphomas, melanoma and other neoplasms (for immunotherapy), viral diseases (for inhibiting viral replication or stimulating immune responses), and some antibody-mediated autoimmune diseases (where T cell help is required for antibody production). To the extent that systemic immunosuppressive agents are used as therapeutics, the extent, chronicity, and severity of skin disease must be factored into the risk-to-benefit equation. The safety of long-term immune suppression with most of the agents listed in Table 263-1 still must be determined. Even so, these agents offer potential benefits over use of current immunosuppressives that have known toxicity for noncutaneous organs. Potential complications of long-term immune suppression (whether with conventional agents or novel immunobiologicals) include increased risk of infections (bacterial, viral, fungal, and mycobacterial), lymphomas, and other neoplasms.

At present, most of the immune antagonists listed in Table 263-1 should be considered as generally contraindicated in pregnancy and pediatric cases. Antibodies and antibody-like fusion proteins would be transferred transplacentally and might have unintended effects on the developing fetal immune system. Likewise, the cellular immune system is “educated” intensively in young children, and immunity to most infectious diseases is acquired during this period. Hence, suppressive immunobiologicals should be considered only after normal immunity is established (from vaccination or spontaneous disease) in childhood. In contrast, therapeutic cytokines, which mainly act as immune-enhancing agonists, might have some use in younger individuals. One agent, interferon-?, is used to enhance antimicrobial immunity in chronic granulomatous disease and much of its use is in pediatric patients.

DOSAGE, SCHEDULE, AND FORMULATIONS

Of the agents listed in Table 263-1, only denileukin diftitox (DAB $_{389}$ IL-2) and the interferons are presently approved for dermatologic indications. Denileukin diftitox, approved for the treatment of CTCL, is administered as an IV infusion on 5 sequential days at a dose of 9 or 18 µg/kg per day, with repeat administration every 21 days (number of administration cycles depends on the clinical response). Interferon-a preparations are variously approved for treatment of condyloma acuminata, Kaposi sarcoma, and melanoma. Treatments range from local injection of 250,000 to 1 million IU into skin lesions of condyloma to IV administration of up to 20 million IU 5 times a week in inductive treatment of melanoma.

Interferon-? is approved as a treatment for chronic granulomatous disease at a dose of 50 µg/m ^{2} administered SC on a three-times-per-week schedule (a dose of 1.5 µg/kg is recommended for patients with a body surface area <0.5 m ^{2}). No formal dose, schedule, or formulation information is available for experimental therapeutics listed in Table 263-1, as related to dermatologic conditions. Muromab-CD3, daclizumab, basiliximab, infliximab, etanercept, IL-11, and GM-CSF are FDA-approved drugs for nondermatologic indications and have recommended doses and schedules for those conditions. However, eventual use in dermatologic conditions may involve significantly different doses or schedules.

ADVERSE EFFECTS

Where available, prescribing guidelines should be consulted for a complete list of adverse effects seen with individual immunobiologicals. All protein-based drugs must be considered as potentially immunogenic and thus capable of producing classic immediate (IgE-mediated) or delayed (T cell–mediated) hypersensitivity reactions. In addition, several T cell–binding antibodies or fusion proteins have a “first-dose reaction,” that consists of flulike or constitutional symptoms, including fever, chills, nausea, and headache. With several antibodies, this effect is related to increased release of cytokines (TNF-a, interferon-?, and IL-6) within 4 to 6 h of administration, and is associated with immunoglobulin isotypes that bind Fc receptors. [1] The underlying mechanism of this effect is thought to be T cell–stimulated production of cytokine synthesis/release from natural killer (NK) cells (bridged with T cells by therapeutic antibodies via Fc receptors), but ligation of only some T cell surface proteins produces this effect. [1] Similar immune activation symptoms (fever, chills, nausea, headache, myalgias) are seen following interferon administration, but symptoms usually persist with repeat administrations. Immune activation or agonist side effects of this type are often dose dependent and may result in dose-limiting toxicity for different immunobiologic agents. Denileukin diftitox, which is ultimately an immune antagonist (through inducing apoptosis of T cells), initially activates T cells through the IL-2 receptor. This agent induces a range of acute “hypersensitivity-type” reactions, which are similar to first-dose effects of immune-activating antibodies and cytokines. In addition, a delayed “vascular leak” reaction (edema, hypoalbuminemia, hypotension) has occurred in a subset of lymphoma patients treated with denileukin diftitox. [6] These effects may be related to the mechanism-of-action of diphtheria toxin sequences (this toxin inhibits protein synthesis in cells that internalize the drug). Injection-site reactions and “rashes” are seen with many different immunobiologicals. Many of these reactions may be mechanistic, that is, related to agonist or immune activating effects of the agents, but true hypersensitivity (allergic) reactions are also possible. Anyone administering protein-based therapeutics should be prepared to treat anaphylactic reactions.

An unresolved concern with immune-modifying biologics is their potential for increasing the incidence of cancer and life-threatening infections if they are used chronically and/or used in combination regimens that produce intense immunosuppression. Several agents, including CD3-antibodies, CD2-antibodies, and alefacept, induce moderate to marked depletion of T cells from the peripheral circulation for variable time periods. The long-term safety of T cell–depleting and/or chronic immunosuppressive treatments need to be determined in unique subsets of dermatologic patients. For example, immunobiologicals may be used mainly as monotherapy in dermatologic diseases as compared to other indications, thus potentially increasing safety. However, compared to patients with internal diseases, more patients with skin disorders may have been treated previously with mutagenic therapies (UVB, PUVA, topical alkylating agents) and thus will be more at risk for cutaneous cancers with immune suppression.

DRUG INTERACTIONS

There are few formal studies of (chemical) drug interactions with immunobiologicals. It is known that interferons can suppress microsomal P450 levels and this could reduce metabolism of some drugs metabolized by P450 enzymes. There is potential for unexpected immune effects when two or more immunosuppressive agents are combined. As judged from experimental systems or other human indications, combinations of immunobiologicals with other immunosuppressives (whether chemical or biologic in nature) often produce increased immunosuppression, but it cannot be predicted whether immunosuppression will be additive or more than additive (synergistic). [3], [4] Sometimes, however, there is unanticipated interference of two agents (less immunosuppression is produced than with either agent alone). Hence, use of immunobiologicals in combination should be based on validated therapeutic protocols.

EVIDENCE-BASED MEDICINE CONSIDERATIONS

FDA-Approved Biologics for Dermatologic Indications

Immunobiologicals are highly successful treatments for some skin diseases. For example, the majority of condyloma and verrucae treated with various interferon-a preparations respond to treatment, whereas response to placebo treatment is quite low. [7] Likewise, interferon-? produces marked reductions in the rate of serious infections in patients with chronic granulomatous disease as compared to placebo treatment. [8] Hence, immunobiologicals can be highly effective drugs that show clinical activity in most patients. However, other diseases treated with immunobiologicals have more variable clinical benefits. This has led to the view that therapeutic activity of immunobiologicals is less predictable than traditional drugs. For instance, the use of interferon a2b in high-risk melanoma patients is based on results of a pivotal study in which 26 percent of placebo-treated versus 37 percent of interferon-treated patients were disease-free with a median follow-up time of 6.9 years. [9] The high doses of interferon used in this study produced dose-limiting toxicity in more than half of treated patients during the trial. Hence, while interferon-a2b is an FDA-approved drug for prophylactic treatment of high risk melanomas, a decision to use it in individual patients often weighs high toxicity versus uncertain benefit. FDA approval of denileukin diftitox for treatment of CTCL was based on a pivotal study in which 71 patients were treated with this agent after failing standard therapies—30 percent of patients had an objective response to treatment (20 percent partial response, 10 percent complete response). [6] While dose-limiting toxicity also occurred in many patients treated aggressively with denileukin diftitox, it remains a viable option for patients with CTCL resistant to other forms of treatment. Likewise, only a small subset of patients with Kaposi sarcoma have disease regression after interferon-a

treatment, [7] but this option is needed less often in an era of highly active antiretroviral therapies.

Investigational Drugs

Immunobiologicals hold promise for treatment of many chronic inflammatory skin diseases, but psoriasis vulgaris has become a particularly important test disease for new immune-regulating drugs. At present, more than half of the agents listed in Table 263-1 are being tested as investigational therapeutics in psoriasis. Psoriasis can be viewed as a T cell–mediated or autoimmune disease in which local infiltration of activated, type 1-biased T cells causes characteristic skin changes. Immunobiologicals geared to psoriasis are thus mainly immunosuppressive and/or target type 1 T cells. [2] The potential utility of immunobiologicals in psoriasis was initially suggested by case reports of clinical improvement brought about by murine monoclonal antibodies to CD3 and CD4. [10] A small study conducted with DAB $_{389}$IL-2 (denileukin diftitox) showed complete clinical and histologic disease reversal in a subset of psoriasis patients, [11] but this agent also commonly causes a poorly tolerated set of side effects. [12] CTLA4-Ig produced more consistent clinical improvements in patients with psoriasis vulgaris, [13] while also reversing pathologic activation of keratinocytes, T cells, dendritic cells, and endothelial cells. [14] However, quite large amounts of protein (25 or 50 mg/kg) were required for consistent clinical activity. Nonetheless, results obtained with DAB $_{389}$IL-2 and CTLA4-Ig were extremely important in showing the underlying immune basis of psoriasis and, to a large extent, these results spurred current investigational studies. Subsequently, improvements in psoriasis have been reported from administration of engineered antibodies to CD2, CD3, CD4, CD25, and CD80, or from therapeutic administration of the “deviating” cytokines IL-4, IL-10, and IL-11 (reviewed in Ref. [2]). Two new agents, a humanized antibody to CD11a [15] and the fusion protein alefacept, [16] have successfully completed placebo-controlled phase II or phase III studies. The latter agent, alefacept, is now approved for treatment of patients with cutaneous psoriasis. Recently, the TNF-a antagonists infliximab, [17] a chimeric antibody, and etanercept, [18] a receptor-domain fusion protein, have shown impressive results in treating cutaneous psoriasis vulgaris or psoriatic arthritis. As many other agents are currently in early phase trials for psoriasis vulgaris, this disease may become the first dermatologic disease for which a wide range of immunotherapeutics is available. In theory, many antipsoriatic biologics could be used in other diseases mediated by activated T lymphocytes, such as graft-versus-host disease, atopic dermatitis, and alopecia areata.

CTCL is viewed not only as a problem in unregulated growth of lymphocytes, but also as a depressed immune state caused by excess production of suppressive (type 2 cytokines). Hence immune-activating (regulatory) cytokines may become important therapeutic tools to treat CTCL and other forms of cancer where immune suppression is a component. IL-12, which activates type 1 T cells (and additionally stimulates cytotoxic T lymphocytes), has shown remarkable activity in some patients with CTCL. [19] Potentially, this immune-enhancing cytokine will find use in treatment of other cancers or “type 2”-deviated diseases such as atopic dermatitis. In addition, the cytokines IL-2, interferon-a, and interferon-? (all of which have immune enhancing effects) have shown activity in some cases of CTCL. [20], [21]

It is important to acknowledge that clinical experience with immunobiologicals is quite limited in comparison to experimental autoimmune diseases and tissue transplant studies. Fortunately, there are major similarities in molecular regulation of immune responses in humans and other species, and, for the most part, clinical trials of immunotherapeutics have helped to solidify similar mechanisms and concepts. Even so, human autoimmune diseases (particularly as related to skin disease) have a number of unique aspects that are not modeled well in experimental systems. Hence, immunobiologicals used in clinical trials become important scientific tools that can help us understand cellular and molecular pathways that ultimately underlie many inflammatory and immunologic skin diseases in people. We have much to learn about pathologic/therapeutic immune regulation in humans, and we must strive to couple investigative medicine and scientific study wherever possible in the emerging era of molecular medicine.

Beginning in 1957, thalidomide was marketed as an over-the-counter drug under various brand names in Europe, Canada, Australia, and several African and Asian countries; only samples for “clinical trials” were dispensed in the United States. A Japanese pharmaceutical company synthesized and marketed thalidomide independently at the same time in Japan. The drug quickly found wide use as a barbiturate-free sedative with potent antiemetic properties, and it was believed safe even for pregnant women. Thus, it was widely used for hyperemesis and insomnia during pregnancy, as well as for a host of other conditions.

Peripheral neuropathy was noted in 1959 as the first serious side effect of thalidomide. Because the neuropathy was not initially ascribed to the use of thalidomide, prescribing physicians were not adequately informed. As a result, an unknown number of patients developed polyneuropathy that was sometimes severe. Beginning in 1961, an increasing number of newborns with severe limb malformations were noted in West Germany; soon, thalidomide was identified as the cause, and the drug was taken off the market—in Europe in 1961 and in Japan in 1962. Nevertheless, more than 10,000 children fell victim to thalidomide embryopathy. Following this tragedy, more appropriate procedures to evaluate the safety, efficacy, adverse effects, and risk:benefit ratio of drugs were instituted worldwide. The “thalidomide tragedy” was a driving force behind the evolution of the ethical principles governing clinical studies today (Good Clinical Practice; Declaration of Helsinki).

The anti-inflammatory effects of thalidomide soon became clear, but no one investigated this activity at first. In 1964, Sheskin noted a rapid anti-inflammatory and analgesic effect of thalidomide in patients with erythema nodosum leprosum (type II leprosy reaction). [1] This beneficial effect occurs in more than 90 percent of patients, which vastly improves the therapeutic options for patients with multibacillary leprosy [2] (see Chap. 202). Initially, and erroneously, interpreted as immunosuppressive, this action of thalidomide has been under investigation since the mid-1960s and is now considered its most relevant activity. Thalidomide has turned out to be an important drug for some inflammatory skin conditions, and the Food and Drug Administration (FDA) approved it as a therapeutic agent for erythema nodosum leprosum in 1998. Thalidomide has been found to be beneficial as an adjuvant drug in the treatment of tuberculosis and in one of the *Mycobacterium avium* complex infections. [3], [4] and [5]

PHARMACOLOGY

Thalidomide (a:- *N*-phthalimidoglutarimide; 2-(2,6-dioxo-piperidine-3-yl)-isoindole-1,3-dione) is a racemic mixture of its (-)(S) and (+)(R) isomers. It is poorly soluble in water and in lipids, which accounts for its very low acute toxicity. Its rapid racemization ($T_{1/2}$ about 2.25 h) hampers studies on pure isoforms of thalidomide. Most of the reliable data on the activities of the isoforms of thalidomide have come from the use of configuration-stable methylated analogues. These studies indicate that the (-)(S) form is the active compound and that its beneficial and untoward effects cannot be separated. The search for more effective and less toxic thalidomide derivatives continues. [6]

In a study of healthy male volunteers, [7] an absorption half-life of 1.7 ± 1.05 h, an elimination half-life of 8.7 ± 4.11 h, and a peak plasma concentration of 1.15 ± 0.2 mg/L at 4.39 ± 1.27 h were seen after a single oral dose of 200 mg thalidomide. The plasma concentration-versus-time curve fits a one-compartment model with first-order kinetics. Excretion is primarily nonrenal, as shown by the fact that after a single oral dose, only 0.6 percent of the total could be recovered in the patients' urine. Elimination of the drug is thought to take place primarily through hydrolysis. Correspondingly, accumulation does not occur in patients with severely compromised organ function, (e.g., in patients

with renal insufficiency).

Accumulation of thalidomide has been weak, except for the kidneys and the hepatobiliary tract, where the increased accumulation is thought to be related to excretion. Thalidomide does not seem to have pharmacologic activities in itself; rather, it requires metabolism in the liver, which yields more than 100 different compounds. Some species (e.g., rats) seem to be unable to metabolize thalidomide effectively, and this may account for the fact that no untoward effects of the drug were detected in the initial toxicologic investigations.

EFFECTS OF THALIDOMIDE

Investigations of the effects of thalidomide in mammals in vitro and in vivo have yielded copious amounts of data, some of which are not easy to interpret. The following activities are rather well established.

Tumor Necrosis Factor

Thalidomide decreases the production of tumor necrosis factor (TNF)-a in stimulated human monocyte cultures, but has no effect on total protein synthesis or the expression of various other cytokines. A reduction in the half-life of TNF-a messenger RNA causes this decrease in synthesis; this is a selective and dose-dependent effect, but does not lead to a complete arrest of TNF-a production. Patients with lepromatous leprosy and manifestations of erythema nodosum leprosum have high levels of circulating TNF-a and other cytokines. The administration of thalidomide to these patients leads to an often dramatic amelioration of their symptoms and to a concomitant decrease of TNF-a levels. [8] In patients with active tuberculosis with or without HIV-infection, thalidomide treatment likewise results in a decrease of TNF-a and interleukin 1 (IL-1) levels, and an increase in interferon (IFN)-? levels. The weight loss often associated with active tuberculosis is probably due at least in part to the high levels of TNF-a in these patients. This may explain why the administration of thalidomide results in a reversal of this weight loss. [9]

Angiogenesis

Thalidomide can inhibit angiogenesis, [10] probably via an antiproliferative effect on vascular endothelia. This antiangiogenic effect is increasingly exploited by the use of thalidomide as an antineoplastic agent, [11] and analogues with enhanced antiangiogenic properties are being developed.

Adhesion Molecules

Thalidomide downregulaties adhesion molecules, at least in animal models. [12] The extent and importance of this is not yet entirely clear. Thalidomide has been shown to downregulate ß $_2$-integrin (CD18) and, to a lesser degree, ß $_1$-integrin (CD29) and a $_4$-integrin on circulating leukocytes of humans; the effect on intercellular adhesion molecule 1 (ICAM-1; CD54) expression was increased on granulocytes, but abolished on monocytes. A highly teratogenic analogue of thalidomide administered to pregnant mice resulted in a profound and consistent suppression of ß $_3$-integrin (CD61) in the fetus. In this study, ß $_1$- and a $_4$-integrin subunits were decreased in the limb buds, but not elsewhere. [12] If this also holds for humans, it may explain the teratogenic action and the type of embryotoxic lesions caused by thalidomide.

Cytokines

Thalidomide has been shown to be a potent suppressor of IL-12 production by human monocytes. [13] This suppression was dose-dependent, additive to that of dexamethasone, and independent of endogenous inhibitors of IL-12 production; IL-12 stimulates IFN-? production and thus plays a critical role in the development of cellular immune responses mediated by T helper T $_H$1 cells. The suppression of IL-12 is not yet entirely understood, and it is not clear whether this contributes to the therapeutic activity of thalidomide; [13] however, it may help explain some of the unexpected phenomena seen when thalidomide is used to treat tuberculosis in HIV-infected patients or chronic graft-versus-host disease.

In cultures of human peripheral blood monocytes, thalidomide inhibited IFN-? production and enhanced IL-4 and IL-5 synthesis. [14] The effects on other lymphokines have varied, probably because of the different experimental settings in which they were obtained.

Thus, thalidomide has potent anti-inflammatory activities, presumably mainly through the inhibition of the pathway of TNF-a—this seems to be mediated by accelerating the decay of its mRNA—and of IL-12. Therefore, it should suppress immunity mediated by T helper cells, but this effect has not yet been unequivocally demonstrated.

Human Immunodeficiency Virus

It has been known for some time that opportunistic infections increase HIV replication. This is very likely due to the induction of TNF-a synthesis, which, in turn, activates the nuclear transcription factor, NF?B, a cytoplasmic protein that enhances HIV transcription and is a regulatory component in the gene transcription of several mediators of inflammation, including TNF-a; the result is a feedback amplification loop. Tat, a protein initiating HIV replication, also activates NF?B. Viral replication is abolished in tat-defective strains and can be restored by TNF-a; NF?B-defective T cell lines are resistant to infection with HIV. Thus, the pathways for the transcription of TNF-a (and probably other cytokines) and of HIV appear to depend on the same regulatory mechanism.

By inhibiting TNF-a production, thalidomide blocks a pathway for the activation of NF?B and, hence, the replication of HIV. In addition to inhibiting the synthesis of TNF-a, thalidomide suppresses I?B-kinase activity, a key in NF?B synthesis [15], [16] and thus interferes at two sites with the positive feedback amplification loop for TNF-a and HIV production. In

summary, the effect of thalidomide or its metabolites on the immune system seems to be a reduction of mediators of inflammation (further effects include inhibition of cyclooxygenase–2 [17]) and a downregulation to normal of an overly activated state.

MONITORING THE USE OF THALIDOMIDE

CELGENE, the U.S. manufacturer of thalidomide, and the FDA have created a unique monitoring program for its distribution and monitoring—the System for Thalidomide Education and Prescribing Safety (STEPS) program. It is designed to make drugs, such as thalidomide, that offer important clinical benefits but carry the potential for serious harm, available for medical purposes while minimizing uncontrolled and potentially dangerous (ab)use. To achieve this, the program uses a threefold approach: [18] (1) controlling access to the drug; (2) educating prescribing physicians, pharmacists, and patients; and (3) monitoring compliance. Clinicians who wish to prescribe thalidomide must register in the STEPS Prescriber Registry administered by CELGENE and must agree to prescribe the drug in accordance with STEPS patient eligibility criteria and monitoring procedures. Pharmacies must also register and agree to comply with patient identification and monitoring criteria. Finally, patients receive visual aids, including a videotape, written material, and verbal counseling about the benefits and risks of thalidomide therapy, the importance of not becoming pregnant during therapy, and the types of contraception required (including emergency contraception) and their availability. Women able to bear children must agree to undergo pregnancy testing before starting therapy and on a regular schedule during therapy. All patients must agree to complete a confidential survey about their compliance with contraception, testing, and drug therapy. The manufacturer not only monitors survey results and outcome data, but also is ready to make whatever modifications to the STEPS program are necessary to ensure its effectiveness.

CLINICAL USES

In 1965, clinicians began to recognize thalidomide's potential as an anti-inflammatory drug, first for the treatment of erythema nodosum leprosum and subsequently for a wide variety of conditions:

Bullous pemphigoid [19]
Cicatricial pemphigoid [19]
Erythema multiforme [19]
Jessner-Kanof disease [20]
Lichen planopilaris [21]
Lichen planus, erosive [22]
Melanoma [23]
Multiple myeloma [24]
Palmoplantar pustulosis [25]
Porphyria cutanea tarda [26]
Postherpetic neuralgia [19]
Prurigo nodularis [27]
Pyoderma gangrenosum [28]
Sarcoidosis [29]
Uremic pruritus [30]
Weber-Christian disease [31]

More possible indications are being added. However, many of these observations have been published as case reports or small series and, thus, await confirmation by larger formal studies.

Although the drug cannot now be recommended for these conditions, thalidomide may provide a therapeutic alternative in selected patients who do not respond to more conventional regimens. Currently, efforts are being made to make better use of thalidomide's unique properties, to gain approval for the use of thalidomide in selected indications, and to develop analogues with better pharmacologic properties (e.g., with more pronounced antiangiogenic activity or even with no teratogenic potential) for use in a variety of neoplastic and inflammatory diseases.

Erythema Nodosum Leprosum

In 4522 patients with erythema nodosum leprosum, 99 percent responded to thalidomide. Lesions resolve within 24 to 48 h after treatment is begun; other symptoms (headache, myalgia, anorexia, vomiting, orchitis, leukocytosis, elevated sedimentation rate) also respond quickly. Motor nerve conduction velocity returns to almost normal within 2 weeks. All this can be ascribed to thalidomide's anti-inflammatory effects, as it does not act directly on *Mycobacterium leprae*. Because of this impressive efficacy, thalidomide may currently be considered the therapeutic standard for erythema nodosum leprosum (see Chap. 202).

Aphthosis and Behçet's Disease in Immunocompetent Patients

Thalidomide therapy is one of the main therapeutic options in complex aphthosis and in Behçet's disease. In one larger study, approximately one-third to more than one-half the patients with aphthosis of varying severity had full remissions; almost all had some benefit from treatment, with thalidomide, but relapses were common after its discontinuation. In a retrospective study of 25 patients with recurrent aphthous stomatitis followed for 1 year, 6 were able to stop treatment with only minor recurrences, 10 needed further maintenance treatment with low doses of thalidomide, 7 did not respond, 1 had to stop because of side effects, and 1 was lost to follow-up. [32] Oral and genital lesions of all 22 patients with Behçet's syndrome studied healed very rapidly in response to thalidomide (400 mg/day for 5 days, then 200 mg/day for up to 2 months); however, no effect on ocular lesions was seen. [33] After cessation of therapy, recurrences were milder

and less frequent.

Lupus Erythematosus

Thalidomide is an effective and relatively well tolerated treatment modality for the lesions of chronic cutaneous and subacute cutaneous lupus erythematosus. The value of this therapeutic measure is hardly debated, as the results of the first observations published in the early 1980s [34] are essentially the same as those in the larger series published more recently. [35] The following facts emerge:

- In a survey of 61 lupus centers from 19 countries around the world, 35 percent reported using thalidomide as a therapeutic option. [36]
- When given thalidomide, 50 to 90 percent of patients with subacute or chronic cutaneous lupus erythematosus achieve complete or near complete remissions of skin lesions; in all studies, at least 80 percent of patients responded.
- Thalidomide dosages used in these studies range from 50 to 300 mg/day, the maximum benefit being achieved within 16 weeks. [35], [37], [38] The higher dosages seem to be associated with somewhat higher response rates, but not with lower relapse rates. However, the use of low-dose regimens is becoming more common, as approximately 50 percent of patients respond and have fewer and milder side effects on such a regimen. [39] Thus, starting at a lower dose (50 to 100 mg/day) and increasing it if there is no adequate response in 2 to 3 months may be an appropriate way to treat lupus with thalidomide: presumably, fewer patients would have to discontinue therapy because of side effects. [37], [39]
- Response may be maintained with 25 to 50 mg/day and, rarely, even lower doses. Relapses after cessation of thalidomide medication occur in 70 to 75 percent of patients, but are usually responsive to a new course of the drug.
- Thalidomide must be discontinued early owing to unacceptable side effects in 10 to 25 percent of patients.
- Thalidomide's effect on the skin lesions of lupus erythematosus notwithstanding, it has no influence on the course and severity of the systemic disease.

Some of these studies are flawed in that it is not clear whether concomitant systemic glucocorticoid therapy was given; one of these studies does address the problem, stating that the use of thalidomide allowed the average daily glucocorticoid dose to be reduced from 40 to 17.5 mg. A Ro antibody–positive patient exemplifies the effect of thalidomide on the skin lesions of subacute cutaneous lupus erythematosus: [34] Azathioprine, 150 mg/day, and 6-methylprednisone, 60 mg/day, given previously had completely failed to control his rash (Fig. 264-1A). Thalidomide at 300 mg/day led to a considerable improvement of the skin disease within 3 weeks and to a complete remission within 10 weeks (Fig. 264-1B), with no additional immunosuppressive/glucocorticoid medication. This remission was maintained with thalidomide, 100 mg/day, and the treatment was tolerated well, with only minor side effects due to sedation. Nonetheless, there was progression, albeit slow, of his renal disease.

FIGURE 264-1 Patient with subacute cutaneous lupus erythematosus unresponsive to treatment with azathioprine/methylprednisone. Skin lesions of the face and neck (*A*) shortly after withdrawal of conventional immunosuppression and at the beginning of treatment with thalidomide, 300 mg/day; (*B*) complete resolution of the skin lesions after 10 weeks of therapy.

Chronic Graft-versus-Host Disease

Besides anecdotal reports, there are three studies of thalidomide in the treatment of chronic graft-versus-host disease after bone marrow transplantation in adults and one in children. [40], [41] and [42] In one, a survival rate of 76 percent among patients with graft-versus-host disease refractory to conventional therapy and of 48 percent of patients with high graft-versus-host disease-risk who received thalidomide was observed, with a complete response in 14, a partial response in 12, and no response in 18 patients. [40] There were only minor side effects. In another, 80 patients who failed to respond to conventional therapy (glucocorticoids with or without cyclosporine) were treated with thalidomide. Of these patients, 36 percent had to discontinue thalidomide because of side effects; 20 percent had a sustained favorable response. Five children with severe glucocorticoid-dependent chronic graft-versus-host disease were treated with thalidomide, 12 to 25 mg/kg per day. [41] All children responded to therapy, which allowed a reduction in immunosuppressive medication. There were only minimal side effects that did not necessitate withdrawal of the drug.

These studies clearly demonstrate that patients with chronic graft-versus-host disease refractory to conventional immunosuppressive/glucocorticoid therapy may benefit from the additional administration of thalidomide at doses of up to 1200 mg/day(!) if they can tolerate the side effects. This beneficial effect seems to be even more pronounced in children, possibly because they tolerate the drug better than adults do.

Although thalidomide is an effective therapeutic agent in chronic graft-versus-host disease, it cannot be used for prevention. In a double-blind, randomized trial with 59 patients who received 400 mg of thalidomide starting on day 80 after transplantation, both the incidence of chronic graft-versus-host and the survival rate were unfavorable, as compared

with a placebo group. [42] Thus, thalidomide cannot be used for the prophylaxis of chronic graft-versus-host disease.

Complications of HIV Infection

Thalidomide has a beneficial effect on the complications of HIV disease. Aphthous ulcers and AIDS wasting associated with tuberculosis have been shown to respond well; other complications, such as prurigo nodularis, proctitis, and refractory microsporidial diarrhea, may also respond. Furthermore, thalidomide may inhibit HIV replication in AIDS patients with active mycobacterial infections. However, HIV-infected patients are at greater risk for developing untoward effects from this therapy and must be selected and monitored accordingly.

APHTHOUS ULCERS Patients with advanced HIV disease develop painful aphthous ulcerations of the mouth and the oropharynx resembling the aphthous ulcerations typically found in patients with Behçet's disease. These aphthous ulcers are usually progressive and can be large (more than 1 cm^2), deep, and destructive; furthermore, they can lead to or aggravate HIV-associated weight loss. These aphthae were generally treated with the local or systemic administration of glucocorticoids, but have been shown to respond very well to thalidomide at daily doses of 100 to 300 mg. In a double-blind, randomized, placebo-controlled study, patients received a 4-week course of either 200 mg of thalidomide or placebo. [43] Complete healing of ulcers after 4 weeks occurred in 55 percent of treated patients, as compared with 7 percent in the placebo-treated group; 6 had to discontinue the drug because of toxicity; somnolence and a skin rash were each noted in 7 patients. Contrary to expectations, [44] plasma levels of TNF-a and of HIV RNA increased in the thalidomide-treated group; the significance of these findings remains to be studied. Similarly, 11 of 12 patients with esophageal ulceration had a complete symptomatic remission; in 9 of them, there was complete healing after they received 200 mg of thalidomide daily for 4 weeks. [45]
AIDS-ASSOCIATED WASTING A double-blind study of the efficacy and safety of thalidomide in AIDS-associated wasting showed a significant weight gain in the thalidomide group. However, rashes, fevers, and the sedation, but not neuropathy, limit its usefulness. [46]
MICROSPORIDIOSIS A common cause of chronic diarrhea in HIV patients, microsporidiosis contributes to their often severe wasting problems. In a study of 19 patients with chronic diarrhea due to microsporidiosis, 7 had a complete and 3 a partial clinical remission when given 100 mg of thalidomide daily. [47] Remarkably, all stages of the life cycle of the causative organism, *Enterocytozoon intestinale,* were disrupted.
KAPOSI'S SARCOMA The response to thalidomide was favorable in several phase II Kaposi's sarcoma trials. [48] Partial responses occurred in about 40 percent of patients treated with thalidomide doses of 400 to 1000 mg/day. This effect is thought to be related to thalidomide's antiangiogenic properties.

Langerhans Cell Histiocytosis

Rather than a neoplastic process (see Chap. 160), Langerhans cell histiocytosis is considered reactive. TNF-a has been shown to play an important role in the induction of proliferation of Langerhans cells, and this process can be reversed by thalidomide's inhibition of TNF-a production. So far, there are reports on seven patients treated with thalidomide, all of them responding. [49] Thus, thalidomide may be considered as treatment of Langerhans cell histiocytosis.

Actinic Prurigo and Polymorphous Light Eruption

Although they do not occur exclusively in Amerindians actinic prurigo and polymorphous light eruption occur primarily in this group (see Chap. 135). More than 90 percent of 99 patients with this condition responded well to thalidomide at initial doses of 100 to 300 mg/day within 3 weeks to 3 months. [50] Some of these patients enjoyed prolonged remissions, but most required maintenance therapy, usually of 50 to 100 mg/day, but occasionally as little as 15 mg/day. The rationale for this therapy comes from the observation that keratinocytes in lesional skin from patients with actinic prurigo contain high levels of TNF-a. [51] Good to excellent results have also been achieved in about 90 percent of patients with polymorphous light eruption, a related condition, in an average of 2 weeks. [52]

CONTRAINDICATIONS

Because of the disastrous effects of thalidomide on the development of the embryo, patients of childbearing age and their partners must understand and take the necessary contraceptive measures. The prescribing physician is responsible for informing them. In addition, it is essential to minimize the risk of thalidomide being dispensed through a “black market.” To these ends, the implementation of the (STEPS) [18] program is part of the recent FDA approval for use of thalidomide in certain diseases (see above). [18]

Thalidomide can be excreted with seminal fluid. Because no information is available on the amount of thalidomide required to cause birth defects, males should be advised to use barrier contraception while on thalidomide therapy. Contrary to earlier concerns, there does not seem to be a danger of second-generation birth defects. [53]

As the possible development of peripheral neuropathy (see below) is one of the major drawbacks of thalidomide therapy, patients with peripheral neurologic disorders should not be considered for this treatment modality.

Despite earlier impressions of a favorable effect, toxic epidermal necrolysis should *not* be treated with thalidomide. In a double-blind, randomized placebo-controlled study, there was a threefold higher mortality rate in the thalidomide group (10 of 12 patients) compared to the placebo group (3 of 10 patients). [54]

DOSAGE OF THALIDOMIDE

In the absence of acute toxicity, the dosage of thalidomide is determined by clinical effectiveness and limited by the side

effects of sedation and constipation. Practical doses range between 100 and 400 mg/day, but they are occasionally as high as 600 mg/day in patients with subacute cutaneous lupus and up to 1200 mg in patients with chronic graft-versus-host disease refractory to more conventional anti-inflammatory/immunosuppressive therapy. There is no strict correlation between plasma levels and clinical effects; sedation, healing of oral ulcers, or complete suppression of cutaneous lupus may occur at doses that do not produce detectable thalidomide plasma levels.

ADVERSE EFFECTS OF THALIDOMIDE THERAPY

The most important adverse effect of thalidomide is the well-known teratogenic effect. Thus, as noted earlier, it is mandatory that female patients of childbearing age for whom thalidomide therapy is planned be carefully selected, informed, and monitored and that they take reliable contraceptive measures.

Teratogenesis

Thalidomide embryopathy has affected an estimated 12,000 to 15,000 patients worldwide; more than 4000 cases have been reported, 3000 of them in West Germany alone. Malformations due to thalidomide embryopathy are related to the time of exposure to the drug in utero, the sensitive period being the embryonal ages from the third to the fifth week; they may be caused by the action of thalidomide on embryonal adhesion receptors. [12] Most prominent are malformations of the extremities, including malformations or aplasia of the thumbs, radiate aplasia, phocomelia or amelia of the upper and/or lower limbs, anotia, facial palsy, microphthalmia, and ophthalmoplegia. In addition, neural tube defects, cardiac malformations, renal malformations, esophageal fistulas, duodenal stenosis or atresia, anal atresia, vaginal obstruction, and midline hemangiomas may occur. These malformations must be differentiated from other dysmelic diseases and radial defects, of which Holt-Oram syndrome, an autosomal dominant disease, is the one most similar to thalidomide embryopathy.

Peripheral Neuropathy

Another serious side effect of thalidomide therapy is a peripheral sensory neuropathy that may later progress to involve motor neurons. Estimates of the incidence of this neuropathy range from more than 60 percent to less than 1 percent of HIV-negative patients who receive thalidomide. Not much is known about its incidence in HIV-infected patients, but as with other thalidomide side effects, such individuals may be at greater risk. Patients treated for chronic graft-versus-host disease may also be at risk because of pretreatment with cytotoxic drugs and the higher doses of thalidomide used in this condition. As this neuropathy can become irreversible, preexistent peripheral neuropathy should be excluded before patients receive thalidomide, and their neurologic status should be assessed frequently.

Other Side Effects

Other dose-related and usually mild side effects are sedation, nausea, mood changes, increased appetite, edema of the face and limbs, menstrual abnormalities, decreased libido, constipation, dizziness, and dryness of the mouth. These effects tend to disappear with time, but can be dose-limiting on occasion.

RASH AND FEVER Occuring predominantly in HIV-infected patients, [55] rash and fever may develop with the use of thalidomide—similar to the well-known reaction to trimethoprim-sulfamethoxazole in these patients. More than 30 percent of such patients, especially those with low CD4+ lymphocyte counts, develop this problem, which requires a cessation of therapy. An erythematous rash with peripheral blood eosinophilia has been observed in two patients with renal insufficiency who received thalidomide for prurigo nodularis. [27] The rash resolved promptly upon withdrawal of the drug.
TOXIC EPIDERMAL NECROLYSIS One female patient receiving thalidomide for the treatment of leioblastoma developed toxic epidermal necrolysis after 5 weeks of therapy. [56]

MECHANISMS OF ACTION

REFERENCES

Over the past few years, the development of irradiation devices with new emission spectra has led to an expanded role for phototherapy in the treatment of skin disease. [1] This development is best illustrated by the increasing frequency with which 311-nm ultraviolet B (UVB) phototherapy is employed for the treatment of psoriasis. [2] In fact, in Europe 311-nm UVB (narrowband UVB or 312-nm UVB) is currently used more often than psoralens plus ultraviolet A (PUVA) therapy for psoriasis and several other cutaneous diseases. Another example of a new device that has improved and expanded the spectrum of skin diseases amenable to phototherapy is ultraviolet A-1 (UVA1). [3] With this modality, doses of UVA1 (340 to 400 nm) up to 130 J/cm ^{2} are delivered to diseased skin. UVA1 was first used to treat patients with atopic dermatitis, but it has since been found to be efficacious in several other skin diseases, such as localized scleroderma, where other therapeutic options are limited. These two examples demonstrate that the introduction of new spectra into dermatologic phototherapy has not only broadened and improved phototherapy as it relates to established indications but, in addition, has fostered the development of new indications for phototherapy such as connective tissue diseases.

PHOTOTHERAPY OF PSORIASIS

One important element in the long-term management of moderate to severe psoriasis is UVB phototherapy. Within recent years, the availability of new fluorescent bulbs with an emission spectrum that closely conforms to the peak of the action spectrum for clearing psoriasis has significantly improved the efficacy of UVB phototherapy for psoriasis, making it as efficient as PUVA therapy.

311-nm UVB: The Phototherapy of Choice for Psoriasis

Parrish et al. demonstrated that wavelengths shorter than 295 nm displayed no antipsoriatic effect, even if used at erythemogenic doses, whereas wavelengths between 300 and 313 nm caused the greatest remission of skin lesions. [4] These seminal observations provided the rationale for the development of more selective UVB phototherapy (SUP) irradiation devices. These units have a spectrum that is still broadband UVB but is enhanced in the range of 300 to 320 nm. As predicted, these light sources proved to be superior to conventional UVB phototherapy for clearing of psoriasis. A major breakthrough was achieved by the development of the Philips TL-01 fluorescent lamp, emitting a narrow UV band at 311/312 nm and thereby matching closely the assumed therapeutic optimum for psoriasis. [2] A large number of clinical trials comparing broadband versus 311-nm UVB phototherapy for psoriasis have been conducted mainly in Europe, and more recently in the United States. Based on these studies, it is now generally accepted that 311-nm UVB therapy is superior to broadband UVB therapy for psoriasis. [5] Patients treated with a 311-nm spectrum show faster clearance of skin lesions, fewer episodes of excessive erythema, and a longer period of remission (Fig. 265-1). This difference in efficacy has been attributed to the fact that 311-nm UVB is capable of more efficiently depleting skin-infiltrating T cells from the epidermis and dermis of psoriatic plaques as compared with broadband UVB. [6] Also, comparative studies of 311-nm UVB phototherapy and PUVA demonstrate that these two modalities are equally effective. [7], [8] and [9] This is of particular interest, because 311-nm UVB therapy, in comparison to PUVA, does not require psoralens, is cheaper, can be used in pregnancy and childhood, and does not require posttreatment eye protection. It has also been suggested that 311-nm UVB may be less carcinogenic than PUVA. [10] For these reasons, 311-nm UVB therapy currently represents the phototherapeutic modality of choice for the treatment of psoriasis in Europe, and is being used increasingly in the United States.

Practical Aspects

For 311-nm UVB therapy, no specific irradiation devices are needed because the Philips TL-01 fluorescent lamps can be fitted into conventional PUVA cabinets. Regardless of whether 311-nm UVB or conventional broadband UVB from fluorescent bulbs (such as Westinghouse FS, Philips TL12, Sylvania UV21) or medium-pressure mercury arc lamps with or without metal halides [8] are used, a number of guidelines should be followed. [11]

In particular, prior to phototherapy, the patient's minimal erythema dose (MED) must be determined in order to establish the optimal dosage schedule. For determination of the MED and subsequent phototherapy, either the same irradiation device or different devices with identical emission spectra must be used. For 311-nm therapy, the initial dose should equal 0.7 MED (Table 265-1). Patients are treated three to five times per week. If the initial dose is tolerated, a 20 percent incremental increase of the previous dose is used at each visit. [12] When a previous treatment results in erythema, no treatment is given the next scheduled visit or the dose is decreased, depending on whether the erythema is asymptomatic or severe and painful (Table 265-1). It should be noted that 311-nm UVB is also very efficient when used at suberythemogenic doses. [13]

1. Determination of minimal erythema dose (MED):	
2. First exposure: 70% of MED	
3. Subsequent exposure:	
a. If no erythema	Increase by 20% at each visit
b. Minimal erythema	Same dose
c. Asymptomatic, well-defined erythema	Postpone exposure until next visit, then same dose; and thereafter 10% increments at each visit
d. Painful erythema ± edema or buller	Omit further exposure until recovery, reduce exposure dose by half, thereafter 10% increments at each visit

[a] According to Hönigsmann and Krutmann[17]

TABLE 265-1 **311-nm UVB Phototherapy Regimen**

For broadband UVB therapy, one MED is given on the first treatment and is increased by 50 percent, 40 percent, 30 percent, and so on, in subsequent treatments. Because ultraviolet radiation is a complete carcinogen, the genitalia and chronically light-exposed areas (e.g., the face, neck, dorsa of hands), if unaffected, should be shielded or protected (with sunscreen) prior to irradiation.

For limited psoriasis, 308-nm excimer laser therapy may represent an option. [14] The 308-nm excimer laser appears to be highly effective even in otherwise therapy-resistant psoriasis. It is selectively directed at lesional skin, thus sparing the surrounding normal skin from unnecessary exposure.

The end point of phototherapy is complete clearance of all psoriatic skin lesions. Psoriasis, however, is a chronic disease and the remission induced by UVB phototherapy is transient. In a randomized, prospective, multicentered trial, postclearing phototherapy was found to significantly increase the disease-free interval, indicating that patients may profit from maintenance phototherapy. [15] On the other hand, maintenance therapy results in a greater cumulative UVB dose, increasing the risk of skin cancer and photoaging. It is therefore preferable, if possible, to maintain remissions with other antipsoriatic modalities. To minimize potential carcinogenic risks from chronic UVB phototherapy, a rotational therapeutic approach including a number of primary and secondary agents has been suggested. [16] Primary agents include UVB, PUVA, methotrexate, and etretinate. If these are no longer effective, then secondary agents, such as cyclosporine, hydroxyurea, and low-dose combination regimens (e.g., retinoids + PUVA + topicals), should be considered.

Combination Therapy (See also Chap. 42)

Along the same lines, phototherapy of psoriasis is frequently used in combination regimens in order to achieve higher clearance rates, longer disease-free intervals, and a lower carcinogenic risk. [16] Phototherapy may be combined with topical or systemic agents. Topical agents include anthralin, vitamin D analogues, retinoids, glucocorticoids, emollients, saltwater baths, and tar. Among these, anthralin and tar are mainly of historical interest and are not discussed.

Antipsoriatic vitamin D analogues include calcipotriol, tacalcitol, and calcitriol, which have antiproliferative, as well as antiinflammatory, effects. [17] Local side effects are limited to moderate skin irritation. [18] To avoid systemic side effects—in particular hypercalcemia with consequent nephrocalcinosis—from percutaneous absorption, the treated body surface should not exceed 30 percent. Under these conditions, long-term safety may be assured. [19] Main indications are psoriatic plaques of limited extent and lesions on the scalp, face, palms, and soles and in the intertriginous areas. The

combination of either broadband UVB or 311-nm UVB therapy with calcipotriol increases the therapeutic efficacy of phototherapy alone. [20] This observation is of particular interest because UVB therapy reduces the irritation caused by calcipotriol. A combination of calcipotriol with UVA radiation or a combined UVA/UVB regimen should be avoided, because UVA radiation leads to degradation of vitamin D_3. Consequently, vitamin D analogues should be applied after (not before) phototherapy.

Another promising combination phototherapy of psoriasis is narrowband UVB irradiation and topical tazarotene gel. Tazarotene is a topical acetylenic retinoid that is efficacious in plaque-type psoriasis. The addition of tazarotene to broadband or narrowband UVB phototherapy was found to promote more effective, faster clearing of psoriasis when compared to either type of phototherapy alone. [21], [22] Pretreatment with tazarotene gel three times per week for 2 weeks before phototherapy significantly reduces the mean minimal erythema dose for UVB and the mean UVA exposure required to induce immediate pigment darkening. Thus, UVB and PUVA therapy can be initiated at lower doses than usual when used in combination with tazarotene. [23]

Several studies have addressed the question whether the efficacy of UVB phototherapy for psoriasis may be enhanced through combination with topical glucocorticoids. Data from these studies are conflicting and the beneficial effects seem to be limited. [24] Topical glucocorticoids are useful, however, for treating psoriatic lesions in skin areas not reached by UV irradiation during phototherapy (e.g., scalp, groin, perianal area, umbilicus), or for the treatment of lesions recalcitrant to standard phototherapy. They may also be used in the early, highly inflammatory state of psoriasis to achieve a quick improvement.

Topical application of emollients alters the optical properties of psoriatic lesions. [25] Lubricants improve transmission of UVB, and a combination of topical lubricants with UVB therapy increased efficacy. [26] This is in contrast to thick applications of petrolatum and water-in-oil type creams and salicylic acid, which act as sunscreens.

Balneophototherapy comprises the combination of saltwater baths with UVB phototherapy, which, under natural conditions, has been successfully employed at the Dead Sea for the treatment of patients with recurrent, severe psoriasis. [27] Modern approaches to balneophototherapy employing synthetically generated Dead Sea salt or sodium chloride solutions for saltwater baths (usually between 5 to 15 percent) are hampered by logistics (the requirement for bathtubs) and environmental problems (caused by the salt consumption). The beneficial effects of saline solutions on psoriasis are thought to involve elution of leukocyte elastase from psoriatic skin [28] and anti-inflammatory effects of magnesium ions. [29] Controlled studies demonstrating a synergistic effect between saltwater baths and phototherapy are still lacking. Similarly, the efficacy of balneophototherapy in comparison with established combination regimens for psoriasis remains to be assessed.

Systemic agents that may be used to treat psoriasis include retinoids, glucocorticoids, cyclosporin A, and methotrexate. Retinoids are the most widely used agents for systemic treatment in combination with phototherapy. In contrast, the systemic use of glucocorticoids in combination with photo(chemo)therapy is limited to special indications, such as generalized pustular psoriasis. Also, combination regimens of UVB therapy with methotrexate or cyclosporin A are not advisable, because both substances increase the possibility of UV-induced skin tumors.

From a theoretical point of view, the advantage of combining retinoids and UVB irradiation is twofold: (1) retinoids exert antipsoriatic effects, which might act synergistically with UVB phototherapy; and (2) they have anticarcinogenic effects and thereby could lower the increased skin cancer risk resulting from long-term UVB therapy. Because of potentially severe side effects, the use of retinoids should be limited to pustular or erythrodermic variants of psoriasis. Combination regimens with broadband UVB or SUP therapy together with etretinate induced improvement in psoriatic patients more quickly than with phototherapy alone, and reduced the number of treatments and cumulative UV doses. [30] Similar results were obtained when acitretin, the major metabolite of etretinate, was used in combination with broadband UVB or 311-nm UVB therapy. [31]

PHOTOTHERAPY OF ATOPIC DERMATITIS (See also Chap. 122)

In the past few years, several new phototherapeutic modalities, including UVA/UVB, [32] 311-nm UVB, [33] and UVA1 phototherapy, [34] were developed to treat atopic dermatitis. As a consequence, dermatologists now have a diverse spectrum of phototherapeutic modalities from which to choose to tailor their treatment to the particular needs of a particular patient. Treatment decisions can now be based on the effectiveness of a given form of phototherapy for a specific stage of atopic dermatitis—i.e., acute and severe versus chronic and moderate disease activity. We recently developed a phototherapeutic approach for atopic dermatitis [34] that should result in phototherapy for atopic dermatitis that is both as effective and as safe as possible. In general, phototherapy of an acute, severe exacerbation of atopic dermatitis may be achieved with high- or medium-dose UVA1 therapy, whereas conventional UVA, UVA/UVB, 311-nm UVB, and low-dose UVA1 phototherapy represent phototherapeutic modalities that are primarily suited for treatment of chronic stages of this disease (Table 265-2).

Indication	Modality	Comment
Acute, severe	High-dose UVA1	Monotherapy; alternative to glucocorticoids; long-term side effects unknown
Chronic, moderate	311-nm UVB UVA/UVB Broadband UVB Broadband UVA Low-dose UVA1	Combination therapy to save glucocorticoids; suited for maintenance therapy

TABLE 265-2 **Concept-Linked Phototherapeutic Approach for Atopic Dermatitis**

UVA1 Phototherapy for Acute, Severe Atopic Dermatitis

UVA1 phototherapy is a highly effective modality that can be used as monotherapy for a limited period of time (10 to 15 exposures). It is most effective for the treatment of patients with a severe, acute exacerbation of atopic dermatitis (Fig. 265-2). Because potential long-term risks of UVA1 phototherapy are not known, patients should not be treated over extended periods of time, for example, for maintenance therapy. For the same reasons its use is not recommended for patients younger than 18 years of age. The therapeutic effectiveness of UVA1 irradiation in the management of patients with atopic dermatitis was first evaluated in an open study in patients with acute, severe exacerbations of atopic dermatitis. [35] They were exposed to 130 J/cm ^{2} UVA1 daily for 15 consecutive days. Its therapeutic effectiveness was assessed by means of a clinical scoring system as well as by monitoring serum levels of eosinophil cationic protein (ECP), a laboratory parameter that can be measured objectively and that correlates well with disease activity in atopic dermatitis. In that study, UVA1 phototherapy was found to be highly efficient in promptly inducing clinical improvement and reducing elevated serum ECP levels. Patients treated with UVA1 were compared with subjects who had been treated with UVA/UVB phototherapy. Significant differences in favor of UVA1 therapy were observed. [35] These results were recently corroborated and extended in a randomized, controlled multicenter trial in which UVA1 therapy, as compared with glucocorticoid treatment, was significantly better at day 10 in reducing the clinical score. [36]

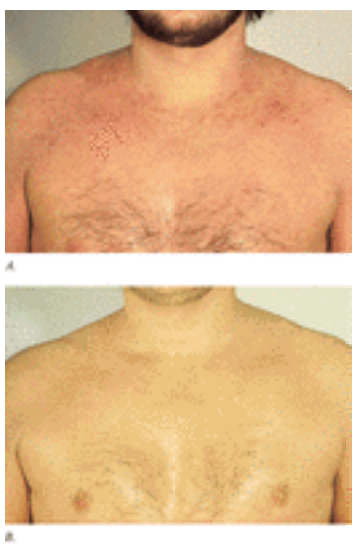

FIGURE 265-2 Patient with severe, acute exacerbation of atopic dermatitis before (*A*) and after (*B*) high-dose UVA1 therapy (15 × 130 J/cm ^{2} UVA1).

The therapeutic effectiveness of UVA1 therapy is dose-dependent. Low-dose UVA1 (30 J/cm ^{2}) is less effective than UVA/UVB therapy, [37] whereas high-dose UVA1 therapy (130 J/cm ^{2}) is superior to UVA/UVB phototherapy. [35], [36] In addition, a medium-UVA1 dosage schedule (50 J/cm ^{2}) was superior to a low-dose UVA1 regimen (10 J/cm ^{2}), whereas no significant difference was detected in a bilateral comparison study between a medium- and a high-dose regimen. [38]

High-dose UVA1 phototherapy may not be used on patients with UVA-sensitive atopic dermatitis or photodermatoses. It is necessary to exclude these diseases prior to initiation of high-dose UVA1 therapy. This can easily be accomplished by photoprovocation testing. Except for eczema herpeticum, no acute side effects have been observed in any of the patients treated with high-dose UVA1 therapy. No other side effects have been observed, although its potential carcinogenic risk is a theoretical concern. It is important to note that exposure of hairless albino Skh-hr1 mice to high doses of UVA1 radiation induced squamous cell carcinoma. [39] The actual contribution of UVA radiation to the development of malignant melanoma in humans is currently under debate and at this point cannot be excluded. [40] Until more is known about high-dose UVA1 therapy, its use should be limited to periods of acute exacerbation of atopic dermatitis and, in general, one treatment cycle should not exceed 10 to 15 continuously applied exposures and should not be repeated more than once per year. [34]

Phototherapy of Chronic, Moderate Atopic Dermatitis

Broadband UVB, [41] combined UVA/UVB, [32], [42] broadband UVA, [43] low-dose UVA1, [37] and, in particular, 311-nm UVB phototherapy [43] are effective treatments in mild and moderate atopic dermatitis. They are not particularly effective in patients with acute, severe exacerbations of their disease. In contrast to UVA1 therapy, these forms of UV therapy are usually not employed as monotherapy. Rather, they are used in combination regimens together with topical glucocorticoids in order to reduce the need for glucocorticoid application. All of these therapies are considered to be relatively safe, even if used over extended periods of time, and they should be used to induce long-term improvement. Patients do best if severe disease is initially controlled by more potent but also more aggressive modalities. For example, 311-nm UVB phototherapy has proved to be an ideal modality for maintenance therapy after high-dose UVA1 has been used in the initial phase of management of an acute, severe exacerbation of atopic dermatitis. [34] If high-dose UVA1 therapy is not available, severe atopic dermatitis should be controlled prior to start of phototherapy by aggressive topical glucocorticoid therapy or systemic immunosuppressive modalities such as glucocorticoids or cyclosporin A.

Studies directly comparing all the different forms of UV therapy for chronic, moderate atopic dermatitis have not been performed, but recent trials indicate that either UVA/UVB combination therapy [37] or narrowband 311-nm UVB therapy [33], [43] is superior to conventional broadband UVB, broadband UVA, or low-dose UVA1 therapy. Also, narrowband UVB appears to be equivalent to bath-PUVA for this indication. [44] The actual choice made for a particular patient also depends on what irradiation devices are available. At the moment, UVA/UVB is more widely available than 311-nm UVB therapy.

Jekler and Larkö, in a paired comparison study, observed significant differences in favor of UVA/UVB therapy over broadband UVB therapy. [37] In this trial, patients were allowed to continue the use of topical glucocorticoids and were irradiated three times per week for a maximum of 8 weeks in a UVB MED-dependent manner.

The therapeutic effectiveness of 311-nm UVB therapy for chronic, moderate atopic dermatitis was first shown in an open trial conducted by George et al. [33] and was recently confirmed in a randomized controlled study. [43] In their well-designed study, George et al. irradiated patients with chronic, moderate atopic dermatitis with 50 100-W TL-01 lamps equipped with reflectors, resulting in a UVB output of 5 mW/cm ^{2} and maximum treatment times of less than 10 min. [44] The irradiation regimen used with 50 lamps was identical to that previously described for 311-nm therapy of psoriasis (Table 265-1). Patients were monitored for severity of clinical symptoms as well as glucocorticoid use 12 weeks prior to phototherapy, during the 12 weeks of phototherapy, and for another 24 weeks after cessation of phototherapy. The 311-nm UVB phototherapy not only decreased the clinical severity, it also significantly reduced the use of glucocorticoids. These beneficial effects were still present in the majority of patients 6 months after cessation of 311-nm UVB therapy. In this study, a specially constructed air-conditioned irradiation unit was used for 311-nm UVB phototherapy. Equivalent therapeutic results could also be achieved if TL-01 lamps were fitted into a conventional PUVA irradiation device, indicating that higher temperatures during 311-nm UVB phototherapy did not lead to heat-induced irritation of eczema. [45] As discussed previously, 311-nm UVB therapy may be associated with a reduced risk of skin cancer compared to broadband UVB or to PUVA therapy. [10] The recent demonstration of 311-nm UVB therapy's effectiveness for treating childhood atopic eczema is therefore of particular interest. [46]

If neither a UVA/UVB nor a 311-nm UVB irradiation device is available, broadband low-dose (0.5 MED) UVB therapy can be used. Placebo-controlled studies show it to be effective for this disease. [41]

PHOTOTHERAPY OF OTHER DISORDERS

In addition to psoriasis and atopic dermatitis, UV therapy is increasingly used for a growing number of skin diseases that previously had mainly been treated with PUVA (e.g., polymorphous light eruption, urticaria pigmentosa, vitiligo, cutaneous T cell lymphoma) or for which no phototherapeutic approach had been available (e.g., scleroderma and lupus erythematosus).

Phototherapy of Polymorphous Light Eruption and Other Photodermatoses

Patients with polymorphous light eruption (PMLE) respond abnormally to ultraviolet radiation (in particular UVA radiation), resulting in an increased and sustained expression of proinflammatory molecules (cytokines, adhesion molecules) and subsequent development of skin lesions (see Chap. 135). In the majority of PMLE patients, exposure to early season sunlight results in induction of tolerance, a process that is termed *hardening*. Artificial induction of hardening or artificial photoprotection constitutes the major principle underlying phototherapy of PMLE. [47] The precise molecular mechanisms responsible for hardening are not yet known, but it is generally believed that phototherapy-induced photoprotection is based on the induction of epidermal thickening, pigmentation, and as-yet-to-be-defined immunologic effects. To maintain phototherapy-induced photoprotection, it is important that patients expose themselves to sunlight, because strict avoidance of sunlight exposure will result in a quick loss of the therapeutically induced hardening effect. The use of phototherapy for PMLE is restricted to severe cases that fail to respond to more simple measures such as light avoidance, photoprotective clothing, and use of broadband sunscreens. For these patients, broadband UVB and PUVA therapy have previously been found to be effective, with PUVA giving better results than UVB therapy. [47] Recent studies, however, indicate that 311-nm UVB therapy represents an effective alternative to PUVA for PMLE-induced photoprotection. In a recent study, 25 patients were randomly assigned to either PUVA treatment or 311-nm UVB therapy, which was administered as previously described (see Table 265-1). [48] When patients were monitored for 4 months following treatment, there was no difference between PUVA and 311-nm UVB therapy with respect to severity of disease and restriction of outdoor activities. For the reasons given above, 311-nm UVB therapy may therefore be considered the treatment of choice for PMLE. The efficacy of 311-nm UVB therapy for photodermatoses other than PMLE has not yet been assessed in controlled studies, but observations from a pilot study indicate that patients with actinic prurigo (in particular), hydroa vacciniforme, and erythropoietic porphyria, but not with solar urticaria, may also benefit from 311-nm UVB therapy. [49] In severe, otherwise therapy-resistant forms of solar urticaria UVA “rush hardening” therapy may represent an option. [50] This novel approach includes multiple UVA irradiations at 1-h intervals per day; it provides significant protection within 3 days.

Phototherapy of Scleroderma

Localized scleroderma has a self-limited course, but skin lesions can cause significant morbidity and discomfort, particularly if they extend over joints and cause flexion contractures, or if they lead to muscle atrophy and disfigurement. [51] In the past, numerous modalities including penicillin, penicillamine, antimalarial drugs, cyclosporin A, interferon-?, and topical or systemic glucocorticoids have been employed. In general, the efficacy of each of these agents is poor. It was therefore of considerable interest to learn that UVA1 phototherapy was of benefit for patients with localized scleroderma [52], [53] (Fig. 265-3).

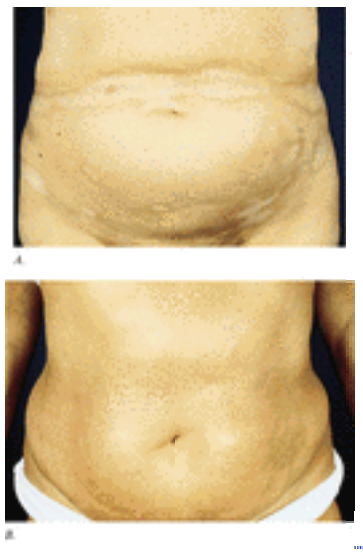

FIGURE 265-3 Patient with localized scleroderma before (*A*) and after (*B*) high-dose UVA1 therapy (30 × 130 J/cm ^{2} UVA1).

In an open study, 10 patients with histologically proven localized scleroderma were exposed 30 times to a single dose of 130 J/cm ^{2} UVA1 radiation. [53] In all patients, high-dose UVA1 therapy significantly reduced thickness and increased elasticity of sclerotic plaques as assessed by 20-MHz sonography. Complete clearance was observed in 4 of 10 patients. These changes were not a result of spontaneous remissions, because they were present only in UVA1-irradiated, but not in unirradiated control, plaques in the same patients. Similar therapeutic benefit could also be achieved by employing a low-dose UVA1 regimen. [52] Direct comparison of low-dose versus high-dose UVA1 therapy revealed that high-dose UVA1 therapy was superior, indicating that the therapeutic efficacy is dose-dependent. [53] Termination of phototherapy was not associated, over a 3-month period, with loss of the beneficial effects achieved by high-dose UVA1 irradiation in 9 of 10 patients, indicating that maintenance therapy may not be required. The precise mechanism by which UVA1 therapy acts in localized scleroderma is unknown, but most likely involves upregulation of collagenase I expression, which was induced about 20-fold in sclerotic skin lesions after successful UVA1 phototherapy. [53], [54]

In addition to localized scleroderma, UVA-1 phototherapy is also effective in patients with systemic sclerosis and chronic graft-versus-host disease. [55], [56]

Phototherapy of Urticaria Pigmentosa

Several studies have demonstrated that PUVA therapy is effective in reducing pruritus and urtication associated with urticaria pigmentosa. [57] In the majority of patients, however, cessation of PUVA therapy leads to recurrence of urticaria pigmentosa after 5 to 8 months. A recent study suggests that beneficial effects may also be achieved in these patients by UVA1 phototherapy. In an open study, four adult patients with severe generalized urticaria pigmentosa were treated with high-dose UVA1 phototherapy, which was given as monotherapy once daily five times per week for 2 consecutive weeks. [58] The initial dose was 60 J/cm ^{2}, which was subsequently increased to 130 J/cm ^{2}. High-dose UVA1 therapy induced reduction of pruritus and loss of urtication from stroking (Darier's sign) after three exposures, whereas hyperpigmented skin lesions faded more slowly. Increased histamine in 24-h urine was reduced to normal levels. In two patients with systemic manifestations of urticaria pigmentosa, such as migraine and diarrhea, relief from systemic symptoms and reduction of serum serotonin to normal levels was observed after 10 exposures. No relapse has occurred in any of these four patients for more than 2 years after cessation of high-dose UVA1 therapy. This is in contrast to PUVA therapy and may be because of the possibility that high-dose UVA1, but not PUVA, therapy leads to depletion of dermal mast cells. [57], [58]

Phototherapy of Miscellaneous Disorders

Several reports indicate that 311-nm UVB is a useful and well tolerated therapy for vitiligo that results in rapid repigmentation in many patients, including Fitzpatrick's skin types IV and V, as well as children. [60], [61] These therapeutic responses were achieved with twice weekly irradiations, the initial dose was 0.25 J/cm ^{2}, independent of the skin type, and the dose was increased by 20 percent each treatment. It should be noted, however, that similar to PUVA or khellin (a furocoumarin) plus UVA (KUVA) therapy, certain anatomic sites (hands and digits, feet and toes) did not respond. There have been no controlled studies comparing 311-nm UVB phototherapy with PUVA or KUVA for this indication.

It has been suggested that daily low-dose UVA1 irradiation is beneficial to patients with lupus erythematosus (Fig. 265-4). In an open study, 10 patients with systemic lupus erythematosus were treated with low-dose UVA1 irradiation (6 J/cm ^{2} daily) for various time periods (15 days to 8 months). [62] A decrease in clinical indices of disease activity, which was most pronounced after 8 months of phototherapy, was observed in all patients. The UVA1 irradiation decreased fatigue, arthritis, photosensitivity, skin rashes, and often depression, headaches, and sleeplessness. In addition, anti-SSA or antinuclear antibodies decreased or even disappeared in most patients. These promising results have been confirmed in an 18-week two-phase study using 6 J/cm ^{2}. [63] No side effects were noted, although UVA1 irradiation, at least at higher doses, may exert detrimental effects on some lupus erythematosus patients.

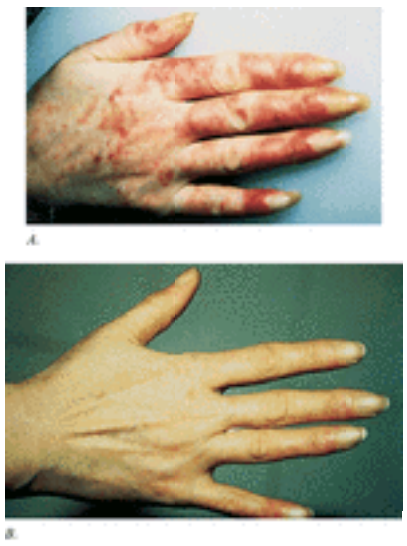

FIGURE 265-4 Hand of a 37-year-old woman with subacute cutaneous lupus erythematosus before (*A*) and after (*B*) low-dose UVA1 therapy. Treatment consisted of irradiation daily for 5 days a week with 6 J/cm ^{2} UVA1 for 3 consecutive weeks. (*Courtesy of H. McGrath, Jr., MD, New Orleans, LA.*)

UVA-1 phototherapy was recently used to treat patients with cutaneous T cell lymphoma (CTCL). In an open pilot study, three of three patients with early stage mycosis fungoides (CTCL stages IA and IB) were treated effectively with a high, as well as medium dose UVA-1 regimen. [64] In a second uncontrolled trial, 11 of 13 patients with widespread plaque-type, nodular and erythrodermic mycosis fungoides (CTCL stages IB, IIB, and III) showed complete clinical and histologic responses upon treatment with a high-dose UVA-1 regimen. [65] These observations are of particular interest because UVA-1 phototherapy offers significant advantages over PUVA therapy. Unwanted side effects resulting from the systemic application of methoxsalen, such as nausea, long-lasting skin photosensitivity and requirement for eye protection are completely avoided. It was recently proposed that 311-nm UVB phototherapy be used to treat early stages of mycosis fungoides. [66]

Local UVA-1 phototherapy appears to be an interesting option in the management of patients with chronic vesicular dyshidrotic hand eczema. In an open pilot study, palms and backs of hands of 12 patients with an acute exacerbation of their disease were exposed to 15 UVA-1 irradiations with a dose of 40 J/cm ^{2} per day over a period of 3 weeks. After 1 week, all but one patient reported a marked relief of itch. After the third week, significant clinical improvement was noted in 10 of 12 patients. [67]

UVA-1 phototherapy has also been used for patients with keloids and hypertrophic scars, [68] pityriasis rubra pilaris, [69] and hypereosinophilic syndrome. [70]

Phototherapy with UVB may be used to treat pityriasis lichenoides acuta et chronica, [71] pityriasis rosea, [72] severe seborrheic dermatitis, [73] and pruritic folliculitis of pregnancy. [74]

MECHANISMS OF ACTION

Through the induction of DNA photoproducts, UVB radiation transiently inhibits cell proliferation. As a result, it was thought that the therapeutic effectiveness of UVB phototherapy in psoriasis is mainly due to its antiproliferative effects. Since the introduction of UVB radiation into dermatologic therapy, however, the number of skin diseases showing a favorable response to phototherapy has grown substantially. The vast majority are immunologic in nature. Studies on the role of UV radiation-induced immunosuppression in photocarcinogenesis and on the effects of UV radiation on the function of epidermal Langerhans cells have provided increasing evidence that UVB, as well as UVA (and in particular UVA1) radiation exert profound effects on the skin immune system (reviewed in Ref. [75]). As a consequence, UVB and UVA phototherapy are currently regarded as modalities whose mechanism of action depends upon immunomodulatory effects that are not specific for a single type of light source. The in vivo relevance of these immunomodulatory effects is dependent on the physical properties of the UV radiation employed. On a per-photon basis, wavelengths within the UVB spectrum possess greater energy than does UVA radiation, but because of their shorter wavelength, they have a more superficial depth of penetration within the skin. As a result, UVB phototherapy primarily affects the function of epidermal keratinocytes and Langerhans cells, whereas UVA1 radiation additionally affects dermal fibroblasts, dermal dendritic cells, endothelial cells, T lymphocytes within the dermis, mast cells, and granulocytes (Fig. 265-5). Photoimmunologic effects induced by UVB and UVA1 radiation fall into three major categories: (1) effects on soluble mediators; (2) modulation of the expression of cell surface–associated molecules; and (3) the induction of apoptosis in pathogenetically relevant cells. The apoptotic effect is currently thought to be of key importance for phototherapy. [75] Both UVB and UVA (particularly UVA1) radiation are highly efficient in inducing apoptosis in human cells. T cells, as compared with monocytes or keratinocytes, have an increased susceptibility to UV radiation-induced apoptosis; this mechanism is, therefore, of particular importance for phototherapy of T cell–mediated skin diseases such as atopic dermatitis and psoriasis. For example, UVA1 phototherapy of patients with atopic dermatitis was shown to induce apoptosis in skin-infiltrating T helper cells, thereby leading to a gradual reduction of the inflammatory infiltrate and concomitant improvement of patients' skin disease. Similarly, successful UVB phototherapy of psoriasis reduced the number of intraepidermal T cells and subsequently normalized keratinocyte morphology. Depletion of T cells was a result of UVB-induced T cell apoptosis. A very detailed, up-to-date review of photoimmunologic mechanisms that are responsible for the efficacy of phototherapy is found in Ref. [75].

PHOTOCHEMOTHERAPY (PUVA)

Psoralen photochemotherapy is a combination of psoralen (P) and long-wave ultraviolet radiation (UVA) that brings about a therapeutically beneficial result not produced by either the drug or radiation alone. This particular form of therapy is currently used in the treatment of several common and uncommon skin diseases. Psoralens can be administered orally or applied topically in the form of solutions, creams or baths with subsequent UVA exposure.

Historical Aspects

Topical application of extracts, seeds, and parts of plants that contain natural psoralens followed by exposure to sunlight has been used as a remedy for vitiligo for thousands of years, beginning with the ancient Egyptian and Indian healers. In modern medicine, the first clinical studies in vitiligo with topical and oral psoralens were performed originally by El Mofty in 1948, and later by Lerner et al. (for references see Ref. [1]).

In 1974, it was shown that orally administered 8-methoxypsoralen (8-MOP) and subsequent irradiation with artificial UVA was a highly effective treatment for psoriasis. This new therapeutic concept was termed photochemotherapy or PUVA, [2] and its efficacy was confirmed in a parallel study. [3] Within a few years the beneficial effects of PUVA were documented worldwide. Subsequently, the use of psoralen baths and subsequent UVA exposure became increasingly popular for reasons that are detailed below. This type of treatment, termed bath-PUVA, originated in Scandinavia. [4] The effectiveness of all variants of PUVA has been widely confirmed and has profoundly influenced dermatologic therapy in general, providing treatment for a number of diverse disorders besides psoriasis (Table 266-1).

Therapy of Disease	Prevention of Disease
Psoriasis	**Polymorphous light eruption**
Palmoplantar pustulosis	Hydroa vacciniforme*
Mycosis fungoides (stages IA, IB)	Solar urticaria
Vitiligo	Erythropoietic protoporphyria*
Atopic dermatitis	Chronic actinic dermatitis*
Generalized lichen planus	
Urticaria pigmentosa	
Cutaneous graft-versus-host disease	
Generalized granuloma annulare	
Pityriasis lichenoides*	
Lymphomatoid papulosis*	
Pityriasis rubra pilaris*	
Localized scleroderma*	

*Experience is limited to a small number of patients.

TABLE 266-1 **PUVA-Responsive Diseases**

Principles of PUVA Therapy

The rationale for PUVA therapy is to induce remissions of skin diseases by repeated, controlled phototoxic reactions. These reactions occur only when psoralens are photoactivated by UVA. According to the penetration characteristics of UVA, absorption of photons is confined to the skin. However, there is also some evidence that PUVA may exert systemic effects through circulating blood cells. Clinically, PUVA-induced phototoxic reactions are characterized by a delayed sunburn-like erythema and skin inflammation.

PSORALENS Psoralens are naturally occurring tricyclic furocoumarins present in a large number of plants, but some synthetic psoralen compounds also exist. Most widely used for oral and bath-PUVA is 8-MOP (methoxsalen, xanthotoxin), which is of plant origin but is also available as a synthetic drug. 4,5', 8-Trimethylpsoralen (TMP, trioxsalen) is a synthetic compound that is less phototoxic after oral administration, but more phototoxic when used for bath-PUVA. Also 5-MOP (bergapten) is therapeutically effective by the oral route and bathwater delivery; it is less erythemogenic in oral photochemotherapy and does not induce intolerance reactions.

Psoralen photochemistry [5], [6] ***and*** [7] Psoralens intercalate between DNA base pairs without UV radiation. Absorption of photons in the UVA range results in the formation of a 3,4- or 4',5'-cyclobutane addition product with pyrimidine bases of native DNA. In the first step of this photochemical reaction, a monofunctional adduct with thymine or cytosine is formed. Some psoralens, including 8-MOP, TMP, and 5-MOP, can absorb a second photon, and this reaction leads to the formation of a bifunctional adduct with a 5,6 double bond of the pyrimidine base of the opposite strand, thus producing an interstrand cross-link of the double helix. [8] This intercalation of psoralens with epidermal DNA produces a suppression of both DNA synthesis and cell division, and it is generally assumed, although not proved, that this effect may be the therapeutic mechanism in psoriasis. However, cross-linking does not appear to be a prerequisite for the therapeutic effect, and successful PUVA treatment of other skin diseases is unlikely to be directly caused by this molecular reaction; psoralens also react with RNA, proteins, and other cellular components, and indirectly modify proteins and lipids via singlet oxygen-mediated reactions or by generating free radicals. [7] Perhaps these mechanisms contribute to the effects of PUVA in diseases that are not hyperproliferative in nature. The formation of mono- and bifunctional photoadducts in DNA results in the immediate inhibition of DNA synthesis. The interstrand cross-links are believed to be largely responsible for eliciting skin photosensitization reactions of linear psoralens such as 8-MOP. Excessive production of these cyclobutane adducts causes cell death. The events of mutation and skin carcinogenesis appear to be the consequence of photoconjugation of psoralens to DNA. Psoralens that form monofunctional adducts as well as bifunctional adducts (interstrand cross-links) can be carcinogenic because the cells surviving DNA damage and undergoing DNA replication tend to repair DNA damage through an error-prone repair process. In type II reactions, reactive oxygen species ($^1O_2$, O_2 or OH) induce the oxidation of cellular lipoprotein membrane lipids, destruction of membrane-bound cytochrome P450, and the activation of the cyclooxygenase pathway. The membrane-damaging events activate the arachidonic acid metabolism pathway, which results in an increase of secondary oxidation products that contribute to the increased synthesis of eicosanoids. Furthermore, the reactive oxygen species can directly damage DNA by generating DNA strand breaks.

Mechanisms of photochemotherapy Hypotheses about the mechanism of photochemotherapy of psoriasis are based on the fact that PUVA causes photoconjugation of psoralens to DNA and a subsequent suppression of mitosis, DNA synthesis, and cell proliferation. This would indeed suffice to revert increased cell proliferation rates in psoriasis to normal. On the other hand, PUVA downregulates certain lymphocyte and antigen-presenting cell functions, influences adhesion molecule expression, and diminishes Langerhans cell numbers within the epidermis. In addition, PUVA may affect specific cells such as lymphocytes or polymorphonuclear leukocytes. Because there is evidence that psoriasis is caused primarily by the action of blood-derived immunocytes [9], it is reasonable to speculate that PUVA therapy may possibly act by an effect on normal or abnormal immune function involving a direct phototoxic effect on lymphocytes in skin infiltrates or on an abnormal immune function. This is in keeping with the observation that several other disorders that are not hyperproliferative in nature also respond well to PUVA. PUVA can revert the pathologically altered pattern of keratinocyte differentiation markers and reduce the number of proliferating epidermal cells. Infiltrating lymphocytes are strongly suppressed by PUVA, with variable effects on different T cell subsets. PUVA is far more potent in inducing apoptosis in lymphocytes than in keratinocytes [10], which may explain the high efficacy in cutaneous T cell lymphoma (CTCL), as well as in inflammatory skin diseases. Although much is known about pathways and mechanisms in psoralen photosensitization, the interactions and relative contributions to the clearing of a specific disease are not well understood. Psoralens also stimulate melanogenesis. This involves the photoconjugation of psoralens to DNA in melanocytes, mitosis and subsequent proliferation of melanocytes, an increased formation and melanization of melanosomes, an increased transfer of melanosomes to keratinocytes, and activation and increased synthesis of tyrosine mediated by stimulation of cAMP activity.

Pharmacokinetics The important steps between the ingestion of a psoralen and its arrival at the site of action include absorption, first-pass effect, blood transportation, and tissue distribution. The absorption rate of a psoralen from the gut depends mainly on the physical characteristics of the preparation and the fat content of the concomitant food intake. Liquid preparations of 8-MOP and 5-MOP give higher and earlier peak serum levels than do crystalline formulations. In addition, peak serum levels are achieved by liquid preparations after a relatively reproducible time interval in all subjects, whereas wide time variability occurs with crystalline formulations. Before reaching the skin via the circulation, psoralens are metabolized during passage through the liver. Plasma levels of 8-MOP administered orally at different doses show a strong nonlinearity, indicating a saturable first-pass effect. The unpredictable pharmacokinetic behavior is probably due to inter- and intraindividual variations of intestinal absorption, first-pass effect, blood distribution in the body, metabolism, and elimination of the drug. Within the same individual, serum levels of 8-MOP correspond fairly well with skin reactivity, the peak of skin phototoxicity coinciding with peak serum levels. However, phototoxic responses to PUVA show large interindividual variations. A correlation between 8-MOP and 5-MOP serum levels and epidermal concentrations has been demonstrated and individuals with low maximum serum concentration usually show an unsatisfactory therapeutic result. The pharmacokinetics of 8-MOP following topical treatment depend on the method of application. 8-MOP topically applied as a 0.15% emulsion or solution leads to plasma levels comparable to those found with oral treatment if large areas of the body are treated. In contrast, plasma levels following bath-PUVA treatment of almost the total body surface are very low. Bathwater-delivered psoralens are readily absorbed in the skin but are promptly eliminated without cutaneous accumulation. [10]

UVA RADIATION UVA sources commonly used for PUVA therapy are fluorescent lamps or igh-pressure metal-halide lamps. The typical fluorescent PUVA lamp has an emission peak at 352 nm and emits approximately 0.5 percent in the UVB range. UVA doses are given in J/cm ^{2}, usually measured with a photometer with a maximum sensitivity at 350 to 360 nm. Although the action spectrum of antipsoriatic activity and phototoxic erythema peaks at 335 nm, longer wavelengths have proved equally effective for clearing psoriasis if delivered in an adequate dose to obtain an equal erythemogenic response. [11]

Photosensitivity effects of PUVA PUVA treatment produces an inflammatory response that manifests as delayed phototoxic erythema. The reaction is related to the dose of both the drug and UVA as well as to the individual's sensitivity to phototoxic reactions. Recently, it was shown that changes in the 8-MOP dose had no detectable effect on the maximum slope of the psoralen plus ultraviolet A erythema dose-response curve. Thus, 8-MOP dose changes within individuals, over a narrow but clinically relevant range, appears to significantly alter the threshold response to PUVA erythema, but not the rate of increase in erythema with increasing ultraviolet A dose. [12] PUVA erythema differs from sunburn or UVB erythema that appear after 4 to 6 h and peak 12 to 24 h after exposure. PUVA erythema does not appear before 24 to 36 h and it peaks at 72 to 96 h, or even later. PUVA erythema has a shallower dose-response curve than UVB erythema (by a factor of approximately 2) and this difference is maintained even at the point of maximum erythema. [11] Severe PUVA reactions may lead to blistering and to superficial skin necrosis. Overdoses of UVA are frequently followed by swelling, intense pruritus and sometimes by a peculiar stinging sensation in the affected skin area, possibly as a consequence of damage of superficial nerve endings. Erythema is at present the only available parameter that allows an assessment of the magnitude of the PUVA reaction with psoralens; thus, it represents an important criterion for UVA dose adjustments. [13] Pigmentation is the second important effect of PUVA. It may develop without clinically evident erythema, especially when oral 5-MOP or TMP is used; this is particularly important in the treatment of vitiligo and for the preventive therapy of certain photodermatoses. In normal skin, PUVA pigmentation maximizes about 7 days after a PUVA exposure and may last from several weeks to months. As with sun-induced pigmentation, the individual's ability to tan is genetically determined, but the dose-response curve is much steeper. A few PUVA exposures result in a much deeper tan than that produced by multiple exposures to solar radiation.

Treatment Protocols

TOPICAL TREATMENT Application of 8-MOP in creams, ointments or lotions followed by UVA irradiation is effective in clearing psoriasis but has several disadvantages. The nonuniform distribution on the skin surface induces unpredictable phototoxic erythema reactions and irregular patches of cosmetically unacceptable hyperpigmentation. Furthermore, if numerous lesions are present, the application is laborious and time-consuming and the treatment does not prevent the development of new active lesions in previously unaffected, untreated areas. Therefore, topical PUVA with psoralen creams, ointments or lotions is now used only for limited plaque psoriasis and for palmoplantar disease.

BATH-PUVA The use of bathwater delivery of psoralens is increasingly popular because it provides for a uniform drug distribution over the skin surface, very low psoralen plasma levels, and rapid elimination of free psoralens from the skin, thereby reducing the risk of accidental sunburns. Bathwater delivery of 8-MOP circumvents gastrointestinal side effects and possible phototoxic hazards to the eyes because there is no systemic photosensitization. Skin psoralen levels are highly reproducible, and photosensitivity lasts no more than 2 h. The higher incidence of unwanted phototoxicity can be prevented by a lower starting dose [50 percent of the minimal phototoxic dose (MPD)] and a more cautious dosimetry in the initial treatment phase. Originally, bath-PUVA was performed with TMP, but 8-MOP and 5-MOP are now being used as well. Bath-PUVA consists of 15 to 20 min of whole-body immersion in solutions of 0.5 to 5.0 mg 8-MOP per liter of bathwater. Irradiation needs to be performed immediately, as photosensitivity decreases rather rapidly. TMP is more phototoxic after topical application and is used at lower concentrations than 8-MOP. MPD testing for bath-PUVA must take into account that the phototoxic threshold declines during the early treatment phase, in contrast to oral PUVA. The MPD obtained with four consecutive daily determinations is approximately 50 percent of the MPD obtained with only one determination. [10] Guidelines for bath, local immersion, and other topical PUVA forms recently published by the British Photodermatology Group are based, where possible, on the results of controlled studies, or otherwise on the consensus view on current practice. [14]

ORAL TREATMENT In oral PUVA, 8-MOP is administered orally (0.6 to 0.8 mg per kilogram body weight) 1 to 3 h before exposure, depending on the absorption characteristics of the particular drug brand. Liquid drug preparations are absorbed faster and yield higher and more reproducible serum levels than microcrystalline forms. For 5-MOP the usual dosage is 1.2 to 1.8 mg per kilogram body weight. The initial UVA doses are established by either skin typing [15], [16] or by MPD testing. [13], [17] In the United States, skin reactivity is determined by the classical skin phototype scheme according to sunburn history. Therapeutic doses of UVA are then given according to an empirical scheme based on this classification [15] (Table 266-2). In Europe, dosimetry commonly relies on MPD determination. [13] The MPD is defined as the minimal dose of UVA that produces a barely perceptible, but well-defined, erythema when template areas of the skin are exposed to increasing doses of UVA. Erythema readings are performed 72 h after testing, at which time the psoralen phototoxicity reaction usually reaches its peak. The MPD test should be performed on previously nonexposed skin (e.g., buttocks). Although the MPD test is more time-consuming than phototyping, it allows for more accurate and higher UVA doses during initial treatment.

	Skin Phototype[a]	Recommended Dose (J/cm^2)
I	Always burn, never tan[b,c]	0.5
II	Always burn, but sometimes tan	1.0
III	Sometimes burn, but always tan	1.5
IV	Never burn, always tan	2.0
V[d]	Moderately pigmented	2.5
VI[d]	Blacks	3.0

[a]Types I to IV are determined by history; types V and VI are determined by physical examination (racial descent).
[b]Patients with erythrodermic psoriasis are to be classified as skin phototype I for determination of UVA dosage.
[c]Patients with natural pigmentation of these types should be classified into a lower skin phototype category if the sunburning history so indicates.
SOURCE: Adapted from Melski et al.[15]

TABLE 266-2 **Skin Phototypes**

Repeated exposures are required to clear PUVA-responsive diseases, with gradual dose increments as pigmentation develops. Lower doses quite frequently result in failure of treatment except in those diseases in which induction of pigmentation is the desired objective. In most dermatoses amenable to PUVA, the frequency of treatments is reduced after satisfactory clearing of disease, and the last UVA dose is used as a maintenance dose if maintenance treatment is

planned. The duration of this maintenance phase and the frequency of treatments depend on the particular disease being treated and its propensity to relapse.

PUVA for Psoriasis

Before the advent of oral PUVA, topical psoralen photochemotherapy was used. This may still be indicated for the treatment of resistant plaques and particularly palmoplantar lesions, in conjunction with total-body oral PUVA. In contrast, bath-PUVA therapy, with whole-body immersion in TMP or 8-MOP baths followed by total-body irradiation, does yield satisfactory results. Bathwater delivery of 8-MOP represents a useful alternative to oral PUVA; because of the higher degree of photosensitivity, the UVA dose can be kept much lower.

The effectiveness of oral PUVA in inducing and maintaining remission of psoriasis has been widely documented and confirmed by large-scale clinical trials (Fig. 266-1, Fig. 266-2, and Fig. 266-3). The first two controlled multicenter clinical trials were conducted between 1975 and 1980 in the United States [15] and Europe. [16] The results of these trials are now the standard of reference for all claims of efficacy of PUVA therapy. Both studies reported similar remission rates, but because of the different treatment schedule in the US Cooperative Clinical Trial (Table 266-3), [15] the duration of the clearing phase was twice as long as in the European study. [16] In addition, total UVA requirements in the US study were more than twice as high, and the final single doses differed by about 90 percent (Table 266-4).

TABLE 266-4 **Treatment Results**

Three studies have compared bathwater delivery of 8-MOP with oral administration. In two reports, initial doses were determined by skin typing, and treatments were given two to three times weekly. Dose increments were instituted with every treatment in one study, whereas smaller increments were given every third treatment in the other. The most recent report, in which patients were treated according to the guidelines of the standard European regimen for oral PUVA, showed the lowest incidence of treatment failures and overdose episodes. In comparison with the results obtained with oral 8-MOP, bath-PUVA showed equal clearing rates with lower numbers of exposures. [10] The greater therapeutic efficacy could be because of a higher penetration of psoralens through the abnormal stratum corneum overlying psoriatic plaques, as compared with healthy perilesional skin where phototoxicity is monitored during the therapy. The incidences of erythema and pruritus were similar or lower compared to oral therapy. Episodes of systemic intolerance such as nausea and vomiting were only recorded with oral PUVA.

As mentioned above, oral 5-MOP–PUVA represents an alternative to 8-MOP–PUVA. Psoriatic lesions are cleared with a comparable number of exposures, but 5-MOP requires significantly higher cumulative UVA doses. This difference is a result of the lower phototoxicity potential of 5-MOP and of its higher tanning activity. Nevertheless, 5-MOP–PUVA therapy seems particularly valuable because of the absence of nausea and vomiting and the lower incidence of pruritus and severe phototoxic skin reactions. [10]

Upon complete clearing, patients are often assigned to maintenance therapy, during which the frequency of treatments is gradually reduced. [18] The purpose of maintenance therapy is to achieve longer remission. Maintenance therapy recommended in the original European regimen consisted of 1 month of twice-weekly treatments, with the last UVA dose used for clearing, followed by another month of once-weekly exposures. According to other recommendations (British Photodermatology Group), [19] maintenance treatment should be considered only upon rapid relapses, because patients with a stable remission may be overtreated, and long-term risks of PUVA are related to the total cumulative phototoxic doses delivered to the skin during continuous or long-term treatment. Although PUVA has now been in use for more than 28 years, the question of whether maintenance therapy can prevent early relapses, particularly in psoriasis, remains unanswered.

Erythrodermic and generalized pustular psoriasis (von Zumbusch type) respond to PUVA (Fig. 266-3), but the time required to induce remission is considerably longer, more treatments are needed, and higher failure rates are reported, as compared to plaque or guttate varieties. Pustular eruptions of palms and soles are quite recalcitrant to treatment, regardless of whether they are true localized pustular psoriasis, nonpsoriatic palmoplantar pustulosis or pustular psoriasis, or pustular eczema. Oral PUVA alone can produce a slow but definite remission in many cases, but a considerable number of patients require adjunctive therapy for clearing. As mentioned above, the combination with topically applied 8-MOP can be beneficial, but bath-PUVA appears to be also quite effective in such cases. The addition of oral retinoids will help to clear the majority of patients (see below).

COMBINATION TREATMENTS

Topical combination PUVA has been combined with other treatment forms to improve efficacy and to reduce possible side effects. Topical adjuvant therapies with glucocorticoids, anthralin, and tar preparations, and, more recently, the combination with calcipotriol and tazarotene have yielded good results. However, adjunctive topical therapy is found unacceptable by some patients because it is considered a step backward to conventional treatment.

Methotrexate A combination of PUVA and methotrexate can reduce the duration of treatment, number of exposures, and total UVA dose and is also effective in clearing patients unresponsive to PUVA or UVB alone. [20] This combination appears to be safe if used during the clearing phase only. However, if used for long-term treatment, PUVA and methotrexate may act synergistically in the development of skin cancers. [21]

Cyclosporin Cyclosporin plus PUVA therapy and retinoids plus PUVA (RePUVA) therapy cleared widespread plaque-type psoriasis in a comparable time. However, RePUVA was significantly superior regarding the cumulative UVA dose required for clearance and the incidence of severe and early relapses. Particularly in view of possible long-term side effects (immune suppression, skin carcinogenesis), the combination of PUVA plus cyclosporin cannot be recommended. [10], [22]

Retinoids The therapeutic efficacy of PUVA therapy is dramatically increased when combined with daily oral retinoid (etretinate, acitretin, isotretinoin; 1 mg/kg) administration 5 to 10 days before the initiation of PUVA, and when this combined treatment is continued throughout the clearing phase. RePUVA was reported to reduce the number of exposures by one-third and the total cumulative UVA dose by more than one-half. RePUVA was also shown to clear “poor PUVA responders” who could not be brought into complete remission by PUVA alone. [23] The mechanism of the

synergistic action of retinoids and PUVA is unknown, but may be a result of the accelerated desquamation that optimizes the optical properties of the skin and to the reduction of the inflammatory infiltrate. As an additional beneficial effect, etretinate and other retinoids may theoretically protect against long-term carcinogenic effects of PUVA, mainly by reducing the number of exposures and by their potential cancer-protective effect. Retinoid toxicity is not a concern because the administration is limited to the clearing phase. The potential teratogenicity of retinoids represents a serious concern. For women of child-bearing age, the use of isotretinoin can be considered because contraception is necessary for only 2 months after discontinuation of therapy, in contrast to etretinate and acitretin, which require 2 years of contraception. [10]

PUVA for Cutaneous T Cell Lymphoma (Mycosis Fungoides) (See Chap. 157)

Based on the known beneficial effect of natural sunlight on early mycosis fungoides, several prospective studies evaluated the effect of photochemotherapy in this disease.

Since the first promising results with photochemotherapy in 1976 [24] (Fig. 266-4), numerous investigators from the United States and Europe have confirmed its efficacy. [25] Treatment schedules and dosimetry in photochemotherapy of CTCL are essentially the same as for psoriasis. The treatment consists of a clearing phase, a maintenance phase, and a follow-up phase without therapy. Remission should be confirmed by histologic examination of previously involved skin sites. The initial treatments are followed by maintenance consisting of two exposures per week for 1 month and one exposure per week for another month. Thereafter, therapy is discontinued and the patient monitored monthly and later bimonthly. If a relapse occurs, the patient is again subjected to a full PUVA course. Some investigators advocate permanent maintenance treatment consisting of treatments once monthly or every other month. Because the course of CTCL varies considerably from patient to patient the final answer remains to be determined. Clinical experience indicates that patients benefit most from individualized schedules. [10]

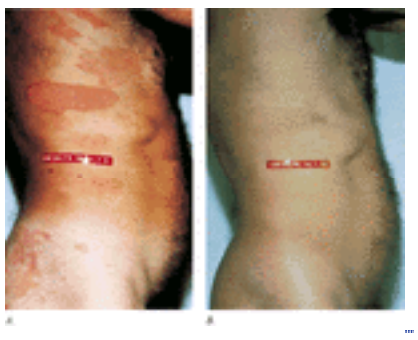

FIGURE 266-4 Forty-six-year-old patient with cutaneous T cell lymphoma (mycosis fungoides), stage IB. *A.* Before PUVA treatment. *B.* After treatment.

Relapses respond as well as the initial lesions when PUVA is resumed. Clinical remissions appear to be directly related to phototoxic destruction of the malignant infiltrate. Thus, complete clearing may be induced when the cells are confined to the epidermis and the superficial dermis and do not exceed the depth of UVA penetration into the skin. Present knowledge indicates that photochemotherapy may induce long-lasting disease-free intervals in CTCL if used in the early stages of the disease. [25] In later stages, PUVA may reduce the tumor cell burden and thus may act synergistically with other treatment. It improves the quality of life and may prolong survival when used in combination with more aggressive treatment modalities. Prolonged remissions were observed with combinations of PUVA with retinoids and with interferon a-2a. [26], [27]

Patients with tumor-stage CTCL exhibit a high rate of early recurrences, which require permanent maintenance treatment, and only the combination of PUVA with local x-ray treatment and/or systemic chemotherapy can result in complete tumor resolution. Most follow-up studies have demonstrated that the great majority of patients with early disease can be kept in remission with or without maintenance therapy for several years. Tumor-stage patients (IIB) usually experience multiple recurrences despite aggressive combination therapies and eventually die within a few years. [25] Currently, no therapeutic regimen is known to arrest the eventual progression of CTCL to tumor formation, dissemination, and fatal outcome. While PUVA therapy is very effective in inducing remission as long as the lymphoma is confined to the skin, the influence of this therapy on the natural course of CTCL and on patient survival is not yet determined. However, data from Sweden show a significant drop in the death rate of patients since the introduction of PUVA. [28]

Successful treatment of the erythrodermic type of CTCL (Sézary syndrome) has been reported with extracorporeal PUVA (photopheresis) (see below). Possible long-term hazards related to frequent PUVA treatments are probably meaningless for patients with CTCL, as compared to patients with benign conditions.

PUVA for Atopic Dermatitis (See Chap. 122)

Many patients with atopic eczema can benefit from PUVA therapy. [29] The treatment guidelines are essentially the same as for psoriasis. However, the condition is more difficult to treat, and quite often a higher number of treatments are required to clear the eczema. There is a high and early recurrence rate, requiring frequent maintenance exposures. As the average patient is young, one should hesitate to initiate long-term maintenance therapy until the possible risks of such treatment are better understood. A combination of PUVA with topical glucocorticoids appears to be superior to PUVA alone in maintaining remissions. The mechanism of action of photochemotherapy in atopic eczema is unclear; current concepts support an alteration of lymphocyte function in the dermal infiltrate.

PUVA for Lichen Planus (See Chap. 49)

In generalized lichen planus, PUVA can provide an effective alternative to systemic glucocorticoid treatment. As indicated by two studies, lichen planus proves to be more resistant to PUVA than psoriasis when treated according to a similar schedule. More exposures and higher cumulative UVA doses are required for clearing, and not all patients respond satisfactorily. An exacerbation during PUVA treatment has been reported in a few patients. In patients who have been cleared, relapses respond equally well when PUVA is resumed. Also, bath-PUVA can clear lichen planus. A combined PUVA-etretinate regimen may accelerate clearing. [30]

PUVA for Cutaneous Mastocytosis (See Chap. 163)

In cutaneous mastocytosis (urticaria pigmentosa), photochemotherapy leads to a temporary involution of skin lesions. [31] The treatment results in loss of Darier's sign, relief of itching, and flattening and even complete disappearance of cutaneous papules and macules. Surprisingly, even systemic symptoms such as histamine-induced migraine and flushing fade gradually as treatment is continued. [31] In most patients reported so far, the manifestations of the disease recurred several months after discontinuation of PUVA, but the recurrences respond as well as the original lesions. The mechanisms that lead to this response are a matter of debate. Both a decrease and no change in mean mast cell counts have been found after clinical clearing of skin lesions. [30], [31]

Despite this uncertainty concerning its mode of action, PUVA seems to be warranted in patients with urticaria pigmentosa when the disease is causing severe distress. Because the treatment of the cutaneous lesions of mastocytosis has been unrewarding with other modalities, the use of PUVA, although not curative, is at present the only therapy available to control the skin lesions in this condition.

PUVA for Miscellaneous Dermatoses

Both acute and chronic pityriasis lichenoides [30] respond to photochemotherapy, and favorable results have been reported for lymphomatoid papulosis. [32] The experience with these conditions is limited to a few anecdotal cases. In pityriasis rubra pilaris, the results are quite inconsistent. Some cases seem to respond well, others may flare, and some require combination treatment with retinoid or methotrexate therapy. Generalized granuloma annulare has been reported to clear completely, but long-term maintenance treatment was required to maintain remissions. [33] Regrowth of hair was noted in alopecia areata with either topical or systemic PUVA exposures localized to the alopecia areas. Follow-up studies of larger patient groups concluded that PUVA is generally not an effective treatment for alopecia areata. [34] The authors' experience has also not been encouraging. Localized scleroderma and pansclerotic morphea have been successfully treated with bath-PUVA and oral PUVA. [35], [36]

PUVA for Chronic Graft-versus-Host Disease (GVHD) (See Chap. 118)

An indication of increasing importance may be acute and chronic cutaneous GVDH. Because of the clinical and histologic similarities of idiopathic lichen planus and lichenoid GVHD, PUVA treatment was evaluated for the latter. [37] The beneficial effects of PUVA in lichen planus-like eruption were demonstrated in patients who had not responded to conventional immunosuppressive therapy alone. PUVA can also improve acute graft-versus-host disease. [38] Reports on the results of PUVA treatment of scleroderma-like variants of cutaneous GVHD are controversial. According to our own experience the more circumscribed, localized forms appear to respond to PUVA more rapidly, concomitantly with softening of the fibrotic, sclerotic connective tissue. However, the more widespread, disseminated lesions hardly respond to PUVA.

Unlike other conditions, PUVA may exert both local and systemic effects because an initial improvement of mucosal erosions followed by healing was observed upon treatment of chronic lichenoid GVHD with PUVA, but this could also be mere coincidence. Apparently, there is no improvement of GVHD of other organs such as the liver.

The therapeutic regimen used for the treatment of chronic GVHD is basically the same as for psoriasis. UVA doses should not be increased too aggressively, in order to avoid erythema and possible (re)activation of GVHD. In general, increase of the UVA dosage by 0.5 J/cm ^{2} at maximum after every second to fourth exposure can be recommended. Patients are exposed to UVA radiation three to four times weekly. After clearing of skin lesions, exposures are reduced according to the outlined maintenance schedule.

Because there may be an overall increased risk of secondary malignancies for all bone marrow/peripheral stem cell recipients, no matter whether they had experienced cutaneous GVHD and whether or not they have been treated with PUVA, these patients must be examined on a regular basis for the development of cutaneous malignancies.

PUVA for Vitiligo (See Chap. 90)

Vitiligo was the first disease treated with an ancient form of psoralen photochemotherapy in folk medicine in India and Egypt. PUVA in its modern form stimulates melanogenesis, melanocyte proliferation and migration, and reconstitutes the normal skin color in more than 50 percent of vitiligo patients.

TREATMENT PROTOCOLS AND RESULTS Oral 8-MOP or TMP are the photosensitizers most frequently used, followed by exposure to sunlight or artificial UVA radiation. From a large controlled clinical trial by the Harvard group, detailed information became available on different treatment schedules and efficacy of treatment. [1] Also, 5-MOP has been studied in a large trial in India, and is used in some European countries with success (Fig. 266-5) (for references see Ref. [10]). To induce repigmentation, patients need constant long-term therapy (12 to 24 months). Because oral TMP is much less phototoxic than 8-MOP, it is preferred for treatment, with sunlight as the radiation source. Treatments should

be given two or three times a week. If there is no response after 6 months or approximately 50 treatments, PUVA should be terminated. Responsiveness is defined as the development of perifollicular macules of repigmentation. If treatment is discontinued, this newly acquired repigmentation may be lost unless treatment is continued until the lesion has completely repigmented. Completely repigmented areas can be stable for a decade or more without relapse. [39]

FIGURE 266-5 Twelve-year-old patient with generalized vitiligo of 4-years duration. *A* and *C.* During the initial phases of PUVA treatment. *B* and *D.* One month after treatment (8-MOP + artificial UVA) with thrice-weekly exposures for 10 months.

Another photochemotherapeutic regimen for vitiligo, using khellin (a furanochromone) as the photosensitizer and UVA irradiation (KUVA), was introduced some years ago. This substance does not lead to phototoxic erythema and exhibits a substantially lower mutagenic activity than do psoralens. Its efficacy and failure rate in vitiligo treatment are comparable to those of PUVA. [40] The major advantage of khellin is that it does not induce phototoxic erythema and thus can be considered safe for home treatment or treatment with natural sunlight. Khellin (not available in the United States) is administered orally at a dose of 100 mg 2 h before treatment or applied topically as a 5% cream. Cream preparations of khellin in concentrations of 5% proved to be effective for topical KUVA. As with psoralens, there is evidence that drug availability and clinical response does not only depend on khellin concentration, but that the vehicle may be of critical importance. The efficacy of topical KUVA in comparison with oral PUVA or other therapeutic modalities has not been established. Patient selection appears to be particularly important in vitiligo treatment. The patients should be age 12 or over and must be available for 12 to 24 months of continuous therapy. Lips, distal dorsal hands, tips of fingers and toes, areas of bony prominences, palms, soles, and nipples are very refractory to treatment, and patients with involvement limited to these areas should be excluded. Segmental vitiligo tends to show a variable response. On average, a complete treatment course consists of at least 150 exposures. However, because of the different response in different body areas, total repigmentation is only rarely achieved, and some 30 percent of patients do not respond at all despite many months of therapy. The mechanisms by which PUVA induces repigmentation in vitiligo skin remain mostly speculative. Bearing in mind the modulating effect of UV radiation on a number of immunologic reactions, one might postulate a hypothetical suppressor cell population generated by PUVA that suppresses the stimulus for melanocyte destruction during therapy.

PUVA as Prevention Treatment for Photodermatoses (See Chap. 135)

Tolerance to sunlight can be induced in several photodermatoses with PUVA. In polymorphous light eruption, the most common photodermatosis, PUVA is the most effective preventive treatment. [41] In approximately 70 percent of patients with this condition, a 3- to 4-week PUVA course of two to three treatments per week suffices to suppress the disease upon subsequent exposure to sunlight. The initial exposure and dose increments during therapy should be performed according to the guidelines outlined above for psoriasis. PUVA has the advantage of a rapid and intense pigment induction at relatively low UVA doses that usually remain well below the threshold doses for eliciting the rash. Approximately 10 percent of patients develop typical lesions during the initial phase of PUVA, but these usually disappear when treatment is continued. The authors' treatment schedule consists of three to four treatments per week for 3 to 4 weeks in early spring; PUVA preventive treatment protects only temporarily, but subsequent sun exposures will maintain protection. However, a considerable number of patients remain protected for 2 to 3 months, even after pigmentation has faded.

The mechanisms by which phototherapy induces tolerance to sunlight are not completely clear. Hyperpigmentation and thickening of the stratum corneum may be important factors for the protective effect. However, other mechanisms may also be involved, because polymorphous light eruption does occur in dark-skinned individuals. In this context, modulations of cutaneous immune functions are being discussed, although there is presently no evidence to confirm the possible role of immune mechanisms. [41]

There is also some experience with PUVA prophylaxis of other photodermatoses. In solar urticaria, PUVA therapy appears to be the most effective preventive treatment available and is certainly better than antihistamines. Tolerance to sunlight can be increased tenfold or more after a single treatment course. The suppressive effect may last throughout the summer if the patients have regular sunlight exposures, which seem to be necessary to maintain tolerance. Problems may arise during the first PUVA exposures, because in some patients the urticaria threshold dose appears to be lower than their MPD. In these cases, careful conditioning by stepwise UVA irradiation of single quadrants of the body surface a few hours before each PUVA treatment have proved useful. Treatments with PUVA are then given during the refractory period.

Successful photochemotherapy has also been reported in occasional cases of chronic actinic dermatitis and hydroa vacciniforme. Limited experience in patients with erythropoietic protoporphyria indicates that, with a very cautious approach and in combination with beta-carotene, PUVA may increase light tolerance considerably. [42], [43]

Considerations about long-term hazards are important, especially in benign disorders such as the photodermatoses. However, extended treatment duration is usually not required in polymorphous light eruption, but in solar urticaria and chronic actinic dermatitis, prolonged therapy may be necessary. There exist no ready-to-use schedules for these latter

conditions and PUVA is usually just one part of the management. [42]

PUVA in HIV-Infected Patients

The use of phototherapy and photochemotherapy in HIV-infected patients with skin diseases is controversial. First, both therapies can induce systemic immune suppression and may modify the immune status of the patient in a way that would lead to a worsening of HIV disease. [44] Second, both UV radiation and psoralen photosensitization were demonstrated to activate the HIV promoter, which could boost viral gene transcription and, eventually, virus production. [45] In addition, HIV-induced immune suppression could support an accelerated development of skin carcinomas in UVB- or PUVA-treated patients. With oral PUVA, treatment of psoriasis did not induce progression of HIV disease or an increase in side effects. [46], [47] It was concluded from these studies that PUVA may be safe for HIV-positive patients with psoriasis. Theoretical modeling of the UVB- and PUVA-induced HIV promoter activation in human skin indicated that UVB is more likely than PUVA to activate viral transcription in vivo. [48] Data from long-term observations are currently awaited. Thus, it is presently impossible to advocate the use of PUVA in (HIV-) immunosuppressed individuals in general, but major hazards are unlikely. The available data and theoretical considerations indicate that UVB is more likely to be a hazard than PUVA in an HIV-infected population. [48], [49]

Side Effects and Toxicity of PUVA

ACUTE SIDE EFFECTS The side effects of PUVA include drug intolerance reactions as well as side effects of the combined action of psoralens plus UVA radiation. Oral 8-MOP (0.6 to 0.8 mg/kg) has a high incidence of nausea (30 percent of patients) and vomiting (10 percent of patients), and this may occasionally require discontinuation of the treatment. These side effects are more common with liquid preparations than with crystalline preparations, probably because of higher psoralen serum levels. With 5-MOP, nausea is almost absent, even with doses of up to 1.8 mg/kg body weight. [8] Undesired acute effects of the combined action of psoralens and UVA can range from an increased delayed erythema reaction to severe burns with blistering. Some patients experience persistent pruritus during PUVA treatment, particularly after slight UVA overdosage, and in rare cases a stinging pain may develop in circumscribed areas. The mechanism is unknown, and the symptoms are unresponsive to antihistamines. These complaints usually subside upon continuation of treatment. Overdosage phenomena occur mostly in body areas not usually exposed to natural sunlight. Careful observation of the criteria for dosimetry can minimize these side effects to acceptable levels. The danger of overdosage is much less with 5-MOP. Very rare side effects of PUVA include polymorphous light eruption-like rashes, acne-like eruptions, subungual hemorrhages caused by phototoxic reactions of the nail beds, and occasional hypertrichosis of the face. These are transient and disappear when treatment is discontinued. Single case reports include exacerbation of systemic lupus erythematosus and bullous pemphigoid during photochemotherapy.
LABORATORY DATA Analysis of laboratory data in several large-scale studies showed no significant abnormal findings in patients receiving PUVA over prolonged periods of time. [15], [16], [50] Serial laboratory examinations performed over a period of several years have not revealed any substantial evidence for an impairment of hepatic function. [18] Liver biopsies after 1 year of therapy did not reveal signs of hepatotoxicity. [51] No evidence exists suggesting impairment of renal function. [15] Several large-scale studies have negated a possible relation between PUVA therapy and the occurrence of antinuclear antibodies. [52]
POTENTIAL LONG-TERM RISKS OF PUVA
Chronic actinic damage Repeated phototoxic injury to the skin can be expected to result in cumulative actinic damage regardless of whether it is induced by sunlight, artificial UV radiation, or PUVA. Chronic exposure to PUVA may produce changes in the skin that resemble photoaging and that may add to the injury induced by sunlight. PUVA lentigines and generalized PUVA lentiginosis result from repeated and prolonged treatment and are commonly associated with high cumulative doses of UVA and a large number of treatments. [16] They exhibit irregular borders and show uneven pigmentation. So far, no increased risk of cutaneous melanoma associated with these lentigines has been recorded, but the cosmetic effect may be quite disturbing.
Carcinogenesis Cutaneous carcinogenicity is the major concern about long-term and repeated PUVA treatment associated with high cumulative UVA doses. In laboratory animals, 8-MOP and 5-MOP have been unequivocally shown to induce skin cancer at levels of drug and UVA irradiation comparable to those used in PUVA therapy. [53], [54] Obviously the risk is related to DNA damage, but PUVA-induced downregulation of immune responses may play an additional role. Although animal studies provide important evidence for the carcinogenic potential, in the human situation this risk has to be assessed against the potential therapeutic benefit. All long-term follow-up studies suffer from the fact that patients are likely to have been exposed previously to other carcinogenic treatments such as ionizing radiation, UVB therapy methotrexate, tar, or arsenic. Correct adjustment for all these factors may be quite problematic, particularly because accurate data are often missing. In PUVA patients, the risk of squamous cell carcinoma, but not of basal cell carcinoma, is significantly increased in comparison with matched controls and the magnitude of the increase appears to be dose-dependent. [21], [54] However, there is uncertainty about PUVA being the sole factor—many of the affected patients had previous exposure to excessive sunlight and to treatments with carcinogenic potential, including arsenic, UVB, and antimetabolite therapy. [55] According to a single study, male genitalia appeared to be particularly susceptible to carcinogenic stimuli of PUVA in patients previously treated with tar and UVB, [56] but the risk seemed not to be increased if only PUVA was used. [57] In a retrospective study from France comprising 5400 patients treated between 1978 and 1998 no case of genital skin cancer was found, despite the fact that the genital area had not been protected during UVA exposure and this makes it unlikely that genital shielding may be indeed absolutely necessary. [58] Carcinogenicity of 5-MOP–UVA therapy in PUVA-treated patients is unknown but 5-MOP has shown a similar activity to 8-MOP in in vitro photomutagenicity studies and photocarcinogenicity studies in mice. Only a few anecdotal cases of malignant melanoma have been observed in long-term PUVA treated psoriatics, and no increased risk of melanoma was found in all large-scale studies. However, Stern et al. reported from the cohort of 1380 patients enrolled in the PUVA Follow-up Study (16-Center Study) that since 1975, 23 patients have developed 26 invasive or in situ cutaneous melanomas. Beginning 15 years after first exposure to PUVA, an increased risk of melanoma was observed in their cohort of PUVA-treated patients. [59], [60] This risk was greater in patients exposed to high doses of PUVA and appeared to be increasing with the passage of time. The conclusions of this study have been questioned, [61] and the authors now agree [60] that the observed

risk of melanoma does not represent an absolute contraindication to PUVA or that PUVA therapy should be abandoned. Rather, the risks of both melanoma and squamous cell carcinoma in PUVA should be weighed against the substantial efficacy of PUVA and the risks of other therapies. [61] Perhaps PUVA has been treated unfairly. Its long-term risks have been subject to much greater scrutiny than the risks of other therapies advocated for severe psoriasis, such as methotrexate and, particularly, immunosuppressive therapies such as cyclosporine; these therapies greatly increase some cancer risks in populations who are less likely to have substantial exposures to known cutaneous carcinogens such as sunlight, or who have attributes such as fair skin, than are patients with severe psoriasis. Early detection through careful long-term follow-up, perhaps lifetime monitoring and education of patients exposed to PUVA, may help to reduce the long-term morbidity and mortality associated with PUVA therapy. Nonetheless, the potential risk of melanoma has to be taken seriously as have the guidelines for PUVA. The cumulative dosages must be kept low and therefore UVA-saving aggressive regimens without prolonged maintenance therapy may be safer than continuous nonaggressive regimens. [62] Based on a recent study of 944 Swedish and Finnish patients, [63] bath-PUVA with TMP seems to bear no relevant risk of carcinogenesis. In addition, no association between cutaneous cancer and 8-MOP bath-PUVA was found in 158 Finnish psoriatic patients. [64] Although hard to understand, these data on the long-term safety of bath-PUVA are encouraging, but premature conclusions should not be drawn. It is important to compare the risks of PUVA with UVB phototherapy. Animal studies show that UVB is carcinogenic but mathematical model studies indicate that the observed risk of squamous cell carcinoma is much higher with PUVA than the calculated risk with UVB. [65] There is a recent trend toward the use of narrowband UVB. The carcinogenic risk of this source in comparison with PUVA is unknown, and it will be crucial to monitor its long-term effects in psoriatics.

Ophthalmologic effects Despite data from animal studies, which indicate a risk of premature cataract formation, clinical evaluation shows no increase in lens opacities, even in patients who neglected careful eye protection. Several studies have shown no indication that psoralen-induced cataracts occur in patients undergoing long-term photochemotherapy. The majority of prospective studies did not report an increased incidence of lens opacities in patients who used eye protection following psoralen ingestion. [66] Obviously, there is no risk with topical or bath-PUVA.

Patient Selection and Contraindications

In view of the potential long-term hazards, the assignment of patients to photochemotherapy should be based on consideration of the risks and the benefit for the individual patient. If only a short-term course of therapy is planned, as, for example, in prevention of photodermatoses, the benefit outweighs the risk. In the treatment of a malignant condition such as CTCL, long-term risks may be meaningless because other treatment options bear the risk of even greater long-term toxicity. The major concerns relate to long-term treatment of psoriasis because this condition represents by far the most common indication for PUVA. As long as the risks of long-term use are not clearly known, careful patient selection appears to be mandatory. Guidelines of care have been published by the American Academy of Dermatology. [17]

Photochemotherapy should not be used during pregnancy, and women should be advised to use contraceptive measures while on PUVA. This precaution is only for reasons of absolute safety as there exists no evidence that either 8-MOP alone or photochemotherapy is teratogenic, as confirmed in a retrospective study in 256 deliveries among the cohort of the 16-Center PUVA Follow-Up Study. [67] However, it has to be emphasized that RePUVA bears the risk of retinoid teratogenicity.

Severe impairment of hepatic and renal functions is usually considered a contraindication to PUVA because metabolism and excretion of psoralens may be inadequate. PUVA is also contraindicated in patients with known light-aggravated or light-induced diseases such as lupus erythematosus, porphyria (but as mentioned above, light tolerance can be induced by PUVA in erythropoietic protoporphyria), and xeroderma pigmentosum. Pemphigus and bullous pemphigoid may be exacerbated by PUVA. Patients with chronic actinic damage and a history of skin cancers may be at higher risk for the development of new cancers. Previous arsenic intake and previous treatment with ionizing radiation also seem to increase the risk of nonmelanoma skin cancers. Immunosuppressed patients should probably not receive PUVA, although this is not yet clearly defined. As outlined above, PUVA can be used in HIV-positive patients. Cataracts and aphakia are not real contraindications if adequate eye protection is guaranteed.

Conclusions and Perspectives

Photochemotherapy is a highly effective treatment for several dermatologic diseases, but it does not lead to permanent cure in most conditions. An exception may be vitiligo, in which PUVA-induced repigmentation may last for many years, or even a lifetime. Although there exists comprehensive clinical experience documenting PUVA's short-term safety when used according to standardized methods, as outlined in this chapter, the risk of potential long-term sequelae has still not been clearly determined. Thus, strategies for treatment should take into account whether other forms of therapy are available that carry a lower risk but are equally effective. Risk-versus-benefit decisions should weigh potential long-term hazards against severity and morbidity of the disease and therefore will vary with the disease being treated. In early stages of mycosis fungoides, the risk-versus-benefit ratio will clearly be in favor of PUVA as an alternative for other treatment options. For polymorphous light eruption, the number of treatments each year necessary to provide relief of discomfort is so small that long-term risks may be negligible. The major concern relates to the treatment of severe psoriasis, as this is the most common indication for PUVA that may require repeated long-term therapy. In many patients with disabling psoriasis, PUVA is more effective than topical therapy, the Goeckerman regimen, or UVB therapy not only in clearing of disease but also in maintaining remission. Regarding chronic toxicity, PUVA appears to be a most valuable alternative to methotrexate and other antimetabolites. Treatment with broadband and narrowband UVB also causes actinic skin changes, alterations of the immune system, and skin carcinomas; and apart from the fact that UVB is not equally effective in all forms of psoriasis, there is no convincing evidence at present that it may be safer than PUVA for long-term use.

Severe widespread psoriasis is a devastating disease that may result in disruption of professional, social, and private life. After almost 28 years of experience with PUVA for the treatment of psoriasis, it has become evident that this therapy offers innumerable patients the chance to resume a normal life. For disabling psoriasis the choice of therapies lies not

between risk and safety but among alternative choices of action (methotrexate, cyclosporine, and UVB), none of which is absolutely safe. [61]

EXTRACORPOREAL PHOTOCHEMOTHERAPY (PHOTOPHERESIS, ECP)

Since 1987, ECP, consisting of extracorporeal irradiation of blood fractions in the presence of 8-MOP, has been used for the palliative treatment of erythrodermic CTCL. [68] The initial success was confirmed by subsequent clinical trials so that ECP can be considered a valuable treatment alternative for erythrodermic lymphoma. [69]

ECP has a very low side-effect and toxicity profile, which has led to its evaluation for other indications. The rational basis for the additional treatment spectrum was supported by a number of experimental studies evaluating the effect of ECP on the immune system. [70], [71], [72] and [73] Under the assumption that ECP can suppress pathogenically relevant T cell clones, a number of studies have been performed in order to evaluate the efficacy of ECP in other inflammatory diseases where autoreactive T cells play a causative role. Initial studies have been performed in systemic sclerosis, pemphigus vulgaris, rheumatoid arthritis, and, to a lesser extent, in psoriatic arthritis, systemic lupus erythematosus, dermatomyositis, atopic dermatitis, and inflammatory bowel disease. Recent studies show that ECP may have a considerable impact on the course of acute and chronic organ graft rejection as well as GVHD after allogeneic bone marrow transplantation.

Treatment Method

The procedure involves passage of blood fractions from one arm vein through a photopheresis machine and back. In the machine, subsequent separation of plasma and the white blood cell fraction (buffy coat, peripheral blood mononuclear cells) from the red cell fraction of nonnucleated cells takes place. The latter is returned to the patient without further treatment. Dissolved 8-MOP, as described by Knobler et al., [74] is added to the heparinized plasma and buffy coat fraction as it flows through an UVA exposure system before it is returned to the patient. This treatment is, on average, repeated on 2 successive days with 2- to 4-week intervals.

Treatment Results

CUTANEOUS T CELL LYMPHOMA Erythrodermic CTCL (Sézary syndrome) was the first disease for which ECP was evaluated. Its efficacy was confirmed in several clinical studies, which led to FDA approval for use of ECP for the palliative treatment of this lymphoma type. In the original study by Edelson et al., [68] 27 of 37 patients responded either with a partial or a complete remission. In a follow-up study in which ECP was compared to historical controls ECP appeared to increase survival from a median of 30 months to over 66 months. Subsequent reports confirmed the initially observed efficacy. [69] These studies report grossly a response rate in up to 75 percent of the patients with complete remissions of up to 25 percent and no response in 25 percent. Based on clinical, immunologic, and laboratory data, the attempt was made to better characterize those patients that are more likely to respond to ECP. A normal CD4/CD8 ratio, a normal absolute count of CD8-positive cells in the peripheral blood, presence of Sézary cells and a malignant clone, as well as short disease duration, appear to be predictors of satisfactory therapeutic response. [69] Because a subpopulation of Sézary syndrome patients does not sufficiently respond to ECP, ongoing studies are evaluating possible synergistic effects with other treatments such as interferon-a, methotrexate, and total-skin electron-beam therapy. [69], [75], [76]

PEMPHIGUS VULGARIS Rook et al. [77] first reported on a therapeutic response in three of four patients with drug-resistant pemphigus vulgaris. Significant remissions with concomitant substantial reduction in glucocorticoid and immunosuppressive therapy was obtained. So far six cases have been treated apparently successful with ECP, [78], [79] but controlled randomized trials have not yet been performed.

PROGRESSIVE SYSTEMIC SCLEROSIS Early T lymphocyte infiltration of affected organs as well as the presence of autoreactive antibodies supports the autoimmune concept of progressive systemic sclerosis (PSS), indicating that photopheresis may be useful in PSS. Following a pilot study in two patients with refractive, rapidly progressive disease, a single-blinded, randomized eight-center trial was conducted, comparing photopheresis to D-penicillamine. Seventy-nine patients with systemic sclerosis of recent onset (mean symptom duration, 18 years) and documented progressive cutaneous involvement 6 months before the study entered this trial. In the 10-month study period ECP was shown to be significantly superior to increasing doses of D-penicillamine, both in reversing skin changes as well as stopping progression of skin involvement. Although a number of questions remain to be answered, ECP may have a beneficial effect, at least on the cutaneous manifestations of PSS. [80], [81] and [82]

RHEUMATOID ARTHRITIS In a pilot study on seven patients with rheumatoid arthritis resistant to conventional therapy, improvement was noted in four patients after 4 months of treatment. This was taken as evidence that it may be unlikely to represent a placebo effect not uncommon in patients with this disease. [83] The observation that all patients who did respond experienced a relapse several months after discontinuation of ECP could support this assumption, suggesting that ECP may be of short-term benefit in selected patients with rheumatoid arthritis. However, no confirmatory report has appeared since.

TRANSPLANTATION AND GRAFT-VERSUS-HOST DISEASE ECP may prove to be important in organ transplantation. Small clinical trials have demonstrated that ECP can be a valuable adjunct in the control and prevention of heart transplant rejection with or without immunosuppressive therapy. [84] ECP significantly decreased cardiac rejection episodes without increasing the incidence of infections. [84] Likewise, beneficial effects have been reported in studies on patients with other organ transplants [85], [86], [87] and [88] and graft-versus-host disease, suggesting that ECP may have increasing indications in the field of transplantation medicine. [89], [90]

SYSTEMIC LUPUS ERYTHEMATOSUS Ten patients who met the criteria of the American Rheumatism Association (ARA) for lupus erythematosus were treated with ECP. [91] For the purpose of this pilot study, only patients whose systemic involvement was not life-threatening, who had mild to moderate disease adequately controlled with conventional treatment, and who experienced repeat consecutive flares of disease activity upon attempted reduction and/or elimination of medication, were included. In this uncontrolled study, response to treatment was significant in seven of eight patients completing the trial. The clinical activity score decreased significantly, but the laboratory abnormalities did not change. Clinical improvement of arthritis and cutaneous manifestations was noted. ECP can thus also be used in patients with

known photosensitivity without inducing an exacerbation.

Perspectives

Extracorporeal photochemotherapy was originally conceived for the treatment of cutaneous T cell lymphoma but there are indications that this treatment modality may have beneficial effects in a number of other conditions, particularly in graft-versus-host disease after allogeneic bone marrow transplantation. The data available so far is based on mostly uncontrolled studies and thus remains controversial. Advances in understanding the mechanisms involved have been made, but additional work leading to a better understanding of these is desirable.

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) aims to destroy the desired target selectively, thereby avoiding or minimizing damage to vital structures. The photodynamic reaction consists of the excitation of photosensitizers (mainly porphyrins) by visible light in the presence of oxygen, resulting in the generation of reactive oxygen species, particularly singlet oxygen. These reactive oxygen species mediate cellular and vascular effects depending on the tissue localization of the photosensitizer. This results in a direct or indirect cytotoxic effect on the target cell. [92] In dermatology, PDT has been used effectively for precancerous and malignant conditions such as actinic keratosis, basal cell carcinoma, Bowen's disease, and superficial squamous cell carcinoma, as well as for inflammatory dermatoses such as psoriasis or localized scleroderma.

Historical Aspects

In 1904, von Tappeiner coined the term *photodynamic therapy* for the oxygen-dependent destruction of tissue after photosensitization and subsequent irradiation with visible light. [93] Together with Jesionek, a dermatologist, he treated human skin tumors effectively by applying a 5% solution of eosin dye followed by exposure to lamps or sunlight. [94] The first report on successful PDT in psoriasis with oral and intramuscular porphyrin administration appeared in 1937. [95] Systemic administration of hematoporphyrin derivative (HpD) and subsequent laser irradiation became the standard of PDT because these substances showed a relatively selective accumulation in different tumor tissues, and thus led to selective cell destruction. Meanwhile, PDT found its way into the treatment of a variety of internal malignancies and some skin conditions. The main disadvantage of systemic PDT is prolonged cutaneous photosensitivity that may last for several weeks after one single treatment. PDT-treated patients are thus at risk of severe accidental phototoxic reactions. To avoid generalized photosensitivity, the interest has now focused on the topical application of sensitizers or on the local induction of endogenous porphyrin synthesis in the target tissue.

Principles of Photodynamic Therapy

PHOTOSENSITIZERS The ideal photosensitizer for PDT in dermatology should meet the following criteria: (1) chemical purity; (2) high singlet-oxygen quantum yield; (3) significant light absorption at wavelengths that penetrate the skin sufficiently deeply; (4) high tissue selectivity; and (5) efficacy after topical application. Photofrin, a mixture of several HpD ethers and esters, has a low selectivity to skin tumors and leads to long-lasting photosensitivity; consequently, it is not ideal for dermatologic use. In contrast, “endogenous” sensitizers such as 5-aminolevulinic acid (ALA), a metabolite of heme biosynthesis, induce the synthesis of the actual photosensitizer (protoporphyrin IX) in the target tissue. [96] In this case, the concentration of the photosensitizer depends on the metabolic status of the diseased tissue. ALA was approved by the FDA in 1999, in combination with blue light for the treatment of actinic keratoses. In Europe, ALA-methyl ester has also been registered for actinic keratoses and superficial basal cell carcinomas. Most of the photosensitizers generate singlet oxygen with a quantum yield between 5 and 20 percent. A high quantum yield means that less sensitizer is required in the target tissue to induce sufficient PDT effects. The absorption maxima of the current sensitizers range from 600 to 700 nm. In this range, light penetration in tissue is only up to 3 mm, limiting PDT to superficial tumors, unless interstitial light propagation is used. A high selectivity for sensitizer accumulation in target tissue is necessary to avoid damage to surrounding normal tissue, and this is particularly important when larger areas are treated (e.g., actinic keratoses). So far, only ALA or ALA-methyl ester shows reasonably high selectivity after topical application. The ratio of porphyrin induction in skin tumors to the surrounding tissue is higher than 10:1. [97]
LIGHT SOURCES AND DOSIMETRY Light penetration into skin increases with longer wavelengths (? =1100 nm). To match the absorption maxima of porphyrin-based photosensitizers, wavelengths around 630 nm are necessary. Therefore argon-pumped dye lasers (? = 630 nm) represent appropriate irradiation sources. However, these laser systems are quite expensive and require regular maintenance. Meanwhile, laser diodes that are smaller, more powerful, and less expensive are replacing these sources. In contrast to other applications, dermatologic applications need no fiberoptics for endoscopic treatment, thus simpler incoherent light sources represent a valuable alternative. With regard to therapeutic results, there is no difference between coherent and incoherent light. New lamps, fluorescent lamps or light-emitting diodes (LEDs), are commercially available with appropriate red or blue light emission designed for treatment of large surface areas. A standardized light dosimetry for PDT does not exist. Dosimetry depends on the photosensitizer used and on the condition to be treated. For PDT of skin tumors and actinic keratoses, light doses of 100 to 150 J/cm ^{2} are necessary. With current incoherent light sources, the treatment duration is about 15 to 20 min. For treating inflammatory dermatoses (psoriasis), lower doses will suffice because the goal appears not to be tissue destruction but rather sublethal cell damage or modulation of cellular functions.
MECHANISM OF ACTION PDT-induced effects are mediated by photooxidative reactions. During irradiation, the photosensitizer absorbs light (energy) and is converted to an excited (triplet) state. The energy can then be transferred to molecular oxygen (type II photooxidative reaction), resulting in the generation of reactive oxygen species, mainly singlet oxygen. The biologic effects can be divided into primary cellular and secondary vascular damage. With HpD, early visible damage consists of cell membrane defects as a consequence of lipid peroxidation with consecutive cell lysis. Depending on the intracellular localization of the photosensitizers, damage to subcellular structures such as mitochondria, lysosomes, or endoplasmic reticulum also occurs, whereas DNA is not a primary target. Besides these direct effects, which probably play a key role in topical PDT, vascular effects after systemic application of photosensitizers appear to be the decisive event for the treatment of solid tumors. These effects consist of vasoconstriction, blood stasis, and

thrombosis of tumor vessels leading to tumor ischemia and subsequent necrosis. [98]

PDT in Dermatology

Table 266-5 lists the potential indications for PDT. In contrast to other organs, the skin can be sensitized by either intravenous administration or direct topical or intralesional application of the sensitizers.

Oncologic	Nononcologic
Actinic keratosis	Psoriasis vulgaris
Bowen's disease	Localized scleroderma
Superficial basal cell carcinoma	HPV-associated dermatoses
Nevoid BCC syndrome	Epidermodysplasia verruciformis
Keratoacanthoma	Verrucae vulgares
Superficial squamous cell carcinoma	Condylomata acuminata
Kaposi's sarcoma	
Cutaneous metastases	
Cutaneous T cell lymphoma	

TABLE 266-5 **Potential Indications for Photodynamic Therapy**

SYSTEMIC PHOTODYNAMIC THERAPY So far, HpD and porfimer sodium are the best-studied sensitizers. PDT following systemic application of these dyes has been performed in both skin cancers and inflammatory dermatoses. However, the treatment protocols (dose of sensitizer, time interval between drug application and irradiation, use of laser versus incoherent light, wavelengths, etc.) differ significantly. Thus a comparison of efficacy is difficult. Phase III studies comparing dermatologic PDT with standard therapeutic procedures do not yet exist.

Systemic PDT for oncologic indications Systemic PDT with porfimer sodium for Bowen's disease is very effective. [99] In contrast, squamous cell carcinomas (SCCs) respond less well to systemic PDT, with recurrence rates of up to 50 percent being reported within 6 months. Systemic PDT for basal cell carcinomas (BCCs) with HpD was first employed by Dougherty in 1981. [100] Feyh treated 67 BCCs with HpD and an argon-pumped dye laser. Only three recurrences were reported in the 4.5-year follow-up period. [101] Schweitzer and Visscher treated five patients with AIDS-associated Kaposi sarcoma with porfimer sodium and red light in the form of surface and interstitial illumination. Complete or partial remission of cutaneous or mucosal nodular lesions was observed in 54 of 92 lesions. [102] Almost the same results were presented later for 8 patients with 83 Kaposi sarcoma lesions. Although the remission rate was 60 to 70 percent, the cosmetic result was rated unsatisfactory because of extensive hyperpigmentation and scarring. [103] Benzoporphyrin-derivative monoacid ring A (BPD-MA) also offers a significantly shorter cutaneous photosensitization time than porfimer sodium (<72 h), [104] and is currently being investigated for BCC.

Systemic PDT for nononcologic indications As early as 1937, Silver reported the use of PDT in the treatment of psoriasis. Six patients received HpD intramuscularly and orally on consecutive days and were irradiated with UV light. After 2 weeks, an improvement of psoriasis plaques was noted. [95] Better results were reported by Weinstein et al. when red light was used instead of UVA. [105] Systemic PDT with BPD-MA is currently being investigated for its efficacy in psoriasis. In a phase I study (using 8 mg/m ^{2}, 690 nm, 60 J/cm ^{2}), clinical severity scores of psoriatic plaques dropped from 4.0 to 2.5 in 15 patients after five weekly injections and consecutive irradiation. [106]

TOPICAL PDT Topical application of photosensitizers avoids generalized cutaneous photosensitivity. Unfortunately, because of their high molecular weight (˜900 g/mol), porphyrins cannot penetrate into the skin in sufficient amounts. In contrast, small hydrophilic molecules such as ALA penetrate well into the skin, particularly if it is covered by a parakeratotic layer as is the case in some epidermal tumors or in psoriasis. [96] ALA application selectively induces the production of intracellular porphyrins in epidermal cells and the pilosebaceous unit. These structures synthesize porphyrins to a much higher amount than fibroblasts, myocytes, or endothelial cells. [96], [107] Epithelial tumors synthesize much higher amounts of protoporphyrin IX than the surrounding tissue and can therefore be destroyed without damage to healthy skin [96], [108], [109] (Fig. 266-6). Topical ALA-induced photosensitivity is restricted to the target area. Systemic porphyrin induction is not observed following topical application. [110] The only significant acute side effect of ALA-PDT is a stinging pain during and shortly after irradiation.

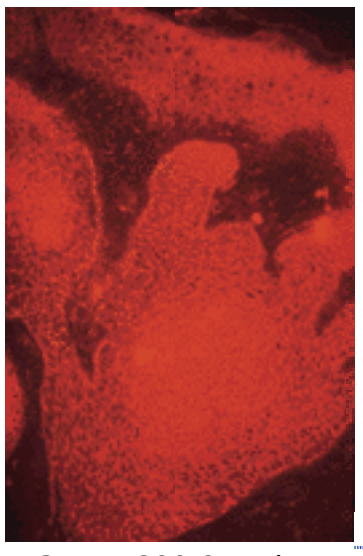

FIGURE 266-6 Endogenous porphyrin fluorescence after topical application of 20% ALA formulation to a solid basal cell carcinoma. Twelve hours after ALA application, there was strong fluorescence of the tumor-bearing areas, and weak to no fluorescence of the surrounding dermis. Also visible is fluorescence in the overlying epidermis (marked by *white arrows*). (*From Szeimies et al.,* [109] *with permission.*)

Topical PDT for oncologic indications [111], [112], [113], [114], [115] ***and*** [116] The experience with treatment of epithelial cancers and precancerous conditions with PDT so far reported in the literature suggest that actinic keratoses, [111], [112] Bowen's disease [114] (Fig. 266-7), superficial BCCs, [115], [116] and initial SCCs (tumor thickness less than 2 mm) are the only tumors that are suitable for topical ALA-PDT with curative intent. For this purpose, ALA is applied topically using 20% in

proprietary cream base formulations with occlusion for 4 to 6 h. Afterwards light is applied; using red light, the light intensity is in the range of 100 to 150 mW/cm ^{2} and the fluence 100 to 150 J/cm ^{2}. For actinic keratoses, topical application of a 20% ALA solution for 14 to 18 h followed by irradiation with blue light at 417 nm for 1000 s (10 J/cm ^{2}) resulted in response rates of 86 percent and 81 percent. It is important to note that neither cutaneous metastases of malignant melanoma, pigmented BCC, nor sclerodermiform variants of BCC respond to ALA-PDT, [117], [118] probably because of insufficient porphyrin synthesis and penetration of light. [109] Tumor thickness appears to be crucial and should not exceed 2 to 3 mm when a single treatment session is planned. Treatment efficacy can be enhanced by repeated treatment sessions. [115], [118]

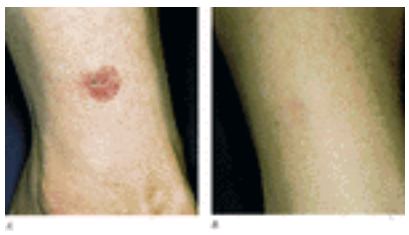

FIGURE 266-7 Bowen's disease. *A.* Lesion located on the right lower leg. *B.* Twelve months after topical ALA-PDT [10% ALA ointment, application for 4 h, irradiation with Argon-pumped dye laser (175 mW/cm ^{2}; 180 J/cm ^{2})], clinically and histologically there were no signs of tumor residue.

CTCL (mycosis fungoides) also responded in experimental trials to ALA-PDT after several treatment sessions. [117] Controlled investigations are currently not available, and, as with PUVA treatment of single lesions, this treatment would not be expected to prevent the appearance of new lesions in other areas.

Topical PDT for nononcologic indications [119], [120], [121], [122] ***and*** [123] Few data are available regarding the treatment of inflammatory skin conditions. Weinstein and co-workers treated psoriatic plaques once weekly using 10, 20, or 30% ALA and dye laser irradiation (10 to 150 J/cm ^{2}). The best results were obtained with 30% ALA and repeated treatments. [119] Boehncke compared the efficacy of ALA-PDT with dithranol in three patients with chronic plaque-type psoriasis with thrice weekly treatments using 10% ALA ointment for 5 h and an incoherent light source (25 J/cm ^{2}). In one patient, the PDT-treated side cleared 1 week earlier than the side treated with dithranol. [120] Karrer studied the efficacy of topical ALA-PDT in five patients with localized scleroderma, in whom conventional therapies had failed. They were treated by application of a gel containing 3% ALA followed by irradiation with red light (40 mW/cm ^{2}, 10 J/cm ^{2}). The treatment was performed once or twice weekly for 3 to 6 months. In all patients, the therapy was highly effective for sclerotic plaques as measured by a quantitative durometer score and a clinical skin score. The only side effect was a transient hyperpigmentation of the treated lesions. [120] Other possible indications for topical PDT are human papilloma virus (HPV)-associated skin diseases. The advantages of PDT for these conditions are the lack of a laser plume, in contrast to CO_2 laser treatment, and perhaps a lower recurrence rate as a result of eradication of subclinical lesions. Complete remission of anogenital condylomata acuminata was achieved in four of seven patients after topical ALA-PDT (20% ALA, 14-h incubation, argon dye laser 100 J/cm ^{2}). [121] Control of disease by topical ALA-PDT was achieved in multiple skin tumors in a patient with epidermodysplasia verruciformis, although in situ hybridization still revealed HPV type. [122] Recently, in a double-blinded, randomized trial, repetitive ALA-PDT with 20% ALA cream and red light (50 mW/cm ^{2} and 70 J/cm ^{2}) resulted in 56 percent clearance rate versus 42 percent in the sham-irradiated placebo group. [123]

Perspectives

The efficacy of PDT in the treatment of superficial neoplastic skin lesion, particularly actinic keratoses, Bowen's disease, and superficial BCCs, has been sufficiently documented. PDT may also find a place in the treatment of selected patients with inflammatory dermatoses. Nonetheless, the limitations of PDT, including its topical variant, have to be kept in mind. Crucial parameters are the depth of the penetration of light, as well as of the sensitizer, into the skin. Moreover, for the treatment of skin cancers with metastatic potential, patients need to be selected carefully, and histologic diagnosis and determination of tumor thickness are a prerequisite. There is still need for controlled studies and for standardized treatment protocols.

Nonablative Dermal Remodeling
Ultraviolet Lasers for the Treatment of Psoriasis and Vitiligo
DIAGNOSTIC APPLICATIONS: CONFOCAL SCANNING LASER MICROSCOPY

REFERENCES

Lasers in medicine defy simple characterization. New technology and new surgical and diagnostic applications for lasers are steadily being conceived. Lasers serve goals as diverse as revascularization of ischemic cardiac tissue, precise sculpting of the cornea, pulverizing urinary stones, and imaging cancers in vivo. Dermatology has been deeply affected by lasers, using them as precise and tissue-selective surgical tools.

ELECTROMAGNETIC RADIATION AND THE LASER BEAM

For centuries, physicists debated the nature of light. While Maxwell and his English colleagues argued that visible light behaved as particles, Fresnel and the French physicists maintained that light behaved as a wave, accounting for phenomena such as diffraction, constructive and destructive interference. Both views are correct, a “duality” now pervasive in quantum physics. Proof that electromagnetic radiation (EMR) travels as discrete particles, or *quanta,* of energy came when Einstein demonstrated that light can liberate single electrons off of a metal foil plate. This led to the present view that all matter and energy—everything in the universe—is quantized. EMR is now conceptualized as a fundamental form of energy, propagating through space at a constant speed *c*, as a wave but comprised of discrete quanta known as photons. As expressed by Planck's law (*E* = *h?* = *hc/?*, where *E* = energy, ? = frequency, ? = wavelength, *c* = speed of light, and *h* = Planck's constant), photon energy is proportional to wave frequency and inversely related to wavelength. Consequently, shorter wavelength photons carry more energy. The EMR spectrum ranges from long-wavelength, low-energy radiowaves and microwaves to short-wavelength, high energy x-rays.

When EMR encounters skin, photons are absorbed by individual molecules, called *chromophores,* and/or scattered by structures in the skin. Scattering is a change in the direction of propagation of light, and accounts for reflection from skin. Absorption extinguishes a photon, and all of the photon energy is transferred to the chromophore molecule that absorbed the photon. Without energy absorption, no photon–tissue interaction can occur. Ionizing forms of EMR such as x-rays and shortwave ultraviolet (UV) light impart enough energy to strip electrons from the absorbing molecules entirely. In contrast, optical radiation has the right quantum energy for moving electrons between their molecular orbit levels. This is the basis for photochemistry, in which a photon provides the activation energy for chemical reactions. For example, visible light is visible because its photon energy exactly matches the activation energy for rhodopsin to isomerize, initiating a retinal action potential. Optical wavelengths are generally expressed in nanometers (1 nm = 10^{-9}m). Infrared radiation, which has a longer wavelength and lower photon energy than visible light, generally excites vibrational and rotational motions, generating kinetic energy (heat).

LASER is an acronym for light amplified by stimulated emission of radiation—a process that explains how the unique characteristics of laser light are obtained, illustrated in Fig. 267-1(*A*). The creation of light is conceptually the inverse of absorption—a photon is created when an electron jumps to a lower-energy orbital. In most light sources, this is a spontaneous, random process. In contrast, laser photons are stimulated into existence by each other. Electrons in the

laser medium are first excited to a metastable state, which will eventually return to the preferred ground state by emitting energy. In stimulated emission, a photon triggers the release of metastable state energy in the form of a second, identical photon. Thus, amplification of light is achieved. The laser chamber or *optical cavity* contains two mirrors at each end in parallel alignment, favoring photons that cycle back and forth through the *lasing medium*. Energy is provided by a *pumping source*. The wavelength of the laser is determined primarily by the lasing medium—which may be a gas, liquid, or solid—and to some extent by the mirrors used.

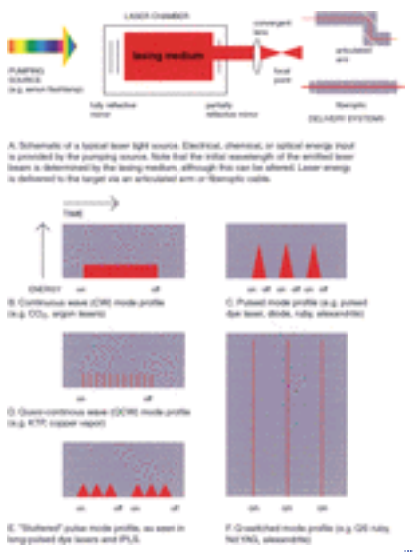

FIGURE 267-1 Schematic of various continuous wave and pulse lasers.

In contrast to natural light, laser light is monochromatic, intense, coherent, and highly collimated. The clinical utilities of lasers stem directly from these fundamental traits. High intensity and collimation allow truly impressive power to be delivered, and focused to spots about equal to the wavelength of light (less than 1 µm). Coherence refers to highly organized waves, which make holograms and a new kind of medical imaging called optical coherence tomography (OCT) possible, for example. Monochromaticity (pure wavelength) allows optimum selective absorption of light by “target” chromophores such as hemoglobin and melanin. Most lasers now in dermatology use the principles of selective absorption and thermal confinement, described by Anderson and Parrish as *selective photothermolysis.* [1], [2]

DOSIMETRY AND LASER CHARACTERISTICS

Light is measured in fundamental *energy* units called *joules* (J). *Power* is the rate of energy delivery, measured in *watts* (1 W = 1 J/s). The “dose” of laser exposure is typically given as energy delivered per unit area (J/cm ^{2}) called *fluence*. Similarly, *irradiance* is the power delivered per unit area (W/cm ^{2}). For pulsed lasers, *peak power* is delivered during the pulse, and *average power* is the time-averaged power delivered. For pulsed lasers, fluence is equal to irradiance multiplied by laser pulse duration, also known as *pulsewidth*. Pulse repetition rate (measured in Hertz) defines the number of laser pulses delivered per second. Wavelength, exposure duration, fluence, and spot size are key determinants of laser–tissue interactions. Wavelength, and to some extent spot size, determine the sites of energy absorption, while pulse duration sets the time over which laser energy is applied. Lasers currently used in dermatology employ pulse durations ranging from seconds to nanoseconds (1 ns = 10 $^{-9}$ s). The same wavelength can exert profoundly different tissue effects depending on pulse duration. For example, in a man with nevus of Ota in the beard area, a 694-nm ruby laser can permanently remove the nevus without removal of hair, or permanently remove hair without removal of the nevus, depending on the pulse duration used. Spot size also affects dosimetry when using visible and near-infrared lasers. For a given fluence, larger spot size yields deeper tissue effect and greater true energy density inside the skin, due to scattering of light.

Continuous wave (CW) lasers emit energy steadily over time (Fig. 267-1B). First-generation CW lasers included the blue-green argon-ion laser (488 or 514 nm) used to treat vascular lesions such as port-wine stains (PWSs), and the carbon dioxide (CO_2) infrared CW laser used for tissue ablation and coagulation. Subsequent CW lasers in dermatology include the argon-pumped tunable dye (577–630 nm), krypton (520, 531, and 570 nm), and CW neodymium-yttrium-aluminum-garnet (Nd:YAG, 1064 nm). The relatively low peak power of CW lasers tends to necessitate long exposure times, allowing heat transfer to produce nonspecific thermal damage. As a rule, CW lasers are safest when used at high power and low exposure duration with a beam scanning or shutter system. Despite the dominance of pulsed CO_2 and erbium lasers for skin resurfacing, CW CO_2 lasers are still popular when delivered by a focused, rapid beam scanner. These lasers “behave” like a pulsed CO_2 laser, delivering a millisecond dwell time (dwell time = spot size/scanning velocity).

Pulsed lasers (Fig. 267-1C) emit energy in so-called long-pulses (millisecond), short-pulses (microsecond and nanosecond), or ultrashort-pulses (picosecond and femtosecond), all of which have been studied in skin. High peak power, short and ultrashort pulses produce unique laser-tissue interactions that are likely to be exploited further in dermatology. When focused inside skin, extreme peak irradiance is achieved (e.g., 10^{18} W/cm ^{2}, a trillion times greater than at the sun's surface), and multiphoton quantum effects appear. For example, multiphoton fluorescence microscopy for imaging live human skin has been reported, using femtosecond lasers. The attosecond barrier was recently crossed, producing optical pulses in the 10^{-18} second domain. For perspective, 1 attosecond is to a second, as a second is to the age of the universe. However, the shortest pulsed lasers routinely used in dermatology are nanosecond Q-switched lasers (Q-switched ruby at 694 nm, Q-switched alexandrite at 755 nm, Q-switched Nd:YAG at 532 or 1064 nm), which contain a photo-optical switch that suddenly releases stored metastable state energy from the laser (Fig. 267-1F). Q-switched lasers typically deliver fluences up to 10 J/cm ^{2} in 10 to 30 nanoseconds (a peak irradiance of about 1 billion

W/cm ^{2}). These lasers are used for selective destruction of very small targets, melanosomes, and tattoo ink particles.

Just as rapidly scanned, high-energy CW lasers can interact with skin in a pseudopulsed fashion, so, too, can rapidly pulsed, low-power systems such as the copper-vapor (512 or 577 nm) and certain potassium titanyl phosphate (KTP) (frequency-doubled Nd:YAG, 532 nm) lasers “behave” in a CW fashion. These *quasicontinuous-wave* (QCW) lasers (Fig. 267-1D), like true CW lasers, tend to produce unwanted thermal damage unless delivered by a scanner to minimize this risk.

“Stuttered” pulses consist of several high-energy pulses separated on the millisecond time scale (Fig. 267-1E). Stuttered pulses are used as a way of mimicking some of the effects of true long pulses, with sources that are technically difficult to operate over a wide range of pulse durations. Stuttered pulse devices are almost always based on a flashlamp. Flashlamp-pumped lasers (dye, ruby, alexandrite, Nd:YAG) and flashlamps themselves [intense pulsed light sources (IPLs), see below] operate efficiently at pulse durations of about 0.3 to 3 msec. When longer pulses are desired, for example, for hair removal, large-vessel treatment, or reduction of purpura, a stuttered pulse can be used in which the interval between several pulses is varied on the millisecond time scale. The skin response to a stuttered pulse can be a combination of short and long pulse effects, not necessarily equal to that after a true, long pulse of similar duration. For example, a stuttered pulsed dye laser emitting several 0.4 msec pulses over approximately 20 msec was developed to reduce purpura associated with classical 0.4 msec dye laser pulses. While reducing purpura substantially in comparison with previous pulsed dye lasers, this device produces more purpura than a true, 20 msec pulse at similar wavelength and fluence. The combination of short and long pulse effects afforded by stuttered pulses may be beneficial in some settings.

IPLs are filtered xenon flashlamps that provide one alternative to long-pulse laser energy. IPLs emit a mixture of wavelengths over a wide range, and cannot produce the peak power of lasers. However, they are less expensive than most long-pulse lasers. Present IPL applications include hair removal, treatment of vascular lesions and lentigines, and, recently, nonablative treatment of facial rhytides. To achieve adequate fluence, IPLs must deliver a far broader spectrum than lasers deliver. Fluences up to 90 J/cm ^{2} are delivered in single, double, or triple pulses. Adjustable parameters include individual pulse duration (2 to 20 msec), interpulse delay, and total fluence delivered. While the ability to deliver wavelengths over a wide range (approximately 500 to 1200 nm) and relatively large “spot” size (e.g., 8 × 35 mm rectangular glass piece) are potential advantages, results vary greatly with operator experience and technique. Table 267-1 lists some CW, QCW, and pulsed lasers and IPLs commonly used in current dermatologic practice.

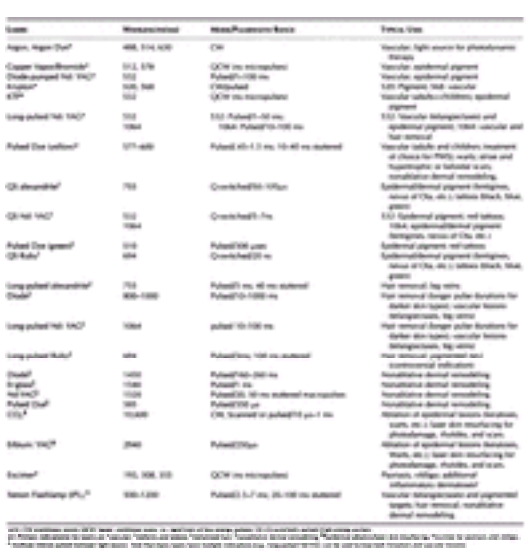

TABLE 267-1 **Commonly Used Lasers in Dermatology**

SKIN OPTICS AND PRINCIPLES OF LASER–SKIN INTERACTION

Laser interactions depend on optical properties of the skin, which are dynamic. Skin color changes subtly with every heartbeat, after a sun exposure, seasonally, and over decades of aging. Skin optics is introduced here anatomically, although the topic could just as well be presented by wavelength region or prominent chromophore. The absorption spectra of the major skin chromophores are diagrammed in Fig. 267-2.

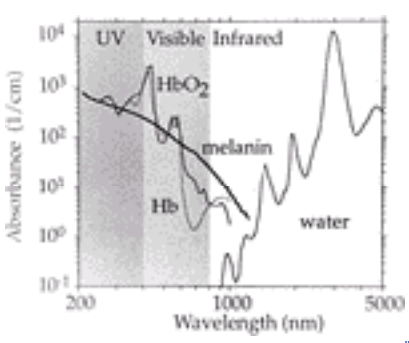

FIGURE 267-2 Optical absorption spectra of the major chromophores in skin. (*Courtesy of S. Prahl, PhD.*)

Surface Reflectance

Approximately 5 to 7 percent of incident light at all wavelengths is reflected from the skin surface, because of the large change in refractive index between air (n = 1.0) and stratum corneum (n ˜1.5). Surface reflectance imparts almost all of

our visual cues regarding the texture of skin, and follows Fresnel's equations for regular reflectance. When surface reflectance is eliminated from view by using polarized light techniques, it is nearly impossible to see wrinkles but easier to see sub-surface structures such as blood vessels and pigmented lesions. Skin examination devices are now available based on this principle.

Epidermal Optics and Melanin

The 93 to 95 percent of incident light not reflected by the skin surface enters the skin, where it is both scattered and absorbed. In the epidermis, UV and visible light absorption by melanin tends to dominate over scattering—therefore it is often appropriate to view the epidermis as a thin, light-absorbing layer on top of the thick, typically more light-scattering dermis. UV wavelengths less than 320 nm are strongly absorbed by both melanin and proteins. For example, about 90 percent of the radiation from the 308 nm XeCl excimer laser, recently introduced for psoriasis phototherapy, is absorbed in the epidermis of even a fair-skinned patient.

Normal and abnormal melanin are frequent targets for laser treatment, and damage to the pigmented epidermis is a frequent cause of unwanted side effects when treating dermal targets. Appropriate laser treatment spares the epidermis, by proper choice of parameters for a given laser and skin pigmentation, and use of skin cooling techniques, discussed below. In hair follicles, a mixture of eumelanin (brown or black hues) and pheomelanin (blonde, red, auburn hues) is present. Safe laser hair removal depends on absorption by hair melanin, without damage to the overlying pigmented epidermis. Melanin absorption extends from the ultraviolet through the visible and near-infrared to about 1200 nm, with a featureless spectrum. Absorption by melanin over this very broad region decreases gradually with increasing wavelength. This absorption spectrum accounts for the brownish hues imparted to normal skin and hair by melanin. Epidermal melanin content varies by at least an order of magnitude across the range of human skin colors from “white” to “black.”

In the mid- and far-infrared wavelengths, water and other molecules absorb photons because of vibrational (kinetic) excitations. Because of a very strong absorption band of water at 2940 nm, this wavelength penetrates only 1 µm into skin, and can therefore be used for precise skin ablation with pulsed erbium:YAG lasers. When a Q-switched Er:YAG laser is used, layers of epidermis can be vaporized with residual thermal injury limited to only a few cells. Dermatologic Er:YAG lasers use longer (microsecond-domain) pulses, which leave somewhat greater residual thermal injury and hence, better hemostasis. CO_2 laser emission at 10,600 nm is also strongly absorbed by water, with a skin-penetration depth of about 20 µm.

Dermal Optics

The dermis is a thick, light-scattering layer punctuated by light-absorbing blood vessels and hair follicles, which have distinct absorption bands associated with hemoglobins and melanin, respectively. Almost all of the visible light returned from within the skin is back-scattered by the dermis, passing twice through the overlying epidermis. Skin color is a result of this back-scattered light component of skin reflectance. The dermis is structurally, functionally, and optically different from epidermis. Dermis has a very large amount of extracellular connective tissue matrix. Collagen, which comprises about 70 percent of dermal protein content, strongly scatters light. Dermal light scattering varies inversely with wavelength, approximately as $?^{-1.5}$. Thus, short (blue) wavelengths are scattered more than long (red) wavelengths. The wavelength-dependence of dermal light scattering accounts for “blue” skin colors induced by nonblue chromophores in dermis, such as hemoglobin (veins), melanin (blue nevi), drug hyperpigmentation (e.g., minocycline), and carbon (blue-black tattoos). Also because of wavelength-dependent light scattering, depth of penetration into the dermis is greater with longer wavelengths across the ultraviolet, visible and near-infrared spectrum to about 1200 nm. The most skin-penetrating wavelength is near 1200 nm, at which approximately 25 percent of incident energy passes entirely through the skin. Intradermal scattering also influences the effective depth of treatment with different laser spot sizes. Small spot sizes (e.g., radius less than 10 times the mean free path between photon-scattering events) suffer attenuation with depth, because photons are easily scattered outside of a narrow beam. Therefore, when treating deep dermal targets such as tattoos, nevus of Ota, hair follicles, PWSs, leg veins, and the like, it is generally best to use the largest feasible spot size. Conversely, smaller spot sizes tend to enhance treatment of superficial targets such as lentigines or small telangiectasias, relative to deeper targets.

Within dermis, hair follicles and blood vessels are the only structures with substantial absorption of visible and near-infrared light. Hemoglobin and oxyhemoglobin have very strong absorption bands at blue, green, and yellow visible wavelengths. The longest wavelength oxyhemoglobin band (577 nm) was initially chosen for targeting microvascular malformations, using pulsed dye lasers in the first example of selective photothermolysis. Present pulsed dye lasers emit slightly longer wavelengths of 585 to 600 nm, which penetrate somewhat deeper into the dermis. Recently, the weak near-infrared absorption bands of hemoglobin and oxyhemoglobin have been used for selective photothermolysis of leg veins using long-pulse alexandrite (755 nm), diode (800 nm), and Nd:YAG (1064 nm) lasers. Because absorption by blood at these wavelengths is less than one-tenth of that for pulsed dye lasers, higher fluences are needed. For hair removal, melanin pigment in the hair shaft and matrix is the target chromophore. Temporary removal of pigmented hair is easily accomplished with red or near-infrared pulses over a wide range of pulse durations. In contrast, nonpigmented stem cells located at the external margin of the outer root sheath appear to be an important target for permanent hair removal. High fluences (e.g., 20 to 50 J/cm^2) and long pulses (e.g., 3 to 100 msec) using ruby, alexandrite, diode, or Nd:YAG lasers delivered in combination with skin surface cooling, permanently remove approximately 30 to 50 percent of coarse dark hairs per treatment.

Photothermal Interactions

Laser surgery consists largely of controlling the anatomic distribution of photothermal injury, that is, controlling the sites and amount of heat generated by light absorption. Temperature is a measure of average molecular kinetic energy—the random translation, rotation, and vibration of molecules. At low temperature, liquids freeze; at high temperature, complex macromolecules unravel. Life operates between these lethal temperature extremes. Thermal denaturation of macromolecules is a rate process, such that both time and temperature influence thermal damage. A useful

time-and-temperature “cookbook” can therefore be constructed for thermal events in skin. For example, fibroblasts and most other human cells are killed at 47°C (116.6°F) in about 20 min, but can withstand 100°C (212°F) for about 10^{-3} seconds. For effective selective photothermolysis with pulsed sources, high temperatures must be briefly achieved in cellular targets such as nevi, blood vessels, and hair follicles. Sublethal thermal injury of cells triggers a complex range of responses including altered metabolism, stress and repair signaling pathways, and/or delayed cell death by apoptosis. Even subtle, controlled thermal injury may be useful. Recently, pulsed dye and mid-infrared lasers were used for “nonablative skin rejuvenation,” by stimulating subtle photothermal injury in the photoaged dermis. Thermal behavior of the extracellular matrix also plays a major role in laser dermatology. Type I collagen is a semicrystalline protein with well-defined melting points. Although soluble collagen monomers melt just above body temperature, fibrillar collagen is much more stable and melts between 60°C (140°F) and 70°C (158°F), or higher depending upon the degree of cross-linking. When denatured, fibrillar collagen shrinks dramatically. Laser resurfacing immediately shrinks the superficial dermis, which may play a role in the final extent of skin tightening.

At temperatures above 100°C (212°F), tissue water vaporizes. Laser skin resurfacing uses pulsed or focused-and-scanned erbium (Er) or CO_2 lasers to vaporize a thin layer at the skin surface with each pass, leaving a layer of residual thermal coagulation caused by heat conduction during the vaporization process. The thickness of this residual thermal injury is critical, both for hemostasis and wound healing. If thinner than approximately 30 µm, hemostasis is a problem; if thicker than approximately 150 µm, retarded wound healing is a problem. The minimum thermal damage layer is at least three times the optical penetration depth, and can be increased by using longer pulse durations. The clinical outcomes of laser resurfacing depend mainly on anatomic depth of injury, which is controlled by fluence per pass and number of passes, and on postoperative care. The choice of laser is somewhat important. In general, Er lasers are easier to use for treating mildly photodamaged skin. When used at equivalent anatomic depth of injury, however, Er and CO_2 lasers produce equivalent clinical results.

Photomechanical Interactions

Q-switched and other short laser pulses can cause predominantly mechanical damage. Rapid vaporization inside the skin causes *cavitation,* the violent expansion and collapse of vapor bubbles. Cavitation occurs around melanosomes and tattoo particles during Q-switched laser treatment of pigmented lesions and tattoos, selectively killing the target cells. Residual gas bubbles remaining after cavitation cause a striking, immediate white color that correlates with clinical efficacy. Immediate whitening is therefore a useful end point during Q-switched laser treatment of tattoos or pigmented lesions. Other mechanical effects can be caused by extremely rapid heating. Q-switched lasers heat intracellular tattoo ink particles by approximately 200°C (392°F) in 10 ns, a heating rate of 20 billion degrees per second! Thermal expansion stresses may alter and/or fragment the particles, which are then removed mainly by lymphatic transport. Extremely rapid heating also produces stress waves, which are positive and/or negative pressure waves. At very high pressure, a “shock” wave forms that travels faster than the speed of sound. Laser-induced shock waves have been shown to nonlethally permeabilize cell membranes, and experimentally to enhance transcutaneous drug and gene delivery.

Selective Photothermolysis

Heat is created at the sites where light is absorbed in skin, and then begins to diffuse by conduction. When a pulse of selectively-absorbed light is delivered within the time for cooling of light-absorbing “targets,” heat is confined to those targets during the laser pulse. This combination of selective absorption plus thermal confinement in desired target structures, is the basis for *selective photothermolysis* (SP). The primary clinical advantages of SP are target-specific efficacy and minimal risk of scarring. Initially conceived for treating pediatric port-wine stains, SP has provided a rationale for nonscarring treatments of pigmented lesions, tattoos, and hypertrichosis. Wavelength and beam geometry (e.g., spot size and focusing) are chosen for optimum absorption in desired targets, exposure duration (e.g., pulsewidth or dwell time) is chosen for the desired degree of thermal confinement to targets, and fluence is chosen to produce the degree of target injury required. The concept of *thermal relaxation time* (t) is useful to describe heat conduction from different target structures. In general, t is defined as the time required for cooling of a structure to 1/e [e = 2.3058] of the temperature difference between the target structure and its surroundings. Thermal relaxation time is proportional to the square of the structure's diameter (d), and inversely proportional to thermal diffusivity (?). Specifically, $t = d^2/4?g$, where g is a factor related to the target shape. A useful approximation is simply $t ? d^2$, when t is expressed in seconds and d is expressed in millimeters. For example, a 1-mm leg vein has a thermal relaxation time of about 1 s, a 0.1-mm port-wine stain vessel has a thermal relaxation time of about 10 msec, a 10-µm nevus cell has a thermal relaxation time of about 100 µs, and a 1-µm tattoo ink particle has a thermal relaxation time of about 1 µs.

Pulses much longer than t for a given target structure tend to cause unwanted gross heating of the skin. However, a pulsewidth less than t is not always desirable. For example, follicular stem cells appear to be an important target for permanent hair removal, but these cells are located at the outer margin of the root sheath, away from the actual site of light absorption, the pigmented hair shaft. Similarly, the target when treating vascular malformations is not blood, which contains the target chromophore oxyhemoglobin, but the surrounding vessel wall. Therefore, it is advantageous to use a pulse duration about equal to t for the actual, intended target geometry—allowing heat to diffuse into the hair follicle or vessel wall during the laser pulse. Other factors, such as the need to protect the epidermis by skin cooling during delivery of an optical pulse, may also affect the choice of pulse duration. For example, the thermal relaxation time of the whole epidermis, which is approximately 0.1 mm thick, is about t ? 10 msec. Skin cooling during a pulse >>10 msec is therefore far more protective than during a pulse <<10 msec.

Avoiding the Epidermal Melanin Barrier

In both plants and animals, skin melanin is used mainly for camouflage; melanins also play roles for vision and neural tissue. In humans, a long life span and lack of fur have fostered the additional adaptation of skin melanin for photoprotection. “White” skin arose in nontropical humans for unknown reasons. Because epidermal melanin is a strong absorber of UV, visible, and to some extent near-infrared light, epidermal injury is a concern when using lasers,

especially when treating dermal targets in dark skin. There are several ways to combat this problem.

DIFFERENTIAL THERMAL RELAXATION TIMES When a laser pulsewidth is delivered that lies between thermal relaxation times for a given large and a small target, the small target tends to escape injury because of a lack of thermal confinement. A good example is pulsed dye laser treatment (pulsewidth ? 1 msec) of microvascular malformations and telangiectasias. Small, normal capillaries (t? 0.1 msec) are spared from injury, while target vessels larger than about 30 µm diameter (t > 1 msec) are selectively photocoagulated. Similarly, the pulse duration of some hair-removal lasers and IPLs can be adjusted to optimally damage terminal hair follicles (t ? 20 to 100 msec) rather than epidermis (t < 10 msec). A combination of long pulsewidth, long wavelength, and skin cooling can be used to safely treat very dark skin, e.g., using very long pulse diode or Nd:YAG lasers for pseudofolliculitis barbae in African-American men.
SKIN COOLING Skin cooling before, during and after a laser pulse helps to protect the epidermis and superficial dermis from thermal injury, and to reduce pain and swelling. Skin cooling is especially useful when treating vascular lesions, leg veins, and hair, and for nonablative dermal remodeling. All methods of skin cooling extract heat from the skin surface into an external medium. The anatomic depth of cooling depends on cooling time. [3] Cooling the epidermis takes about 0.1 s of good contact with a cold, heat-conducting medium, whereas bulk cooling of the skin takes tens of seconds. Icing a PWS before argon laser treatment was shown long ago to reduce scarring, [4] an example of bulk skin cooling. Cooling technology now uses a variety of chilled contact (solid, liquid, or gas) or cryogen spray devices. Dynamic precooling with tetrafluoroethane cryogen spray [boiling point –26°C (–14.8°F); 20 to 100 msec duration] is the most aggressive epidermal precooling technique, but provides little or no cooling during and after a laser pulse. Cryogen spray cooling is excellent when used with pulsewidths shorter than about 10 msec, for example, when treating PWSs with a pulsed dye laser. In a retrospective review of 196 Asian patients with PWSs treated with a 585-nm, 450-msec pulsewidth laser, either with (n = 98) or without (n = 98) cryogen spray cooling, cooling allowed higher fluences to be used (8 to 10 J/cm ^{2} versus 5 to 7 J/cm ^{2}), and was associated with improved clearance, and decreased incidence of scarring and pigmentary side effects. [5] Contact-cooling handpieces typically cool before, during, and after each laser pulse. Cold sapphire windows are an excellent cooling medium, being transparent, hardy, and with high thermal conductivity. In contrast with cryogen spray cooling, contact cooling is best suited for use with long pulses, e.g., hair removal. Forced cold [as low as –30°C (–22°F)] air was tested as a bulk cooling method on 166 patients treated for various indications with different laser systems (long-pulse alexandrite for hirsutism, pulsed dye laser for PWSs and hemangiomas, Q-switched ruby and Nd:YAG lasers for tattoos). [6] There was improved analgesia and epidermal protection (reduced purpura, crusting) in comparison with ice gel precooling.
FOCUSED LASER BEAMS Lasers can deliver very-high-power density at a focal spot, which can be as small as 1 µm, and as deep as about 1.5 mm into the skin. It is possible, and may eventually be practical, to cause precise, selective thermal injury by aiming a laser beam at various targets. Such a system would need to be automated, but the basic technology for this exists. For example, computer writable-CD drives now use a focused laser to record millions of data bits per second inside the disk. Computer-driven focused lasers are already used for skin resurfacing, but could become much more sophisticated, in theory targeting non-pigmented structures such as sebaceous glands and immune effector cells. A combination of emerging technologies would be required: small solid-state lasers, noninvasive microscopy, computer vision, and fast optical scanners.

LASER SAFETY

The importance of safe, intelligent laser practice cannot be overemphasized; every year, laser mishaps are responsible for accidental blindness, skin burns, explosions and electrocution in medicine and industry. IPLs pose most of the same risks as lasers. To minimize these risks, all individuals should receive comprehensive safety training prior to performing any type of laser or IPL therapy. In addition, both the operative environment and procedural format should be designed to protect patients, physicians, and support staff from inadvertent laser or IPL injury. While specific precautions may vary depending on the type of laser in use, all laser procedures require appropriate eye protection, fire precautions, and fume extraction if ablation is involved. All laser personnel should have a mandatory baseline ophthalmologic examination, followed by annual screening for early signs of retinal damage.

Anyone in the operative area is at risk for laser-related injury. This includes the laser surgeon, support staff, patient, and bystanders such as family members. The major laser hazards include eye injury, skin burns, and accidental ignition of clothing, hair, flammable substances, or surgical drapes. Rarer but significant risks include explosion and electrocution caused by electrical malfunction. Respiratory hazards such as transmission of bacterial, viral and fungal pathogens, inhalation of pulmonary irritants and potential carcinogens, remain the subject of active debate. The major laser-associated hazards are summarized in Table 267-2.

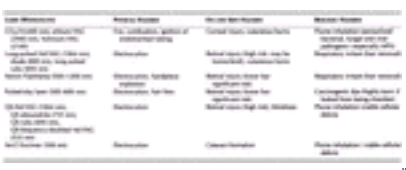

TABLE 267-2 **Commonly Used Lasers and Associated Hazards**

Eye and Skin Hazards

Of all human organs, the eye is the most vulnerable to accidental laser injury because of its optical focusing properties. Crucial ocular structures such as the retina, cornea, and lens may be damaged irreversibly by an errant laser beam within microseconds, long before the lid reflex has had time to protect them. The melanin-rich retina is especially vulnerable to lasers operating in the visible to near-infrared wavelengths (400 to 1400 nm)—the so-called retinal hazard region. These wavelengths readily transmit through the clear ocular media, with the cornea and optic lens concentrating the incident laser beam 100,000-fold onto a retinal spot measuring between 10 and 20 µm. While this injury zone may

appear to be small, central retinal or foveal damage from a single incident beam may be enough to cause almost total loss of visual acuity in the affected eye. Because retinal neural tissue has minimal regenerative capacity, such damage is typically permanent.

While all lasers in the 400 to 1400 nm wavelength range are capable of causing significant retinal damage, lasers with high peak powers, such as Q-switched (e.g., QS-Nd:YAG, QS-ruby, QS-alexandrite) and pulsed devices, pose an especially high risk. Special caution should be taken when using high-energy optical pulses near the eyes. For example, all hair removal lasers and IPLs are specifically designed to damage melanized tissues through several mm of tissue. The ocular retina and choroid have the highest melanin concentration in the body, such that retinal injury can be caused even by exposure through the sclera. Laser or IPL hair removal should not be attempted within the bony orbit. Collimated lasers present an added danger, because the energy of highly collimated beams does not diminish significantly over distance. Hence, a collimated beam reflected off of a remote metal surface could be as dangerous as one aimed directly into the eye. Collimated lasers include the CO_2 laser many Q-switched lasers, and some pulsed dye and green lasers, used for tissue ablation and photocoagulation. Most surgical lasers are focused, typically limiting the zone of maximal eye or skin injury to 1 to 2 meters from the focal point, which typically includes the surgeon, patient, and other personnel.

Anterior ocular structures are also susceptible to laser injury. The cornea can be damaged by ultraviolet (e.g., XeCl excimer at 308 nm) and infrared wavelengths beyond 1400 nm (e.g., CO_2 at 10.6 µm; erbium:YAG at 2940 nm; holmium:YAG at 2100 nm). The depth of corneal injury depends on both incident laser fluence and dwell time. Although superficial corneal injury is reversible, deeper photothermal damage to the stroma and corneal stem cells will cause permanent scarring, with corneal transplantation needed to restore normal vision. Of note, UV lasers such as the 308-nm XeCl excimer laser can damage the protein-rich optic lens, causing immediate cataract formation.

Eye damage can be prevented by ensuring that the surgeon, staff, patient, and observers wear appropriate protective eyewear (wraparound glasses, goggles, or eye shields) at all times during any laser procedure. Eyewear should be labeled clearly with both filtered laser wavelength and optical density parameters, and lenses and fittings should be checked regularly for damage and replaced as needed. For CO_2 and Er:YAG lasers, prescription glasses or wraparound plastic goggles made of burn-through-resistant polycarbonate provide adequate protection. The risk of reflected beams should be minimized by using only rough, black polymer-coated metallic objects (such as eye shields) in the surgical field. When not in use, the laser should always be kept on standby, with foot pedal and triggering devices well-labeled and positioned safely to avoid inadvertent triggering.

In contrast to their effects on the eye, isolated accidental laser pulses typically produce reversible thermal skin injury (first- or second-degree burns). Nevertheless, conduction of heat into the deeper dermis can cause third-degree burns and permanent scarring. This becomes especially problematic in sedated or anesthetized patients, who may lack the withdrawal reflexes necessary to protect them from thermal injury. As discussed below, accidental ignition of clothing, hair, flammable compounds, surgical drapes, rubber tubing, or oxygen in the surgical field are factors more likely to cause significant burns.

Mechanical Hazards: Fire, Explosions, Electrocution

Significant and even life-threatening third-degree skin burns have been caused by inadvertent laser ignition of surgical drapes, clothing, hair, oxygen, and endotracheal tubing. While any laser poses a potential fire hazard, CO_2 and Er:YAG lasers present the greatest risk. Ignition of hair, especially when a leaking oxygen mask is present, can be rapid and impressive. To prevent accidental combustion, the laser surgeon should remove all flammable materials from the operative field and avoid using flammable skin preparations containing alcohol. Patients should not wear combustible substances (e.g., hair sprays, gels) on the day of surgery. In addition, treatment areas must always be draped with moistened towels or gauze, and all potentially exposed hair-bearing areas (e.g., hairline and eyebrows during facial resurfacing) should be covered with a protective layer of water or hydrophilic gel.

The use of supplemental oxygen in the surgical field poses a special combustion risk, especially for procedures taking place near the nose and mouth. There are horrific case reports including instances of endotracheal tube ignition and patient demise. Most fires occur from laser exposure to combustible material rather than exposure to skin. While lasers are designed to minimize any electrocution risk, their high-voltage requirements pose significant danger to repair staff or individuals foolish enough to tamper with the device without adequate maintenance training.

Respiratory and Infectious Hazards

The “plume” produced by laser or electrosurgical vaporization, poses both respiratory and infectious hazards, with some risks being more well defined than others. At one extreme, inhaled laser smoke clearly irritates the respiratory mucosa, potentially exacerbating pulmonary diseases such as asthma and emphysema. Long-term inhalation of laser smoke causes interstitial pneumonia, bronchiolitis and emphysema in rats. Hair removal lasers may cause asthmatic flares, triggered by noxious smoke. Particles inhaled from the laser plume may also pose an infectious risk. Viable bacterial skin pathogens (e.g., *Staphylococcal aureus* and *Neisseria*) and fungi have been isolated from laser plumes, especially those produced by the CO_2 and Er:YAG lasers. Laser plumes also contain potentially infectious fragments of human papillomavirus (HPV), a viral pathogen linked to genital and mucosal condylomata, cutaneous warts, cervical dysplasia, and squamous cell carcinoma. While the risk of acquiring HPV from the laser plume remains unclear, the risk of developing nasopharyngeal warts has been noted to be slightly higher in a group of CO_2 laser surgeons when compared to population-based controls from the same region. [7] Proviral HIV DNA has been detected by polymerase chain reaction (PCR), in debris collected from CO_2-vaporized, HIV-infected tissue-culture pellets. [8] With this data in mind, all laser debris should be handled following universal infectious precaution guidelines, including the use of gloves, eye protection, face masks, and frequent hand washing. In addition, laser plumes should be viewed as biohazards and contained by using vacuum smoke evacuators equipped with ULPA-rated (ultralow-penetration air) filters.

Laser pyrolysis products have been shown to be mutagenic in vitro by using a *Salmonella* mutagenicity assay. Any real-life carcinogenic risk remains to be determined. Nevertheless, laser smoke inhalation should be minimized, especially because any cancer risk, however small, is likely to be cumulative. There is no evidence that the laser-induced plume differs from that of electrosurgery; it is prudent to evacuate smoke during any surgical procedure.

CLINICAL APPLICATIONS

Vascular Lesions

One of the first uses for laser light in dermatology was the selective targeting of vascular lesions in the skin, including capillary malformations (e.g., port-wine stains) and hemangiomas. Whether continuous or pulsed, all modern vascular lasers target intravascular oxyhemoglobin (HbO_2) as the primary chromophore. Intuitively, laser wavelengths that closely approximate the absorption peaks of hemoglobin in the blue, green, and yellow bands (418, 542, and 577 nm) should be most effective at targeting blood vessels for selective photothermolysis. Yet additional variables, such as blood vessel depth, caliber, and the pigmentation of overlying epidermis, play equally important roles in determining the ultimate clinical outcome. Skin optics are such that longer wavelengths tend to be preferable, in order to minimize melanin absorption and maximize depth of penetration.

Different vascular lesions often demand different laser parameters for good results. For instance, dilated capillaries and venules in superficial PWSs respond well to the flashlamp-pumped pulsed dye laser (FPDL, 585 to 600 nm) used at pulsewidths ranging from 450 µs to 1.5 msec. These parameters are logical, as the laser has excellent HbO_2 absorption, sufficient penetration into the papillary and upper reticular dermis, adequate energy delivery to induce irreversible vessel damage, and a pulsewidth range approximating the thermal relaxation time of the target vessels (t ? 1 msec for vessel diameters of 30 µm). In contrast, reticular leg veins respond best to systems with deeply penetrating wavelengths in the near-infrared range with longer pulse durations, such as the long-pulse Nd:YAG (1064 nm) and diode (810 nm) lasers, operating at high fluences in the >10 msec pulsewidth range.

Surprisingly, the mechanisms of laser-induced irreversible vessel damage in vivo remain unclear, although complete and irreversible cessation of blood flow appears to be one prerequisite. Lasers delivering high energies over short pulsewidths (e.g., FPDL) tend to induce a combination of photothermal and photomechanical injury, such as intravascular cavitation, vessel wall fragmentation, and hemorrhage. [9] In contrast, longer pulsewidths approximating or exceeding the target vessels' thermal relaxation times cause mainly photothermal damage, with intravascular coagulation and collagen contraction within the vessel wall and surrounding tissue. Both photothermal and photomechanical mechanisms of vessel damage cause clinically visible purpura, providing a helpful end point when using pulsed dye lasers. For all vascular laser systems, epidermal cooling devices (e.g., cryogen spray or contact cooling) help to reduce epidermal damage, especially when using higher fluences or treating darker skin types. A phase of local vasculitis occurs several days after pulsed dye laser treatment, which appears to be important for clinical results. This delayed purpura should be distinguished from the immediate purpura caused by conventional pulsed dye lasers. Patients should be warned that delayed purpura caused by vasculitis often develops following treatment with a stuttered pulsed dye laser that is marketed to be “purpura-free.”

Port-Wine Stains (Nevus Flammeus)

PWSs (nevus flammeus) are cosmetically disfiguring, congenital capillary and venular malformations that affect up to 0.5 percent of newborns. At birth, lesions are first noted as subtle, light pink patches, commonly appearing on the face and often in a trigeminal dermatomal distribution. Approximately 5 percent of these trigeminal PWS are associated with underlying leptomeningeal, ocular, and central nervous system (CNS) involvement, meeting criteria for the Sturge-Weber syndrome. In addition, PWSs may occur on the trunk and extremities, with extremity lesions occasionally developing progressive lymphectasia and soft-tissue hypertrophy (Klippel-Trenaunay-Weber syndrome). Although similar in appearance, congenital “stork-bite” (occipital) and “angel's kiss” (glabellar) telangiectatic patches are extremely common, tend to regress over time, do not merit treatment, and may represent focal areas of persistent fetal circulation.

On histopathology, PWSs consist of dilated, ectatic vessels in the superficial papillary dermis. In contrast to capillary hemangiomas, these vessels are not proliferative and therefore only grow proportionally with the individual. Unfortunately, while hemangiomas undergo spontaneous regression, PWS vessels become progressively tortuous, dilated, and engorged over time. Unless treated, larger PWS will eventually evolve into disfiguring violaceous plaques containing areas of nodular hypertrophy. Prior to the advent of laser surgery, such cosmetically disfiguring lesions were treated with nonspecific, destructive modalities, including cryosurgery, ionizing radiation, dermabrasion, and surgical excision with skin grafting. Although most of these techniques could improve function and to some extent cosmesis, none could avoid the problem of potentially disfiguring scarring.

In contrast, selective photothermolysis can specifically target PWS vessels while sparing surrounding tissue. Despite promising initial results in adult patients with PWSs, the CW argon laser (488 and 514 nm) fell short of this ideal, causing significant scarring in up to 38 percent of treated children younger than 12 years of age. [10] This was mainly a result of nonspecific thermal injury, because the original CW argon exposure time (around 200 msec) far exceeded the t of PWS vessels (1 to 10 msec).

After observing encouraging results in adults with PWSs, Tan et al. conducted a clinical trial using a 577-nm FPDL (360 µsec) to treat pediatric PWSs in 35 white children 3 months to 14 years of age (mean age, 7.2 years). Treated lesions were all located on the head or neck, macular, and pink to red in color. By using minimally overlapping spots (5-mm spot size, 6±0.25 J/cm^2 fluence), they observed impressive fading in all 35 patients after the first treatment, with complete clearing after a mean of 6.5 treatments. [11] Laser-associated adverse effects were minimal, with two children (5.7 percent) developing superficial, depressed scars. Twenty treated children (57 percent) developed transient facial

hyperpigmentation, which cleared within 4 months. In general, this early report is viewed as being overly optimistic in light of subsequent studies. Of note, PWSs over bony prominences and in children younger than 7 years old achieved clearance with fewer treatments. Subsequent studies question both of these findings; instead of PWS location and patient age, Van der Horst et al. found lesion size and depth to be the key predictors of treatment response. [12]

Over the past decade, FPDL treatment of cosmetically significant PWSs has become the standard of care. Most pediatricians advocate early treatment of PWSs to prevent hypertrophy and progression, especially because these lesions can cause significant psychological distress during childhood and adolescence. To attain deeper penetration and faster treatment, FPDLs have been shifted toward using longer wavelengths (585 to 600 nm) and larger spot sizes (7 to 10 mm). As a result of reduced HbO_2 absorption at these longer wavelengths, somewhat higher fluences are used to achieve adequate vessel damage, typically 8 to 12 J/cm ^{2}, delivered in pigmented skin with cryogen spray cooling. As Dierickx et al. demonstrated, target vessel damage may be ideal using longer pulsewidths (1 to 10 msec) that better approximate the t of PWS vessels. [13]

Adverse effects such as scarring, pain, and pigmentary alterations can be reduced significantly by using cryogen spray or contact cooling devices. Cryogen spray cooling has greatly improved the ability to treat darker skin types with PDLs, because the epidermis is specifically cooled prior to arrival of the laser pulse. Although bulk cooling may somewhat reduce efficacy at a given treatment fluence by cooling target vessels, bulk cooling greatly increases tolerance to high fluences. The enticing combination of bulk skin cooling and pulsed dye laser treatment at high fluence has not been adequately studied in clinical trials.

Mature PWSs pose additional therapeutic challenges, including the presence of deeper vessels and overlying hypertrophy. Deeper, violaceous vessels respond better to longer wavelength lasers, higher fluences, and longer pulse durations. Treatment during diascopy to blanch superficial vessels is a useful approach to facilitate destruction of deeper vessels, because superficial overlying vessels often shield deeper targets from photothermal injury. A glass slide is used to press gently on the hypertrophic vascular lesion, until the color is seen to lighten. At this point, a laser pulse is delivered. After one pass in this manner, a second pass can be performed to treat the superficial component. PWSs resistant to pulsed dye laser treatment may improve significantly when treated with alternative lasers such as the modulated KTP laser system (532 nm; 1 to 50 msec; 5 to 50 J/cm ^{2}) or IPL. Both IPL and one version of the pulsed dye laser offer tunable wavelengths. Raulin, et al. [14] used an IPL with 550-nm (for red to pink PWSs) or 515-nm (for purple PWSs) cutoff filters, pulsewidths of 2.5 to 5.0 msec, and high fluences of up to 60 J/cm ^{2} with coupling gel, and observed minimal adverse effects comparable to those seen with standard PDL treatment. Potential advantages of the IPLS include the ability to set multiple wavelengths, deliver high fluences, and use split pulses. However, a prospective trial comparing IPL and PDL treatment over a range of fluences has yet to be done.

Factors to consider when evaluating any PWS for treatment include patient age, skin type, prior treatment response (if any), lesion location and anatomy. It is unknown why some PWS are resistant to therapy with lasers or IPLs. Emerging noninvasive imaging techniques such as high-resolution ultrasound, confocal microscopy, and optical Doppler tomography may help to better guide laser therapy of PWSs in the future. A “cookbook” approach to the treatment of PWSs should be discouraged, and laser parameters and cryogen spray settings must be tailored to each individual.

Capillary Hemangiomas

Hemangiomas are benign vascular endothelial cell tumors found in the skin and, less frequently, other organ systems such as the liver. Hemangiomas typically present in infancy, and may be found in 1 to 2 percent of neonates, with an estimated prevalence of 10 to 12 percent by 1 year of age. Premature infants show an even higher prevalence of up to 20 percent. Fortunately, growth of infantile hemangiomas is restricted to an early proliferative phase, followed by growth arrest and spontaneous involution. As a rule, 50 percent of hemangiomas show regression by 5 years, 70 percent regress by 7 years, and more than 90 percent ultimately regress by adolescence. Lesions classically evolve from pink-red, telangiectatic macules and patches to raised nodules, although congenital hemangiomas may present in the nodular phase or as bleeding ulcerated plaques. While some regressed hemangiomas leave normal skin in their wake, more than 50 percent leave residual changes such as hyper or hypopigmentation, telangiectases, “anetoderma-like” scarring, and atrophy. This can be especially distressing in cosmetically sensitive areas such as the head and neck, where an estimated 50 percent of infantile hemangiomas occur. Up to 30 percent of infants have multiple lesions, and neonates with numerous small (<1 to 2 cm) cutaneous hemangiomas should be evaluated for potential visceral involvement of the liver and gastrointestinal tract—a condition known as multiple neonatal hemangiomatosis. Large, rapidly growing purpuric lesions suggestive of kaposiform hemangioendothelioma should prompt evaluation for Kasabach-Merritt syndrome.

Three main types of infantile hemangioma are recognized: the common, superficial or “strawberry” hemangioma (50 to 60 percent); the mixed hemangioma, consisting of both superficial and deeper cavernous components (25 to 35 percent); and the deep or “cavernous” hemangioma (15 percent). Histologically, all of these lesions show clusters of thin-walled vascular spaces surrounded by sheets of proliferative but benign-appearing endothelial cells. Mixed and cavernous subtypes have deeper, more dilated vessels. Additional features common to most hemangiomas include dermal mast cells and variable atrophy of the overlying epidermis. Small, superficial hemangiomas in cosmetically innocuous areas generally do not require treatment, and should regress spontaneously without significant sequelae. The major indications for treatment include life- or function-threatening hemangiomas, such as those obstructing airways or impairing vision; hemangiomas that tend to leave disfiguring scars or deformities in cosmetically sensitive areas, such as the nose, glabella, lips, ears, and breasts; large facial hemangiomas, especially those with deep components; hemangiomas in exposed areas such as the face and hands; and pedunculated or ulcerated hemangiomas. Therapeutic decisions should be tailor-made to each individual lesion, and should always take into account psychosocial factors, including the emotional well being of both child and parents. Because no treatment is without risks, all potential complications should be detailed prior to initiation of therapy.

Treatment options range from conservative monitoring to local (FPDL or Nd:YAG laser, cryotherapy, intralesional glucocorticoids, surgical excision, embolization) and systemic [oral glucocorticoids or interferon (INF)-a] modalities. Individual treatment risks differ, but all procedures may result in scarring. Laser treatment, for example, with pulsed dye lasers, appears to reduce the risk of spontaneous ulceration and scarring. Treatment choice may vary depending on factors such as lesion location, size and depth, growth phase, presence or absence of functional impairment, and parental preference. Systemic glucocorticoids, IFN-a, and embolization are often reserved for function- or life-threatening lesions, because these treatments carry significant risks (e.g., spastic paresis in infants receiving IFN-a). As a rule, lasers such as the 585-nm flashlamp- pumped pulsed dye laser are most effective when used to treat superficial capillary hemangiomas. The role of laser therapy for these lesions remains somewhat controversial.

FPDL were specifically designed for treating PWS, which are structurally very different from hemangiomas. In theory, a shorter pulsewidth and much longer wavelength selectively absorbed by blood, might work better for these lesions. However, FPDL treatment of hemangiomas appears to accelerate lesion involution, leading to significant lightening with minimal complications. Hohenleutner et al. recently reported long-term results of 617 childhood hemangiomas treated with the FPDL (585 nm; 5 to 7 mm spot; 0.45 msec pulsewidth; 5 to 10 J/cm ^{2} fluence; 10 percent pulse overlap). Forty-nine percent of these were localized to the head and neck. [15] After a mean of 2.5 treatments (1 to 12 treatments given at intervals of 4 to 6 weeks), 96.6 percent of hemangiomas showed no further growth, with 13.8 percent showing total regression and 14.9 percent showing marked regression. These results differ markedly from the expected time-course of involution without treatment, but specific age and lesion-matched controls were not reported. Small, atrophic scars were noted in 4 percent of cases, with transient hypo- or hyperpigmentation seen in 7 percent of cases. Patient age did not appear to influence treatment results. As expected, treatment response varied with lesion depth, with complete remission seen in 42.6 percent of small superficial lesions (<5 mm), 14.5 percent of nodular lesions, and only 6.5 percent of compound lesions. Larger superficial lesions fared poorer than small lesions, with only 19 percent showing complete regression. Infantile hemangiomas also may respond well to the frequency-doubled Nd:YAG (532 nm), KTP (532 nm), and other similar laser systems. Laser treatment causes purpura, is painful, and often requires pretreatment with topical or intralesional anesthetics, or general anesthesia.

Cavernous and mixed hemangiomas with deep, dilated vessels pose a special therapeutic challenge sometimes met by a combination of medical, laser, and excisional surgery. Deep hemangiomas respond to penetrating infrared lasers such as the 1064-nm Nd:YAG, which has been used in both pulsed and CW modes to treat arteriovenous malformations and cavernous hemangiomas. Intense pulsed light sources have also been reported for treatment of deeper hemangiomas. Scarring is common. The best future approach to treating deep hemangiomas will likely involve combination therapies, and/or specific inhibitors of angiogenesis inherent in these lesions.

Telangiectases and Leg Venulectases

Facial telangiectases are extremely common, superficial dilated vessels 0.1 to 1 mm in diameter, generally localized to the nose, malar cheeks, and chin in fair-skinned individuals, particularly those with rosacea. Telangiectasia formation is attributed to a combination of genetic, hormonal and environmental factors such as chronic sun exposure. Vasomotor flushing with centrofacial telangiectasia is a cardinal feature of rosacea, and several inflammatory, metabolic and hereditary skin disorders feature telangiectatic vessels of varying caliber and distribution. Facial telangiectases are located superficially in the papillary dermis, making them simple targets for selective photothermolysis using vascular lasers in the blue, green and yellow wavelength range (418 to 585 nm). Most vessels will clear using relatively low fluences, and more than two sessions per treatment area are seldom required. Both the flashlamp-pumped (585 nm; 450 µs) and long-pulsed (595 to 600 nm; 1.5 msec) dye lasers provide reliable clearance, leaving purpura that typically fades over 1 to 2 weeks. Additional effective systems include the Nd:YAG (1064 nm) and frequency-doubled (532 nm) Nd:YAG, copper bromide, and krypton lasers. Many of these are equipped with cooling devices, and purpura is not required to obtain vessel clearance.

Other telangiectatic processes responsive to vascular laser treatment include generalized essential telangiectasia, hereditary hemorrhagic telangiectasia, radiotherapy-induced telangiectases, telangiectasia macularis eruptiva perstans (TMEP), angioma serpiginosum, nevi aranei (spider nevi), and unilateral nevoid telangiectasia syndrome, although the latter condition tends to recur even after multiple treatments. Spider nevi have a central arteriolar trunk, which must be eradicated to achieve clearance. Treatment during diascopy is helpful for this purpose. Lasers such as the PDL and long-pulsed 532-nm Nd:YAG have also been used to treat poikiloderma of Civatte, which features both telangiectatic and pigmentary changes in a “V”-shaped distribution on the neck and anterior chest. However, this common photoinduced condition should be approached with caution, using low fluences and minimally overlapping treatment spots to avoid the potential problems of irregular “checkerboard” hypopigmentation and scarring. Initial treatment of a small test area is advised, followed by treatment of the entire cosmetic unit. Facial laser skin resurfacing in patients with poikiloderma commonly results in striking pseudohypopigmentation at the margin of the resurfaced areas.

Numerous laser and intense pulsed light systems have been marketed specifically for the treatment of leg venulectases (spider veins). The lasers use higher energies, longer wavelengths, and contact cooling devices to achieve selective photothermolysis of both superficial and deeper leg vessels, which generally range in diameter from 0.1 to 1 mm. Superficial, arborizing networks of spider veins are often fed by reticular veins and varicosities, and treatment of these deeper vessels is a prerequisite for effective, durable clearing. Optimal results usually require a combination approach that incorporates conventional therapies such as venous compression, sclerotherapy, and ambulatory phlebectomy for larger-caliber feeding vessels. At present, most “sclerolasers” seem best suited for the treatment of isolated, superficial telangiectases, vessels too small to inject, and for those cases of postsclerotherapy matting that do not spontaneously resolve. Although needle-phobic patients may prefer the concept of laser treatment over sclerotherapy, the latter is typically *less* painful, more effective, and has lower risk of local side effects, in competent hands.

Initial trials using the 585-nm FPDL at 450 µs showed poor efficacy for leg vessels larger than 0.2 mm in diameter, with a disappointingly high rate of posttreatment hyper- and hypopigmentation. Recently, more promising results were reported

by using high-fluence, longer wavelength, long-pulsewidth lasers and intense pulse light sources equipped with contact cooling devices (Fig. 267-3). Some examples include the long-pulsed FPDL (595 to 600 nm), long-pulsed frequency-doubled Nd:YAG (532 nm), long-pulsed Nd:YAG (1064 nm), long-pulsed alexandrite (755 nm) and long-pulsed diode (800 and 940 nm). Good clearance of reticular veins as large as 4 mm in diameter has been reported using a long-pulsed 1064 nm Nd:YAG laser (7 msec; 130 J/cm ^{2}; 6-mm spot size, one to three treatments). Treatment was well tolerated, with adverse effects limited to transient postinflammatory hyper- and hypopigmentation. [16]

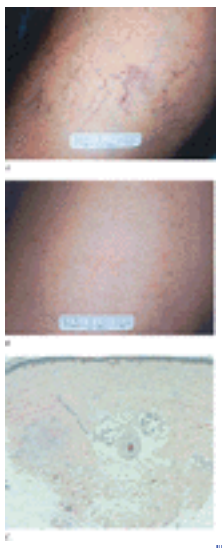

FIGURE 267-3 Leg venulectases in a patient with Fitzpatrick skin phototype I, before (*A*) and 6 months after (*B*) a single treatment with a long-pulsed Nd:YAG laser (350 J/cm ^{2}, 50-msec pulse duration). Histology taken 1 month after treatment shows an organized thrombus with fibrosis occluding the vascular lumen (*C)*. (*Images are courtesy of Kittisak Suthamjariya, MD.*)

Additional Vascular Neoplasms and Malformations

Hemoglobin-targeting lasers such as the PDL, argon, krypton, long-pulsed frequency-doubled Nd:YAG, copper vapor, and KTP, can also clear a wide range of benign vascular ectatic processes including cherry hemangiomas, venous lakes, and angiokeratomas. These lesions all feature relatively superficial blood-filled aneurysmal dilatations, rendering them susceptible to laser-induced selective photothermolysis. As in the case with PWSs, lesion anatomy (depth, size, location, blood flow, etc.) should influence both laser selection and treatment parameters. For instance, venous lakes may persist unless pulse stacking and diascopy are used to reach the deep portions. Long pulsed, near-infrared vascular lasers delivered with cooling (diode, alexandrite, Nd:YAG) are especially useful for deep lesions. Vascular lasers may also be used to improve cosmesis and reduce the risk of traumatic hemorrhage in syndromes featuring prominent vascular ectases such as hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu), blue rubber bleb nevus syndrome (with multiple venous dilatations), and Fabry's disease (angiokeratoma corporis diffusum).

Lesions Featuring Prominent Vasculature

Vascular lasers have also been used to target lesions in which proliferative vasculature is a component, such as fibrous papules, angiofibromas, acne cysts, sebaceous hyperplasia, hypertrophic scars, keloids, HPV-induced viral warts, and local plaques of psoriasis. In such instances, the mechanism of action is often obscure, and results are mixed. Warts, for instance, have a rich supply of papillary dermal capillary loops that are precisely destroyed by vascular lasers such as the FPDL. This alone might lead to ischemia of the overlying epidermis, with subsequent wart involution. Yet heat can also diffuse away from capillary loops into the surrounding papillary dermis and overlying epidermis, causing nonspecific thermal effects, including tissue necrosis, cellular apoptosis, and localized induction of antiviral cytokines and heat shock proteins. This mechanistic complexity has direct clinical implications, because even subtle differences between laser treatment protocols may result in different therapeutic outcomes. Not surprisingly, the literature reflects this ambiguity.

WARTS Lasers are useful, among the list of many other wart treatments. Laser treatment, however, is not particularly more effective than standard therapies. Reported clearance rates vary dramatically from 21 to 95 percent. In the initial study examining pulsed dye laser (PDL) treatment of warts, 39 patients were treated, with warts on the fingers and hands (n = 14), plantar surfaces (n = 6), periungual skin (n = 7), and other body sites (n = 12, including three patients with flat warts), that had been refractory to cryotherapy, CO_2 laser ablation, caustic topical agents, or surgery. [17] Warts were pared, then treated with single nonoverlapping PDL pulses (585 nm; 450 µsec pulsewidth; 6.25 to 7.5 J/cm ^{2} fluence; 5-mm spot size). This induced immediate gray discoloration of the wart, which turned into a black residuum similar to that seen after cryotherapy or topical agents. Pain was minimal during and after the procedure, and 28 patients (72 percent) experienced clearance after an average of 1.68 treatments, spaced 1 to 3 weeks apart. Only one patient developed wart recurrence during a follow-up period that was limited to an average of 5 months. Histology showed intravascular thrombosis of the dermal papillary vessels attributed to laser treatment. Robson et al. reported a prospective randomized trial comparing pulsed dye laser versus “conventional” therapy in 40 patients with 223 common, plantar, or periungual warts. [18] Fifteen of these patients received PDL treatment (585 nm; 450 µsec pulsewidth; 9.0 to 9.5 J/cm ^{2} fluence; 5-mm spot size with 1- to 2-mm overlap) and 20 were treated with either standard cryotherapy (n = 17; 15 s freeze/thaw cycles ×2), topical cantharidin (n = 1), or both cryotherapy and cantharidin (n = 2). Most treatment sessions were spaced 3 to 4 weeks apart. Results for patients in the PDL and conventional groups were statistically comparable by all parameters, including the percentage of complete responders (66 percent with PDL versus 70 percent with conventional therapy), percentage of partial responders showing >50 percent clearance (87 percent with PDL versus 82 percent with cryotherapy) and mean number of treatments needed for complete response (2.00 with PDL versus 2.06 with cryotherapy). Interestingly, warts that had been recalcitrant to prior therapies—including cryotherapy, CO_2 laser

ablation, topical cantharidin, and electrodesiccation—seemed to be no less responsive than treatment-naïve warts in either group. Based on this and other available data, the overall success rate of PDL wart treatment seems to depend on multiple factors, including wart anatomy, laser type and settings, prior treatment history, and treatment intervals. Clinical experience suggests that pulse stacking greatly increases the efficacy of PDL for wart treatment, although this has yet to be assessed in a controlled fashion.

SCARS Laser treatment of hypertrophic and keloidal scars is even more controversial than treating warts. Both types of pathologic scarring feature fibrocytic hyperplasia, excess collagen deposition, prominent telangiectasia and variable inflammation (primarily with mast cells and lymphocytes), yet keloids also contain hyalinized, thick collagen bundles and clinically tend to extend beyond original wound margins. The impetus for treating hypertrophic scars and keloids with vascular lasers stems from a lack of satisfactory alternatives, because traditional therapies, such as intralesional steroid injections, excision, radiation therapy, silicone gel sheeting, and CO_2 laser ablation, are of limited efficacy and may even exacerbate the scarring process. Keloids and hypertrophic scars clearly feature a prominent vascular component, especially during the early stages of development. There is some evidence that early pulsed dye laser treatment of immature scars may lead to improved cosmesis in areas prone to hypertrophic scarring, suggesting a potential prophylactic role. [19] The effects of 585-nm FPDL treatment on keloidal median sternotomy scars were initially reported by Alster and Williams in 16 patients (skin phototypes I to III), treating only one half of each sternotomy scar and leaving the other half as an internal control. [20] The scars had been present for a mean of 17 months, were uniformly hypertrophic, and had not received any prior treatment. Following two treatment sessions (585 nm; 450 µs; 6.5 to 7.25 J/cm ^{2}; 5-mm spot size) spaced 6 to 8 weeks apart, the investigators reported significant improvement in scar characteristics, including erythema, scar height, pliability, texture, and symptoms (pruritus, burning, and tenderness). Biopsy specimens taken from control and laser-treated sites revealed an apparent reduction in collagen fiber density and in the number of fibroblasts and mast cells in the latter. Intrigued by these results, Reiken et al. implanted fragments of human hypertrophic scar (HS) into the fascia of athymic mice, allowing these transplants to grow for 5 days before subjecting them to variable FPDL fluences and wavelengths. [21] They noted a fluence and wavelength-dependent reduction in HS implant size that correlated directly with the extent of vessel damage. Optimal vessel damage and implant size reduction was observed at higher fluence. These results suggest that selective laser-induced vessel damage can cause hypertrophic scars to regress, at least ex vivo. In contrast, a randomized, observer-blinded, controlled trial comparing FPDL (585 nm; 450 µs; 6.5 to 8 J/cm ^{2}; 5-mm spot size; 10 to 20 percent overlap) treatment of hypertrophic scars with silicone gel sheeting failed to show any difference between these two modalities and nontreated control sites. [22] Paradoxically, some PDL-treated scar segments actually showed evidence of increased blood flow following laser irradiation. This well-designed study failed to show efficacy, raising the need for further understanding and confirmation. Interestingly, high-fluence treatment may be detrimental, while low fluences may be effective. A similar situation may hold for an even more controversial use of pulsed dye lasers, “nonablative rejuvenation.” Manuskiatti et al. recently reported that PDL-treated sternotomy scars tended to show more improvement in erythema, induration and height scores when treated using lower laser fluences (3 to 5 J/cm ^{2} versus 7 J/cm ^{2}). [23]

Melanin-Containing Pigmented Lesions

Melanin is well adapted for both coloration and photoprotection in humans, strongly absorbing DNA-damaging ultraviolet radiation, with absorption decreasing steadily with increasing wavelength. Melanin (specifically eumelanin) absorbs well throughout the visible light spectrum, rendering it vulnerable to photothermal and photomechanical injury from a broad range of laser types. Although the absorption spectra of melanin and oxyhemoglobin overlap, preferential absorption by melanin occurs in the 600- to 1100-nm region, providing a useful “window” for selective photothermolysis of melanin-laden targets. Most melanin-targeting lasers, including the Q-switched ruby, alexandrite, and Nd:YAG, operate in this region of the spectrum, and are capable of reaching dermal melanin at various depths. Short pulses from Q-switched lasers are capable of targeting individual pigmented cells, while long pulses (millisecond domain) are capable of targeting collections of pigmented and nonpigmented cells, such as occur in some nevi. In contrast to dermal pigmented lesions, laser-responsive epidermal pigmented lesions have been successfully treated with almost any wavelength/pulsewidth combination at appropriate fluences.

Pulse durations of less than 1 µs can achieve thermal confinement within melanosomes, the subcellular organelle of pigmentation. Nanosecond-pulsed lasers (e.g., Q-switched ruby, alexandrite, and Nd:YAG) operate under these conditions, rapidly heating melanosomes to temperatures high enough to induce cavitation and rupture. Electron microscopy has elucidated this process, which begins with the formation of central zones of lucency within the melanosomes followed by melanosomal membrane rupture. This latter event occurs at a threshold fluence, and correlates with the clinical appearance of immediate epidermal whitening. Subthreshold fluences appear to enhance melanin production by unknown mechanisms. In contrast, suprathreshold fluences cause blebbing and rupture of the melanosome membranes, followed by vacuolar cell degeneration with the appearance of “ring cells.” Ring cells represent damaged basal keratinocytes and melanocytes containing peripherally dispersed melanin and nuclear debris. Animal studies have demonstrated a wide action spectrum for selective photothermolysis of pigmented cells, which correlates well with melanin absorption from UV through near infrared.

In the practice of treating pigmented lesions, thermal confinement within individual melanosomes or melanocytes is not always desired. For instance, compound and congenital nevi are composed of nests or complex aggregates of cells, only some of which may be pigmented. In the case of permanent laser hair removal, the putative target—the stem cell-containing bulge region of the follicle—does not contain melanin except in very darkly pigmented skin. Thermal conduction from the major site of light absorption in hair follicles—a heavily pigmented hair shaft—is needed for stem cell necrosis. Using the same wavelength, a laser can be “tuned” to target melanin-containing structures of varying sizes by altering the pulse duration and fluence parameters. This approach is what separates the actions of Q-switched and long-pulsed lasers. The former is used primarily for targeting pigmented cells, while the latter is used for targeting larger structures which contain some pigment.

EPIDERMAL MELANOCYTIC AND MELANIN-CONTAINING LESIONS: EPHELIDES, LENTIGINES, PIGMENTED SEBORRHEIC KERATOSES, AND CAFÉ AU LAIT MACULES Given their superficial location, one would expect all epidermal melanocytic lesions to be highly responsive to virtually any laser modality, even those that are not especially

melanin selective. Indeed, simple epidermal ablation with pulsed CO_2 or erbium:YAG lasers will remove benign epidermal lesions such as lentigines and ephelides. Pigmented seborrheic keratoses appear to respond equally well to a broad range of melanin-selective and nonselective lasers (and also to cryotherapy). Targeting of individual pigmented cells is not important for their destruction. In contrast, café au lait macules and melasma are far less responsive to both selective and nonselective laser removal, for reasons that are still poorly understood. Lentigines are benign epidermal lesions consisting of variable epidermal and melanocytic hyperplasia with basal keratinocytic hypermelanosis. Solar lentigines follow a photodistribution and accumulate with age, whereas the far-less-common lentigo simplex may occur as an isolated lesion or in association with genetic disorders such as Peutz-Jeghers, LEOPARD [lentigines, electrocardiographic (conduction abnormalities), ocular (hypertelorism), pulmonary (stenosis), abnormal (genitalia), retardation (of growth), and deafness], and Carney's syndromes. Ephelides (freckles) are exceedingly common, especially in Celtic skin types, and represent photodistributed foci of basal keratinocytic hypermelanosis. Lentigines and ephelides have been treated successfully using both nonspecific (CO_2, erbium:YAG) and melanin-selective (510-nm copper vapor, 532-nm KTP, frequency-doubled Q-switched Nd:YAG, Q-switched ruby, Q-switched alexandrite, etc.) wavelength lasers (Fig. 267-4). Although all of these modalities can achieve comparable lesion lightening at relatively low energy settings, distinguishing criteria include treatment expense, risks of adverse effects (scarring, erythema, pain, pigmentary changes), and overall patient preference. Based on these considerations, not all systems are equal, and some may be no better than far cheaper, conventional therapies. For instance, Stern et al. reported that in their hands, solar lentigines lightened more with liquid nitrogen cryotherapy than with low-fluence carbon dioxide (CW) or argon laser treatment. [24] The Q-switched ruby laser is excellent for treatment of lentigines on mucosal surfaces such as those seen in Peutz-Jeghers syndrome. Caution must be taken when treating clinically atypical lentigines, because these may be lentigo maligna, which can recur even years after apparently successful laser treatment. [25]

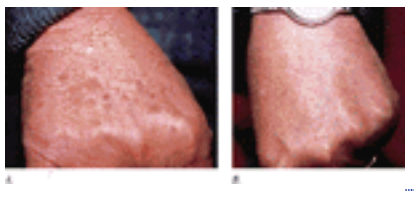

FIGURE 267-4 Solar lentigines on dorsal hand before (*A*) and after (*B*) treatment with Q-switched Nd:YAG 532-nm laser.

In contrast to lentigines, café au lait macules (CALMs) show less-predictable response to laser treatment, running the gamut from clearance to persistence, recurrence, or even darkening. These tan- to brown-colored macular skin lesions are present in approximately 10 percent of the population, occurring sporadically or in association with neurocutaneous genodermatoses such as neurofibromatosis and McCune-Albright syndrome. Both isolated and syndrome-associated CALMs are characterized histologically by the presence of basal keratinocyte hypermelanosis, variable degrees of melanocytic hyperplasia and macromelanosome production. Most attempts to clear CALMs have employed nanosecond-pulsed, melanin-selective lasers such as the Q-switched ruby and frequency-doubled Q-switched Nd:YAG. Grossman et al. used both of these systems to treat nine CALMs, all located on the trunk or proximal extremities in adult patients with skin phototypes I to III. [26] Although some lesions lightened significantly after one treatment, others failed to respond or even showed paradoxical darkening with histopathologic evidence of melanocyte activation. Eight of the nine CALMs had recurred by 6 months, and the remaining CALM recurred at 7 months following sunlight exposure. Two types of CALMs were defined using histopathologic criteria: those with melanocytic hyperplasia and those with only basal keratinocyte hypermelanosis. In addition, three patients had type I neurofibromatosis, and their CALMs contained prominent macromelanosomes. Unfortunately, none of these differences correlated clearly with treatment response. In contrast, Somyos et al. reported more durable CALM clearing (>70 percent at 22 months follow-up) in 15 of 16 Asian patients treated with a scanned, continuous mode 511-nm copper vapor system. [27] Unfortunately, response to laser treatment of CALMs remains an enigma. At present, patients with CALMs seeking treatment should be advised that they will likely require multiple treatments to achieve unpredictable results. Multiple treatments at closely spaced intervals may yield the best chance for durable lightening, but this approach has not been subjected to prospective, blind studies. Specific criteria for predicting CALM response to laser irradiation remain ill-defined, and are largely based on anecdotal experience. Childhood CALMs appear to clear more frequently after laser treatment than adult lesions, however this observation has yet to be confirmed objectively. Transient improvement of CALMs is often followed by recurrence after a few months. Impressive clearing of a large facial CALM, which had failed to lighten despite multiple prior treatments with Q-switched lasers and topical bleaching creams, was reported following two resurfacing treatments with an erbium:YAG laser, and remained clear at 18 months follow-up. [28] This and Somyos' study suggest that some degree of nonspecific epidermal or dermal injury may be important for CALM response to laser treatment.

MELANOCYTIC NEVI: NEVUS SPILUS, NEVOCELLULAR MELANOCYTIC NEVI, CONGENITAL NEVI, AND DYSPLASTIC NEVI Nevus spilus presents as a speckled, localized or segmental pigmented lesion consisting of both CALM and nevocellular melanocytic nevus components, although variants containing foci of Spitz nevi, lentigines, blue nevi, dysplastic nevi, or even melanoma have been described. As in the case with CALMs, larger lesions may be associated with systemic abnormalities such as neurofibromatosis. Laser treatment of nevi spilus is hindered by three main concerns: (1) the CALM component may be refractory to treatment and prone to recurrence; (2) the speckled nevus component may contain deeper nests of cells that are hard to eradicate using nanosecond-pulsed melanin-selective lasers; and (3) while exceedingly small, the risk of melanoma developing within some larger nevi spilus raises additional treatment concerns. Despite these concerns, an excellent and durable clinical response of the speckled lentiginous portion of these lesions can often be obtained by treatment with either Q-switched or normal ruby or alexandrite lasers. When treating nevi spilus, it seems prudent to biopsy any atypical components prior to initial laser irradiation, and to avoid treating patients with a personal or strong family history of melanoma. Patients should be monitored closely for recurrence. Laser treatment of nevomelanocytic nevi remains a problematic area, especially when nevi have clinically atypical features suggestive of dysplastic nevus syndrome. Laser treatment of these lesions is not recommended. While no clinical data to date suggest that laser treatment increases the risk of malignant transformation, there are concerning reports of melanoma occurring within previously laser-treated pigmented lesions. In addition, pseudomelanoma can arise within congenital and acquired melanocytic nevi shortly after CO_2 or argon laser ablation. [29] These CW systems destroy melanocytic lesions through nonselective thermal destruction—a process that denatures dermal collagen and typically leads to some degree of scarring. Residual nevomelanocytic cells may repopulate the scar in irregular nests, clinically

and histologically mimicking regressing melanoma. While CO_2 laser vaporization has recently been used for the palliative debulking of inoperable melanoma and cutaneous metastases, Strobbe et al. reported rapid recurrence in 469 in-transit or satellite lesions following laser treatment, [30] suggesting that even this indication is very limited. At present, there is little or no role for nonselective CW lasers in the treatment of nevomelanocytic lesions, especially those with a dermal component. Instead, most recent attempts to treat nevomelanocytic nevi have employed melanin-selective lasers such as the Q-switched ruby, Q-switched alexandrite, and normal-mode ruby, with the goal of selectively destroying pigmented nevi cells and nests. Vibhagool et al. showed that the Q-switched ruby laser (694 nm; 8 J/cm ^{2}; 28 ns; 5-mm spot size) is highly effective at treating small nevomelanocytic nevi, especially when these benign pigmented lesions are confined to the epidermis. [31] Sixty-seven percent of the treated nevi showed complete clinical and histologic clearance, with no recurrence after a limited follow-up period of 10 weeks. The 33 percent of treated nevi that failed to clear contained persistent melanocytes at depths of 0.10 to 0.40 mm. However, none of these showed irregular nesting or any other features of pseudomelanoma. The Q-switched ruby laser is less effective at clearing congenital nevi, apparently because these lesions contain deeper dermal melanocytic nests, occasional adnexal involvement and amelanotic components. [32], [33] Grevelink et al. noted that Q-switched Nd:YAG (1064 nm) or Q-switched ruby (694 nm) lasers were only capable of removing the superficial portions of congenital nevi, leaving residual nests at depths of 0.16 mm and 0.44 mm, respectively. [33] Primarily in Japan, congenital nevi have been treated with normal-mode, long-pulsed ruby lasers (694 nm; 0.3 to 1.0 ms; 10 to 30 J/cm ^{2}, 10- to 15-mm spot sizes). After an initial report showing impressive clinical results in three patients with extensive congenital nevi, Ueda et al. reported a larger case series with histologic follow-up to 8 years. All nevi faded significantly following four laser treatments, with minimal clinical scarring and an overlying skin appearance approaching that of adjacent normal skin. Despite these impressive cosmetic results, long-term follow-up showed the persistence of residual melanocytic nests, located 1 mm or more beneath the epidermal surface and covered by zones of dermal fibroplasia. [34] This superficial layer of “masking” fibrosis may account for at least some of the observed cosmetic improvement. The long-term risk from leaving residual melanocytic nests remains unclear, and theoretical considerations such as laser-induced melanocyte activation remain. Fibrosis induced by prior laser treatments can complicate the interpretation of subsequent histopathology, and superficial dermal fibrosis could conceivably conceal an evolving focus of melanoma, potentially delaying diagnosis. For these reasons, it is hard to advocate laser treatment for congenital nevi that are amenable to surgical excision. Lesions that are treated using lasers warrant close clinical follow-up. Data on laser treatment of dysplastic nevi is understandably sparse. In one small study, Duke et al. treated a combined group of benign, congenital and atypical nevomelanocytic nevi with either the Q-switched ruby laser, the normal-mode ruby laser, or both lasers together. [35] Although a single treatment yielded significant clinical lightening in 52 percent of the nevi, no lesion demonstrated complete histologic destruction of all nevomelanocytes. Whether or not multiple treatment sessions could achieve complete eradication of atypical nevi remains to be determined, but destruction of purely epidermal lesions might be attainable. Although surgical excision should remain the standard of care for treatment of dysplastic nevi, a better understanding of how lasers interact with these common lesions is sorely needed, because dysplastic nevi may easily be treated inadvertently as benign nevi or during laser hair removal.

DERMAL MELANOCYTIC LESIONS The group of dermal melanocytic lesions includes nevus of Ota, nevus of Ito, dermal melanosis (mongolian spot), and blue nevi. While these latter two lesions are far more prevalent, most attention has focused on laser treatment of the nevus of Ota (nevus fuscoceruleus ophthalmomaxillaris)—a cosmetically disfiguring accumulation of dermal dendritic melanocytes presenting with bluish gray discoloration along one or more branches of the trigeminal nerve. This hamartomatous lesion, which typically presents during childhood, is primarily found in Asian populations but may affect other ethnic groups. A rarer variant of nevus of Ota occurs in association with an ipsilateral or contralateral capillary malformation (PWS)—a condition termed phakomatosis pigmentovascularis. Before the advent of Q-switched melanin-selective lasers such as the Q-switched ruby, alexandrite, and Nd:YAG, no practical, nonscarring treatment options for nevi of Ota existed. In the early 1990s, impressive clearance of nevi of Ota was reported [36] using the Q-switched ruby. Subsequent larger studies by Watanabe and Takahashi [37] and others confirm that the Q-switched ruby, alexandrite, and Nd:YAG lasers are all capable of selectively destroying dermal melanocytes without inducing significant scarring or surface epidermal change. The Q-switched ruby laser selectively destroys melanocytes to a depth of 1.5 mm below the skin surface—a depth that approximates the thickness of the entire epidermis and dermis in the temporal area where nevi of Ota are typically located. Variables affecting treatment response include pigment depth and color, with deeper lesions tending to be more refractory to treatment and prone to recurrence. Color, which reflects both melanocyte depth and density, appears to be an especially useful clinical predictor of treatment response. To this end, Ueda et al. recently found that predominantly brown nevi of Ota required only three treatments to achieve >75 percent clearance. In contrast, all blue-green nevi in their study group needed at least six treatments to obtain comparable clearance, while brown-violet and violet-blue nevi showed an intermediate response. [38] For most nevi of Ota, excellent clearance can be obtained by using Q-switched laser fluences ranging from 5 to 10 J/cm ^{2}, although lower fluences are associated with less hypopigmentation. [39] While multiple treatments increase the response rate, some nevi of Ota will show substantial clearance following a single treatment, with progressive fading noted for months after laser irradiation. Multiple treatments are typically spaced 2 to 3 months apart, but should be delayed, if necessary, until transient hyperpigmentation has resolved. Hypertrophic scarring and textural changes rarely occur, however mottled hypopigmentation was reported in up to 16.8 percent of Asian nevus of Ota patients treated with the Q-switched ruby laser at fluences of 5 to 7 J/cm ^{2}. [40] Risk factors for this hypopigmentation, which persisted for at least 12 months after treatment, included darker patient skin type, the use of multiple treatments, and higher fluence settings. [40], [41] Chan et al. noted an especially high incidence of hypopigmentation in patients receiving combined laser therapy with both the Q-switched alexandrite and Q-switched Nd:YAG lasers (38 percent), although some of these cases may have been temporary in nature. In contrast, they noted posttreatment hypopigmentation in 10.5 percent of patients treated with the Q-switched alexandrite alone and in only 7.6 percent of those treated with the Q-switched Nd:YAG alone. [41] Laser-treated nevi of Ota rarely recur. While nevi of Ota clear well in most locations independent of size, the persistence of periorbital pigmentation may be more common than previously thought—a phenomenon Chan et al. recently termed the “panda's sign.”

Hamartomas: Becker's Nevus, Epidermal Nevus, Nevus Sebaceus

Becker's nevus typically presents during puberty as a tan- to brown-toned hypertrichotic plaque located on the shoulders, upper back, chest, or proximal arms. The lesion, which is far more prevalent in males and usually presents during

puberty, is rarely associated with underlying soft-tissue hypoplasia or musculoskeletal abnormalities. Histologically, Becker's nevi feature variable degrees of basilar keratinocytic hypermelanosis, epidermal hyperkeratosis, and acanthosis with underlying hypertrichosis and smooth muscle fascicles. The combination of hypertrichosis and epidermal pigmentation makes Becker's nevi appealing targets for melanin-selective photothermolysis. Unfortunately, laser treatment has yielded disappointing results characterized by partial response and recurrence. Although good response has been reported after long-pulse ruby laser treatment, [42] large case series addressing the average treatment response in Becker's nevi are lacking.

Epidermal nevi represent a range of hamartomatous processes characterized by epidermal and adnexal hyperplasia with variable ectodermal differentiation. They are classified according to the predominant type of differentiation (epidermal, sebaceous, follicular, etc.) and distribution, ranging in extent from localized plaques to generalized streaks and whorls distributed along Blaschko's lines. While localized, sporadic lesions are relatively common (occurring in an estimated 1 per 1000 live births), extensive and generalized lesions may be associated with a wide range of systemic abnormalities, including musculoskeletal, neurological and ocular defects—a constellation termed the epidermal nevus syndrome. Treatment options for epidermal nevi include surgical excision, dermabrasion, cryosurgery and laser ablation. Topical therapies such as retinoic acid and 5-fluorouracil are far less effective. Epidermal nevi featuring hamartomatous dermal components tend to recur when treatment is confined to the epidermis; unfortunately, procedures that also ablate the dermis tend to produce significant scarring. For localized epidermal nevi amenable to surgical excision, this remains the best treatment option. Nevertheless, laser ablation using CO_2 or argon CW devices can yield impressive and durable cosmetic improvement (Fig. 267-5), even in cases of generalized epidermal nevi. Scarring, which was especially problematic with the earlier generation of CW argon and CO_2 lasers, can now be minimized by using a combination of pulsed or scanned CO_2 and erbium:YAG lasers. Michel et al. obtained encouraging results using a super-pulsed CO_2 laser to treat 10 linear epidermal nevi, 5 of which were inflammatory linear verrucous epidermal nevi (ILVEN). They observed only two recurrences within a 2-year follow-up period, both occurring in younger patients who had been treated with lower energy parameters. [43] Pigmented epidermal nevi have also responded favorably to either Q-switched or normal-mode ruby laser treatment.

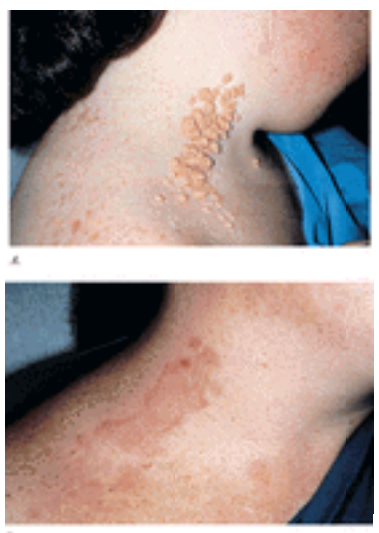

FIGURE 267-5 Epidermal nevus in the neck before (*A*) and after (*B*) treatment with a rapidly scanned CO_2 laser.

Nevus sebaceus of Jadassohn—a relatively common form of epidermal nevus featuring epidermal papillomatosis, prominent sebaceous and apocrine gland hyperplasia—typically presents as a solitary verrucous lesion during childhood. Characteristically located on the scalp, this yellow- to pink-colored hamartoma responds to hormonal stimuli, flattening during childhood but then becoming raised and verrucous during puberty. Although CO_2 laser ablation may yield significant cosmetic improvement in inoperable cases, nevus sebaceus should be completely excised surgically whenever possible given the lesion's known malignant potential.

Melasma, Drug-Induced and Postinflammatory Hyperpigmentation

Melasma is a very common pigmentary disorder featuring smoky brown, photodistributed discoloration, classically involving the face in a masklike distribution. Women are primarily affected, with exacerbating factors including sun exposure, hormonal influences such as pregnancy and oral contraceptive use, ethnicity (Hispanic, Asian, African American) and hereditary predisposition. Three clinical variants are recognized: (1) epidermal melasma, in which melanin deposition is limited to the basal and suprabasal epidermal layers; (2) dermal melasma, featuring perivascular and dermal melanophages; and (3) mixed melasma, in which pigmentation is found in both epidermal and dermal locations. Wood's lamp illumination will enhance epidermal pigmentation alone, providing a convenient bedside diagnostic tool. This distinction is useful, because the epidermal type of melasma is responsive to topical hydroquinone and retinoids. In contrast, dermal pigmentation is notoriously difficult to treat.

Melasma should be responsive to Q-switched lasers capable of selectively targeting melanin, yet this has not been the case in practice. Rather, all forms of melasma have proven refractory to laser treatment, with recurrence or even pigment darkening being the rule. There is little doubt that Q-switched laser treatment destroys the dermal melanophages present in the dermal form of melasma, but treatment necessarily damages the epidermis in the process, potentiating further melasma. Patients with refractory facial melasma or postinflammatory hyperpigmentation typically do not improve after Q-switched ruby laser treatment. [44] Transient improvement had been noted after using erbium:YAG skin resurfacing to treat refractory facial melasma; however, all patients experienced significant postinflammatory hyperpigmentation. [45] At present, laser treatment of melasma cannot be advocated as a single-line therapy, although judicious use of Q-switched laser irradiation or erbium:YAG resurfacing in combination with topical bleaching creams and sun protection may yield

cosmetic improvement in some individuals.

Laser treatment of postinflammatory hyperpigmentation is less disappointing, but variable, especially in darker skin types prone to laser-induced pigment alteration. In lighter skin types, however, Q-switched lasers such as the ruby, alexandrite, and Nd:YAG have been used to treat postsclerotherapy, or drug-induced, hyperpigmentation with good results. In contrast to postinflammatory hyperpigmentation, which is caused by melanin pigment incontinence, postsclerotherapy hyperpigmentation is caused by vessel rupture, erythrocyte extravasation, and perivascular hemosiderin deposition. Tafazzoli et al. used the Q-switched ruby laser (5.6 to 10.5 J/cm ^{2}; 4-mm spot size) to treat this common sclerotherapy complication in eight patients, noting significant lightening in 92 percent of treated areas. [46]

Drug-induced hyperpigmentation may be caused by dermal and epidermal deposition of drug metabolites, hemosiderin, melanin, or a combination of pigment types. The unwanted pigmentation—which can vary from slate-gray to blue, lilac, brown, yellow, or red depending on the culprit drug—often follows a photodistribution (e.g., amiodarone, imipramine), but may also occur on mucosal surfaces, nails, teeth, or in a generalized distribution (e.g., minocycline, busulfan). Q-switched ruby, alexandrite, and 1064 nm-Nd:YAG lasers have all been used to lighten minocycline-induced cutaneous hyperpigmentation with good results. Significant cosmetic improvement has also been reported by using Q-switched lasers to treat amiodarone- and imipramine-induced hyperpigmentation.

Exogenous Dermal Pigment: Tattoos

Prior to the advent of Q-switched laser technology, individuals desiring tattoo removal had to choose between keeping their tattoo or accepting a scar in its place. While a major step forward, Q-switched laser treatment of tattoos is still far from ideal. In skilled hands, ablative techniques, including salabrasion, dermabrasion, cryotherapy, excision, and CO_2 laser vaporization, are capable of yielding cosmetically acceptable results, yet none can promise uniform, scar-free tattoo removal. With the introduction [47] and subsequent refinement of Q-switched laser technology for the treatment of tattoos, selective removal of tattoo pigment without scarring became a real clinical possibility.

An ideal treatment should remove all traces of tattoo pigment without leaving residual scarring. Most tattoo pigment particles are localized to lysosomes, primarily within dermal fibroblasts, macrophages, and occasional mast cells. [48] Pigment particle size ranges from about 2 to 400 nm, with the predominant pigment type being an oval-shaped 40-nm granule. Q-switched lasers produce nanosecond pulses, thereby achieving thermal confinement within individual lysosomes. With Q-switched laser treatment, the irradiated pigment particles reach peak temperatures in excess of 300°C (572°F) within nanoseconds, producing internal changes such as mechanical rupture and chemical alteration (e.g., combustion for carbon-based particles). Taylor et al. and others have described the morphologic appearance of such irradiated pigment particles as “lamellated” or “shell-like,” with central zones of lucency and diminished opacity. [48] These intrinsic structural and chemical changes alone may account for some of the tattoo lightening that follows Q-switched laser irradiation. Each heated pigment particle also vaporizes a shell of water surrounding it, creating a shock wave and cavitation that may contribute to the mechanical rupture and dispersion of the pigment throughout the host cell. Cell rupture and release of pigment fragments into the extracellular space occurs, and the ink is partially eliminated via lymphatic drainage, rephagocytosis, or transepidermal elimination—all proposed mechanisms of posttreatment tattoo clearance. Strategies to augment these “pigment-elimination pathways” may hasten the process of tattoo lightening. In addition, there is some evidence that a new generation of picosecond-pulsed lasers may be even more effective at achieving both thermal and inertial confinement within individual tattoo pigment particles, leading to enhanced photoacoustic effects and more effective tattoo pigment clearance. [49] At present, technological and cost constraints have limited the clinical availability of picosecond lasers.

Over the past decade, the term “laser tattoo removal” has found its way into popular culture, and there is a current misconception that modern lasers can simply erase any tattoo. Recently, the incidence of decorative body art in the United States has skyrocketed to in excess of 10 million people. While many of these new tattoos will lighten with appropriate Q-switched laser treatment, the majority of multicolored tattoos cannot be removed completely. This has become increasingly true as the complexity of tattoo inks continues to increase.

Cosmetically, the best results are obtained when treating blue-black, amateur tattoos, which are produced with carbon-based pigment such as India ink. Using the Q-switched ruby laser at settings of 4–10 J/cm ^{2} (5-mm or 6.5-mm spot size), these tattoos clear without scarring after four to six treatment sessions, spaced 3 to 4 weeks apart. In contrast, professional tattoos often contain multiple pigment types (black, blue, green, red, yellow, orange, purple, etc.), typically deposited in a dense band in the papillary and upper reticular dermis. While some professional tattoos will clear, treatment response can be difficult to predict, especially for tattoos featuring bright, iridescent colors. In general, one should use a Q-switched laser wavelength that is complementary to the tattoo color. For example, green tattoos are best treated with red laser light, and red tattoos are best treated with green laser light. Blue, black, and green tattoos are responsive to Q-switched ruby (694 nm) or Q-switched alexandrite (755 nm) treatment. Both lasers produce significant but transient hypopigmentation in darker skin types. The 1064-nm Q-switched Nd:YAG laser is better tolerated by darkly pigmented skin, and is probably the laser of choice for most black tattoos, but is usually incapable of removing green tattoos. Yellow and orange pigments absorb minimally at any of the commercially-available laser wavelengths, making these colors notoriously difficult to remove.

Theoretically, in vivo absorption spectra can guide laser wavelength selection by providing absorption profiles for any tattoo pigment regardless of its composition. Absorption, however, does not necessarily translate into clinical efficacy. Green tattoo pigment, for instance, absorbs Q-switched ruby laser energy well, as evidenced by the formation of a vigorous epidermal whitening reaction during treatment with this device. Nevertheless, green tattoos often resist laser lightening for unclear reasons that may relate to the chemical composition of the ink itself (e.g. copper or chromium content) (Fig. 267-6). Chemical analysis of tattoo ink stock samples reveals that they are complex mixtures of metallic salts, organic dyes and solvents containing crystalline structures of various sizes (20 to 900 nm) and shapes (cubes, needles, bars, platelets, etc.). For colored tattoos, industrial organic azo and polycyclic dyes have largely replaced

inorganic metallic pigments such as chromium, cobalt, iron, mercury, and cadmium—a trend that is of special concern because organic dyes are known to produce carcinogenic compounds (e.g., aromatic amines) when heated above 200°C (392°F). [50]

FIGURE 267-6 Professional tattoo before (*A*) and after (*B*) multiple Q-switched ruby laser treatments. Note resistant green and red colors and mild hypopigmentation. Red pigment should be responsive to treatment with a Q-switched Nd:YAG 532-nm laser, while green is commonly refractory to “appropriate” wavelength lasers.

Laser-induced chemistry can also induce unwanted color changes within tattoos. When laser-irradiated tattoo particles reach high temperatures, tattoo compounds such as ferric oxide (Fe_2O_3, rust-colored) and titanium dioxide (TiO_2) may shift from their oxidized to reduced states, producing dramatic color changes. In particular, flesh-toned, pink or red cosmetic tattoos, such as those used for “permanent lip-liner,” can permanently blacken immediately after Q-switched laser irradiation. Titanium dioxide, an inert compound that is commonly used to lighten tattoo colors, also darkens from white to blue-black following in vitro Q-switched Nd:YAG laser irradiation—a phenomenon that may contribute to the treatment resistance or paradoxical darkening seen in some modern colored tattoos. [51] Consequently, cosmetic tattoos on the face should be approached cautiously, using test spots before any broad treatment attempt is made. Alternative methods for cosmetic tattoo removal, such as gentle pulsed CO_2 or Er:YAG laser ablation, should also be considered. Finally, patients must be questioned for any history of oral or parenteral gold use before initiating Q-switched laser treatment, because these patients are at risk for laser-induced chrysiasis—an iatrogenic blue-purple skin discoloration caused by laser-induced fragmentation of dermal gold deposits. [52]

Laser and IPL Hair Removal

Photoepilation is one of the most popular dermatologic applications of laser and intense pulsed light. Emphasis has been placed on the potential permanence of laser hair removal, but long-lasting temporary hair removal by lasers or IPLs is also useful. Optical devices may someday challenge the dominance of even the conventional razor blade.

Although often considered a “cosmetic” procedure, important medical indications for photoepilation include the treatment of hypertrichosis and hirsutism, both of which are potentially disfiguring. Hypertrichosis may be caused by genetic, endocrine, or acquired endogenous (e.g., paraneoplastic hypertrichosis lanuginosa, malnutrition) or exogenous factors (e.g., cyclosporine use). In contrast, hirsutism features increased terminal hair growth in androgen-dependent areas such as the upper lip, chin, jaw line, chest, lower abdomen, and upper thighs. Hirsutism caused by polycystic ovary disease is very common, and responds well to laser treatment. Excess hair often causes significant emotional distress and poor self-image in affected individuals, depending to some extent on cultural context. Traditional hair removal methods such as shaving, waxing, plucking, and chemical epilation can only provide temporary improvement and often cause irritation. Electrolysis (direct current) and electrothermolysis (RF current) destroy both pigmented and nonpigmented hairs, but these techniques require the passage of electrical current into individual hair follicles, making them time-consuming, painful, and highly dependent on the operator. It should be emphasized, however, that electrolysis provides advantages not yet achieved by laser hair removal, notably the ability to treat white hair.

In 1996, Grossman et al. first reported the successful, selective destruction of pigmented hair follicles using a normal-mode ruby laser (694 nm; 270 µs; 6-mm spot size) set at high fluence parameters (30 to 60 J/cm^2), and delivered through a cold sapphire lens to minimize epidermal injury. [53] Histologically, hair loss in treated areas correlated with selective thermal injury of individual follicular units, and there was a fluence-dependent growth delay at treatment sites for up to 6 months. Four of the 13 patients in this small cohort had nonscarring alopecia in the laser-treated areas 2 years later. [54] Histologically, there was an increase in vellus-like, miniaturized hairs without scarring, mimicking the appearance of androgenetic alopecia. Laser-induced alopecia was greater in areas that had been shaved rather than plucked prior to treatment, suggesting that the presence of a pigmented hair shaft within the follicle is one prerequisite for efficacy. Terminal hair loss was greatest at sites treated with the highest fluence (60 J/cm^2).

An impressive variety of laser hair removal devices has ensued, and largely eclipsed the stately ruby laser. The most popular laser for hair removal at present is a high-powered diode array (800 nm, 5 to 100 msec), delivered with contact skin cooling. Other popular systems include a long-pulse alexandrite (755 nm, 3 msec) delivered in combination with cryogen spray cooling, and long-pulse Nd:YAG lasers with skin-cooling handpieces. There are at least two key follicular targets: the matrix region of the hair bulb and the bulge region of the outer root sheath. The follicular unit is a dynamic structure, changing as the terminal hair cycles between periods of active growth (anagen), transition (catagen) and rest (telogen). The hair bulb, for instance, varies in depth from 2 to 7 mm below the epidermal surface and is located most superficially during early anagen, which may be somewhat more susceptible to laser-induced injury. [55] The bulb region is responsible for hair shaft growth and contains matrix cells and melanocytes that are highly active during anagen but undergo apoptosis and regression during catagen and telogen. Injury to the bulb during anagen will precipitate premature but temporary hair loss. In contrast, the bulge region of the follicle is a poorly melanized, subtle structure located 1 to 1.5 mm below the epidermis near the insertion of the arrector pili muscle, and at the maximum distance from the hair shaft, at the margin of the outer root sheath. Destruction of the bulge is probably a prerequisite for permanent hair removal (Fig. 267-7), because this region contains stem cells thought to be essential for follicular bulb renewal and hair cycling.

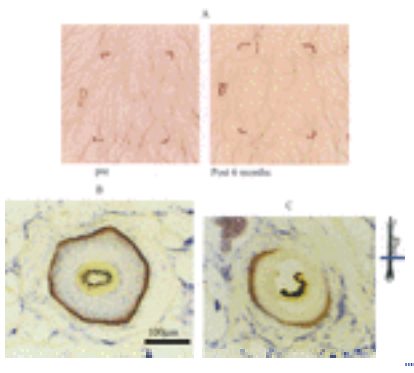

FIGURE 267-7 Laser hair removal using a diode laser with chilled-sapphire cooling tip (810 nm; 40 J/cm ^{2}; 30 msec). Representative clinical pictures of thigh hair at baseline and 6 months following a single laser treatment (*A*) are shown, along with pre- (*B*) and immediately posttreatment (*C)* histology images (Giemsa stain) taken from ex vivo diode-laser treated human scalp hair. Note the laser-induced thermal damage (loss of NBTC staining) to outer root sheath cells that stain positive with the stem-cell marker C8/144B, correlating with stem cell damage (*C)*. (*Images are courtesy of Dieter Manstein, MD.*)

Longer wavelength lasers, such as the diode (810 nm) and long-pulsed Nd:YAG (1064 nm), achieve deeper penetration than the long-pulsed ruby laser (694 nm) and alexandrite (755 nm). Campos et al. reported fluence-dependent permanent hair loss following one to four treatments with a sapphire-chilled 800-nm pulsed diode laser array system [parameters: 10 to 40 J/cm ^{2}; mean fluence = 33.4 J/cm ^{2}; pulsewidth (msec) = 50% of fluence (J/cm ^{2}); 9 × 9 mm ^{2} spot size]. They noted only sparse regrowth in 59 percent of their test subjects after a mean follow-up period of 8.7 months. [56] Alster et al. used a long-pulsed Nd:YAG laser to induce permanent hair reduction in patients with darkly pigmented skin (phototypes IV to VI), observed 12 months after the last of three monthly treatment sessions. Even though high treatment fluences of up to 50 J/cm ^{2} were used in most patients, only 5 percent experienced transient pigmentary alteration and vesiculation was seen in only 1.5 percent. [57] African Americans with hirsutism or pseudofolliculitis barbae tend to respond well to treatment with either diode or Nd:YAG lasers, with minimal side effects when used at lower fluences. While not exact, the general correlation between skin color and hair color appears to be such that high fluences are not necessary in many darkly pigmented patients. The best combination of safety and efficacy for dark skin is achieved by long pulse duration (30 to 100 msec or more), low fluence settings, and aggressive contact skin cooling to minimize epidermal injury.

IPLs are also useful for hair removal. As with many lasers, pulsewidth can be adjusted to some extent using stuttered pulses; unlike lasers, there is also wavelength flexibility by filtering the IPL output. The IPLs can generate fluences of up to 90 J/cm ^{2}, delivered in single, double, or triple pulses. Long-term epilation has been demonstrated using fluences of 34 to 42 J/cm ^{2}, comparable to laser devices. [58] IPL-associated adverse effects such as transient hyperpigmentation and crusting are similar to those seen with lasers.

Because all of these photoepilation devices target melanin within the hair follicle, blonde, white, and gray hairs pose a treatment challenge. Unfortunately, there has yet to be a demonstrated solution to this problem. Exogenous, topical chromophores capable of infiltrating the hair follicle could in theory be employed, but have thus far failed to produce permanent hair removal. Pigmented and nonpigmented hair follicles should be equally susceptible to photochemical injury—a concept that has fueled recent interest in the use of photodynamic therapy (PDT) as an alternative means for hair removal. One promising approach utilizes topically applied aminolevulinic acid (ALA)—a heme precursor that is rapidly metabolized in vivo to the potent photosensitizing compound protoporphyrin IX (PP IX). Several hours after ALA application, PP IX is concentrated within follicular units and sebaceous glands, where it releases singlet oxygen upon exposure to red light (e.g., 635 nm). If adequate ALA concentrations are paired with a sufficiently high fluence, the resulting follicular damage can lead to partial hair loss, reported to persist for up to 6 months in one small study. [59]

Infrared, Ablative Lasers: CO_2 and Erbium:YAG

Both CO_2 and Er:YAG lasers emit light in the infrared portion of the electromagnetic spectrum, a region that is strongly absorbed by tissue water. Specifically, the water absorption coefficients for CO_2 (10,600 nm) and Er:YAG wavelengths are 800 cm $^{-1}$ and 13,000 cm $^{-1}$ respectively, making both of these lasers well-suited for selective ablation of the water-rich epidermis. The earliest CW CO_2 lasers were used for tissue cutting (in the focused mode) or ablation (in the defocused mode), with ablation primarily limited by excessive residual thermal damage and the associated high risk of scarring.

With the introduction of short-pulsed and rapidly scanned, high-energy infrared lasers, it became possible to ablate the epidermis while limiting residual thermal damage to a predictable, superficial dermal zone. This type of controlled ablation has proven to be especially useful for the destruction of primarily epidermal lesions such as seborrheic and actinic keratoses, epidermal nevi, and warts. In addition, both CO_2 and Er:YAG lasers have been used effectively to debulk lymphangiomas and a variety of appendageal tumors, including syringomas, xanthomas, xanthelasma, trichilemmomas, and angiofibromas. Although recurrence rates are high for many of these conditions, cosmetic improvement can be dramatic and potentially life altering.

Despite their clinical versatility, infrared lasers such as the CO_2 and Er:YAG are most commonly used in dermatology to treat photodamaged skin and acne scarring. The dual properties of high water absorption and predictable residual thermal damage make these lasers especially useful for these indications. For a detailed review of laser skin resurfacing, see Chap. 271.

Nonablative Dermal Remodeling

Enthusiasm for the long-term benefits of laser skin surfacing has been tempered by short-term adverse effects including pain, prolonged downtime, persistent erythema, postinflammatory hyperpigmentation, and the need for diligent and time-consuming postoperative wound care. Furthermore, permanent hypopigmentation or scarring, while rare, remain potentially disfiguring complications. To address these challenges, recent attention has focused on various lasers and IPLs capable of inducing selective dermal injury without epidermal ablation. The physical principles behind such nonablative dermal remodeling or “subsurfacing” are not new, but the actual efficacy and potential biological response mechanisms involved have yet to be elucidated in detail. It is clear that photothermal injury is the stimulus. Injury to vascular endothelial cells and fibroblasts may initiate a dermal remodeling process through the induction and release of soluble factors involved in normal wound healing such as collagenase, type I collagen and platelet derived growth factor. [60], [61] Ideally, thermal injury is confined to the dermis, thereby circumventing the prolonged wound healing, erythema and pain associated with ablative modalities such as laser skin resurfacing (LSR).

The first report of nonablative dermal remodeling stems from the anecdotal observation that pulsed dye laser treatment of facial telangiectases is associated with subtle softening of rhytides in the treated areas. Pulsed dye lasers have also been used to treat atrophic striae distensae with modest success, suggesting that selective injury of dermal vessels may influence dermal collagen remodeling. [62] Encouraged by these preliminary observations, Zelickson et al. used a pulsed dye laser (585 nm; 450 msec; 7- or 10-mm spot size with 10 to 15 percent overlap; 3.0 to 6.5 J/cm ^{2}) to treat 20 subjects with photodamaged facial skin. [63] They observed subtle PDL-induced improvement in 9 of 10 patients with moderate and 4 of 10 patients with severe sun-induced rhytides. Representative skin biopsies taken 6 and 12 weeks after treatment showed that areas of solar elastosis had been replaced by superficial, thickened, grenz zones of organized collagen. These features, combined with the findings of increased dermal mucin and active fibroblasts, were all suggestive of dermal collagen remodeling. Interestingly, lower fluences may be more effective. The FDA has cleared a 0.3-msec pulsed dye laser operating at low fluence without skin cooling for this indication; comparative studies are lacking.

More recently, lasers and IPLs capable of inducing nonablative dermal remodeling with little or no associated purpura have been developed and marketed specifically for this indication. The lasers, including the 1320-nm Nd:YAG, 1540-nm erbium glass, and 1440-nm diode lasers, all feature penetrating wavelengths absorbed by water, with essentially zero melanin or hemoglobin absorption. Epidermal sparing is achieved via a combination of approaches including contact or cryogen spray cooling and intradermal beam focusing. Nelson et al. first reported using a 1320-nm Nd:YAG laser in combination with cryogen spray cooling to achieve selective dermal injury in porcine dermis, using laser fluences of up to 36 J/cm ^{2}. Similar fluences without cryogen spray cooling caused epidermal blistering and necrosis. [64] Subsequently, Menaker et al. used a cryogen spray-cooled 1320-nm Nd:YAG laser to treat periocular rhytides and postauricular skin in 10 healthy volunteers (three treatments, every 2 weeks; parameters: 1.32 µm; 20-msec macropulses; 32 J/cm ^{2}; 5-mm spot size; 33 percent overlap; DCD (or dynamic cooling device) 20 ms spray time/10 ms delay time. [65] They assessed rhytid severity, pigment alterations, scarring and patient discomfort at 1 and 3 months posttreatment, noting minimal rhytid improvement in 4 of 10 patients. Four of 10 postauricular skin biopsies (taken 1 month after treatment) showed a statistically insignificant increase in dermal collagen. Of note, four patients developed posttreatment hyperpigmentation, and three patients developed periocular blistering followed by pitted scarring. [65] A larger study by Kelly et al. found statistically significant improvement only in subjects with severe periorbital rhytides, assessed at 6 months follow-up. They also noted blistering when the surface temperature of treated skin exceeded 50°C (122°F), with pinpoint scarring occurring at four sites in two blistered subjects (2.8 percent). [66]

Ultraviolet Lasers for the Treatment of Psoriasis and Vitiligo

Excimer lasers employ a mixture of a noble gas and halogen to produce a molecule that only exists in its excited (metastable) state within the laser cavity. Such molecules are called excited dimers, or excimers. Excimer lasers produce high-average power quasicontinuous trains of nanosecond UV pulses, and are widely used in industry and ophthalmology for extremely precise ablation. The 193-nm, KrF excimer laser ablates about 0.1 µm of corneal tissue per pulse, which allows precise permanent correction of refractive disorders such as myopia.

Recently, a fiber-optic–coupled 308-nm XeCl excimer laser was used in dermatology as a source for local narrow-band UVB therapy of psoriasis and vitiligo. UVB phototherapy is a well-established treatment for a variety of inflammatory dermatoses. Bonis et al. first reported the efficacy of narrow-band conventional UVB versus excimer laser therapy for the treatment of chronic plaque psoriasis in 10 patients. [67] Some plaques were treated with progressively escalating doses of the excimer laser, applied thrice weekly. This regimen yielded uniform plaque clearance following 7 to 11 treatments, requiring a mean cumulative irradiation dose of 4.45 J/cm ^{2}. In contrast, UVB-treated plaques took 2.27 times longer to clear and required significantly larger cumulative doses of UVB (mean 31.1 J/cm ^{2}). At 2 years follow-up, the authors reported that 8 of the 10 original patients still remained plaque-free in excimer-treated areas. [68] A subsequent dose-response study solidified the 308-nm excimer laser's role as an effective treatment for localized chronic plaque psoriasis, especially when used at high energy settings [4 to 6 minimal erythema doses (MEDs) or greater]. [69] Treatment at very high doses (8 to 16 MEDs) frequently causes a blister, which heals without scarring and often without psoriasis after a single treatment. At medium fluences (2, 3, 4, and 6 MED multiples), multiple treatments (twice per week for up to 20 treatments) correlated with greater plaque clearance, however fluence was the main determinant of clinical response. Of note, blistering doses were painful, while lower fluences produced no discomfort or adverse effects. A main advantage of excimer laser over conventional phototherapy is the ability to limit unnecessary, cumulative UVB exposures to unaffected skin. Other sources of narrow-band UVB may become available based on the excellent results obtained by the excimer laser. Narrow-band UVB phototherapy is also an effective vitiligo therapy, capable of inducing at least partial repigmentation in most treated patients. Initial reports suggest that the 308-nm XeCl excimer laser is effective treatment for localized vitiligo. [70]

DIAGNOSTIC APPLICATIONS: CONFOCAL SCANNING LASER MICROSCOPY

While this chapter has focused on the therapeutic use of lasers in dermatology, novel diagnostic applications for laser light warrant attention, especially in view of recent developments and refinement of confocal scanning laser microscopy (CSLM) and optical coherence tomography (OCT). These evolving technologies have made it possible to obtain clear, detailed cross-sectional images of human skin in vivo (Fig. 267-8). Confocal microscopic images are created by detecting backscattered or fluorescence emission coming from a small, scanned focus of light inside the tissue. The focal spot, usually provided by a laser, is in a *con*jugate *focal* plane to a pinhole aperture, which filters unwanted light from above or below the plane within the tissue. This creates a virtual "section" image in vivo, comparable to actual sectioning of the tissue but without the need for a biopsy. A near-infrared confocal microscope was constructed specifically for imaging skin. [71] The device achieves resolution similar to regular light microscopy, and is capable of imaging cells, some subcellular organelles, and extracellular matrix to a depth of about 0.4 mm in skin. The device produces a real-time "histology movie," of horizontal sections inside the living skin. Changes in refractive index within the tissue are responsible for light scattering, which provides the image contrast for reflectance confocal microscopy. Melanin provides the strongest contrast in human skin since its high refractive index (n = 1.7) is much greater than that of the surrounding cytoplasm. [72] Already a useful research tool, clinical applications for confocal microscopy are under investigation, including tumor margin detection, analysis of pigmented lesions, and differentiation of contact from irritant dermatitis.

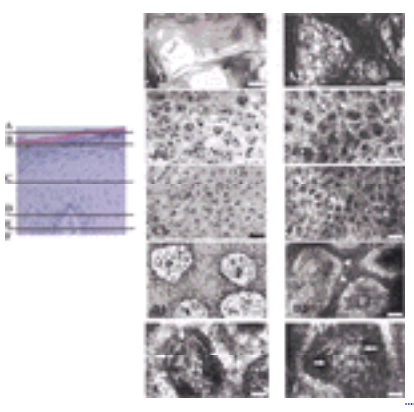

FIGURE 267-8 Correlation between vertical and transverse sections [hematoxylin and eosin (H& E) and in vivo confocal] of normal skin. In confocal images, the corneocytes appear as bright polygonal shapes (*A2, arrows*), and measure 10 to 30 µm in diameter. Granular cells (*B2, arrows*) are regularly seen at depths of 10 to 15 µm. The dark oval areas correspond to nuclei within the bright cytoplasm. Spinous keratinocytes (*C2, arrows*) are seen at 20 to 100 µm below the stratum corneum. Note that the basal keratinocytes (*D2, arrows*), located around dermal papillae (*p, D*), are brighter than the keratinocytes of the stratum spinosum (*ss, C2*) and granulosum layers (*sg, B2*). Blood vessels (*arrows, E*) and collagen bundles (*arrows, F*) are also seen (A1, A2, B1, C1, D1, ×40/0.65 NA dry objective lens; B2, C2, D2, E, F, ×30/0.9 NA water immersion objective lens; scale bar, 25 µm). Reprinted by permission of Blackwell Science, Inc.*)

Optical coherence tomography is another technique for virtual-section imaging of light reflected from tissue. OCT relies on the coherence properties of light, detected by wave interference in a device called an interferometer. A low-coherence optical source is split into two beams, one of which travels to the tissue, while the other provides a reference path. When the optical pathlength of light traveling in each arm of the device is equal, wave interference can be detected. Thus, OCT is conceptually similar to detecting optical "echoes" from the tissue, and like ultrasound echoes, provides a vertical section. The resolution of OCT is not yet capable of imaging individual cells, but structures such as hair follicles, sweat glands, and tumors are easily seen. Doppler and polarization-sensitive versions of OCT and confocal microscopy are under development, which emphasize functional imaging of blood flow and collagen structure, respectively. It is likely that laser-based imaging will play some role in dermatology in the future.

REFERENCES

Over the past 30 years, dermatology has become an organ-specific specialty combining medical and surgical approaches to the skin and its appendages. The expansion of technology and treatment options by dermatologists has widened the scope of practice in cutaneous surgery, laser surgery, Mohs micrographic urgery, and cosmetic surgery. The 1980s and 1990s were a time of explosive development of laser technology and growth of dermatologic uses (see Chap. 267 and Chap. 271). The next decade promises to be one of growth in tissue augmentation. In the 1980s, there was a steady rise in the use of collagen as injectable material. Other emerging biologic nonautologous materials (e.g. hyaluronic acid, cadaver materials), as well as nonbiologic materials (e.g., expanded polytetrafluoroethylene, polymethylmethacrylate microspheres) promise to support similar growth in the next decade. As dermatologists explore the aesthetic uses of these new materials, reconstructive indications will evolve. The two aspects of dermatologic surgery, aesthetic and reconstructive, support one another. This chapter introduces the basic concepts of dermatologic surgery and provides the framework for subsequent chapters focusing on specific dermatologic surgery techniques.

PATIENT SELECTION

Before performing dermatologic surgery, a careful history, review of systems, and focused physical examination are essential. Special attention should be paid to atherosclerotic heart disease, hypertension, presence of a cardiac pacemaker, renal disease, diabetes, immunosuppression, healing ability (poor healing, keloids, or hypertrophic scars), bleeding tendency, allergies to systemic and topical agents, pregnancy, and a history of syncope, especially from injections or phlebotomy. A detailed medication history should be obtained, with special attention to platelet-inhibiting agents such as aspirin, nonsteroidal anti-inflammatory drugs, and dipyridamole; coagulation-inhibiting agents, such as Coumadin; beta-blocking agents; phenothiazines; tricyclic antidepressants; thyroid hormones; and monoamine oxidase inhibitors. A history of abnormal heart valves, heart murmur, or prosthetic joints, valves, or vessels should be ascertained, as some of these patients may require preoperative prophylactic antibiotics to prevent bacterial endocarditis or prosthesis infection. [1] Smoking may interfere with the survival of skin grafts or flaps because of vasoconstriction, [2] while alcohol ingestion may increase the patient's bleeding tendency by causing qualitative platelet inhibition.

Aspirin, nonsteroidal anti-inflammatory drugs, and warfarin increase intraoperative bleeding, [3] but have not been clearly demonstrated to increase postoperative bleeding. [3] If the patient's medical condition allows and these medications are stopped, warfarin and nonsteroidal anti-inflammatory drugs should be held for 3 days preoperatively, while aspirin should be held for at least 10 days because it causes irreversible inhibition of platelet function. [4] Alcohol and cigarettes should be stopped during the perioperative period. Epinephrine should be used with caution in patients taking beta-blocking agents, tricyclic antidepressants, thyroid hormones, and monoamine oxidase inhibitors because of the risk of severe hypertension. However, in routine dermatologic surgery where small amounts of local anesthetic with epinephrine are used, the risk of this problem is remote. [5] A detailed oral and written informed consent discussing the potential benefits, risks, and alternative treatments should be obtained from the patient or, if the patient is mentally incompetent or younger than age 18 years, from the patient's legal guardian.

INFECTION CONTROL

Skin preparation before surgery is designed to reduce but not eliminate the extensive bacterial flora present on intact skin. For minor procedures such as biopsies and electrodesiccation, cleansing with isopropyl alcohol and barrier protection with nonsterile gloves is sufficient. As the procedure increases in complexity to excisional surgery with skin

closure, the skin should be prepared with a povidone-iodine (Betadine) or chlorhexidine scrub followed by draping the surgical field with sterile towels. Hair in the surgical field should be clipped with scissors. Preoperative shaving of hair is associated with an increase in wound infections. [6]

Povidone-iodine is active within a few minutes, but once it has dried, is wiped away, or comes in contact with blood, it loses its bactericidal activity. Some patients are allergic to the iodine, [7] which attacks cell membranes and is bactericidal for most bacteria, has a rapid onset of action, and is preferred as an antiseptic agent by many. It binds to cell membranes, with bactericidal activity lasting several hours after application. Because it is toxic to the cornea [8] and tympanic membrane, it should be avoided for use around the eyes and ears. As povidone-iodine and chlorhexidine are toxic to tissue in open wounds, they should not be used within such wounds. Because hexachlorophene and quaternary ammonium compounds are not bactericidal against many gram-negative organisms, they are rarely used for skin preparation. In addition, hexachlorophene is absorbed through intact skin and is potentially neurotoxic, especially in neonates. [9]

All patients are considered as being infected with HIV, hepatitis B or C, or other blood-borne agents. Therefore, universal precautions must be adhered to in order to protect the surgical staff, as well as patients, against cross-contamination. [10] For skin surgery, this means wearing sterile surgical gloves, masks, and protective eyewear. Double-gloving reduces the risk of glove perforation during surgery by a factor of 3 to 8. [11] If significant exposure to body fluids is anticipated, waterproof gowns and caps should be worn as well. Healthcare workers are most commonly exposed to blood by needle sticks. To reduce the risk of needle-stick injury, needles should never be recapped, suture needles should be handled only with instruments, and all sharps should be disposed of in puncture-proof containers immediately after use. All instruments that come in contact with a patient's blood or tissue must be carefully sterilized or discarded.

The risk of wound infection after skin surgery is quite small. [12] Therefore, prophylactic antibiotics are usually not indicated except for patients or anatomic sites at greatest risk for infection. If such antibiotics are given, they must be in the bloodstream at the time surgery starts in order to be effective. [13] Infections are more likely to develop in patients who are immunosuppressed or debilitated, or who have reduced blood flow to the surgical site, such as the legs in patients with peripheral vascular disease or diabetes. Anatomically, the ears, [12] perineum, legs, and feet seem to be the areas at greatest risk for postoperative wound infection. Open wounds almost never become infected, while closed wounds with hematomas or a large amount of necrotic tissue are at increased risk for infection. For surgery around the lips, prophylactic antiherpesvirus medications are indicated to prevent activation of herpes labialis. [14]

The risk of bacteremia after surgery of intact skin by using proper sterile techniques is slight; this risk is similar to that among normal human volunteers not undergoing surgery. [15] Recommendations for the use of prophylactic antibiotics in skin surgery have been extrapolated from situations with a much higher incidence of bacteremia, such as urologic or dental procedures. One approach recommends prophylactic antibiotics for patients with eroded skin lesions satisfying the American Heart Association (AHA) criteria for being at high risk for developing bacterial endocarditis (e.g., patients with artificial heart valves, mitral valve prolapse with regurgitation, congenital cardiac malformations, rheumatic or other valvular dysfunction, and history of previous endocarditis). [1] However, according to the AHA, if the skin is intact and surgically scrubbed prior to incision, antibiotic prophylaxis is not indicated. [16] If the skin lesion to be surgically manipulated is infected or the patient has active infection elsewhere on the skin, prophylactic antibiotics should be given to those in the AHA's high-risk groups as well as to patients with orthopedic prostheses or internal shunts. [1] Traditionally, antibiotics such as dicloxacillin, with good coverage for gram-positive organisms, and especially *Staphylococcus aureus,* should be given 1 to 2 h before surgery, with a second dose given 6 h after the first. Single dosing is possible with cephalexin 2 g 30 to 60 min before surgery.

SURGICAL ANATOMY: DANGER ZONES

Anatomic structures at risk for damage during surgery, such as motor nerves, lie deep to the fascia. Muscles of facial expression are innervated by the facial nerve, which exits the base of the skull through the stylomastoid foramen and enters the deep lobe of the parotid gland. Within the parotid gland, the facial nerve divides into five major branches that travel within the parotid gland, between the superficial and deep lobes. Once the branches have left the parotid gland and before they have significantly arborized, they are at risk during surgery, as transection of one of these branches will result in permanent motor paralysis of the related muscle group. This danger zone is approximately between the anterior surface of the parotid gland and a vertical line drawn from the lateral canthus to the inferior border of the mandible at the insertion of the masseter muscle. [17]

The temporal (frontal) branch of the facial nerve is at risk as it crosses the temple after having left the parotid gland and before it has entered the deep surface of the frontalis muscle. It is very superficial, located within or on top of the superficial fascia. [18] Transection of the temporal nerve may result in unilateral eyebrow ptosis. This deficit, if permanent, can be corrected through a unilateral eyebrow lift. [19] Undermining in the temporal and zygomatic region should be carried out in the superficial fat. The temporal artery is a useful guide to depth of undermining, as it lies superficial to the temporal nerve.

The zygomatic branch of the facial nerve is at greatest risk as it crosses the zygoma after exiting the parotid gland and before entering the deep surface of the orbicularis oculi muscle. Transection of the zygomatic nerve may result in unilateral inability to close the eyelid and ectropion, with resultant exposure conjunctivitis. Partial correction of the deficit can be achieved by placing gold weights into the upper eyelid, which will allow the eyelids to close properly. [20]

The buccal branch of the facial nerve is at risk as it crosses the masseter muscle in the middle of the cheek after leaving the parotid gland parallel with the parotid duct. It is located on top of the masseter muscle fascia, which is covered by a thick fat pad in most patients. Therefore, injury to this nerve during dermatologic surgery is quite rare. If the nerve is severed, the patient will develop significant facial asymmetry and an inability to pucker his or her lips, with a resultant

difficulty in keeping fluids in the mouth. Nerve grafting and/or repair offer the best chance for restoring function. [21]

The marginal mandibular branch of the facial nerve is at risk as it crosses the mandible at the insertion of the masseter muscle, where it is located within the subcutaneous fat in close proximity to the facial artery. Injury to this nerve may result in facial asymmetry. Nerve grafting or repair may be necessary in order to restore normal muscle function. The cervical branch of the facial nerve exits the inferior pole of the parotid to innervate the platysma. Injury to this branch is not usually associated with any functional impairment.

The spinal accessory nerve traverses the posterior triangle of the neck deep to the superficial cervical fascia, from the posterior surface of the sternocleidomastoid muscle to the anterior surface of the trapezius muscle. The posterior triangle of the neck is bounded by the sternocleidomastoid muscle anteriorly, the trapezius muscle posteriorly, and the clavicle inferiorly. The spinal accessory nerve exits the posterior surface of the sternocleidomastoid muscle at the junction of the superior and middle thirds of the sternocleidomastoid muscle. Injury to the spinal accessory nerve will cause weakness of the shoulder and winged-scapula deformity. [22]

Transection of sensory nerves may result in permanent anesthesia of the denervated area. The anesthetic area may regain sensation over 2 to 3 years with tingling or burning starting at 6 months. Occasionally, a painful traumatic neuroma develops at the site of nerve injury. The possibility of permanent sensory loss in an area of surgery should be included in the informed consent prior to surgery.

The blood supply of the face has extensive anastomoses between the various arteries. Therefore, transecting the facial arteries has no clinical significance as long as effective hemostasis is achieved. Small vessels can be electrocoagulated. But larger, named vessels, such as the temporal artery, should usually be tied off with a suture to reduce the risk of delayed bleeding, which can develop after the vasoconstricting effect of epinephrine has dissipated. In the elderly, atherosclerosis may limit vasoconstriction and even smaller vessels need to be ligated. The external and internal carotid systems communicate in the periorbital and perinasal areas via anastomoses between the angular artery (external carotid system) and branches of the ophthalmic artery (internal carotid system). [22] Therefore, injection of any material, such as a sclerosant, has the potential for retrograde diffusion into the internal carotid system, with the possibility of cavernous sinus thrombosis. Interruption of lymphatic drainage with skin surgery in the head and neck area causes brief periods of edema, except in the infraorbital region. A long horizontal incision in the infraorbital area may lead to prolonged lymphedema of the lower eyelid. On the extremities, incisions should involve less than 50 percent of the circumference of the limb in order to prevent distal lymphedema.

LOCAL ANESTHESIA

Mechanism of Action

Local anesthetics diffuse through the tissue to the nerves and pass through the nerve cell membrane to block Na+ influx during depolarization. This blocks action potentials from occurring. Smaller unmyelinated C-type nerve fibers that conduct temperature and pain sensation are blocked more easily than myelinated A-type nerve fibers, which carry pressure sensations and motor fibers.

Local anesthetics are weak organic bases that, to be water-soluble and injectable, require the addition of a hydrochloride salt. In aqueous solution, the salt equilibrates between the ionized and nonionized form. The ionized form is water-soluble and allows injection into the tissues, but it is the nonionized, lipid-soluble base that diffuses through the tissue to the nerve cell membrane, where the ionized cation is responsible for blocking nerve conduction. At physiologic pH of 7.4, some 80 percent or more of most local anesthetics is in the cationic ionized form. Cocaine is vasoconstricting, but all other local anesthetics are vasodilating.

Types of Anesthetics

Local anesthetics consist of a hydrophobic aromatic end and a hydrophilic secondary or tertiary amine end. The two ends are joined together by an ester or amide linkage (Table 268-1). Esters include benzocaine, chloroprocaine, cocaine, procaine, and tetracaine. They are hydrolyzed in plasma and liver by cholinesterases and subsequently excreted by the kidneys. Amides include bupivacaine, dibucaine, etidocaine, lidocaine, mepivacaine, and prilocaine. They are N-dealkylated and subsequently hydrolyzed by microsomal liver enzymes.

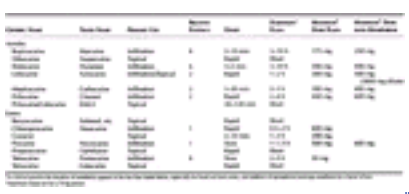

TABLE 268-1 **Local Anesthetics**

Lidocaine 1% with 1:100,000 epinephrine is the standard local anesthetic used for skin surgery. This mixture is very acidic in order to keep the epinephrine component from becoming inactivated. The addition of 1 mL of 1 mEq/mL $NaHCO_3$ to 10 mL of lidocaine with epinephrine before injection neutralizes the anesthetic solution, reducing burning on injection and facilitating anesthetic diffusion but also somewhat reducing the hemostatic effect. [23] For anesthetic effects that are to last more than 1 to 2 h, bupivacaine or etidocaine can be used.

Side Effects

Contraindications to local anesthetics include severe blood pressure instability, history of true allergy to the anesthetic, psychological instability, severe liver compromise (for amide-type anesthetics), and severe renal compromise (for ester-type anesthetics). The most frequent side effect encountered is a vasovagal reaction manifest by hypotension and bradycardia. Injecting with the patient recumbent or in the Trendelenburg position will usually keep the vasovagal reaction from becoming symptomatic. Local side effects include bruising and edema, especially in the periorbital area, and transient motor nerve paralysis. Prolonged paresthesia from sensory nerve injury can occur with nerve blocks if the needle traumatizes the nerve being anesthetized.

Overdosage is rarely a problem in dermatologic procedures as long as the maximum recommended doses of 5 mg/kg of 1% lidocaine or 7 mg/kg of 1% lidocaine with 1:100,000 epinephrine are respected. For tumescent anesthesia, the maximum safe dose appears to be at least 55 mg/kg of 0.05 to 0.1% lidocaine with 1:1,000,000 epinephrine. [24] Signs of overdosage start with circumoral numbness and tingling and can progress to seizures and cardiovascular collapse with severe overdosage. [25] Toxic effects are exacerbated by acidosis and hypoxia.

Local anesthetic allergic reactions are usually IgE-mediated type I reactions that are manifest by urticaria, angioedema, or anaphylaxis with hypotension and tachycardia. True allergic reactions to ester anesthetics are infrequent, but there is cross-reactivity with para-amino benzoic acid, sulfonamides, sulfonylureas, thiazides, and paraphenylene diamine. Patients who are allergic to one of the ester anesthetics can cross-react to other ester anesthetics but not to the amide anesthetics. Amide anesthetics do not cross-react with other drugs and true allergic reactions are extremely rare. Many multidose bottles of local anesthetics contain methylparaben and/or bisulfite preservatives, which can cause allergic reactions and may be the most frequent cause of local anesthetic “allergy.” Management of patients with local anesthetic allergy includes skin testing, use of a preservative-free anesthetic, or substitution of amide for ester, or vice versa. [26] Diphenhydramine hydrochloride (Benadryl) 12.5 mg/mL can be used for local anesthesia, but the patient may develop systemic antihistamine side effects. Normal saline injected intradermally can achieve very brief anesthesia.

Prilocaine metabolizes to orthotoluidine. This is an oxidizing agent capable of converting hemoglobin to methemoglobin—an effect that can be significant with large doses of <500 mg. Bupivacaine poses a greater risk of cardiac toxicity—with ventricular arrhythmias and cardiovascular collapse—than lidocaine.

Epinephrine

Epinephrine prolongs the duration of anesthesia by 100 to 150 percent and decreases the anesthetic's systemic toxicity by slowing its absorption. It is hemostatic in a dilution of up to 1:1,000,000. It is absolutely contraindicated in patients with hyperthyroidism and pheochromocytoma. Relative contraindications include hypertension, severe cardiovascular disease, pregnancy, and narrow-angle glaucoma as well as in patients taking beta blockers, phenothiazines, monoamine oxidase inhibitors, or tricyclic antidepressants. Injection of epinephrine into digits and the penis should be avoided, especially in patients with peripheral vascular disease. When a relative contraindication is present, epinephrine should be used with caution by diluting it to 1:500,000 and using it sparingly.

Side effects of epinephrine include self-limited palpitations, anxiety, fear, diaphoresis, headache, tremor, weakness, and tachycardia. Serious side effects include arrhythmias, ventricular tachycardia, ventricular fibrillation, cardiac arrest, and cerebral hemorrhage. Serious side effects are extremely rare when appropriate dosages are used in patients without significant contraindications. Skin necrosis can occur in patients with poor perfusion or in anatomic sites with limited perfusion or limited collateral circulation, such as the digits.

Topical Anesthetics

The conjunctiva can be anesthetized with proparacaine or tetracaine eyedrops. Superficial mucous membrane anesthesia can be achieved with various topical anesthetics including Surfacaine, Topicale, Dyclone, Anbesol, viscous lidocaine, and lidocaine jelly. For more thorough anesthesia, especially of the intranasal mucosa, a 4 to 10% cocaine solution is effective, with the added benefit of being hemostatic. Partial anesthesia of intact skin can be achieved with eutectic mixture of local anesthetics (EMLA) cream [27] or 30 to 40% lidocaine in acid-mantle cream applied under occlusion 1 to 2 h before the procedure. The resulting anesthesia is variable and in general effective only for very superficial surgery and some laser procedures. [28], [29] Iontophoresis of lidocaine can also achieve superficial skin anesthesia. [30] Cryoanesthesia with several agents can achieve sufficient anesthesia for superficial procedures and is especially useful for dermabrasion.

Local Anesthesia

Minimizing the pain of anesthetic infiltration is for many patients the most important part of the procedure. Minimizing pain starts with verbal reassurance and distraction, accompanied by mechanical distraction through pinching at the injection site, using small, 30-gauge needles and small 1- to 3-mL syringes to reduce the pressures generated on injection. A buffered anesthetic solution is helpful to reduce the burning sensation of the anesthetic being injected. Injections should be made very slowly, with additional sticks through already anesthetized tissue. Injection into the subcutis is less painful than into the dermis. Injection is started on the side where the sensory innervation originates and proceeds distally. Cryoanesthesia or EMLA is used before injecting sensitive areas or in children. Before injection, oral sedatives such as diazepam can be useful for very anxious patients. Long-acting local anesthetics may serve as supplements for prolonged procedures.

Large areas such as the scalp for hair transplantation can be anesthetized with field-block anesthesia, in which infiltration is into the tissues surrounding the surgical field. In certain areas a specific nerve can be blocked by injecting 1 to 2 mL of

anesthetic into its vicinity. Blocks of the supraorbital and supratrochlear nerves anesthetize the central forehead and frontal scalp. Block of the infraorbital nerve anesthetizes the medial cheek, upper lip, and nasal ala, and block of the mental nerve anesthetizes the lower lip. [31] The entire foot can be anesthetized with nerve blocks of the tibial, sural, superficial peroneal, and deep peroneal nerves. [32]

SUTURING TECHNIQUES

Correct suturing technique [33] is crucial for functionally and cosmetically outstanding results from skin surgery. In addition to approximation of wound edges, properly placed sutures are important for skin-edge eversion, minimization and redistribution of tension, elimination of dead space, and maintenance or restoration of natural anatomic contours, while avoiding the formation of permanent suture marks on the skin surface. The suturing technique chosen for a specific wound closure depends on the anatomic location and thickness of the wound edges.

Suture Materials

The two main characteristics differentiating suture materials are the suture configuration and its absorbability (Table 268-2). Sutures can have either monofilament (single-strand) or multifilament (braided) construction. Advantages of monofilament sutures include decreased tendency of infection or suture reaction and ease of passage through tissue, including easy removal. The main advantage of braided sutures is low memory. Memory is the tendency of the suture to retain its original shape. Low suture memory increases knot security and ease of handling. Monofilament suture, with its high memory, has reduced knot security and less ease of handling. Braided sutures pose a greater risk of causing suture reactions and infections and are more difficult to pass through tissue and remove.

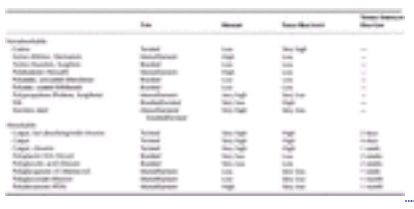

TABLE 268-2 **Suture Materials**

Sutures that lose at least 50 percent of their tensile strength within 2 months are considered absorbable, even though such sutures may not dissolve completely for many months. Absorbable sutures are used mainly as buried sutures. They can also be used as surface sutures in cases when suture removal is impractical, as in the case of patients who live far away from the surgeon's office; those who are difficult to treat, such as young children; and in the case of skin grafts, where the wound bed should not be disturbed. Nonabsorbable sutures maintain their tensile strength for more than 2 months and are used mainly on the surface, with the intention of removing them as soon as the wound edges have fully reepithelialized. They are used for skin-edge approximation and exact alignment, with any tension across the wound having been eliminated by the deeper absorbable sutures. Occasionally, permanent sutures are used as buried sutures that are left in place indefinitely in order to provide long-lasting support, as in rhytidectomy.

Synthetic sutures have almost entirely replaced natural sutures in dermatologic surgery. Because natural sutures—including silk and catgut—are much more reactive than synthetic sutures, they are used only in very limited situations. Silk, a nonabsorbable braided natural suture, is useful near mucous membranes, as it is a very soft and pliable suture with low memory. This makes it much less irritating to the mucous membrane than a stiff monofilament suture. Fast-absorbing catgut or mild chromic catgut suture is a monofilament suture that is rapidly absorbed; it is useful for securing skin grafts and for eyelid skin closure.

Selection of suture size depends on skin thickness, body site, and amount of tension across the wound. Small-gauge 5–0 and 6–0 sutures should be used on facial skin, with eyelid skin receiving only 6–0 sutures. The trunk, extremities, and scalp can be sutured with 3–0 and 4–0 sutures and the neck, digits, and genitals with 4–0 and 5–0 sutures. If a larger suture than that recommended above is needed to close a defect, the wound is under too much tension and additional manipulation is in order, such as increased undermining, relaxing incisions, or redesign of the closure plan.

Interrupted Sutures

The simple interrupted suture is the most basic and versatile suture used by dermatologic surgeons. If the suture is placed close to the wound edges, very precise coaptation of the wound edges can be achieved, even in wounds with edges of unequal thickness. If it is placed further from the wound edges, deeper tissues can be pulled in with redistribution of tension across the wound. When the suture is properly placed in a flask-shaped configuration, eversion of the wound edges can be achieved (Fig. 268-1). Wounds in which the edges are of unequal thickness can be aligned by taking a larger bite from the thinner edge and a smaller bite from the thicker edge. Wounds in which one edge appears higher than the other can be similarly aligned. The simple interrupted suture can also be used as a temporary tacking suture to align complex wound edges or position a flap properly.

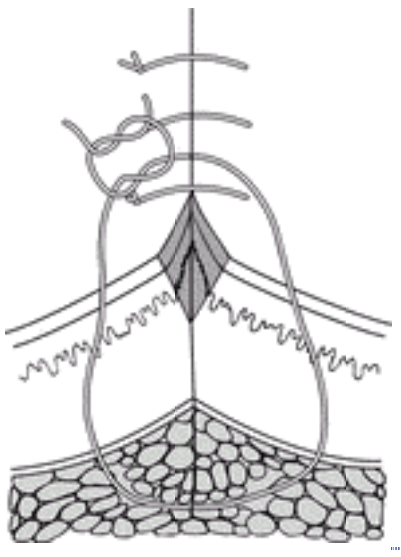

FIGURE 268-1 “Flask-shaped” simple interrupted suture.

The risk of crosshatch marks across the suture line can be minimized by removing the sutures within 5 to 7 days before the formation of epithelial suture tracks is complete, using minimally reactive monofilament suture such as polypropylene and eliminating tension across the wound with appropriate planning of wound closure, adequate undermining, and the use of buried sutures. A simple interrupted suture is more time-consuming to place and remove than is a running suture. In settings where wound healing may be impaired because of the patient's advanced age or underlying disease, interrupted suture techniques may be preferred, as interrupted sutures may have, with all other factors being equal, greater tensile strength and less potential to cause edema, induration, and impaired microcirculation than running sutures. In addition, the progress of wound healing may be monitored by removing alternate sutures. If it seems that dehiscence will occur, the remaining sutures may be left in place for 3 to 4 additional days.

The vertical mattress suture provides wound-edge eversion, reduces dead space and minimizes tension across the wound (Fig 268-2). It does the job of both a buried dermal suture and a skin suture. Because this suture requires four entry points in the skin, significant crosshatching can be expected if the suture is not removed within 5 to 7 days. Even though the vertical mattress suture can be used anywhere on the body, its use on the trunk and extremities results in significant suture marks because it must be left in place longer than 7 days. Even when deep dermal sutures are used, a few vertical mattress sutures can be placed along the wound for maximal wound-edge eversion, [34] and the intervening areas can be precisely approximated with simple interrupted sutures.

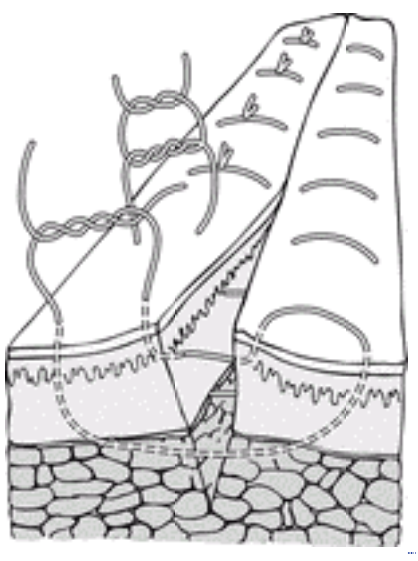

FIGURE 268-2 Vertical mattress suture.

The half-buried vertical mattress suture is a modification of the standard vertical mattress suture; it is designed to eliminate half of the four suture marks in areas such as the face, where minimal scarring is important. This suture is intermediate between a simple interrupted and standard vertical mattress suture in terms of relieving tension across the wound and achieving eversion of the wound edges. It is sometimes used along the hairline, where the buried component is placed on the face and the exposed part of the suture is placed in the hairline.

Classically, the horizontal mattress suture has been used to reduce tension across wound closures that are under significant tension (Fig. 268-3). This suture can be placed as an initial tension-reducing or holding suture and to bring the wound edges closer together, so that subcutaneous sutures can be placed to distribute tension and close the wound. At this point, if the tension has been adequately distributed, the horizontal mattress suture may be removed. If tension across the wound persists, the horizontal mattress suture may be left in place for a few days while early wound healing proceeds and removed before suture tracks have had a chance to form. In areas at high risk for wound dehiscence, such as the lower extremities, the horizontal mattress suture may even be left in place for a few days after the skin sutures have been removed. However, when left in place for more than 7 days and sometimes even less time, significant suture tracks are almost certain to form.

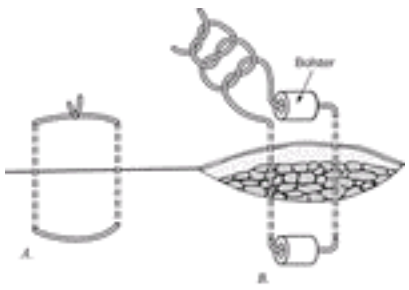

FIGURE 268-3 Horizontal mattress suture (*A*) without and (*B*) with a bolster.

Alternatively the horizontal mattress suture may be used to presuture 12 to 24 h before a proposed excision that may be under considerable tension. This short-term tension on the wound edges may allow as much as 30 percent more tissue to be removed at the time of definitive excision. Presuturing has been used successfully in alopecia reduction, rhytidectomy, and congenital nevus excision. [35]

The main disadvantage of this suture is the possibility of wound-edge necrosis, as this suture can easily strangulate the dermal plexus between its limbs. This problem is minimized by taking large bites with the needle to encompass large amounts of tissue, by using bolsters, by tying the suture only as tight as necessary to accomplish the task of bringing the wound edges together, and by removing the suture as soon as possible, ideally within 2 days of wound closure. Prior to contemplating the use of a horizontal mattress suture for tension reduction, the surgeon should consider other means of reducing tension across the wound, including appropriate use of undermining and closure orientation, flaps from areas of tissue excess, preoperative or intraoperative tissue expanders, serial excisions, and subcutaneous sutures.

Another effect of the horizontal mattress suture is prominent wound-edge eversion. This is accomplished by using a relatively fine suture material and taking relatively small bites when placing the suture across a tension-free wound that has been closed with buried sutures. This method achieves wound-edge eversion and, if the suture is not tied too tightly, wound-edge necrosis is unlikely to develop. [36]

The half-buried horizontal mattress suture is primarily indicated for the positioning of various corners and tips including flap tips, M-plasty tips, and V-Y closure tips (Fig. 268-4). It can also align the edges of tangential flaps and flaps with ischemic wound edges. The buried limb of this suture is placed in the potentially ischemic area in order to minimize interference with the dermal vascular plexus. [36] This reasoning has been challenged, because a superficial simple interrupted suture through a flap tip does not appear to result in increased risk of flap tip necrosis. [37]

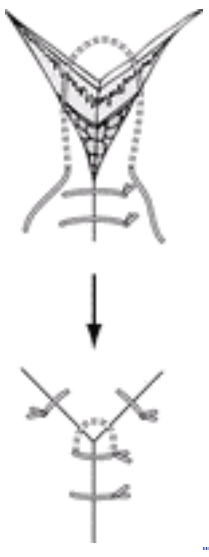

FIGURE 268-4 Half-buried horizontal mattress suture.

A wound gains only 7 percent of its final strength after 2 weeks. [38] As most skin sutures are removed within 1 week of placement, absorbable buried sutures are used as part of layered wound closure. This provides support for the wound until tensile strength has increased sufficiently to prevent wound dehiscence. Deep, buried sutures are placed into wounds to reduce or eliminate tension on the wound edges. On the trunk and extremities, where tension across wounds is greatest, the use of buried sutures may reduce the amount of scar spread. Buried sutures can align the wound edges, so that the skin edges are closely approximated even before the placement of skin sutures. Deep sutures can eliminate dead space and align deep structures such as skeletal muscle or fascia. Deep sutures can also be used to anchor overlying tissue to underlying fixed structures, such as periosteum, to maintain proper facial contour and function. This is exemplified by the anchoring to the maxillary periosteum of a melolabial flap used to close a nasal defect. [39]

The buried dermal suture is used routinely as part of layered closures in dermatologic surgery to eliminate tension across the superficial wound edges and align the wound edges properly. A properly placed buried dermal suture will allow the easy placement of skin sutures without tension. As this suture is placed at the junction of dermis and fat, the knot must be buried so as to minimize tissue reaction to the suture and extrusion through the wound.

The deep subcutaneous suture is entirely subcutaneous. It is used to decrease the amount of dead space, to anchor flaps, and to align deep structures. Because it is deep, tissue reaction to the suture or suture extrusion through the wound is very unlikely even if nonabsorbable suture material is used. Therefore the knot need not be buried.

The buried horizontal mattress suture is a “purse-string” suture that is occasionally used to eliminate dead space or reduce tension across wounds in areas where there is not enough room to place vertical sutures, as in defects on the

nose, with its stiff dermis and minimal subcutaneous tissue. Also, this suture can be used to close off dead space in other areas, such as after the removal of an epidermal cyst. It must be placed deeply and not tied too tightly, as the enclosed tissue can easily become strangulated.

One disadvantage of the standard buried dermal suture is that the wound edges are pulled flat without significant wound-edge eversion. The buried vertical mattress suture incorporates a modification of the buried dermal suture, which maximizes prolonged wound-edge eversion with resulting improved wound healing. [40] The buried vertical mattress suture can be visualized as a standard vertical mattress suture that is completely moved below the skin surface while maintaining its shape. The suture is more superficial further from the wound edge than at the wound edge.

Running Sutures

The simple running suture can be used in situations where the wound edges are of equal thickness without tension, closely approximated, and with an absence of subcutaneous dead space (Fig. 268-5). This suture is most useful for wounds that have already been closed by buried sutures, for the attachment of full-thickness or split-thickness skin grafts, and in areas of thin skin such as the eyelids, ears, neck, and scrotum. By eliminating all but two knots, there is less suture material resting against the skin, resulting in the development of fewer scars from suture marks. However, fine adjustments along the suture line are difficult to make and the uture has a tendency to pucker when very lax and thin skin, such as eyelid skin, is being sutured. In thin skin, the knots at each end may be tied over small bolsters to prevent them from cutting into the tissue. [34]

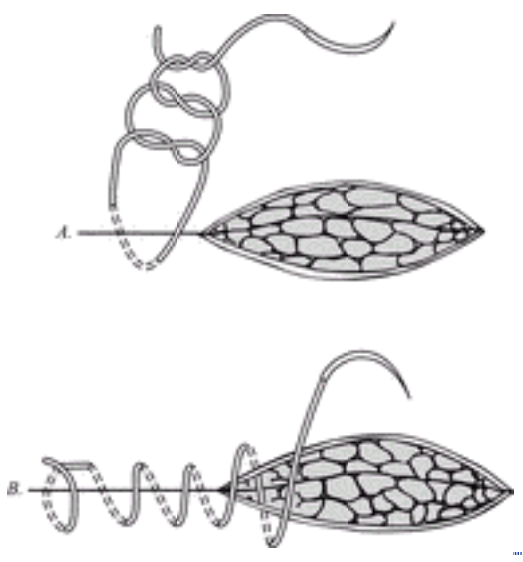

FIGURE 268-5 Simple running suture.

The running locked suture is a variant of the simple running suture in which, after the placement of each loop, the needle is passed through the previous loop prior to starting the next loop. It is intended for the closure of well-vascularized wounds under a moderate amount of tension. The wound edges should be stiff and of equal thickness without a tendency for inversion. It is stronger than a simple running suture. However, if it is placed too tightly or if significant postoperative swelling develops, tissue strangulation with wound-edge necrosis may ensue. It is used primarily on the scalp for the closure of scalp reduction defects and hair transplant donor sites. This suture is strong but should be used sparingly and only when clearly indicated because of the potential for tissue strangulation if it is not placed properly. [34]

The running horizontal mattress suture is primarily a skin-edge–everting suture. It is the ideal suture for closure of wounds with a significant tendency for wound-edge inversion. In addition, by pulling in additional tissue to the wound edge, spreading of facial scars (as seen in young patients) can be minimized. If it is tied too tightly, wound-edge strangulation and necrosis may develop.

The running subcuticular suture is basically a buried running horizontal mattress suture (Fig. 268-6). It is ideal for the closure of wounds in areas such as the trunk and extremities where the suture must remain in place for more than 7 days. As the suture is buried, there are no suture marks and the suture may be left in place for several weeks; when absorbable suture material is used, it may be left in place until it is absorbed. [41] As this suture is capable of only modest wound-edge alignment, it should be reserved for wounds in which the tension has been eliminated with deep sutures and the wound edges, of approximately equal thickness, are closely approximated. The running subcuticular suture should be placed with a nonreactive monofilament suture such as polypropylene to facilitate suture removal and prevent suture breakage within the wound. Some surgeons advocate the use of permanent sutures left in place indefinitely, as this can reduce scar stretching. [42] If nonabsorbable sutures are to be used and to be totally buried, clear, nonreactive suture material such as polypropylene should be used. [34]

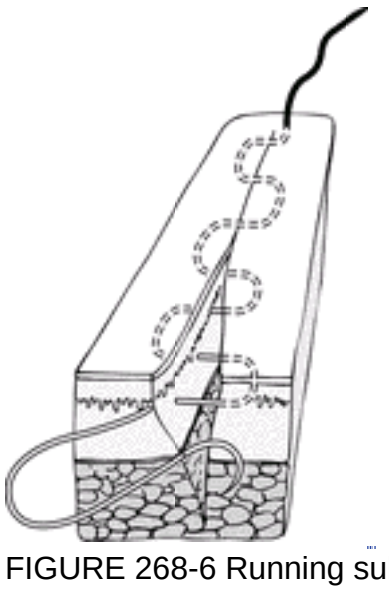

FIGURE 268-6 Running subcuticular suture.

The running subcutaneous suture is designed for the closure of the deep component of relatively long surgical defects that are under only moderate tension. It replaces the buried dermal interrupted suture in selected situations. The main advantage of this suture over interrupted sutures is the speed of placement. However, if the suture material were to rupture anywhere along the suture line, the entire wound might dehisce or a subcutaneous dead space could form under the skin edge without being apparent at the surface. [43]

Suture Removal

Suture marks are caused by epidermal downgrowth along the suture track that is seen within 5 to 7 days of suture placement and aggravated if sutures have been tied too tightly. [34], [36] Sutures should be removed at the earliest possible time to prevent or minimize suture reaction, infection, and suture marks. However, they should remain in place long enough to prevent wound dehiscence and scar spread. In general, the less blood supply to an area and the greater the tension across a wound, the longer the sutures should be left in place. On the face and ears, most skin sutures should be removed within 5 to 7 days, with eyelid sutures being removed in 3 to 5 days. Neck sutures should be removed in 7 days and scalp sutures in 7 to 10 days. On the trunk and extremities, risk of wound dehiscence takes precedence over suture marks. Sutures on the trunk and upper extremities should be left in place for 10 to 14 days. Lower extremities may require 14 to 21 days of suture support.

Absorbable sutures are left in place. However, some patients develop suture reactions, consisting of suture abscesses and suture extrusion through the wound. If this happens, the suture should be picked up carefully with small forceps and cut out of the wound. Any purulent material should also be drained.

Stainless Steel Staple Closure

Staple closure of wounds is an alternative to suture closure. The staples have the advantage of very quick placement, minimal tissue reaction, and very strong wound closure. [44] Staples are most often used with long wounds, especially on the scalp, where the suture line is hidden by scalp hair. Potentially contaminated wounds that are closed with staples appear to be more resistant to infection than wounds closed with sutures. [45] Staples provide efficient wound closure; but when exact wound-edge alignment is required, sutures should be used. Also, surgical staples are far more expensive than suture material. [44] Staples are removed with a staple remover.

Tissue Adhesive

Tissues adhesives, which have been studied for over 40 years, work by polymerizing in an exothermic reaction when they contact a fluid or basic medium, thus forming a strong bond when applied to moist skin. A new tissue adhesive, 2-octyl cyanoacrylate (Dermabond; Ethicon Inc., Norwood, MA) was approved by the Food and Drug Administration and is used most often in the emergency department and for children. Tissue adhesive is less time-consuming to apply, leading to short, more efficient patient encounters with less need for sedation in children. In large studies of laceration wounds, tissue adhesive was shown to be comparable to suture-repaired wounds. [46] However, the cosmetic outcome of cutaneous excisional surgery closed with standard suturing was found to be superior to that of wounds closed with octyl cyanoacrylate. [47]

Wound Closure Tapes

Wound closure tapes are used to provide additional support to a suture line, especially when a running subcuticular suture has been used. [34] In addition, they are helpful in supporting the wound edges after the skin sutures have been removed. Wounds closed with wound closure tapes have a lower risk of wound infection than sutured wounds. [48] However, as they fail to achieve adequate wound-edge eversion and tension reduction, wound closure tapes are rarely used as primary wound closure materials. [49] /SUP>Keeping them in place for several weeks may reduce the amount of scar spreading. [50]

EXCISIONAL SURGERY

A fusiform (elliptical) excision is indicated for the removal of small to moderate-size benign or malignant neoplasms as well as for excisional biopsy. Fusiform closure can be used wherever there is sufficient skin laxity to allow direct side-to-side closure of the defect, after adequate undermining, under minimal tension, and without distortion or functional impairment of surrounding structures. For optimal cosmetic results, the

long axis of the fusiform excision should be oriented along the relaxed skin tension lines, which are generally perpendicular to the muscle pull in the area, without crossing over cosmetic unit boundaries, such as the nose-cheek concavity. [51] If relaxed skin tension lines are not obvious, testing skin tension between the surgeon's index finger and thumb will indicate the direction of least tension. An alternative to fusiform excision is disk excision. The lesion is excised as a circle with adequate margins and the wound is either allowed to heal by second intention or the defect is closed into a straight line with excision of the resulting bilateral standing cones of excess tissue.

ELECTROSURGERY

Electrosurgery is a simple, quick, and effective technique for the treatment of various benign and malignant lesions. Electrosurgery is often combined with curettage in debulking the lesion and removing charred tissue. The main disadvantage of electrosurgery is that there is no histologic confirmation of the lesion having been destroyed. Therefore, if there is any doubt as to the diagnosis, a biopsy should be performed prior to destroying it with electrosurgery. Also, when used to destroy malignant lesions, electrosurgery does not provide tissue for histologic checking of margins. If tissue is obtained from an area subjected to significant electrosurgery, significant tissue artifact is generated, making reliable histologic interpretation very difficult.

Electrodesiccation and electrocoagulation are the most frequently used forms of electrosurgery. They both consist of a high-frequency, high-voltage, low-amperage damped current. [52] The main difference is that in electrodesiccation, there is no dispersive electrode, and the voltage, frequency, and current damping are all greater, while amperage is lower than with electrocoagulation. The observed tissue effect is from contact of the treatment electrode with tissue, generating resistive heating of tissue with resultant tissue dehydration and coagulation. Electrodesiccation is less destructive than electrocoagulation, as less current passes into the tissue and there is less channeling of current along conductive structures such as blood vessels and nerves. Electrodesiccation is most often used for the destruction of verrucae, seborrheic keratosis, superficial nonmelanoma skin cancer, and actinic keratoses. Epidermal lesions can be effectively removed by electrodesiccating their surface. This causes dermal–epidermal separation, which can be taken advantage of with a dermal curette to scrape the lesion away. Electrocoagulation, with its affinity for tracking along blood vessels, is ideally suited for achieving hemostasis during scalpel surgery. In bipolar electrocoagulation, there is no dispersive electrode; instead, both electrodes are part of a forceps. The tissue to be coagulated, usually a blood vessel, is gently picked up by the forceps and current is applied to coagulate it.

Electrofulguration uses a current of very-high voltage, very-high frequency, and very-low amperage that is highly damped without a dispersive electrode. [52] Treatment is performed by holding the electrode tips slightly above the lesion surface in order to generate a spark that carbonizes the surface through resistive heating. The carbonized surface protects deeper tissue from additional fulguration. Therefore, this modality is ideal for very superficial benign lesions, such as dermatosis papulosa nigra and skin tags. Healing is rapid and scarring rare.

Electrodesiccation uses a high-voltage, low-amperage, high-frequency undamped current to cause tissue separation with extremely localized molecular oscillations and heat generation. As the effect is very localized, there is minimal tissue damage; consequently, no hemostasis is achieved with a pure undamped current. To make electrical cutting more practical by achieving hemostasis as the tissue is separated with the current, most devices deliver a blended current that damps the current slightly with increased tissue coagulation and hemostasis. [52] Electrodesiccation is useful in patients with bleeding disorders or on anticoagulants that cannot be stopped before the procedure. By this method, as compared with scalpel surgery, the wound heals more slowly with decreased tensile strength early on, due to the thermally coagulated tissue left in the wound.

In electrocautery, a high-amperage, low-voltage direct or alternating current is passed through a treatment tip that becomes red hot through resistive heating. The heated tip is applied to tissue to coagulate it through direct conduction of heat. As compared with electrodesiccation, electrocautery can cause greater tissue damage through heat conduction from the treatment site. One advantage of electrocautery is that it can work in a bloody surgical field and on nonconductive surfaces such as cartilage, bone, or nails.

Galvanic current is a direct low-voltage, low-amperage current in which the treatment electrode is negative and the dispersive electrode positive. The negative polarity of the treatment electrode generates hydroxides and hydrogen gas in the tissue. These hydroxides liquefy the tissue. Only very small areas can be destroyed with galvanic current, minimizing the risk of scarring, but slowing the treatment process down significantly. [53] The most frequent use of galvanic current is for electrolysis of unwanted hair and destruction of small facial telangiectasias. However, as this technique is so slow, it has generally been replaced by electrodesiccation and electrocoagulation, which is referred to as thermolysis. [53]

Modern pacemakers are very well shielded from standard electrosurgical current. However, it is prudent not to use electrosurgical current near the heart or the pacemaker; when the current is used, it should be applied in short bursts so that any interference would be limited in duration. [54] The best option is to use bipolar electrocoagulation where the current passes between the two tips of the forceps or electrocautery where no current enters the body.

Electrosurgery can cause fire, especially in an oxygen-enriched environment or in the perianal area from the release of methane gas. [55] Electrosurgery generates a significant amount of smoke, which is not only carcinogenic, [56] but may contain viable tissue fragments containing infectious particles, such as HIV. Therefore, the use of smoke evacuators is advisable when electrosurgery is being performed. Electrode tips should be changed after each patient, as electrodes can transmit viral particles. [57]

HEALING BY SECOND INTENTION

Healing of full-thickness skin wounds by second intention is indicated for patients who are poor surgical risks for reconstructive surgery and those who refuse reconstructive surgery. It is also used for infected wounds, to allow observation of the wound bed after resection of tumors at high risk for recurrence, for selected pathologic ulcers, and when the anticipated cosmetic result is at least as good as that achieved by reconstruction. Wounds that are allowed to granulate are very resistant to infection and cannot form a hematoma. The locations that lend themselves best to wound healing by second intention, with superior cosmetic results, are concave areas such as the nose-cheek junction, medial canthus, ear

concha, preauricular cheek, and retroauricular scalp. [58] Wounds allowed to heal by second intention may decrease in size as much as 50 percent or more. [59] Superficial wounds heal with less wound contraction, since there is less deposition of collagen. Therefore, a superficial wound, even on a convex surface such as the forehead or the nose, will usually heal well. Because all wounds contract to some degree, it is important that there be no “free” margin along one side of the wound that can be pulled up during wound contracture and cause distortion at the site. This may be encountered along the eyelid margins, ear margins, eyebrow, nasal ala, and lip vermilion border. These areas are better managed with appropriate reconstructive surgery. [58] Disadvantages of healing by second intention include prolonged healing time of several weeks, the need for daily wound care by the patient, and the somewhat unpredictable cosmetic results.

LOCAL SKIN FLAPS

When simple primary closure cannot be done because a wound is too large, there is too much tension on the wound edges, or an unacceptable functional or cosmetic result would ensue, a tissue-movement procedure such as a flap or a graft should be considered. A local skin flap is a portion of full-thickness skin transferred from a donor site into a surgical defect while maintaining its blood supply from the donor site via a random or axial vascular pedicle that remains attached to the donor site. For random flaps, the blood supply is provided by the skin that remains attached to the surrounding dermis; the length-to-width ratio should not exceed 3:1 or 4:1 on the face, and 2:1 on the trunk and extremities. [56] Flap incisions should, whenever possible, be made so that they fall into relaxed skin tension lines. The two movements involved in placing a flap are the action of placing the flap into the defect, which is the primary movement, and the secondary movement of tissue in the donor area, which closes the secondary defect and facilitates primary flap movement. Both movements are important in terms of distributing tension in the proper direction and over a larger area so as to minimize tension on the flap itself, which might compromise its survival. [60]

The primary motion of the flap provides its name. In an advancement flap, the tissue movement is in a straight line from the donor area to the recipient site. [56] A classic example is the advancement flap to close a defect of the rim of the ear helix by relying on excess tissue present in the earlobe. [61] A bilateral advancement flap is an A-to-T flap, in which incisions extend from the base of a triangular defect and the two sides are slid together along this baseline. Common areas for the use of advancement flaps include defects of hair-bearing skin in the eyebrow [62] (Fig. 268-7) or mustache area, where orientation of the hair shafts is critical. The rotation flap slides skin into the defect by rotating it on its axis. It is classically used to close relatively large defects on the cheek, forehead, or scalp. A rotation flap with a back cut can increase tissue movement in areas of limited tissue laxity, such as the nose.

FIGURE 268-7 *A.* Right eyebrow surgical defect after tumor resection. *B.* Immediately after repair with a laterally based advancement flap and a medially based island pedicle flap. *C.* Final result (7 months postoperative).

Transposition flaps move skin from one site to another, crossing normal skin as the flap moves into its new location, which is often on the face. The classic transposition flap is the rhombic flap (Fig. 268-8). The defect is visualized in the shape of a rhombus with equal sides and angles opposite each other of 60 and 120 degrees, respectively. The flap is created by drawing a line out from and bisecting either of the 120-degree angles. The line is equal in length to one side of the rhombus. The next line creates a 60-degree angle with that line and is parallel to and equal to the side of the rhombus. [63] Other transposition flaps include the note flap, banner flap, nasolabial (melolabial) flap, bilobed flap, Webster's 30-degree modified rhombic flap, and Z-plasty.

FIGURE 268-8 Rhombic transposition flap: (*I*) design with shaded area representing surgical defect, (*II*) transposition after undermining, and (*III*) final suture line.

A subcutaneous island pedicle flap may be considered as a variation of an advancement flap that has had all of its connections to the epidermis and dermis severed, maintaining its blood supply only through a subcutaneous tissue pedicle (see Fig. 268-7). [64] This flap is usually slid from the defect apex into the center to close an area that would be under great tension if closed by side-to-side approximation of the wound edges. [65] , [66]

The most commonly used axial vascular pedicle flap on the face is the paramedian forehead two-stage transposition flap [67] (Fig. 268-9). Tissue is mobilized from the forehead, based on one of the supratrochlear arteries, and transposed to repair large distal nasal defects with the pedicle remaining attached in the glabellar region. Division of the pedicle is performed in 2 to 3 weeks after the flap has established a local blood supply from the original defect's wound bed. [67]

FIGURE 268-9 *A.* Dorsal nose surgical defect after tumor resection. *B.* Immediately after first stage of paramedian forehead flap with upper forehead donor area to heal by second intention healing. *C.* Final result 8 months after flap division and inset.

Flaps require careful postoperative wound care to assure that vascular compromise does not occur. Tightly applied bandages may compromise the blood supply to the flap and cause necrosis. The area under the flap must be free of any bleeding or oozing as hemorrhage or hematoma formation may jeopardize flap survival and increase the risk of infection. Patients who smoke may compromise the blood supply to the flap, and large defects in smokers may require grafting rather than risking failure of a flap. [68] The “trapdoor” effect occurs with some flaps when the center of the flap becomes elevated and the suture line becomes depressed. It may resolve spontaneously over a period of 6 to 12 months. However, if it fails to resolve, it may respond to intralesional glucocorticoids and/or flap elevation with flap thinning, possibly combined with multiple Z-plasties to break up the curved scar line. [69] The trapdoor effect may be prevented with wide undermining around the primary defect, proper thinning of the flap, proper size of the flap, and the use of a geometric shape for the flap. [69]

SKIN GRAFTS

Grafts are totally detached from the donor site and receive all nutrients from the wound bed of the recipient site. They are named for their composition (epidermis, dermis, fat, hair, cartilage, bone). Full-thickness skin grafts (FTSG) consist of epidermis with full-thickness dermis, while split-thickness skin grafts (STSG) consist of epidermis with a varying thickness of dermis.

A STSG is used to cover large defects to allow better wound bed surveillance, to line a large pedicle flap or cover the donor site of a large FTSG, or to resurface mucosa. [70] It is usually harvested from the upper inner arm, thigh, buttock, scalp, or abdomen. The STSG is placed on the wound and fixed in place with absorbable sutures or staples. The main advantage of a STSG is that it will survive even in locations with poor vascularization, such as a leg ulcer. Cosmetically, this graft is suboptimal, with absent appendages, poor color match, and frequent wound contracture under the graft. The donor site will reepithelialize rapidly and relatively painlessly with the use of bio-occlusive dressings. [71]

A FTSG is generally indicated for relatively shallow full-thickness facial defects that may not be amenable to primary closure or local flap repair or to temporarily cover a defect that needs to be observed for possible tumor recurrence. A FTSG contracts less than a STSG and skin color match is better than with a STSG. It is usually harvested from the preauricular, nasolabial, postauricular, conchal bowl, supraclavicular, or eyelid areas. The donor site is chosen so as to match the recipient site in skin texture, thickness, color, and appendiceal structure density. [72] The graft is trimmed to exactly fit the defect and defatted. The donor site is closed with a primary side-to-side closure or second intention healing. The graft is sutured onto the recipient site, including basting sutures as needed. A bolster dressing may be placed over the graft to keep it in place and to prevent fluid accumulation underneath it. Because skin grafts do not bring any blood supply with them, they are more vulnerable to necrosis than simple closures or flaps. Skin color match is difficult to predict. Fairer-skinned individuals with even pigmentation and less sun damage do well with FTSGs. The more darkly pigmented or mottled the surrounding skin, the less likely a good color match will be. Uneven edges around the graft may be smoothed out with dermabrasion 6 to 8 weeks after surgery. [73], [74]

Composite grafts include a component in addition to the epidermis and dermis. The most common composite graft includes cartilage and is used for the correction of full-thickness nasal ala defects. The graft is harvested from the ear helix so that it contains a sandwich of skin surrounding a piece of cartilage. After being sutured in place, the graft receives its blood supply only from its lateral margins. Therefore, only up to 1 cm of nasal ala rim can be replaced with a composite graft, as a larger graft will not receive sufficient nutrients to allow its central portion to survive. [75]

COMPLICATIONS ARISING FROM CHEMICAL PEELS
COMBINATION SKIN RESURFACING—COMBINING CHEMICAL RESURFACING WITH LASER OR DERMABRASIVE RESURFACING

REFERENCES

Chemical peeling, also called chemical resurfacing, chemexfoliation, or chemosurgery, involves the application of one or more exfoliating agents to the skin, resulting in the destruction of portions of the epidermis and/or dermis with subsequent regeneration. This produces a controlled wound and reepithelialization.

HISTORICAL ASPECTS

Dermatologists pioneered skin peeling for therapeutic benefit. In 1882, P.G. Unna, a German dermatologist, described the properties of salicylic acid, resorcinol, phenol, and trichloroacetic acid (TCA); and during the first half of the twentieth century, phenol and TCA were used in several centers. The combination of two agents, solid carbon dioxide followed by TCA, to produce the first medium-depth combination peel was reported in 1986. These peels have replaced the more risk-prone 50 percent TCA peel. a-Hydroxy acids (AHAs) became available as superficial peeling agents in the late 1980s and the 1990s. Presently, resurfacing lasers can be used in combination with or in addition to peeling agents.

HISTOLOGIC CLASSIFICATION

Based on the study of histologic changes in wound depth, a classification of peels can be developed (Table 269-1). The strength of a dermal wounding agent is based on evaluating the reaction at its peak by noting the depth of the wound as opposed to the depth of inflammation. Examination of the wound at 90 days to evaluate the mid-dermis is imperative for proper evaluation of dermal collagen remodeling. [1]

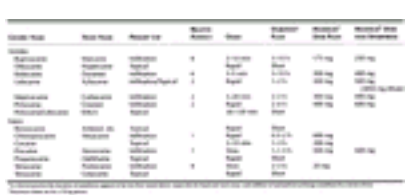

TABLE 269-1 **Chemical Peeling Wounding Classification***

Epidermal injury (superficial wounding) without clinical vesiculation results from Jessner's solution (JS), the AHAs [2], [3], [4], [5], [6] and [7] and solid carbon dioxide (CO_2), with results similar to those from tretinoin application. [8], [9]

Upper dermal injury (medium-depth wounding) follows the use of 40 to 60% TCA and the medium-depth 35% TCA peeling combinations. Ninety days after peeling, a normal-appearing zone of expanded papillary dermis, referred to as a Grenz zone, is seen. The thickness of this zone varies with the strength of the wounding agent used and the depth of the wound. A band of thick, amorphous brown fibers in the middle to upper dermis is composed of elastotic fibers and glycosaminoglycans (GAGs). The thickness and depth of staining of this band increases with the strength of wounding agents. [10], [11]

Mid-dermal injury (deep wounding) with phenol formulas results in a deeply stained elastotic dermal band. The new subepidermal, horizontally arranged collagen band in the papillary dermis is probably responsible for the lessening of wrinkles. [12], [13]

Dermal peeling can be compared with CO_2 laser treatments. A single or double pass with a superpulse laser at 400-mJ, 10-W, 0.33-s interval in sun-protected and sun-exposed periauricular skin produces a depth of injury approximating that seen with medium-depth chemical peels. Healing at 90 days occurs in a similar fashion as with chemical peeling, but perhaps with less inflammation. [14], [15]

INDICATIONS FOR CHEMICAL PEELING

Actinic keratoses and sun-induced rhytides respond to chemical peeling. Medium-depth peels will reduce the number of visible actinic keratoses by 75 percent with results sustained for as long as 30 months in a majority of patients. This is comparable to 5-fluorouracil (5-FU). [1], [16] Regeneration of the actinic damage may occur and necessitate repeat treatment after 2 to 4 years. Pigmentary dyschromias in the form of melasma or postinflammatory hyperpigmentation also respond. Serial repetitive peels of increasing strength are used to treat melasma. In a study that compared 70% glycolic acid to Jessner's solution in the treatment of melasma resistant to medical therapy, there was a 63 percent reduction in the patients' melasma area and severity index, statistically significant lightening on colorimetry, and equal response to both agents. [17] Glycolic acid caused mild irritancy. Topical glycolic acid can be used between peels, but is not imperative for good results. Depressed scarring responds variably to chemical peeling. Dermabrasion or the resurfacing laser are generally more effective. Medium-depth peeling with solid CO_2 to efface the rims or the edges of depressed scars, combined with the immediate repetitive application of 35 to 50% TCA to the rims, has resulted in substantial improvement. [11], [15] Acne vulgaris may be improved by superficial chemical peeling, although medium peeling can aggravate or actually produce acne. In rosacea the existing erythema of the disease makes medium peeling more risky because of persistent tenderness or erythema.

PATIENT SELECTION—RELATIVE CONTRAINDICATIONS

Prior to peeling, patients must be evaluated for relative contraindications (Table 269-2). [15], [18], [19] Fitzpatrick's classification measures pigmentary responsiveness of the skin to ultraviolet light, most often based on the ethnic background. Skin types I to III are ideal for peeling. Types IV through VI can also be peeled with all peeling agents, but the risk of unwanted pigmentation is greater. A classification of photoaging is helpful in assessing sun damage (Table 269-3). [20] The past or present use of systemic isotretinoin must be ascertained, since retinoids may be associated with a greater risk of scarring after peeling. If the patient has a past history of superficial x-ray treatment for acne, the adnexal structures should be assessed by observing the presence of vellus hairs or by punch biopsy to ensure adequate reepithelialization. Smoking may multiply the wrinkling effects of sunlight. There are few absolute contraindications to the entire spectrum of chemical peeling, since superficial peeling may be tolerated with little risk in all patients of all skin types regardless of their general state of health. Postmenopausal estrogens and oral contraceptives may sensitize the skin to the sun or may produce postinflammatory splotching. Patients infected with HIV may experience delayed healing or be at risk for secondary infection after peeling. Patients with a history of recurrent herpes simplex may be given prophylactic acyclovir, valacyclovir, or famciclovir during medium-depth or deep peeling. True hypertrophic scar or keloid formers may be at greater risk to scar with deep as opposed to medium-depth peeling. A method to document the evaluation prior to peeling includes the mapping and detailing of the defects on a diagram as well as good photography (Fig. 269-1). An interval of 4 to 12 weeks is recommended between peeling and procedures involving undermining such as rhytidectomy, a coronal brow lift, or blepharoplasty. Following peeling, patients must use sunscreens to prevent continuing damage.

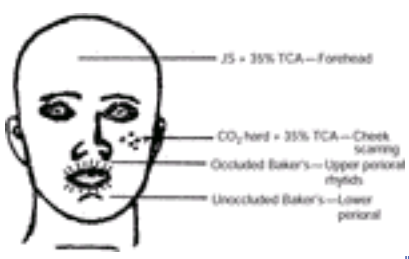

FIGURE 269-1 Example of rubber-stamp diagram mapping the defects and types of peels performed on a given patient.

Fitzpatrick skin type
Degree of actinic damage and photoaging
Philosophy of sun exposure
Present and past sebaceous gland density; previous isotretinoin or radiation
Prior cosmetic surgery
Philosophy of smoking
General state of physical and mental health
Medications
Pregnancy history
History of herpes simplex
History of hypertrophic scarring
Realistic expectations

TABLE 269-2 **Factors in the Assessment for Relative Contraindications**

Group I: Mild, usually age 28–35 years
No keratoses
Little wrinkling
No scarring
Little or no makeup
Group II: Moderate, usually age 35–50 years
Early actinic keratoses—slight yellow skin discoloration
Early wrinkling—parallel smile lines
Mild scarring
Little makeup
Group III: Advanced, usually age 50–65 years
Actinic keratoses—obvious yellow skin discoloration
Wrinkling—present at rest
Moderate acne scarring
Makeup always worn
Group IV: Severe, usually age 60–75 years
Actinic keratoses and skin cancers have occurred
Wrinkling—actinic, gravitational, and dynamic
Severe acne scarring
Makeup is worn; does not cover but cakes on skin

TABLE 269-3 **Photoaging Groups: Glogau's Classification**

Rejuvenation Regimen for the Skin before and after Peeling

The daily, morning use of a sunscreen and the nightly application of tretinoin will reduce solar pigmentation as well as

promote faster healing in the immediate postpeel period. Tretinoin application before and after TCA does not significantly enhance the efficacy of the peel. It potentiates the action of hydroquinone, although the role of hydroquinone in prepeel treatment, to prevent pigment return after peeling, is unsubstantiated. [19] Hydroquinone gel 4%, for example, may be used twice daily for at least a month prior to peeling to test the patient's reactivity to the product and begin bleaching epidermal pigment. It can be reinstituted after reepithelialization. Prolonged use of high concentrations of hydroquinone may paradoxically produce ochronosis in Fitzpatrick types V and VI skin. This is much more common in South African black skin. Kojic acid has a similar tyrosinase-suppressive mechanism and may be used in the program.

PRINCIPLES OF WOUNDING AGENT APPLICATION

Prior to the application of all wounding agents, cutaneous lipids are removed by cleansing with alcohol or acetone-soaked sponges. [15] Excessive defatting prior to 70% glycolic acid peels may cause untoward peeling, erythema or pigmentation. The amount of wounding agent applied, the degree of rubbing, and the duration of skin contact must be carefully monitored to ensure good results. Documentation of application with one or two cotton-tipped applicators, with a more aggressive 4 × 4-inch gauze sponge, or with a sable brush should be written into the patient's record. Frosting with different wounding agents is variable in rate and appearance and depends on the preexisting degree of photodamage, the choice of applicator, and the adequacy of defatting. Observation of the frost itself as a measure of depth is not as valuable as the actual selection of proper wounding technique or wounding agent. [21] The appearance of the frost does give an index of protein agglutination and indicates how evenly the agent has been applied. “Neutralization” of TCA with alcohol or water immediately after frosting is useless to reverse the effect of the application of the wounding agent. Once complete frosting has occurred, penetration is already achieved, and dilution with water is not necessary. AHAs are dependent upon the contact time with the skin, and washing them from the skin after a given amount of time is important.

Superficial Peeling

Superficial peels, which are generally epidermal and pose little risk of scarring, usually require multiple weekly or monthly applications for effectiveness. [15] They do not vesiculate, and patients generally continue normal activities. They can be used on all Fitzpatrick skin types, skin colors, and body areas. These agents may amplify 5-fluorouracil and are preparatory agents to make papillary dermal peeling agents (e.g., TCA 35%) penetrate deeper. It has been postulated that superficial peeling agents induce increased upper dermal collagen production in response to repeated epidermal sloughs. Minimal postoperative care is needed for superficial peels, and patients may return to their normal daily activities immediately, wearing cosmetics to conceal erythema.

TRICHLOROACETIC ACID 10 TO 35% TCA should be prepared by the weight-to-volume (wt/vol) method, mixing the desired concentration in grams of United States Pharmacopeia (USP) TCA crystals with the appropriate volume of distilled water to make 100 mL. [15] Although TCA is marketed as a paste mask application, it is more expensive in this form and offers no clear therapeutic advantage over the aqueous application. Strengths of TCA from 10 to 35% are used to accomplish superficial chemical peeling on facial and nonfacial areas; such peels may be repeated every 7 to 28 days. **MODIFIED UNNA'S RESORCINOL PASTE** In the late 1800s, Unna described the use of resorcinol paste as a peeling agent in concentrations of 10 to 30%. Letessier's modified formula to treat acne, melasma, and sun damage avoids excessive erythema by using axungia, a derivative of pig fat or lard added to a clay-bearing soil with 40% resorcin. [22] **JESSNER'S SOLUTION** Jessner's combination of resorcinol, salicylic acid, and lactic acid in ethanol was formulated to lower the concentration and toxicity of any one agent and to enhance the keratolytic effects (Table 269-4). Application can be light or heavy, and may be repeated after 3 to 4 min. [16], [23] The advantages of Jessner's solution are that only a single solution is needed, timing the duration of application is unnecessary, and dilution or “neutralization” is not performed. The lactic acid in Jessner's solution is an AHA, and it is very effective in the treatment of melasma (Fig. 269-2). The combination in which Jessner's solution or glycolic acid amplifies the effects of 5-FU is called the fluor-hydroxy pulse peel.

Resorcinol	14 g
Salicylic acid	14 g
Lactic acid (85%)	14 mL
Ethanol (95%) qs ad*	100 mL

*Quantity sufficient to add up to.

TABLE 269-4 **Jessner's Solution**

SALICYLIC ACID Salicylic acid, a ß-hydroxy acid, can be used as a 50% ointment under occlusion to peel lentigines,

pigmented keratoses, and actinically damaged skin from the dorsa of the hands and forearms. [24] The dressing is removed after 48 h, and mild salicylism with tinnitus and headache is expected. A peeling solution of 35% salicylic acid in ethanol has been applied to the face with cotton-tipped applicators for improvement of comedones. Erythema and edema are minimal, and the peel can be repeated every 2 to 4 weeks.

SOLID CARBON DIOXIDE Solid CO_2 (dry ice) is a physical modality for peeling and not a true chemical peeling agent. It may be used alone or to amplify TCA as a medium-depth peel. [15] The dry ice is wrapped in a small hand towel and dipped as needed in a solution of approximately 3:1 acetone and alcohol, which serves to facilitate application to the skin. A moderate application of 8 seconds to excoriated areas will serve to improve acne excoriée.

a-HYDROXY ACIDS AHAs are naturally occurring but synthetically mass-produced carboxylic acids normally found in many foods. The AHAs include glycolic, lactic, malic, citric, and tartaric acids. The two acids with the shortest carbon chains, glycolic and lactic, are most commonly used in dermatology and are naturally found in sugar cane and sour milk, respectively. Although irritancy of a product is often directly related to lower pH, vehicle irritancy must be considered also. The available free acid, which is difficult to ascertain, is the best method to judge concentration and irritancy. [2], [5] The factors that determine whether AHA peels result in desquamation or epidermolysis are the concentration of the acid, the pH, the degree of buffering or neutralization with sodium bicarbonate, the vehicle formulation, the frequency of application, the conditions of delivery, the amount of acid delivered to the skin over a given period, and, most importantly, the length of time that the acid remains on the skin. Glycolic acid peels become more unpredictable following overzealous scrubbing. The agent is applied in any cosmetic unit order, rapidly—covering the entire face within about 20 seconds—with a large cotton applicator. A starting application time for a weekly or monthly application with 50 or 70% unbuffered glycolic acid is generally in the range of 3 min, and the time is increased with subsequent peels. Neutralizers with sodium bicarbonate have no advantage over water rinsing as long as all acid is removed thoroughly from all rhytides and cosmetic units. This peeling is very forgiving, complications are very rare, and results are slow to appear. Patients should be realistic about subtle results. [25], [26]

TRETINOIN Topical tretinoin, all- *trans*-retinoic acid, is a supplement to most peel regimens along with daily application of sunscreen. [9], [19] Daily application of 0.1% tretinoin cream for 2 weeks prior to a 35% TCA peel significantly enhanced the healing time of the facial, forearm, and hand skin in a double-blind, placebo-controlled study. However, tretinoin application before and after TCA does not significantly enhance the clinical efficacy of the peel. [19], [27], [28]

Medium-Depth Peeling

Medium-depth peels are usually performed as a single procedure to remove actinic keratoses, mild rhytides, or pigmentary dyschromias or to flatten depressed scars. They may be repeated approximately every 3 to 12 months based on the amount of actinic damage still remaining or recurring after the peel or for continued scar effacement. The classic peel for this depth category was the 50% TCA peel. Because TCA is prone to produce increased scarring and hypopigmentation with higher concentrations, the use of a more superficial epidermal peeling agent such as solid CO_2, [1], [11], [15] Jessner's solution, [16], [21], [23] or glycolic acid [29] prior to the application of 35% TCA will produce a wound equivalent in depth to the higher-strength 50% solution or full strength 88% phenol. This technique is called combination medium-depth peeling.

The addition of emulsifiers or additives to TCA may increase its penetration to the lower dermis, leading to overtreatment and scarring. Combinations of medium-depth peels to blend cosmetic units are effective and useful. Resurfacing of the perioral region with the laser, dermabrasion, or deep phenol peel and blending the rest of the face with combination medium-depth peeling is very effective, as is discussed below. Wet to dry soaks of tap water or povidone-iodine skin cleanser twice daily in the shower, followed by application of an occlusive ointment such as bacitracin or petrolatum to minimize crusting, is the optimal aftercare for rapid healing.

Deep Peeling

The traditional chemical peel formula with phenol was described in 1961 by Baker and Gordon (Table 269-5). The application of waterproof tape for 48 h will increase penetration. More aggressive cleaning of the skin prior to application of the wounding agent and the application of more peel solution may eliminate taping. Occlusive petrolatum may be substituted for the tape. The 55% phenolic Baker-Gordon formula has always been thought to penetrate further into the dermis than full-strength undiluted phenol because the latter causes immediate coagulation of epidermal keratin proteins and blocks further penetration of phenol. [10], [12], [13] The concentration of croton oil may be the principal ingredient in the formula responsible for the effects and occasional accompanying hypopigmentation. The phenol may act as a carrier for the croton oil. [14]

Phenol USP	3 mL
Tap water or distilled water	2 mL
Septisol liquid soap	8 drops
Croton oil	3 drops

TABLE 269-5 **The Baker-Gordon Phenol-Croton Oil Formula**

For full-face application, regional nerve blocks or preoperative sedatives and analgesics such as Diprivan and midazolam are employed. Because phenol is partially detoxified in the liver and excreted by the kidney and because phenol may induce cardiac arrhythmias, hydration with 500 mL of lactated Ringer's solution prior to the procedure, and 1000 mL during and after the peel, will prevent phenol toxicity on these organ systems.

The face is degreased prior to the application of the wounding agent and divided into six esthetic units: forehead, perioral, right and left cheeks, nose, and periorbital areas. [15], [20] Peel solution is usually applied in this order, allowing 10 to 15 min between units to minimize renal and cardiac toxicity; thus the entire procedure would take 60 to 90 min. If indicated, tape is applied to each segment. After 48 h, the exudate has lifted the tape considerably, with drainage from

the mask's lower edge, and it is easily removed. Wet-to-dry soaking three to five times daily in the shower using tap water, half-strength boric acid, or dilute antiseptic povidone-iodine skin cleanser will dry the exudative edema. An occlusive moisturizer (e.g., petrolatum) should then be used.

Application of Baker's phenol to one cosmetic unit or less does not require intravenous hydration or cardiac monitoring. The amount of phenol applied to the skin in this fashion is equivalent to or less than that applied for a phenol nail matrixectomy. Oral hydration may be given in the form of 8 to 16 oz of water prior to the peel if patients have not been drinking much fluid on the day of the procedure. After phenol has been applied to the perioral area, for example, medium-depth peeling or other resurfacing modalities may be utilized on other cosmetic units [30] (Fig. 269-3).

FIGURE 269-3 Fitzpatrick type II and Glogau photoaging type IV skin with the most severe defects in the perioral area (*A*). Three months later, there is no perceptible color change after application of perioral occluded Baker-Gordon formula and CO_2 plus TCA 35% on the remainder of the face (*B*). (*From Brody,* [15] *with permission.*)

COMPARISON OF DEEP PEELING WITH CO_2 RESURFACING LASER

Clinical comparison between the laser and Baker's solution reveals that the laser improves severe photodamage by approximately 50 percent. [14] The laser may eliminate mild wrinkles in one treatment with little risk of pigmentary change. The peel does the same but may be more likely to cause slight hypopigmentation. In contrast, very severe rhytides may require multiple touchups by the laser for adequate treatment. However, the Baker's peel can eliminate the vast majority of deep rhytides in one treatment. [30] Neither procedure for severe rhytides leaves bothersome residual hypopigmentation, but mild pigment loss is not unexpected with both peel and laser for this indication.

COMPLICATIONS ARISING FROM CHEMICAL PEELS

A favorable test spot result in patients at higher risk for pigmentation or scarring does not guarantee the behavior of the rest of the facial skin, but it may ease the patient's fears. [15], [20]

Pigmentary changes in the form of hyperpigmentation may occur in darker skin types and is caused by sunlight, estrogens, photosensitizing drugs, or pregnancy. [31] Hypopigmentation after Baker's phenol application is a function of patient selection and mode of application as well as subsequent wound care. The hypopigmentation is proportional to the amount of phenol and croton oil applied, and a small loss of pigment is an expected result and not a complication. The rate of hypopigmentation with laser resurfacing is not uncommon, depending on depth and skin type, and can be as high as 16 percent. Treatment of such hyperpigmentation with hydroquinone regimens is effective.

The risk of hypertrophic scarring is less than 1 percent with the three combination medium-depth peels. By itself, 50% TCA is capable of unpredictable hypertrophic scarring while 35% TCA is relatively safe. The incidence of scarring with the traditional Baker's phenol formula in a series of more than 1000 patients was less than 2 percent. The rate of scarring may increase with deviations in technique, the use of preliminary treatments or topicals to increase absorption, recent isotretinoin use, or improper patient selection. Comparison with the CO_2 laser reveals comparable safety with less than 3 percent complications. The delayed healing syndrome, probably caused by a defect in transepidermal water loss, has been noted after TCA and phenol peeling, as well as after laser resurfacing. [15], [32] The constellation of symptoms includes friable, stellate, nonindurated, painful, unhealed erosions with serous granulation tissue persisting for 10 days after peeling. The areas may heal with hypopigmented flat scars and should be treated with artificial semipermeable dressings or very dilute triamcinolone injections into the wound margins. Other treatments for scars include topical, intralesional, or tape-impregnated glucocorticoids, silicone gel sheeting, or the 585-nm flashlamp-pumped pulsed dye laser (FPDL). [33]

Bacterial, viral, or fungal infection may occur after peeling. Toxic shock syndrome, induced by Staphylococcus aureus exotoxin, has been reported rarely following Baker's phenol face peels. Patients with a positive history of herpes should be treated prophylactically during healing with therapeutic doses of acyclovir, valacyclovir, or famciclovir beginning on the day of the peel. Unusual and unexpected postpeel pain may reflect the onset of herpes viral infection. Candidiasis has been reported more frequently after dermabrasion and CO_2 laser resurfacing, probably because of the partially protective presence of a nonviable epidermis remaining after peeling and because of the lack of occlusive dressings. [15]

Prolonged erythema, which may occur after peeling, may be treated with topical hydrocortisone. Isotretinoin administration prior to peeling, atopic problems in the patient, rosacea, contact dermatitis, or minimal amounts of alcoholic beverages may also affect redness. Textural changes in the form of large pores may occur temporarily after peeling. Milia or acne occurring after peeling may be aggravated by thick ointments. A poor physician/patient relationship in the face of minor, manageable complications can result in a loss of follow-up and litigation.

Skin atrophy, cardiac arrhythmias, laryngeal edema, and exacerbation of a Koebnerizing pemphigus-like disease may occur with phenol/croton oil peels. [34]

COMBINATION SKIN RESURFACING—COMBINING CHEMICAL RESURFACING WITH LASER OR

DERMABRASIVE RESURFACING

As discussed above, deep phenol peeling will eliminate rhytides in the perioral area and medium peels can be used on the remainder of the face if warranted. [15] The resurfacing CO_2 laser or dermabrasion can also be used to eliminate rhytides or reduce scars in the perioral, periorbital, or cheek areas. [14], [35] The remainder of the face can be blended with chemical peeling. Operator-sensitive differences in technique in the three modalities make comparison of the three resurfacing modalities difficult.

Skin Resurfacing: Dermabrasion

HISTORICAL FACTORS
INDICATIONS
PATIENT SELECTION
EQUIPMENT
ANESTHESIA
WOUND CARE
COMPLICATIONS
MICRODERMABRASION

REFERENCES

Over the past decade, the availability of many pulsed and shuttered CO_2 lasers has rekindled an interest in resurfacing treatments of the skin. Many of the current laser surgery practices such as patient selection, postoperative dressings, and management of complications are based on years of experience with dermabrasive resurfacing and chemical peeling. While chemical peeling uses the application of exfoliating chemicals to remove epidermal and dermal layers of the skin, dermabrasion surgically abrades or planes the epidermis and dermis with the use of a rapidly rotating wire brush or diamond fraise. A working knowledge of the limitations and advantages of each of these resurfacing options is requisite in optimizing surgical outcomes for the entire spectrum of clinical presentations.

HISTORICAL FACTORS

Armed with the success of 200 cases performed over a 2-year period, Dr. Abner Kurtin presented “corrective surgical planing of skin” to the Dermatologic Section of Mount Sinai Hospital New York, in January 1953. [1] His technique combined the use of high-speed rotary dermabraders, intraoperative freezing, and various cutting-end pieces for resurfacing facial skin. [2] This office-based surgical procedure laid the groundwork for modern dermabrasion and introduced the subspecialty of cosmetic dermatologic surgery.

INDICATIONS

The indications for dermabrasion include those lesions and defects of the epidermis, papillary dermis, and upper reticular dermis that can be partially or completely removed by surgically planing to the level of the reticular dermis. Wound healing by second intention allows re-epithelialization to occur from the underlying adnexal structures. During the maturation phase of wound healing, fibroblasts replace and remodel collagen bundles in the papillary and upper reticular dermis. [3] These mechanisms allow the superficial and saucer-shaped scars of facial acne to be greatly improved, while ice-pick scars and deep post-varicella scars may require elevation or punch grafting prior to dermabrasion. [4]

Programmed dermabrasion of surgical and traumatic scars performed 6 to 8 weeks following injury frequently yields complete elimination of visible evidence of scar formation. [5] While the cellular mechanisms of this phenomenon are not completely understood, ultrastructural studies have demonstrated an increase in collagen bundle density and size with a tendency toward a more normal unidirectional fiber orientation, parallel to the epidermal surface. Furthermore, immunohistochemical assays have shown a postabrasive upregulation in tenascin expression in the papillary dermis, and an alteration in integrin expression in the spinous layer of the epidermis. These observations suggest that dermabrasive scar revision produces a less-perceptible scar by modifying the extracellular ligand expression of the primary cicatrix, thereby influencing epithelial cell-to-cell interaction and the reorganization of underlying connective tissue. [6]

As a resurfacing treatment for photoaging, dermabrasion can be used to treat actinic keratoses, solar elastosis, and wrinkles [7] (Fig. 270-1). Benign conditions, such as rhinophyma, adenoma sebaceum, epidermal nevi, syringomas, small cysts, milia, and seborrheic keratoses can easily be removed. Abrasion can also be used to eradicate superficial malignancies, including Bowen's disease and superficial basal cell carcinomas. [8] Pigmentary disorders, such as melasma, tattoos, and lentigines, can be improved with dermabrasion when it is used in conjunction with bleaching and tretinoin creams. [9]

FIGURE 270-1 *A.* Perioral rhytides prior to wire brush dermabrasion. *B.* Improved perioral rhytides 6 months following wire brush dermabrasion.

PATIENT SELECTION

In evaluating patients for dermabrasive procedures, a complete history and comprehensive consultation are paramount. A review of “before” and “after” photographs is often helpful in preparing the patient and providing realistic expectations of improvement. The risks of preoperative, intraoperative, and postoperative care should be discussed in obtaining informed consent. A recent history of isotretinoin therapy is a contraindication because of many reports of hypertrophic scarring and poor healing attributed to concomitant or recent isotretinoin usage. Generally, 6 months is considered an adequate interval between isotretinoin treatment and any abrasive surgery. [10], [11], [12] and [13] Similarly, dermabrasions should not be performed for at least 6 months following any extensive undermining (i.e., face lifts, brow lifts, etc.) so as to allow reestablishment of the vascular bed of the area to be abraded. [14]

Drug allergies, clotting disorders, abnormal scarring, cold intolerance, pigmentary disorders, or Koebnerizing skin conditions are other important historical factors to be considered. Preoperative antiviral prophylaxis obviates the great potential for activation of herpes simplex with perioral or full-face abrasions. Furthermore, the risk of aerosolization of viral particles mandates universal precautions. [15], [16]

EQUIPMENT

Various manufacturers produce hand engines capable of providing 15,000 to 60,000 rpms for driving the cutting-end pieces. The wire brush and diamond fraise are the most commonly used. The fraises come in a variety of shapes, sizes, and grades of coarseness. Pear-shaped fraises and cones are often used around the nose and oral commissure, whereas the wheels can be used over broad, flat surfaces. Diamond fraises can be used without cryogenic spray and offer a broader safety margin than the wire brush. The wire brush removes greater amounts of tissue with less thermal injury, thereby allowing the surgeon to plane deeply into the mid-reticular dermis with less risk of scarring. For more aggressive abrasions with a wire brush or a coarse diamond fraise, the use of intraoperative cryogenic sprays provide a firm surface on which to work and prevents the skin from grabbing or gouging. However, excessive freezing or the use of sprays with extremely low boiling points can produce unwanted tissue damage and scarring. The products containing Freon 114 and Freon 114–ethylchloride mixtures are safe, while products using Freon 11 and Freon 12, which lower skin temperatures more, may cause excessive skin damage. [17], [18]

ANESTHESIA

Today, most dermabrasions are performed as outpatient procedures in offices, ambulatory surgery facilities, or hospital operating rooms. Regional or spot dermabrasions can usually be performed with local anesthesia and no additional analgesia. However, full-face abrasions may require oral or IM sedation in conjunction with cryoanesthesia, local or tumescent anesthesia, or nerve blocks. Intravenous sedation or general anesthesia is rarely necessary. Like cryoanesthesia, the tumescent technique offers local anesthesia and a solid surface for planing. Some surgeons prefer the increased hemostasis of tumescence, and choose to eliminate the refrigerant spray because of the chance of unintended tissue damage. [19] A topical eutectic mixture of local anesthetic may provide supplemental surface anesthesia, but its use should be limited to less than 10 g. [20] The controversial and potential benefit of abrading scars frozen into place may be lost with the distention of tumescence.

WOUND CARE

Following dermabrasion, white petroleum ointment or an antibiotic ointment is applied to the abraded area. Significant advances have been made in the development of semipermeable hydrogel dressings that can be applied directly on top of the ointment. By maintaining a critical plane of humidity for epithelial cell migration, these dressings have reduced the time of reepithelialization to only 5 or 6 days. [21], [22] During this time, the ointment and dressing can be changed daily. A mild soap or nonmentholated shaving cream can be used to clean the area and to prevent any buildup or crust formation. Once the treated area has been reepithelialized, the new skin is pink-to-red in color and requires the frequent application of moisturizer. The pinkness can be covered with makeup and usually fades over a period of 6 to 12 weeks.

COMPLICATIONS

Postoperative complications include scarring, pigmentary changes, persistent erythema, and infection. The deeper the

dermabrasion, the greater the risk of scarring, especially over the upper lip, mandible, and bony prominences. Because of the decreased number of adnexal structures in nonfacial skin, dermabrasions performed away from the face are also more likely to produce scarring. Hypertrophic scars and keloids may be treated with topical flurandrenolide tape, intralesional steroids, or silicone gel sheeting. [23] Some 30 to 50 percent of all patients may experience some degree of hypopigmentation following dermabrasion. The chance of hyperpigmentation is greatest during the first 6 weeks after surgery, especially in skin types III and IV, and can often be prevented with the postoperative use of hydroquinone and retinoic acid creams. Because of the low incidence of bacterial infections following dermabrasion, prophylactic antibiotics can produce more harm than good by promoting gram-negative superinfections. Primary bacterial infections are extremely rare and best managed with culture-directed antibiotic regimens. Antiviral prophylaxis, on the other hand, should be performed on a routine basis for full-face abrasions and perioral treatments (see Chap. 260). Careful patient selection, attentive surgical technique, state-of-the-art postoperative dressings, and prompt management of any developing problem can greatly reduce the risk of postabrasive complications and significantly enhance surgical outcomes.

MICRODERMABRASION

Microdermabrasion is a recently developed resurfacing technique that uses aluminum oxide or sodium chloride microcrystals to superficially remove the stratum corneum and epidermis. The microcrystals circulate through a high-speed system and are collected in a waste container. With this method of abrasive resurfacing, the depth of ablation is easily controlled by dialing in the appropriate pressure setting on the machine.

Histologic evaluation of biopsies taken immediately following microdermabrasion demonstrates compaction and homogenization of the epidermis. After six treatments, thickening of the epidermis and an increased number of elastic fibers is seen within the dermis. Clinically, the treated skin has a smoother contour and visible erythema that persists for 2 to 3 days postoperatively. This technique is useful in treating early photodamage, fine wrinkles, dyschromia, and superficial scarring. [24], [25] and [26] Simple postoperative wound care with a hydrating moisturizer allows for rapid recovery and minimal discomfort. Treatments are usually successive, 2 to 4 weeks apart, and maintenance of results requires periodic repeating procedures.

REFERENCES

In the 1980s and early 1990s continuous wave CO_2 lasers were used in an effort to resurface photoaged skin. Although the results of this procedure performed by a few were quite impressive, the risk:benefit ratio of the procedure was very high. Dwelling too long on a specific area led to excessive thermal diffusion and thermal damage resulting in scarring. The technique was never widely used for this specific reason. However, with the development of short-pulse high-peak power and rapidly scanned focused-beam CO_2 lasers and normal mode erbium:yttrium aluminum garnet (Er:YAG) lasers, the ability to remove photodamaged skin layer by layer in a precisely controlled manner while leaving behind a very narrow zone of thermal damage became possible (see Chap. 267). [1], [2]

THEORETICAL CONSIDERATIONS

The CO_2 Laser

The CO_2 laser, first developed in 1964, has an emission wavelength of 10,600 nm in the infrared part of the electromagnetic spectrum, where the major chromophore is water. The thickness of water that absorbs 90 percent of the radiant energy of the incident beam from the CO_2 laser is approximately 30 µm. [3] However, when the energy is delivered in a continuous beam, thermal coagulation occurs to a depth of up to 1 mm because of heat diffusion. To control the depth of thermal damage that occurs in tissue, the continuous wave CO_2 laser beam needs to be scanned at a rate that results in a tissue dwell time of less than the thermal relaxation time or the energy must be delivered in a pulse shorter than this time. The thermal relaxation time of the 30 µm tissue layer heated by the CO_2 laser has been calculated to be less than 1 msec. [4] The necessary pulse energy fluence to achieve pulsed CO_2 laser ablation of skin tissue is approximately 5 J/cm ^{2}. [3] Delivering 5 J/cm ^{2} in less than 1 msec to skin limits the thermal damage zone to 20 to 150 µm depending on how many passes are done with the depth of thermal damage increasing with increasing number of laser passes. [5] Several resurfacing CO_2 lasers that meet the above criteria have been developed (Table 271-1).

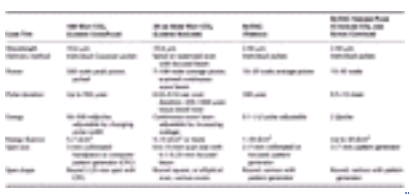

TABLE 271-1 **Representative Resurfacing Lasers**

Erbium:YAG Laser

The 2940-nm wavelength of the Er:YAG laser has 16 times greater water absorption than the CO_2 laser. Its shallower skin penetration (1 µm as compared with 30 µm for CO_2 laser light) allows more precise ablation with less thermal damage. In addition, Er:YAG laser light is efficiently absorbed by collagen. The Er:YAG laser has been tested in a pulsed (normal) mode with a pulse width of 200 µsec and in a Q-switched mode with a pulse width of 90 nsec. At fluences below 25 J/cm ^{2}, 2.5 to 30 µm of tissue was ablated and the zone of damage was limited to 10 to 40 µm with normal mode laser and 5 to 10 µm with the Q-switched laser when tested in guinea pig skin. [6] In the Q-switched mode, residual thermal damage is insufficient to coagulate blood vessels, leaving a bloody surgical field limiting its clinical utility. In the normal

mode, skin vaporization leaves a relatively bloodless field after two to three passes. Bleeding becomes a greater problem with successive passes. [7]

The normal mode Er:YAG laser ablates approximately 4 µm of tissue for every J/cm ^{2}. The residual thermal damage is in the range of 10 to 40 µm in clinical practice. Unlike the CO_2 lasers, pulse stacking with an Er:YAG laser does not seem to increase the thickness of thermal damage. Each pass ablates a reproducible thickness of tissue so that with a sufficient number of passes, the laser can ablate into the subcutaneous fat. However, bleeding becomes a problem as the laser ablates into the deep papillary dermis making deeper ablation difficult to achieve in a controlled manner and, unlike the CO_2 laser, there is no immediate tissue shrinkage from thermal coagulation.

Variable Pulse Er:YAG Laser

In the belief that immediate tissue contraction is important for long-term laser resurfacing results, variable pulse Er:YAG laser systems have been introduced. Clinical use of these lasers demonstrates immediate tissue contraction along with a rate of healing intermediate between that of the resurfacing CO_2 lasers and short-pulse Er:YAG lasers. [8]

HISTOLOGY

Resurfacing lasers are designed to ablate a superficial zone of skin, leaving minimal thermal damage. Macroscopically, shrinkage is seen during CO_2 and long-pulse Er:YAG laser treatment and appears to be directly proportional to the number of passes. [9] Contraction has not been measured in photoaged human skin, but shrinkage in pig skin was proportional to the number of passes and to fluence, resulting in a 10 to 30 percent reduction in area. [10]

A study of porcine skin compared the CO_2 laser with trichloroacetic acid and phenol peels and dermabrasion. [11] The depth of residual thermal necrosis was 40 µm, but it was up to 53 and 106 µm with second and third passes, respectively, and increased with increased pulse energy. Dermal vaporization plus necrosis depth was directly proportional to pulse energy; that is, with each pass, the depth of vaporization decreased while the residual thermal damage increased.

One study examined the depth of ablation and residual damage with each pass. [5] Three different laser systems, were compared with a continuous wave (CW) CO_2 laser as a control. One was a pulsed laser with a computerized scanner; another was a scanned CW laser; and the third a superpulsed laser. At the settings used, which were those proposed for optimal response to each laser, the CW laser caused a zone of thermal necrosis 400 to 500 µm thick. Both the scanned CW laser and the superpulsed laser ablated 30 to 50 µm of tissue and completely removed the epidermis. Subsequent passes with these lasers ablated into the dermis. The zone of coagulation necrosis also increased with each pass. Another report of 40 patients tested the flashscanner and superpulsed lasers and confirmed that the first pass ablated the epidermis, the third pass removed the papillary dermis, and the fourth pass penetrated into the reticular dermis. [12]

In summary, the following statements can be made about CO_2 laser resurfacing: (1) With each laser pass, there is a reproducible tissue effect with three distinct zones. (2) The depth of tissue vaporization increases with each pass. (3) The residual thermal damage increases with each pass. (4) A repair zone with new collagen is seen in follow-up biopsies.

The histologic changes with the Er:YAG show minimal thermal damage, but vaporization that is additive after each pass. Therefore, ablation can be carried out all the way through the dermis and into the fat. There is little, if any, additive residual thermal damage. With longer pulses the thermal damage zone increases, but as each pass ablates the previous thermal damage, the thermal damage zone remains constant. [6] With long Er:YAG laser pulses, visible contraction similar to that seen with the CO_2 laser can be observed.

Skin tightening after laser resurfacing seems to be related to biphasic contraction. There is immediate contraction due to thermally denatured and altered collagen (CO_2 and long pulse Er:YAG). This effect seems to diminish during the first couple of weeks as the thermally denatured collagen is sloughed off. A second phase of contraction develops over 3 to 18 months as fibroblasts lay down new collagen as part of long-term wound repair (CO_2, Er:YAG, and long-pulse Er:YAG). Histologically, this is manifested by horizontally oriented collagen fibers in the papillary dermis consistent with mild fibrosis (scar).

INDICATIONS

Rhytides

To evaluate the severity of wrinkling and photodamage present and therefore achieve some degree of predictability of response to resurfacing, a clinical classification and numeric scoring system was devised. [1], [2] Use of this scoring system allows broad classification into mild, moderate, and severe categories, as well as a more objective numerical severity score.

Assessing patients both before and after CO_2 laser resurfacing in studies with an average follow-up of about 90 days revealed that the average patient's preoperative score decreased approximately 50 percent as a result of resurfacing (Fig. 271-1). [1], [2] This means that mild wrinkles generally resolve completely, and that moderate and severe wrinkles improve by one class. These are realistic expectations for the patient, although, occasionally, even severe wrinkles may completely resolve. The treated area continues to improve up to 18 months after laser resurfacing as collagen remodeling takes place. Periorbital, perioral, and other actinically induced rhytides improve, whereas dynamic rhytides such as glabellar and nasolabial folds show only minimal and temporary improvement. In general, both wrinkling and photodamage of the epidermis and dermis are responsive to treatment. Neck and hand photodamage and wrinkles

should be approached with extreme caution as the risk of scarring and hypopigmentation is far higher than on the face. [13]

FIGURE 271-1 *A.* Prior to CO_2 laser resurfacing. *B.* Three days after full-face laser skin resurfacing. *C.* Ten days after full-face laser skin resurfacing. *D.* Three weeks after full-face laser skin resurfacing.

As far as epidermal pathology associated with aging is concerned, actinic keratoses, squamous cell carcinoma in situ, lentigines, and seborrheic keratoses are all removed with stripping of the epidermal layer. Photodamage of the dermis results in fragmentation of elastin and collagen fibers, most profoundly in the papillary dermis. This is seen clinically as altered surface texture and pallor with crepe-like changes progressing to those of severe photoaging with cream yellow discoloration and deep creases. These layers of altered dermal tissue may be removed by vaporization and thermal necrosis and replaced with new healthy collagen developed over a tightened matrix of shrunken collagen. The ability to change these tissues dramatically relates to the depth of damage with the more superficial damage being more responsive. These dermal changes result in loose, sagging, or folded skin. These folds may be particularly visible under the eyes, on the medial lower cheeks, on the lateral cheeks anterior to the ears and to a certain extent at the nasolabial folds. These areas tend to be very responsive to the tightening effects achieved with CO_2 laser resurfacing. [1], [2], [14]

When resurfacing with the traditional, short-pulsed Er:YAG laser, more passes than with the CO_2 lasers are required to ablate to the same depth. The CO_2 lasers ablate more tissue per pass and leave a larger zone of thermal damage, with associated immediate collagen contraction. Studies comparing equivalent combined thickness ablation and coagulation with CO_2 and Er:YAG lasers have shown the CO_2 laser to achieve better wrinkle improvement but the postlaser recovery is faster with the Er:YAG laser. [15]

With the variable pulse Er:YAG lasers, thermal damage zones intermediate between that of the CO_2 and normal mode Er:YAG laser are achieved. Studies comparing a pulsed CO_2 laser with a computerized scanner on one half of the face and a variable pulse Er:YAG laser on the other half suggest that for equivalent depths of combined ablation and coagulation the wrinkle improvement is very similar while the reepithelization times and post-laser erythema duration are shorter for the variable Er:YAG laser–treated patients. [8]

Scars

The treatment of facial acne scars was found to be less effective than wrinkle treatment. [16] Mild to moderate acne scarring has improved significantly more than severe scarring. The procedure is most suited for distensible depressed or elevated acne scars. [16], [17] The edges of the scars are sculpted and more tissue is vaporized in the areas of scar tissue while doing only superficial resurfacing in the rest of the cosmetic unit being treated. Ice-pick and bound-down scars should first be removed with subcision, punch excision, linear excision, punch elevation or punch grafting, [17] with laser resurfacing being performed 6 to 8 weeks later. Alternatively, the surgical procedures may be performed at the time of the laser resurfacing either immediately before or after resurfacing. Any suturing is done immediately after resurfacing. [18]

Facial crateriform varicella scars can be improved with spot laser resurfacing. The area around and over the scar is vaporized with one pass of the laser. Additional passes are concentrated along the edge of the scar crater until it has been completely effaced. When done 6 to 10 weeks after varicella, the scar can be almost totally effaced. Older scars respond, but less completely. Postsurgical and traumatic scars can be dramatically improved, especially if resurfaced 6 to 10 weeks after the surgery or injury. [14] Immediate resurfacing after surgery of well-vascularized wound edges just prior to skin suture placement can make the final scar less noticeable. [19] Immediate resurfacing and sculpting of wound edges of nasal wounds that are to be allowed to heal by second intention enhances the final cosmetic result by allowing the scar to blend in better with the surrounding skin. [20]

Other Indications

Actinic cheilitis can be successfully treated by performing a laser vermilionectomy using one of the resurfacing lasers. [14], [21] Depending on its thickness, this usually requires one to several passes over the vermilion region. This has significantly reduced postlaser healing to approximately 10 days, in contrast to the 4 weeks it took when the conventional CO_2 laser was used. The risk of scarring seems to be greatly reduced as the extent of thermal damage is much less. The end point of treatment is complete epidermal ablation with superficial submucosal coagulation. Ablating only the epidermis has resulted in frequent actinic cheilitis recurrence. Actinic keratoses unresponsive to conventional treatment with liquid

nitrogen and topical 5-fluorouracil can be removed by ablating the epidermis and superficially ablating the upper papillary dermis to remove follicular involvement using one of the resurfacing lasers. This is especially useful on the dorsal hands and scalp.

Pigmentation irregularities such as postinflammatory hyperpigmentation and dark circles under the eyes can sometimes be improved with laser resurfacing. It is very important to use tretinoin and hydroquinones for an extended period of time before and after the procedure. Other lasers more specific for melanin or medium depth chemical peels are often preferable as they do not require anesthesia and the recovery time is much shorter. Melasma responds variably similar to other modalities used for its treatment.

Rhinophyma, epidermal nevi, and various small benign growths such as syringoma, trichoepithelioma, dermatosis papulosa nigra, xanthelasma, adenoma sebaceum, and sebaceous hyperplasia have traditionally been treated with the conventional CO_2 laser. [21] Using a resurfacing laser may reduce the healing time and risk of scarring by reducing the extent of unwanted thermal damage. [21] Sometimes a combination approach can be employed. For example, a rhinophyma can be debulked using the CO_2 laser in the superpulse mode, and the remaining tissue can be removed with the resurfacing mode of the laser to finish the procedure. When treating epidermal nevi, it is important to cause damage into the papillary dermis with residual hypopigmentation expected. Failure to cause some degree of dermal fibrosis often results in nevus recurrence.

TECHNIQUE

Preoperative Considerations

As with any cosmetic procedure, patient expectations are the most important determinant of patient satisfaction. Realistic expectations, an understanding of the postoperative care involved, and excellent preoperative photographs are essential. Resurfacing can improve wrinkling caused by photodamage, while dynamic rhytides need to be managed with other methods, such as botulinum toxin A injections.

Skin that was recently undermined, as in a facelift or blepharoplasty, has an altered blood circulation for several months. Resurfacing procedures done at the same time as or soon after skin undermining increase the risk of skin necrosis with associated scarring. [22] Therefore, laser resurfacing of undermined skin should be deferred for 6 months after the original surgical procedure. It is unknown how long after laser resurfacing a patient can safely undergo a procedure that undermines the resurfaced skin but a wait of 3 to 6 months would seem prudent.

Prior isotretinoin treatment has been reported, in case reports, to be associated with atypical scarring after dermabrasion or chemical peel even if the procedure was performed more than 1 year after isotretinoin treatment. Whether this represents a true increased risk or is only coincidental is unknown. Therefore, patients who have received isotretinoin should receive additional warnings about the possibility of scarring from laser resurfacing and the procedure should probably be done more conservatively. Waiting at least 1 to 2 years before undergoing laser resurfacing after isotretinoin treatment, because of the unknown effects on wound healing presented by isotretinoin, would seem prudent.

Tretinoin speeds reepithelialization after dermabrasion [23] and chemical peels, and it may work similarly after laser resurfacing. Therefore, tretinoin is usually prescribed for at least 6 weeks before laser resurfacing. Postinflammatory hyperpigmentation develops in a majority of Fitzpatrick type IV patients, as well as in almost all darker-skinned individuals. [1] To reduce the incidence of postinflammatory hyperpigmentation, sun avoidance for several weeks before and for several months after the procedure is recommended. While there is debate over whether preparing the skin with lightening agents prior to resurfacing decreases the risk of hyperpigmentation, many laser surgeons give skin types III to VI patients hydroquinone, kojic acid, or azelaic acid. To be effective, bleaching creams have to be used for a number of weeks before the procedure. The ideal time for laser resurfacing is late fall and winter.

All patients, regardless of cold sore or fever blister history, are prophylactically given either acyclovir 400 mg PO tid, valacyclovir 500 mg PO bid, or famciclovir 250 mg PO bid starting up to 2 days before and continuing for at least 10 days after the procedure. After laser resurfacing, there is a layer of necrotic, thermally coagulated dermis that will slough over several days. This material serves as an ideal bacterial culture medium. Therefore, patients are usually given prophylactic antibiotics, such as dicloxacillin 250 mg PO QID or, in penicillin allergic individuals, azithromycin 500 mg followed by 250 mg PO QD starting up to 1 day prior to surgery and continuing for a total of 5 days. Since introducing oral antibiotics, impetiginization of the treated areas has been almost totally eliminated. A few laser surgeons recommend a dose of fluconazole on the day of resurfacing to reduce the risk of candidal infection in the treated area.

Surgical Procedure

Except for the most superficial laser resurfacing, complete anesthesia of the treated area is required. For limited areas, local anesthesia is sufficient, but when treating the entire face, intravenous sedation or general anesthesia is usually preferred. However, there are some surgeons that have been able to successfully resurface the entire face under topical anesthesia alone. [24] To minimize visible lines of demarcation, the entire cosmetic unit with feathering at the edges is recommended. Patients with actinic bronzing or those in whom more than one anatomic unit is to be treated should have the entire face from the hairline to below the jaw line treated.

Carbon Dioxide Lasers

The various laser systems available will have different recommended power and energy fluence setting. The key thing is to limit the number of passes to achieve effacement of the offending pathology while keeping the thermal damage within the papillary or upper reticular dermis and minimizing adjacent pulse overlap, because pulse stacking (overlap of laser-irradiated sites, especially after the first pass) can increase the depth of thermal injury significantly. When the

dermis is entered, visible shrinkage because of collagen denaturation is clearly visible and desired when treating rhytides. At the conclusion of treatment, the tissue will have a yellowish tinge to it, which represents thermal damage within the dermis. Wiping away the thermally altered debris between passes, but not after the last pass is recommended to reduce the depth of thermal damage. Not wiping the debris after the final pass seems to speed reepithialization. [25] There is rarely a reason to perform more than four passes with a CO_2 resurfacing laser in any given area, as studies show that, with the energy fluences used, both vaporization and collagen tightening plateau at three to four passes, while residual thermal damage gradually increases with each additional pass. [26] After the final pass, one to two passes with an Er:YAG laser will remove some of the residual thermal damage and seems to speed healing with a reduced duration of post-resurfacing erythema. [27]

Er:YAG lasers

The treatment field is covered with moderately overlapping laser pulses. Overlapping of laser pulses seems to achieve a more even result. Pulse stacking is acceptable with the Er:YAG laser as additive thermal damage does not develop. Approximately 4 µm of tissue is vaporized per J/cm ^{2} of energy. [7] Settings are adjusted depending on how much tissue one wishes to ablate per pass taking into account any overlapping of pulses. With 50 percent overlap one “pass” will remove tissue equal to two nonoverlapped passes. With an energy fluence of 5 J/cm ^{2}, the epidermis is vaporized away in four passes. At 8 to 12 J/cm ^{2}, the epidermis is vaporized away with two passes. Additional passes are performed until the lesion or rhytid has been effaced, bleeding has been encountered or a maximum safe number of laser passes has been completed. Wiping the tissue between passes, except when the epidermis is ablated, is not necessary. It is important to keep track of the number of laser passes to determine the level of ablation. Er:YAG laser ablation in the papillary dermis gives a smooth, glistening surface. Once the reticular dermis is entered, the surface becomes uneven with sebaceous gland lobules becoming visible. At this point bleeding begins to interfere with deeper treatment. No immediate tissue shrinkage is evident with Er:YAG laser resurfacing.

Long-Pulse Er:YAG Laser

When using the variable pulse Er:YAG laser in the long-pulsed mode, heat is delivered to tissue in a manner very similar to the pulsed CO_2 laser. Therefore, immediate tissue tightening because of collagen denaturation is evident and the procedure is relatively bloodless because of coagulation of small dermal blood vessels. The short-pulsed mode may be used for purely ablative functions such as fine sculpting of tissue irregularities and removal of the final necrotic layer of thermal damage.

The settings used will be similar to the short-pulse Er:YAG laser. A fluence of 10 J/cm ^{2} will remove 40 µm of tissue per pass. The ablation is done overlapping spots by 50 percent so that one pass achieves tissue ablation equivalent to two passes. The variable pulse duration gives this laser added versatility. The pulse duration used will depend on the degree of thermal coagulation and visible shrinkage desired. Deeper wrinkles are best treated with the longest pulse durations available while fine lines and minimal photodamage are treated with the short-pulse option.

Nonfacial Resurfacing

Laser resurfacing other than on the face should be approached with caution as the risk of complications increases dramatically. [13] With the minimal residual thermal damage left behind by the Er:YAG laser, it is useful for the treatment of nonfacial photodamage and may have a role to play in the treatment of nonfacial rhytides, including the dorsal hands and neck. [28] The CO_2 laser is generally not used for resurfacing below the face. However, aggressive hydration of the skin with a topical anesthetic under occlusion seems to reduce the depth of thermal injury sufficiently to allow a CO_2 resurfacing laser to be used for superficial treatment of the neck. [29] Only the epidermis should be ablated with the expectation that dyspigmentation of the skin will be improved while the associated rhytides are only minimally affected. The main indication for neck resurfacing is to reduce color mismatch between the laser resurfaced face and sun-damaged bronze color neck.

Wound Care

Reepithelialization takes 3 to 10 days, depending on the depth of ablation and thermal coagulation (Fig. 271-1). Pretreatment with tretinoin and the use of bio-occlusive dressings during the first few days seems to speed reepithelialization. During the first few days, the thermally denatured collagen is sloughed off. The edema that develops in the first 48 hours can be controlled with ice packs, head elevation at night, and oral glucocorticoids. Once dressings are stopped, continued moist wound healing is achieved with frequent 0.25% acetic acid, normal saline or cool tap water soaks followed by application of a nonocclusive water-in-oil emulsion. Polysporin and bacitracin ointment cause frequent allergic contact dermatitis in these patients and petrolatum may cause a folliculitis, especially if it is not stopped immediately after reepithelialization is complete.

Moderate burning discomfort experienced by some patients during the first 24 h after laser resurfacing is controlled most effectively with bio-occlusive dressings. In patients treated with the open technique, ice packs, cold compresses and analgesics are helpful. Pruritus frequently develops during the first few weeks after resurfacing and responds to antihistamines and topical glucocorticoids. Many patients experience a tightness in the treated areas lasting several weeks to several months.

After reepithelialization, there is a variable period of erythema lasting 1 to 4 months (Fig. 271-1). The intensity and duration of the erythema is related to the depth of ablation and the thickness of the residual thermal damage. The redness can be successfully camouflaged with makeup containing green foundation. Sun avoidance during the entire period of postlaser erythema is essential to reduce the risk of postinflammatory hyperpigmentation.

SIDE EFFECTS AND COMPLICATIONS

Side effects following CO_2 laser resurfacing are frequent and predictable. They are similar to those following medium to deep chemical peels and dermabrasion, but they are less common and can be prevented if excellent technique is followed and postoperative management is fastidious. They can be divided into six categories: immediate, predictable effects; pigmentary changes; infection; follicular effects; eczematous effects; and scarring (Table 271-2).

TABLE 271-2 **Side Effects and Complications Associated with Laser Resurfacing**

Erythema is universal and is considered part of the normal healing process. It lasts an average of 6 to 12 weeks, while erythema and flushing, which develop in the treated site with exertion or emotional upset, are frequent up to a year after resurfacing. Some individuals do have persistent continual erythema lasting up to 12 months; this may be related to the depth of ablation. [2]

The most frequent complication is pigmentary alteration. Transient hyperpigmentation has been reported in up to 36 percent of patients, mainly affecting those with Fitzpatrick types III and IV skin. [16] More recent studies demonstrate rates of hyperpigmentation as low as 2.8 percent. Pretreatment with tretinoin and hydroquinone and fastidious sun avoidance after the procedure during the period of erythema may account for the lower incidence. Hyperpigmentation can last up to 6 months. Resolution may be hastened by continued treatment with tretinoin and hydroquinone. Permanent hypopigmentation has also been reported in up to 16 percent of individuals. [30] It is most frequent in patients with skin bronzing induced by actinic damage. In most patients it is a relative hypopigmentation with the resurfaced skin lacking visible changes of actinic damage. However, in some patients it is true hypopigmentation. Hypopigmentation is more common in patients who have previously been treated with dermabrasion [16] and appears to be related to depth of treatment.

Milia are a result of follicular reepithelialization compounded by the use of occlusive moisturizers and develop during the first 3 months after resurfacing. They are seen far less often after laser resurfacing than after dermabrasion. Treatment with tretinoin and extraction of persistent milia are effective in resolving the problem. Ointments should be discontinued as soon as reepithelialization is complete. Acne is a frequent postoperative event, especially in patients with a past history of acne. It usually develops in the first few weeks after resurfacing and responds to usual acne treatments. Occasionally, aggravation of rosacea and/or perioral dermatitis can be seen from a few weeks to a number of months after resurfacing.

Contact dermatitis, noted with the use of some topical antibiotic preparations, does not correspond with patch-test findings but resolves with appropriate treatment. [1], [2] This occurrence increases the chances of postoperative erythema and hyperpigmentation. For this reason, topical antibiotics are usually not recommended after resurfacing. Eczematous dermatitis occasionally develops in the first 4 weeks after treatment. It responds rapidly to moisturizers and topical mid-potency glucocorticoids.

Hypertrophic scarring is seldom seen following laser resurfacing. [2] It may result from a large number of passes or use of excessive energy that results in overly deep ablation and residual thermal damage. Pulse stacking with the CO_2 laser causes excessive thermal damage and an increased risk of scarring. [26] Pulse stacking with the Er:YAG laser is not a problem as each pulse ablates the thermal damage from the previous pulse so there is very limited additive thermal damage. Infection that is not recognized and treated promptly is another frequent cause of scarring. In rare cases, scars develop as a result of delayed reepithelialization that may take up to 1 year after resurfacing. Early management of incipient scars with topical and intralesional glucocorticoids, pulsed dye laser photocoagulation, silicone gel sheeting, and 5-fluorouracil injections may significantly reduce or even eliminate permanent scarring.

In a procedure that removes the epidermis and part of the dermis, infection is a concern. Laser surgeons have learned from past experience with dermabrasion and have avoided bacterial infection through the judicious use of prophylactic antibacterials. Antiviral chemoprophylaxis was originally confined to those with a history of herpes simplex infection, but results suggest that subjects with no past history of infection frequently develop activation of herpes simplex in treated areas. [1], [2] It is now standard practice to use antiviral prophylaxis in all laser resurfacing treatments. Yeast infections can be seen, but they respond well to oral treatment. [2] Some laser surgeons add oral antifungal medications to their wound care regimen.

The main advantage of the Er:YAG laser is thought to be the improved side-effects profile. However, the side-effect profile is dependent on the combined depth of ablation and thermal damage. If the ablation is carried out to the same depth as with the CO_2 laser, the risk of complications is similar. If the procedure is done superficially, it is less painful and may be completed under topical anesthesia. There is less oozing and crusting and the subsequent erythema, although dependent on the number of passes, lasts a shorter time than that following CO_2 laser treatment.

FUTURE CONSIDERATIONS

CO_2 laser resurfacing technology has matured. However, new indications and technique refinements are being

developed. Treatments are less aggressive than in the early days of laser resurfacing. This enables the procedure to be done with a greater safety margin and faster recovery time at the cost of slightly reduced efficacy. The greatest current interest from both laser surgeons and the public is in minimally invasive procedures that have minimal to no downtime or adverse effects. With this in mind, nonablative laser resurfacing using lasers and intense pulsed light sources with several different wavelengths and pulse durations has been developed and are being studied for dermal remodeling without epidermal damage (see Chap. 267).

An “occlusive” or moisture-retentive dressing is one that maintains its moisture vapor transmission rate (MVTR) to permit optimal healing for a given wound. Moisture-retentive dressings maintaining MVTRs of less than 35 g/m^2 per hour in partial-thickness wounds such as donor sites permit moist wound healing.

HISTORICAL ASPECTS

Prior to the twentieth century, wounds were left open to dry, allowing the wound to “breathe.” [1] In 1958, Odland first observed that a blister healed faster when left unbroken. [2] In 1962, a landmark article by Winter demonstrated the beneficial effect of a polyethylene film on wounds in domestic pigs. [3] This study, which showed that wounds in pigs reepithelialize faster under occlusion, revolutionized the approach to wound care and paved the way for the development of occlusive dressings. The first experimental work performed on human volunteers, conducted by Hinman and colleagues in 1963, established the beneficial effect of occlusion on wounds. [4] Since then, a large number and variety of wound dressings have become available, accounting for more than $200 million in sales in 1987, as compared with practically no sales in 1980. [5] In 2000, there were more than 30 different companies offering more than 300 different dressings capable of creating or maintaining a physiologically moist local wound environment. [6]

EFFECT OF MOIST ENVIRONMENT ON ACUTE WOUNDS

Acute wounds are wounds with no underlying healing defect that proceed to heal in an orderly and timely fashion. The beneficial effects of a moist environment have been well studied in this type of wound.

Enhancing Débridement and Reepithelialization

A moist environment enhances the rate of epithelialization. Covered wounds resurface up to 40 percent faster than those exposed to air. [7] Enzymes that débride wounds of necrotic tissue or fibrin need water to become active. Thus, water retained at the wound surface plays a vital role in enhancing débridement and subsequent reepithelialization. Rovee and co-workers stressed that greater epidermal cell movement rather than mitosis accounts for the faster healing time. [8] Keratinocyte migration is facilitated by the absence of necrotic tissue. However, the formation of a functional stratum corneum is delayed under occlusion, as demonstrated by an elevated transepidermal water loss (TEWL) in epithelialized wounds as compared with unwounded skin. [9]

Keeping a wound moist maintains a lateral voltage gradient that aids the repair process. [5] Fibroblasts exposed to electrical energy proliferate and increase the synthesis of collagen by increasing the number of growth factor receptors. [10]

Dermal Effect

The beneficial effects of occlusion extend to the dermis. The dermis of occluded acute wounds—as opposed to the dermis of air-exposed wounds—demonstrates a modified cell infiltrate. [11] Occlusion seems to accelerate the transition from a predominantly neutrophilic to a macrophage-rich infiltrate. In pigs, full-thickness wounds demonstrated an acceleration of the inflammatory and proliferative phases of dermal repair under moist as compared with dry conditions. [12] Initial breaking strength in a wound, which is largely related to collagen tissue deposition, is delayed under occlusion. Interstitial collagenase, a crucial enzyme for initiating collagen degradation, is increased under occlusion and is closely

associated with keratinocyte migration and reepithelialization. [13] Actual in vivo collagen deposition has not been measured, and the exact relationship between the rate of epidermal resurfacing and dermal collagen synthesis remains to be determined. However, occluded wounds remain cosmetically superior, suggesting a modulation of the inflammatory process and accelerated remodeling and wound contraction.

Angiogenesis

Oxygen is both stimulatory and inhibitory to the wound-healing process. Nucleated cells require oxygen for cellular activities such as mitosis or migration, and it is well established that hypoxia is a potent stimulus of angiogenesis. The oxygen gradient between the wound's edge and its center stimulates capillary ingrowth toward the relatively hypoxic center. [14] The accumulation of factors stimulating angiogenesis under occlusion, such as heparin and tumor necrosis factor (TNF), may partly account for this enhanced angiogenesis.

In vitro trials have demonstrated that optimal growth of fibroblasts in tissue culture occurs at a low PO_2 (5 to 10 mmHg), and that epidermal cell growth is inhibited at an O_2 level higher than that of the surrounding air. Thus a delicate O_2 balance is reached under occlusion that may facilitate the formation of granulation tissue.

Retention of Wound Fluid

Acute wound fluid beneath occlusive dressings stimulates the proliferation of the various cells involved in wound healing. Katz and co-workers have demonstrated that acute wound fluid obtained up to 3 days postoperatively stimulates growth of both human dermal fibroblasts and umbilical vein endothelial cells in vitro. [15] Identified growth factors included platelet-derived growth factor (PDGF), basic fibroblast growth factor (bFGF), epidermal growth factor (EGF), transforming growth factor (TGF)-ß, and interleukin (IL)-1. [16] PDGF and PDGF-like peptides may be particularly involved in fibroblast stimulation, as well as being chemotactic to neutrophils and mononuclear cells. [17] Other growth factors important for cell migration and matrix formation are TGF-ß and EGF. [18] TGF-ß stimulates the production of fibronectin by fibroblasts and keratinocytes, promotes angiogenesis, and regulates collagen synthesis. EGF stimulates keratinocyte proliferation and locomotion and inhibits fibroblast proliferation. Alteration of the expression or action of endogenous growth factors occurs within 24 h after wounding. The dressing may be removed between 24 to 48 h without loss of rapid reepithelialization. [19]

Protection against Infection

The presence of either aerobic or anaerobic organisms does not influence wound healing, and there is no relationship between the rate at which the ulcer heals and the appearance or disappearance of the organisms. Although there might be an increased rate of bacterial colonization of occluded wounds, the rate of infection remains lower than in nonoccluded wounds.

Hutchinson, in his extensive review of clinical and research studies, reported an infection rate of 7.1 percent with conventional dressings, compared with 2.6 percent with occlusive dressings ($p < .001$). [20] Hydrocolloids fostered the lowest infection rate, followed by the foams and the hydrogels. In vivo hydrocolloids prevent the invasion of a heavy external inoculum of *Staphylococcus aureus* and *Pseudomonas aeruginosa* applied to the outer surface of the dressing and the skin around it. A polyurethane foam dressing prevented wound contamination by organisms applied to the dressing but not by those inoculated around it.

Several mechanisms account for the low infection rate under occlusion. [21] First, there are enhanced defense mechanisms, as demonstrated by enhanced phagocytic and lysosomal activity under occlusion. Neutrophils infiltrate moist wounds more easily than dry wounds and their presence may be bactericidal. Second, necrotic tissue, which may act as a foreign body predisposing to wound infection, is absent under occlusion. Third, the dressing acts as a physical barrier against exogenous bacteria and viruses. Fourth, the relatively hypoxic environment under occlusion results in an acidic pH that inhibits bacterial growth, particularly of *Pseudomonas*.

EFFECT OF MOIST ENVIRONMENT ON CHRONIC WOUNDS

Chronic wounds are wounds with an underlying pathology that do not heal in a timely fashion. The effect of occlusion on chronic wounds is less well studied due to the paucity of good animal models and well-controlled clinical trials. Chronic wound fluid, unlike acute wound fluid, was found to be inhibitory to cell proliferation and contained fibronectin and vitronectin degradation products, which are inhibitory to keratinocyte migration. [22]

In venous ulcers, moisture-retentive dressings increased the rate of healing over the first month of treatment; but at the end of 12 weeks, controlled studies failed to show any difference between compression plus occlusion versus compression alone. [21] In clinical trials comparing moist saline gauze and other types of moist wound dressings in the treatment of pressure ulcers, no significant differences in healing outcomes were noted. [23]

For patients with chronic wounds, moisture retentive dressings offer the advantage of pain relief, painless wound débridement, containment of wound exudate, reduction in incidence of complications, and improved quality of life.

DRESSING CATEGORIES

There are five basic types of moistures-retentive dressings: the hydrogels, alginates, foams, films, and hydrocolloids (Table 272-1). New categories of dressings are emerging that combine some of the above characteristics. The choice of a dressing is dictated by the location of the wound, the nature of the wound bed, the amount of exudate, the surrounding skin, and the patient's comfort level. On many occasions, several different categories of wound dressing will be needed

during the healing process.

Predictable	Erythema, pruritus, swelling, oozing, crusting
Pigmentary	Hyperpigmentation; permanent hypopigmentation
Infection	Bacterial; viral; yeast
Dermatitis	Eczema
Scarring	Delayed healing (3 to 12 months); atrophic, hypertrophic, keloidal
Follicular	Acne; acneiform eruption; milia

TABLE 272-1 **Wound Dressings**

Hydrogels

Hydrogels consist of a matrix of polymers with up to 96 percent water content. [24] They are semitransparent, nonadherent, and semipermeable to gas and water vapor. These dressings have a soothing and cooling effect when placed over a wound, reducing the temperature by up to 5°C (9°F) for up to 6 h. Hydrogels interact with aqueous solutions by swelling (at 200 to 300 percent saline absorption, their absorbing capacity is high), but their rate of absorbency is low. They are not good bacterial barriers. A secondary dressing is usually needed to secure them in place. They are primarily indicated for treatment of dry to mildly exudating wounds and second-degree burns, split-thickness skin grafts, donor sites, and chronic wounds.

Alginates

Alginates are naturally occurring polysaccharides found in the cell walls of brown seaweeds (*Phaeophyceae*). The principal constituent is isomeric alginic acid present in varying proportions, depending on the seaweed source. The building blocks are mannuronic and guluronic acids. They occur in different ratios and with different structures, depending on the algal species. The higher the amount of guluronic acid in the fiber, the greater its integrity or the tendency to remain in one piece. This characteristic allows for easy removal of the hydrated dressing with a forceps. In comparison, the higher the mannuronic acid content, the greater the speed of absorption, resulting in the formation of a soft gel that can be irrigated from the wound for complete removal (Fig. 272-1).

FIGURE 272-1 An alginate dressing on a wound. The alginate forms a gel over the wound surface but stays dry around the wound margins.

When in contact with a small volume of sodium-rich solution, such as saline or wound exudate, calcium alginate fibers gel at the interface, owing to ion exchange of sodium for calcium-generating free calcium ions; this amplifies the clotting cascade and creates a gel-like substance that conforms to the wound and provides a soft, moist healing environment. [1] Some alginates can absorb up to 20 times their weight, allowing the wound to remain undisturbed for several days at a time and minimizing dressing changes.

Being nonadherent, alginates require a secondary dressing over them. They are useful in heavily exudating wounds and can be packed into deep wounds and sinuses. They are also used as hemostatic dressings and are to be avoided on dry wounds.

Hydrocolloids

Hydrocolloids consist of a mixture of adhesive, absorbent polymers and a gelling agent (sodium carboxymethyl cellulose). They are opaque and impermeable to gas and water. In the presence of wound exudate, they interact with wound fluid to form a gel over the wound (Fig. 272-2).

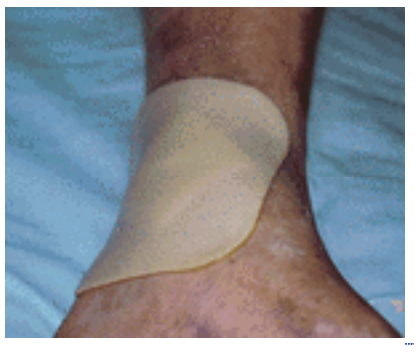

FIGURE 272-2 An opaque hydrocolloid dressing placed over a chronic wound.

Hydrocolloids have been well studied in vivo and in vitro. When factor VIII–related antigen antibodies were used to stain sections of tissue from porcine full-thickness wounds, there was significant enhancement of angiogenesis under certain hydrocolloid dressings compared to a dry dressing on days 3, 6, and 9 after surgery. [25] Macrophages in wounds elicit an angiogenic response through the release of growth factors, and hydrocolloid dressings stimulate macrophages. Furthermore, the relatively hypoxic environment under hydrocolloids is another potent stimulus for angiogenesis. The hydrocolloids have fibrinolytic activity, as demonstrated by the promotion of clot dissolution in a lysis assay in vitro and resolution of ^{131}I-labeled clots in experimental wounds. [26]

Some of the therapeutic benefits of the hydrocolloid dressings in the treatment of chronic wounds may be related to their ability to suppress excessive keratinocyte proliferation and activation and stimulation of epidermal migration. Hydrocolloids inhibit bacterial overgrowth by their physical barrier properties and by their provision of an acidic microenvironment.

Hydrocolloid dressings are convenient to use, offering infrequent dressing changes, ease of application, and a water-resistant surface that allows patients to bathe or take showers. They may cause maceration of the surrounding skin, and patients should be warned about the malodorous, yellow-brown exudate that can form underneath them. In wounds heavily contaminated by anaerobes or caused by hemoglobinopathies such as sickle cell anemia, oxygen-permeable dressings rather than hydrocolloids should be used.

Hydrocolloids are used to treat mild to moderate exudating wounds, pressure ulcers, venous ulcers, donor sites, ulcerative lesions of scleroderma, and epidermolysis bullosa.

Foams

Polyurethane foam dressings contain a hydrophilic surface that comes into contact with the wound and a hydrophobic backing to prevent leakage. They are semiocclusive and permeable to both gas and water vapor. [24] Their absorptive ability varies with the manufacturer and depends partly upon agents impregnated in the dressing. Being nonadherent, they are good alternatives for wounds with surrounding dermatitis and on bony prominences. They are used for mild to moderately exudating wounds and after dermabrasion or Mohs surgery. [1] They are opaque, can adhere to wounds if exudate dries, and sometimes require a secondary dressing to keep them in place. Foams with adhesive borders are now commercially available.

Films

Films are clear polyurethane dressing materials with an acrylic adhesive that facilitates adherence to the wound margins. They are thin and transmit moisture vapor and gases but are impermeable to fluid and bacteria. Being transparent, they allow the physician to inspect the progress of healing without disturbing the dressing or the wound. Clinical trials on surgical incisions have demonstrated that film dressings offer advantages over conventional postoperative dressings in reducing discomfort, edema, redness, and discharge and facilitating wound maturation. [27] They are used in the treatment of skin donor sites, stasis and decubitus ulcers, and superficial burn wounds (Fig. 272-3).

FIGURE 272-3 A transparent film dressing on a wound.

Films require frequent dressing changes. The problem with leakage primarily depends on the amount of fluid accumulated and the technique of application. Needle puncture to aspirate large amounts of fluid and careful observance of the recommended technique of application on the package insert will reduce the incidence of leakage. [28] Good preparation of the surrounding skin by cleaning with hydrogen peroxide and thorough drying with a dry gauze pad helps to assure good adhesion. As secondary dressings, films may be used as waterproof coverings over polyurethane foams, alginates, and hydrogels.

Many new dressings have emerged, such as antimicrobial dressings, hydrofiber dressings, hyaluronic acid dressings, and collagen dressings.

Antimicrobial Dressings

Slow-release antimicrobial dressings combine antibacterial properties with moist, interactive healing. A slow-release formulation of iodine, cadexomer iodine, seems to be useful in contaminated venous ulcers. Cadexomer iodine is composed of microspheres of starch cross-linked with ether bridges and iodine. It absorbs moisture and slowly releases iodine, in low concentrations, which have antibacterial activity yet are non cytotoxic. [29] Cadexomer iodine should be used with caution in patients with iodine allergy or thyroid disease. Slow-release ionized or nanocrystalline silver dressings (Fig. 272-4), also have antibacterial activity. In a pilot study in human chronic wounds, silver dressings were observed to decrease metalloproteinase activity, a possible mode of enhancing wound healing. [30] These slow-release antimicrobials have a broad spectrum of antibacterial activity and can decrease the bacterial burden of the wound bed surface.

FIGURE 272-4 Slow-release silver dressing covering the wound bed of a venous leg ulcer.

Hydrofiber Dressings

Hydrofiber dressings are composed of carboxymethyl cellulose, the main ingredient of hydrocolloids. Fluid is absorbed directly into the fibers. The fibers swell, resulting in a reduction of interstitial space and the formation of a gel. These dressings are highly absorbent and useful in very exudative wounds. In a small multicenter, prospective, randomized study in leg ulcers, there were less dressing changes required per week in wounds treated with hydrofibers as compared to alginate dressings. [31]

Hyaluronic Acid Dressings

Hyaluronic acid is a biodegradable absorbent biopolymer that forms a hydrophilic gel with serum or wound fluid. In chronic wounds, there is depolymerization and degradation of mucopolysaccharides, particularly hyaluronic acid. [32] Topical application of hyaluronic acid may facilitate granulation tissue formation and reepithelialization.

Collagen Dressings

Collagen-containing dressings, with or without hydrogel or alginate, are available in gels, pads, and particles. They are postulated to provide a matrix for cellular migration.

The choice of an appropriate dressing for a wound depends on the nature of the wound, the amount of exudate, the condition of the skin around the wound, and the patient's history. Treatment of the underlying cause is paramount, particularly in the case of chronic wounds. Frequent reassessment of the wound is important, to determine the need to change to a different type of dressing.

REFERENCES

Bulging varicose veins and unsightly “roadmap” telangiectatic webs affect millions of patients. Telangiectases comprise the most common of cosmetic complaints, occurring in up to 50 percent of women, while larger varicose veins are seen in up to 20 percent of the American population. [1] Varicose veins may cause significant morbidity including chronic stasis dermatitis, ankle edema, spontaneous bleeding, superficial thrombophlebitis, recurrent cellulitis, lipodermatosclerosis, and ulceration on the ankle and foot.

The incidence of varicose veins increases with each decade of life. Increased incidence has led to increased demand for treatment of varicose and telangiectatic veins as the average age of the US population grows. While 41 percent of women in the fifth decade have varicose veins, this number rises to 72 percent in the seventh decade. [2] Statistics for men are similar, with a 24 percent incidence in the fourth decade, increasing to 43 percent by the seventh decade. Six million workdays per year may be lost in the United States as a result of complications of varicose veins. [3]

The main techniques employed in the dermatologist's office for treatment of cosmetic spider veins are sclerotherapy and lasers. For larger varicose veins, dermatologic surgeons employ sclerotherapy (with or without Duplex ultrasound guidance), ambulatory phlebectomy and endovenous occlusion by radiofrequency or laser. Sclerotherapy which is defined as the intravascular introduction of a sclerosing substance, is the most frequently used procedure. Sclerotherapy gained acceptance as a highly effective treatment during the early 1990s because it can be used for veins of all sizes. [4] It also serves as an effective addition to techniques such as ambulatory phlebectomy for saphenous tributaries [5], [6] or endovenous obliteration of refluxing saphenous veins. [7], [8] Knowledge of venous anatomy and physiology, principles of venous insufficiency, methods of diagnosing venous abnormality, uses and actions of sclerosing solutions and proper use of compression are essential elements of successful venous therapy.

HISTORICAL ASPECTS

Primitive stripping and cauterization were practiced by Celsus, while ligation was mentioned by Antillus (30 A.D.). In the second century A.D., Galen proposed tearing out the veins with hooks, a precursor to the modern day technique of ambulatory phlebectomy originated by the Swiss dermatologist Robert Muller in the late 1960s.

A crude concept of sclerotherapy appeared in 1682, as Zollikofer described injection of acid into a vein to create a thrombus. By the late 1700s, the critical role of saphenofemoral reflux in the pathogenesis of varicose veins had been recognized by the Swiss surgeon Rima. Reports of use of absolute alcohol as a sclerosing agent appeared from 1835 to 1840. In 1851, Pravaz attempted sclerotherapy with ferric chloride using his new invention, the hypodermic syringe.

The foundation of modern sclerotherapy can be traced to World War I when Linser and Sicard both noticed the sclerosing effect of intravenous injections used to treat syphilis that often resulted in vein sclerosis. Tournay greatly refined the sclerotherapy technique in Europe. It was not until 1946, when a safe sclerosant, Sotradecol (sodium tetradecyl sulfate), had been tested and described that sclerotherapy began to be studied seriously in the United States. [9]

Another key to success and acceptance of the treatment of varicose veins by sclerotherapy was the addition of compression. Sigg and Orbach in the 1950s, and Fegan in the 1960s, emphasized the importance of combining external compression immediately following injections. Starting in the 1980s, Duffy promoted the technique among dermatologists and advocated the use of polidocanol and hypertonic saline as safe and effective sclerosing solutions. [10] In March 1999, the first endovenous obliteration technique using radiofrequency was cleared by the US Food and Drug Administration.

Dermatologic surgeons were instrumental in developing this technique. [8] Goldman's first American textbook of sclerotherapy integrated the world's phlebology literature, introduced new sclerosing solutions and validated dermatology's claim to expertise in vein treatment. [11] Several additional textbooks by dermatologic surgeons have now firmly established phlebology within the domain of dermatology. [12], [13]

PATIENT SELECTION—VENOUS ANATOMY AND PHYSIOLOGY, SYMPTOMS AND CONTRAINDICATIONS

The venous system is comprised of a primary deep venous compartment and superficial compartment with thousands of small veins (perforating veins) connecting the two systems. The deep compartment, “the muscle pump,” normally acts as a conduit for 85 to 90 percent of venous return from the leg. During contraction of the calf muscles, the valves of the perforating veins and associated superficial veins close, allowing blood to flow only proximally at high pressures through the deep system. This generates the primary propulsive force returning venous blood to the heart (Fig. 273-1).

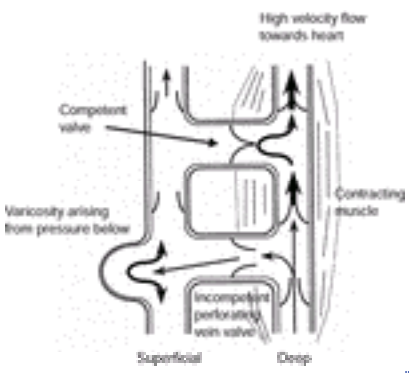

FIGURE 273-1 Schematic of the calf muscle pump with malfunctioning perforating vein connecting the superficial and deep system. High pressures are generated when the gastrocnemius muscle contracts to pump blood proximally. A malfunctioning valve is shown diverting pressure to the skin surface. Competent valve directs flow proximally.

The superficial venous system consists of three primary territories: the greater saphenous vein, the lesser saphenous vein and the subdermic lateral venous system (Fig. 273-2). Comprising the three major patterns are multiple collateral veins (accessory) and multiple tributary veins emptying into each respectively. The points of connection (perforating veins) between the superficial and the deep system play important roles as these are sites through which reflux or reverse flow often develops (Fig. 273-3).

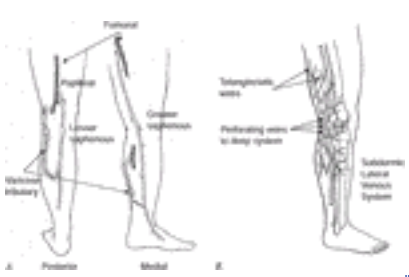

FIGURE 273-2 Schematic of the major portions of the superficial venous system. *A.* Greater saphenous vein and lesser saphenous vein. *B.* Subdermic lateral venous system. When varicosities or telangiectatic webs are present within the distribution of these saphenous veins, the source of pressure must be elucidated. The lateral venous system is the most common source of telangiectasias.

FIGURE 273-3 Diagram indicating major junction points of the superficial venous system with the deep venous system. Larger varicose veins may originate from any of these points.

Due to gravitational hydrostatic pressure, sequential retrograde breakdown of venous valve function often follows a leak at one point leading to propagation of a varicosity. Increased diameter between valve leaflets with failure to oppose properly, caused by a genetically weak venous wall or venous valve structure, may initiate these events. Calf muscle pump pressure plus gravitational hydrostatic forces are transmitted directly via the incompetent perforating vein or

communicating veins to the surface veins. Venous pressure may reach as high as 300 mmHg in the cutaneous venules with the patient erect. Transmission of this pressure may result in venular dilatation over a wide area of skin including the formation of telangiectatic webs.

When present in significant quantity, the volume of blood sequestered and stagnant in reticular veins and associated telangiectatic webs (particularly of the lateral venous system) may cause enough distention to produce symptoms. [14] Symptoms are relieved by the wearing of support hose or with rest and elevation of the legs. Prolonged standing or sitting worsens symptoms. The size of the vessels causing moderately severe symptoms may be as small as 1 to 2 mm in diameter. Sclerotherapy has been reported to yield an 85 percent reduction in these symptoms, as well as superb cosmetic results. [14]

Contraindications to Treatment of Spider Veins (Table 273-1)

TABLE 273-1 **Indications and Contraindications for Sclerotherapy**

Vein treatment, particularly sclerotherapy, may be performed safely and effectively in virtually all types of veins, except when reflux exists at the saphenofemoral junction. Because the goal of sclerotherapy is to eliminate reflux at its origin, the goal of noninvasive diagnostic evaluation is to uncover primary sources of high reverse flow pressure. A high rate of recurrence for sclerotherapy is commonly seen when reflux originates at the major saphenous junctions. The techniques of endovenous occlusion by radiofrequency or laser have been developed to address reflux occurring at the termination point of the saphenous veins. Two-year data indicates that these techniques are as effective as the surgical techniques of ligation and stripping to eliminate saphenous veins. [15]

Venous treatment is contraindicated in a bedridden patient because ambulation is important for minimizing risks of thrombosis. Similarly, patients under general anesthesia for nonrelated procedures should not undergo simultaneous sclerotherapy. Severely restricted arterial flow to the legs necessitates postponement of vein treatment. A history of deep venous thrombosis (DVT) or previous trauma to the leg (e.g., auto accident) should preclude sclerotherapy until adequately evaluated by duplex ultrasound. Previous urticaria or suspected allergy to a sclerosing agent should serve as a relative contraindication to use of that particular sclerosing agent.

Pregnancy should be considered a contraindication during the first and second trimesters, although extremely painful or bleeding varices may be treated in the last trimester. Treatment is typically postponed since many varicosities and telangiectasias will resolve spontaneously 1 to 6 months postpartum.

Obesity should be considered a relative contraindication since maintaining adequate external compression is difficult. Sclerotherapy of larger varicosities should be postponed until weight reduction is achieved. During hot summer months, heat-induced vasodilatation and inability to comply with wearing of compression hose may also require postponement of treatment.

TREATMENT TECHNIQUES

Pretreatment Evaluation

Physical examination is performed by viewing the patient's legs in a 360-degree rotation. Palpation is performed along the saphenous vein distributions to rule out early large axial varicosities that cannot be seen. Based on the history and physical examination noninvasive diagnostic vascular tests are performed as necessary. [16] Those patients with a family history of large varicose veins are more likely to have early axial (saphenous) reflux, even when presenting with telangiectasias alone. [5] Previous venous surgery may warrant further testing before proceeding.

Once the patient is judged to be a candidate for vein treatment, informed consent is obtained. Any veins visible or palpable suggestive of saphenous system involvement should be minimally evaluated by handheld Doppler ultrasound, which is equivalent to using an enhanced “stethoscope” to hear vein flow. In order to generate or augment an audible signal of flow, a maneuver such as manual compression of the calf must be performed by the examiner. When compression is released, gravitational hydrostatic pressure causes reverse flow to cease within 0.5 to 1 second when valves are competent, but a long flow sound is audible when valves are incompetent.

The most essential part of the Doppler examination is the examination of the saphenofemoral junction below the inguinal fold just medial to the femoral arterial signal. During a Valsalva maneuver, a continuous and pronounced reflux signal is a reliable sign of valvular insufficiency. An equivocal result may require a duplex ultrasound examination for a definitive answer. Methods of complete Doppler examination are detailed elsewhere. [5]

Another noninvasive method used to quantify reflux is photoplethysmography (PPG). PPG permits assessment of the physiologic significance of anatomic Doppler findings. Digital (quantitative) PPG measures total venous insufficiency, changes in venous function after treatment and allows evaluation of deep venous function (venous ejection fraction)

during a defined series of calf muscle movements. [17]

The gold standard of noninvasive examination of the venous system is duplex ultrasound. This allows direct visualization of the veins and identification of flow through venous valves. An image is created by an array of Doppler transducers, which are switched on and off sequentially. The duplex examination is often used to uncover hidden sources of reflux prior to beginning any method of treatment or to delineate reflux sources when patients experience poor results from sclerotherapy.

Sclerosing Solutions

Sclerosing solutions are classified into groups based on chemical structure and effect: hyperosmotic, detergent and corrosive agents (chemical toxins—salts, alcohols, and acid or alkaline solutions). Table 273-2 summarizes commonly employed sclerosing solutions.

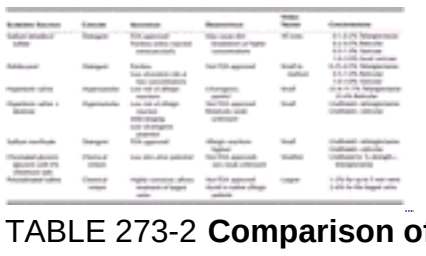

TABLE 273-2 **Comparison of Commonly Employed Sclerosing Agents**

HYPERTONIC SALINE Although approved by the FDA only for use as an abortifacient, it is a commonly employed solution in the United States. Used at a concentration of 23.4%, a theoretical advantage of hypertonic saline (HS) is its total lack of allergenicity when unadulterated. HS has been commonly used in various concentrations from 10 to 30%, with occasional addition of heparin, procaine or lidocaine. Additional agents typically provide no benefit. Therefore, HS is used either unadulterated or diluted to 11.7% with sterile water for smaller telangiectasias. [18] With hypertonic solutions, damage of tissue adjacent to injection sites may easily occur. Skin necrosis may be produced by extravasation at the injection site particularly when injecting very close to the skin surface. Injection of hyaluronidase into sites of extravasation may significantly reduce the risks of skin necrosis with HS. [19]

HYPERTONIC SALINE AND DEXTROSE Hypertonic saline and dextrose (HSD) is a viscous mixture of dextrose 250 mg/mL, sodium chloride 100 mg/mL, propylene glycol 100 mg/mL, and phenethyl alcohol 8 mg/mL. HSD is a relatively weak sclerosant for local treatment of small vessels, with a total volume of injection not to exceed 10 mL per visit with 0.1 mL to 1.0 mL per injection site. HSD is marketed predominately in Canada. Although a slight burning sensation occurs, pain is far less than with HS.

POLIDOCANOL The detergent-based polidocanol (POL) a urethane compound, was originally developed as an anesthetic, but was found to have the property of sclerosing small diameter vessels after intradermal injection. POL contains hydroxypolyethoxydodecane dissolved in distilled water with 5% ethanol as a stabilizer. First used as a sclerosing agent in the late 1960s in Germany, POL is popular worldwide for smaller vessels because of painless injection and lowest incidence of cutaneous necrosis with intradermal injection. Lower concentrations of POL were initially suspected to have a lower incidence of hyperpigmentation than HS or sodium tetradecyl sulfate (STS), but recent clinical trials indicate a significant percentage of hyperpigmentation occurs. [20] The FDA has not yet approved POL.

SODIUM TETRADECYL SULFATE STS is a long-chain fatty acid salt with strong detergent properties. It is a highly effective sclerosing agent used worldwide. Approved for use in the United States since 1946, it has been popular with vascular surgeons since the 1960s and first described for use in telangiectasias in the 1970s. A relatively high incidence of postsclerosis pigmentation was reported at inappropriately high doses (1% STS). More appropriate concentrations for superficial telangiectasias are 0.1 to 0.2%. Other concentrations are 0.2 to 0.5% for reticular veins or small varicosities (1- to 3-mm diameter), and 0.5 to 3% for larger varicosities related to major sites of valvular reflux.

SODIUM MORRHUATE Sodium morrhuate (Scleromate, Palisades Pharmaceuticals, Inc., Tenafly, NJ) is a 5% solution of the salts of saturated and unsaturated fatty acids in cod liver oil. Approximately 10 percent of its fatty acid composition is unknown and use is limited by reports of fatalities secondary to anaphylaxis. [11] Although sodium morrhuate is approved by the FDA for the sclerosis of varicose veins, use in treatment of telangiectasias is not common because of the caustic qualities with potential for cutaneous necrosis and higher risks of allergy. This agent is reserved primarily for sclerosis of esophageal varices.

CHEMICAL IRRITANTS The chemical irritants include polyiodinated iodine (very caustic) and chromated glycerin (very weak), and are believed to have a direct toxic effect on the endothelium. After injection of polyiodinated iodine salt, the endothelium near the site of injection is destroyed within seconds. The corrosive action is limited because of rapid inactivation by blood proteins. At the sites of endothelial destruction the chemical can penetrate further and diffuse into deeper layers of the vessel wall causing further destruction. These agents are not approved by the FDA.

Sclerotherapy Technique

A basic principle of treatment is to begin at the largest (reflux sources) and progress to the smallest varicosities. Sclerotherapy of telangiectasias is approached by combined injection of visibly connected reticular veins, venulectases, and telangiectatic webs or networks. Progression from proximal to distal regions will focus initial treatment on vessels most likely to be proximal pressure sources.

Reticular veins are treated only after all sources of reflux from major varicosities have been treated by sclerotherapy and/or surgery. When no clear feeder vessel is seen or identified by Doppler, the transillumination (Veinlite, 3Gen, Dana Point, CA) method can be used to identify the “feeding” reticular vein (Fig. 273-4). When unable to locate an associated reticular vein, then the point at which the telangiectasias begin to branch out is the site at which to begin injection. Injection of telangiectasias is simultaneously performed with injection of reticular veins in the hopes of decreasing the

number of treatments. [21]

FIGURE 273-4 Transillumination of a reticular vein. The reticular vein shows up as a dark curvilinear object against a light background.

The injection method for telangiectasia is basically as previously described by Duffy and Goldman. [10], [22] The sclerotherapy tray is prepared with the necessary equipment (Table 273-3). A 30-gauge needle, bent to an angle of 10 to 30 degrees with the bevel up, is placed on the skin so that the needle is parallel to the skin surface. A 3 cc syringe filled with 1.5 to 2 cc of solution is held between the index and middle fingers, while the fourth and fifth finger support the syringe against the leg in a fixed position, facilitating accurate penetration of the vessel. The nondominant hand is used to stretch the skin around the needle and may offer additional support for the syringe (Fig. 273-5). Magnifying lenses or operating loops on the order of 1.5 to 3× may help cannulation of the smallest telangiectasias.

FIGURE 273-5 Position of the hands for sclerotherapy. While the dominant hand holds the syringe and creates a platform with the fifth digit, the nondominant hand stretches the skin and acts as a support for the needle hub so that fine changes in position are permitted.

- Cotton balls soaked with 70% isopropyl alcohol
- Protective gloves
- 3 cc disposable syringes
- 30-gauge disposable transparent hub needles
- Cotton balls or STD pads for compression
- Transpore and/or paper tape
- 2% Nitroglycerine paste (for prolonged blanching or extravasation)

Sclerosing solutions:

1. Sodium tetradecyl sulfate (concentrations from 0.1 to 0.5%)
2. Hypertonic saline (11.7 to 23.4%)
3. Hypertonic saline (10%) and dextrose (25%) (may be mixed by local pharmacy)
4. Polidocanol (0.25 to 1%) (pending FDA clearance)

TABLE 273-3 **Sclerotherapy Tray**

The initial treatment of telangiectatic webs begins with the lowest possible concentration that will cause a telangiectasia to sclerose over a period of 1 to 6 months postinjection. This typically occurs with 0.1% sodium tetradecyl sulfate or 0.2% polidocanol. When ineffective sclerosis occurs judged at a subsequent visit, the concentration, but not the volume per site of sclerosing solution, is increased. Posttreatment compression consists of graduated 20 to 30 mmHg or 30 to 40 mmHg support hose for 2 weeks for larger veins and over-the-counter 15 mmHg compression support hose for smaller veins. Treatment intervals vary but allowing 4 to 8 weeks between treatments helps to minimize the number of necessary sessions. Figure 273-6 shows typical results.

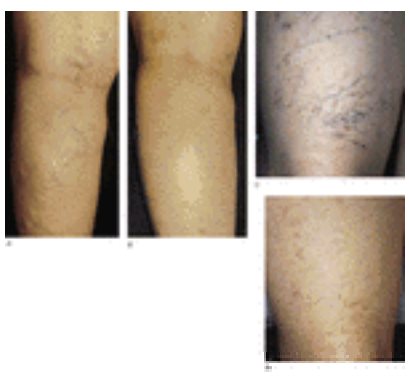

FIGURE 273-6 Typical results following sclerotherapy. *A.* Large varicose vein treated twice with 0.5% STS. *B.* Excellent clinical results at 15-month follow-up. *C.* Sixty-two-year-old patient with focal burning symptoms on anterior thigh. *D.* Results 5 months later and after three treatments with 0.1% STS and 0.5% POL.

SIDE EFFECTS AND COMPLICATIONS OF SCLEROTHERAPY

Postsclerotherapy Hyperpigmentation

Postsclerosis pigmentation is defined as the appearance of increased visible pigmentation along the course of a treated vein of any size. Initially perivascular hemosiderin deposition and not increased melanin production causes this appearance; [23] however, over time, the hemosiderin is replaced by melanin. The incidence of pigmentation is related to dilution and type of sclerosing agent as well as diameter of treated vessel. [24] Pigmentation incidence ranges from 11 to 30 percent after using HS, [14] 11 to 30 percent after using POL, [10], [25] and up to 30 percent with STS. The incidence of pigmentation may be reduced in varicose veins by expressing the dark, viscous blood thought to be a liquefied coagulum or intravascular hematoma, which may accumulate 1 to 4 weeks following sclerotherapy.

Pigmentation clears in 70 percent within 6 months, and rarely persists for more than a year. [24] Attempts to hasten resolution of pigmentation have been mostly unsuccessful as the pigment is dermal hemosiderin and not epidermal melanin. Bleaching agents, exfoliants such as trichloroacetic acid or phenol, cryotherapy, various lasers and intense pulsed light have achieved limited success. [26], [27] The Q-switched ruby laser is the most consistently effective for treatment of postsclerosis pigmentation. [28]

Telangiectatic Matting

Telangiectatic matting is defined as the appearance of groups of new, fine (<0.2 mm diameter) telangiectasias surrounding or replacing a previously treated area in a blushlike manner. A retrospective analysis of more than 2000 patients reports an incidence of 16 percent in patients treated with HS and POL. [29] Resolution usually occurs spontaneously within a 3- to 12-month period with 70 to 80 percent spontaneous resolution within the first 6 months. [30]

Matting may also occur as a result of trauma to the leg, in association with pregnancy or hormonal therapy, or in scars around previous sites of surgical stripping. Predisposing factors include predilection for certain areas of the leg, such as the medial lower thigh, obesity, hormonal therapy with estrogen, family history, and a longer history of telangiectasias. [29] The relative risk factor for development of telangiectatic matting is 3.17 times greater for female patients taking hormonal supplements. [31] Successful treatment of matting with flashlamp-pumped pulsed dye laser (FPDL)is reported accompanied by temporary hyperpigmentation. [32] The use of enhanced visualization with a cross-polarized light source (Syris Scientific, LLC, Grey, MA) assists injection of sclerosing solution into telangiectatic matting. Treatment is often not required because matting will resolve spontaneously except when caused by a source of reflux superiorly.

Cutaneous Necrosis and Ulceration

Cutaneous ulceration may occur with all sclerosing solutions in spite of the most skilled technique. Unavoidably, a tiny amount of sclerosing solution may be left along the needle tract as the needle is withdrawn. Sclerosing solution may also leak out into the skin through the small puncture sites of vessel cannulation. The varicose vein may have a fragile, thin wall, with the injection causing rapid injury leading to sudden unexpected rupture with perivascular accumulation of sclerosant. Additionally, injection may inadvertently occur into a small arteriole associated with telangiectatic varicosities with resultant necrosis and ulceration.

When the dermatologic surgeon recognizes that extravasation has occurred, the risk for necrosis can be minimized by injecting normal saline in a ratio of 10:1 into the extravasation site. Extensive massage of small subcutaneous blebs to spread the trapped sclerosing agent as quickly as possible will minimize prolonged blanching of the area. We have found that application of topical 2% nitroglycerin paste applied immediately to the suspected extravasation site greatly reduces the risks of necrosis, but will not always prevent it.

Superficial Thrombophlebitis

This complication is most commonly mistaken for the normal nodular fibrosis (endosclerosis) that occurs with proper sclerotherapy. After sclerotherapy, a nontender, nonpigmented, nonerythematous fibrotic cord may normally be palpable along the course of a treated 4- to 8-mm vein. This frequent finding is caused by a liquefied intravascular hematoma with surrounding vein wall sclerosis and is not a thrombosis. In contrast, superficial thrombophlebitis is characterized clinically by a very tender, indurated, linear erythematous swelling. Incidence of superficial thrombophlebitis is quite variable estimated at 0.01 to 1% following sclerotherapy, [33] although a recent report indicates that the incidence is higher than previously suspected. [34] Treatment consists of leg elevation and/or compression and regular administration of aspirin or other nonsteroidal anti-inflammatory drugs. Extension of superficial thrombophlebitis into the deep system is extremely rare.

Pulmonary Embolism

Pulmonary emboli probably occur from extension of a superficial thrombus into the deep venous system. Evidence of extension from superficial thrombus to deep thrombophlebitis should be treated promptly by anticoagulation. The incidence of pulmonary embolism is associated with injection of large quantities of sclerosant at a single site. The incidence is extremely low, with fewer than 1 case in 40,000.

Arterial Injection

This dreaded medical emergency is fortunately extremely rare. Classic warning signs include immediate intense pain far beyond the normal discomfort at the initiation of injection, although leakage of sclerosant into the arterial circulation may present in an atypical fashion. Continuous intense burning pain with immediate bone-white cutaneous blanching over an area of several square centimeters is the usual initial sign. Progression to a sharply demarcated cyanosis within minutes

is typical for arterial injection. Emergency treatment involves immediate application of ice, attempts to flush the inadvertently injected artery with normal saline and/or heparin, injection of 3% procaine to inactivate STS, and vascular surgery consultation for intravenous anticoagulation. Rarely, arterial injection may not be accompanied by any pain or cutaneous signs. The atypical cases are suspected to arise from arteriovenous malformations. [35] Arterial injection may lead to wide areas of skin necrosis and damage to subcutaneous tissue and muscle which take months to heal.

MODERN MINIMAL SURGICAL APPROACHES FOR VARICOSE VEINS

Endovenous Occlusion Techniques

When it has been determined by ultrasound that the originating point of reverse flow or reflux is the greater saphenous vein, endovenous radiofrequency (RF) or laser techniques are now the methods of treatment. The efficacy for RF elimination of reflux is 90 percent at 2 years. [15] This method involves the placement of a catheter or fiberoptic within the varicose vein through a small puncture or incision. The catheter is threaded up to the saphenofemoral junction typically under duplex ultrasound guidance. Following placement of tumescent local anesthesia between the vein and the skin and or in a perivenous location, energy is applied as the catheter is slowly withdrawn. This results in a collagen shrinkage of the vein wall accompanied by complete occlusion. Studies suggest a very favorable comparison to traditional ligation and stripping, with far less morbidity and without the risks of general anesthesia.

Surgical Ligation and Limited Stripping

For larger varicose veins, particularly originating from an incompetent valve at the saphenofemoral junction, ligation of the greater saphenous vein with short stripping of its proximal half in the thigh is the traditional surgical method. After proximal ligation without stripping of the saphenous vein, varicography has shown persistent mid-thigh perforator incompetence in 34 percent, a patent portion of saphenous vein in 54 percent, and residual or recurrent femoral-saphenous communication in 80 percent of patients. [36] High ligation combined with sclerotherapy or with varicosity excision is inferior to high ligation and stripping of the saphenous vein. [37]

Ambulatory Phlebectomy

This technique, originally described by Robert Muller and further refined by Albert-Adrien Ramelet, another Swiss dermatologist, involves the use of tiny incisions through which the varicose vein is removed by a small hook. [38], [39] This safe, outpatient technique performed with local anesthesia allows removal of almost any varicose vein except the saphenofemoral or saphenopopliteal junction. Areas or veins that are resistant to sclerotherapy (axial) are particularly indicated for ambulatory phlebectomy (Fig. 273-7). Deep venous thrombosis, postsclerotherapy pigmentation, skin necrosis, and superficial phlebitis occur less frequently with ambulatory phlebectomy than with sclerotherapy. In many cases, larger varicose veins coexist with smaller reticular veins and associated telangiectatic webs. It is reasonable to treat larger varicose veins by various surgical techniques and follow up with sclerotherapy of the remaining reticular networks.

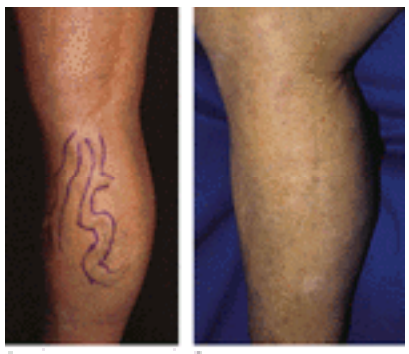

FIGURE 273-7 Ambulatory phlebectomy of a large truncal varicose vein. *A.* Marked just prior to surgery. *B.* Clinical results with complete disappearance at 6 weeks. Bruising usually lasts no longer than 2 weeks.

Lasers and Light Sources

New trends for improved results with lasers and light sources for spider veins include longer wavelengths, larger spot sizes, and cooling to protect the skin. The first report of 1064nm Nd:YAG laser indicated that at 3 months 75 percent improvement was possible after a single treatment. [40] These findings were confirmed and the mechanism of action explained as heat-induced vessel damage and subsequent fibrosis. [41] Recent reports also indicate effectiveness of the 940-nm diode laser. [42] Shorter wavelengths used in the past, such as the pulsed dye laser, have limited utility on leg veins, although many devices are now being adapted to longer pulse durations up to 40 msec. A broadband, noncoherent pulsed light (IPL) has been reported to improve 70 percent of patients responding, with up to 5 treatments per region. [43] In our practice, the vast majority of laser treatments are performed using the 1064-nm Nd:YAG laser in the millisecond domain on isolated telangiectasias, sclerotherapy-resistant telangiectasias, ankle telangiectasias, and suspected arteriovenous malformations.

Chapter 274

Rhoda Narins Arnold Klein Jeffrey Klein

Tumescent Liposuction

REFERENCES

The modern phase of fat transplantation began in the late 1970s when Fischer and Fischer reported on the “extraction of fat with the cellusuctiotome.” [1] This was the forerunner of liposuction. In the late 1970s, Yves-Gerard Illouz introduced the technique known today as liposuction and revolutionized the field of fat harvesting and transplantation when he reported reinjecting viable fat that had been obtained during liposuction surgery. [2], [3] and [4] The innovations that made this liposuction procedure possible were the development of a blunt cannula and the injections of small amounts of a hypotonic saline solution into the subcutaneous tissue, both of which diminished bleeding. [3]

In 1987, Klein [5] introduced tumescent anesthesia. The technique involves directly infiltrating and tumescing the targeted fatty tissue with large volumes of dilute anesthetic solution consisting of lidocaine, epinephrine, and sodium bicarbonate in physiologic saline, enabling the procedure to be done under local anesthesia alone. This approach revolutionized liposuction surgery [6], [7] and also the ability to obtain fresh fat for grafting. Klein's procedure involves significantly less blood loss, decreased anesthetic risk, and longer-lasting anesthesia, with no need for postoperative analgesia as compared to the previously used methods of liposuction. [6] Also, when using the tumescent technique, there is no need to replace intravenous fluids. There are better aesthetic results as liposuction can be done more accurately and uniformly because the patient can get into any position necessary for exact removal of fat, thus making the procedure more precise. There is also a more rapid postoperative recovery. [7] With this technique, the patient avoids general anesthesia and has a milder postsurgical course. Tumescent liposuction is the most evolved form of liposuction. [8], [9] Indeed, with the advent of liposuction surgery, the technique of fat transplantation was dramatically reawakened. [2], [10], [11], [12], [13], [14] and [15]

Liposuction surgery is a procedure that can be performed on many areas of the body. The lateral cheeks, jowls, and upper neck are common areas for liposuction that respond beautifully in both men and women. [16], [17] The most common body areas in younger women are the lateral thighs with or without the hips and buttocks and in older women the abdomen. In addition, the waist, back, breast, inner and anterior thigh, arms, calf and ankle fat can be treated. Circumferential liposuction is excellent for the abdominal area in patients where the waist, lower back, and hips are done at the same time as the abdomen for a more youthful, hourglass shape. [18] The most common body areas in men are the flanks and the abdomen. Gynecomastia and pseudogynecomastia can be treated in males. Disorders such as lipomas, buffalo humps, lipodystrophy, and axillary hyperhidrosis can also be treated. [19], [20] Liposuction can be used in association with skin reconstruction. It can be employed to assist in flap elevation and movement and can also serve as means of subcutaneous debulking. [21] Liposuction has revolutionized facelift procedures and has been reported useful in treating lymphedema and type I diabetes, and in harvesting stem cells. [22], [23] and [24]

Presently, the available anesthesia techniques for liposuction are the rarely used dry technique, which uses general anesthesia without preinfiltration of vasoconstrictive solution; [1], [25], [26] the wet technique, which uses general anesthesia and preinfiltration with a low volume of vasoconstrictive solution, which is fairly commonly used, especially by plastic surgeons; [27], [28] the use of tumescent anesthetic solution with general or IV anesthesia, a technique also used mostly by plastic surgeons who understand the benefits of high volume tumescent anesthesia; and the tumescent technique of local anesthesia alone, with no general anesthesia and the preinfiltration of a high volume of low-dosage lidocaine/epinephrine anesthetic solution. It is this latter technique, used mostly by dermatologic surgeons, that has essentially revolutionized the liposuction process and is the current state of the art for this procedure. [29], [30], [31], [32] and [33]

Liposuction surgery is done to improve the contour of the patient's body and to rearrange deposits of adipose tissue without changing the surface of the skin. It is not a treatment for obesity, striae, spider veins, or cellulite, nor does it tighten the overlying skin. It is important to choose a patient with realistic expectations for the procedure and to do an extensive preoperative evaluation and consultation. [34], [35]

The hallmark of the tumescent technique of local anesthesia is the concentration of lidocaine, which is usually 0.05%, 0.075%, or 0.1%, and the concentration of epinephrine, which is usually 1:1 million. Table 274-1 provides formulas for these solutions. For smaller areas, a 250-mL bag of saline can be used rather than a 1000-mL bag. The total safe concentration of lidocaine is based on the published figure of 55 mg/kg. [36] Thus, if a patient weights 150 lb, this is divided by 2.2, giving 68 kg. Multiplying 68 kg by 55 mg/kg would allow the safe use of approximately 3740 mg of lidocaine. A 1000-cc bag of 0.1% lidocaine anesthetic solution has 1000 mg of lidocaine and a 1000-cc bag of .05% lidocaine anesthetic solution has 500 mg of lidocaine. This 68 kg patient can use approximately 3.75 bags of 0.1% solution or 7 bags of .05% solution to stay under the safe limit of 3740 mg of lidocaine. If greater amounts of fluid are necessary for the surgery (a large number of treatment areas), then the 0.05% solution can be used. Indeed, any mixture of solutions that totals 3740 mg of lidocaine is acceptable in a patient who weighs 150 lb. The preceding calculations and formulas can easily be extrapolated to determine the “safe” amount and concentration that can be used in a given patient.

Normal saline	0.9%	1000 mL	1000 mL	250 mL
Lidocaine	2%	25 mL	50 mL	12.5 mL
Epinephrine	1/1000	1 mL	1 mL	0.25 mL
Bicarbonate	8.4%	12.5 mL	12.5 mL	4 mL
Total		500 mg	1000 mg	230 mg
Lidocaine		0.05%	0.1%	0.1%
Epinephrine		1:1 million	1:1 million	1:1 million

TABLE 274-1 **Tumescent Liposuction Solutions**

In the tumescent technique, the anesthesia is delivered in a three-step procedure wherein the incision sites (the openings through which the cannulas are inserted) are first injected with a small amount of local anesthetic using a syringe and a 30-gauge needle. [37] The second stage is the delivery of a small amount of anesthetic solution through a spinal needle radially through these incision sites, fanning out to achieve preliminary anesthesia. This preliminary anesthetic can be pushed in with a pressure cuff around a bag of saline or by the use of an infiltration machine on settings 1 to 3. [37], [38] and [39] Finally, the tumescent anesthetic is delivered through an infiltration cannula with multiple openings. During this final step in the anesthetic process, the infiltration machine is on settings 5 to 7 and the tissue is infiltrated ("tumesced") until firm. After the fatty tissue has been tumesced, it is necessary to wait 30 min or so for the full vasoconstricting effect of the epinephrine solution. The anesthesia is injected at deep as well as intermediate levels to obtain a full effect.

Liposuction surgery is the removal of fatty tissue through tiny excisions in the skin using small, blunt cannulas. [40] It is remarkably safe and should be performed using a sterile technique. The surgery is done using cannulas of various sizes and designs, which are introduced into the incision sites and criss-crossed over the area to produce a smooth, even result. Suction is used at many levels throughout the fatty tissue during the procedure. Suction can be obtained with an aspiration machine or with syringes. [41], [42] and [43]

Sometimes, especially if the area of surgery is very large or very fibrous (male breasts, back anterior thighs, areas of previous liposuction, etc.), ultrasonic or powered liposuction cannulas may be used prior to, or instead of, conventional liposuction cannulas. The ultrasonic devices (ultrasonic liposuction) cavitate the fat, liquefying it and enabling it to be extracted more easily. [44], [45] Ultrasonic liposuction is rarely used by dermatologic surgeons, except occasionally for a short time to make tunnels through fibrous tissue, because of problems with burns, seromas, and hematomas. [46] Some plastic surgeons use ultrasonic liposuction for the entire procedure. Ultrasonic liposuction requires tumescent anesthesia to work and initially the benefits were thought to be a result of the use of ultrasound until it was realized that the tumescent anesthesia was responsible. After this many plastic surgeons kept on using tumescent anesthesia along with general anesthesia to continue to reap these benefits that include decreased bleeding and no need for transfusions and minimal postoperation discomfort. This technique is mistakenly referred to as the tumescent anesthesia technique, even though general or IV anesthesia is used. All of the problems that have been reported with so-called tumescent anesthesia have been with this type of anesthesia. [47], [48] and [49] The true tumescent anesthesia technique is with local anesthesia alone and is extremely safe, as has been reported in several surveys by Hanke et al. [7], [50], [51] When dermatologic surgeons use this technique with local anesthesia alone, there are additional benefits, including the ability of the patient to move into the position required to remove the fat; no risk of general anesthesia; feeling better and recovering more quickly postoperatively; the patient being able to move during surgery and walk out of the operating room, which minimizes the occurrence of pulmonary emboli; and the procedure being much safer. Powered liposuction is also used by many dermatologic surgeons. It has been reported to make the surgery easier for the physician and the patient. [52]

While the results from fat removal are almost immediate, subsequent normal elastic retraction of the skin may take up to 6 or more months to occur. Complications from tumescent liposuction are extremely rare, with the usual postoperative sequelae. [7], [54], [55] and [56] Occasionally, dysesthesia and ecchymosis may occur, with the former lasting a few months and the latter 2 to 3 weeks.

Guidelines for liposuction surgery have been written be the American Academy of Dermatology [57] and the American Society for Dermatologic Surgery. [58] The tumescent technique of local anesthesia is extremely safe and efficacious [24] for removing adipose tissue to effect a change of contour.

Chapter 275

Arnold Klein

Substances for Soft-Tissue Augmentation

INJECTABLE BOVINE COLLAGEN
FAT TRANSPLANTATION
OTHER MATERIALS

REFERENCES

Soft-tissue augmentation has become increasingly important as more individuals seek aesthetic improvement without major surgical procedures. Today, physicians have a much larger armamentarium of techniques and implant materials with which to improve facial contours, ameliorate wrinkles, and stall the tell-tale signs of the aging face. There is reinterest in the concept of the two-dimensional look of the overpulled face because the youthful face has a much fuller look, not a pulled, flat look. Filling has replaced pulling.

For a substance or device to be amenable for soft tissue augmentation by the general medical community, it must have certain intrinsic properties. It must have both a high “use” potential, producing pleasing cosmetic results with a minimum of untoward reactions, and a low “abuse” potential, such that widespread and possibly incorrect or indiscriminate use would not result in significant morbidity. [1] Additionally, it must be nonteratogenic, noncarcinogenic, and nonmigratory. Moreover, the agent must provide predictable persistent correction through reproducible implantation techniques. Finally, if not autologous, the substance, agent, or device must be FDA approved. The search for the perfect material to eradicate rhytides, smooth scars, and fill traumatic defects continues. New products appear, sometimes with great fanfare, which often fail to fulfill the promise of a better alternative to what we use now. Although no currently available implant fulfills all of these criteria, many options exist that are adequate for a given task, satisfy patients, and offer excellent safety profiles. Of course, safety should be the primary concern when using any implant material and to do no harm.

Currently, in the United States, the commonly available injectable filling agents include autologous fat and Zyderm/Zyplast collagen. These are discussed in this chapter. Newer injectable agents, such as the hyaluronic acid products and Artecoll, techniques such as subcision, and surgically implanted agents, such as Gore-Tex, have become part of the field of soft tissue augmentation and are briefly addressed.

INJECTABLE BOVINE COLLAGEN

Injectable bovine collagen, Zyderm collagen implant, has been in use since 1977, receiving FDA approval in 1981. This was the first approved injectable xenogenic agent in the United States for soft-tissue augmentation and its approval reawakened interest in the entire field of filling agents. At present an estimated 1,900,000 individuals worldwide have received injectable collagen implants. Following the release of Zyderm I (ZC-I), two additional forms, Zyderm II (ZC-II) and Zyplast (ZP), received approval. [2] They are regarded as the “gold standards” of injectable or implantable fillers and are standards against which newer materials are measured. ZC-I, ZC-II, and ZP are suspensions of bovine dermal collagen. Processing of the material involves purification, pepsin digestion, and sterilization. Pepsin digestion removes the more antigenic end portions of the bovine collagen molecule (the telopeptides) without disturbing the natural helical structure. The resulting agent is more immunologically compatible with the human host. Zyderm collagen implants are all 95 to 98 percent type I collagen; the remainder is type III. [3] The products are suspended in phosphate-buffered physiologic saline containing 0.3% lidocaine. It should be noted that these substances are all taken from the skin of a closed American herd, negating the possibility of contamination with the bovine spongiform encephalopathy virus or prions. [4] ZC-I, the original material, and ZC-II differ only in concentration. ZC-I is 3.5 percent by weight bovine collagen whereas ZC-II (introduced in 1983) is 6.5 percent by weight bovine collagen. ZP, approved in 1985, is the third form of implantable collagen, which is lightly cross-linked by the addition of 0.0075% glutaraldehyde. These cross-links are intramolecular and intermolecular, as well as between fibrils, resulting in a more robust implant that is essentially an injectable latticework of bovine collagen. [5] ZP is more resistant to proteolytic degradation and less immunogenic. [6], [7] Furthermore, the more substantive nature of ZP makes it applicable for deeper contour defects that are unresponsive to ZC-I or ZC-II. [8], [9] All the products are provided in preloaded syringes that are stored at low temperature (4°C/39.2°F) so that the dispersed fibrils remain fluid and small. Once implanted, the human body temperature causes the products to undergo consolidation into a solid gel.

Treatment with injectable collagen requires an initial screening skin test. Approximately 0.1 cc of the material is placed intradermally in the volar area of the forearm and the site is evaluated after 1 month. A positive test, which is an absolute contraindication to treatment, consists of redness, swelling, or both occurring 6 h or more after test implantation. Approximately 3 to 3.5 percent of persons will have a positive skin test. [10], [11] and [12] Nevertheless, despite one negative skin test, 1.3 to 6.2 percent of patients will have treatment-associated hypersensitivity responses. [10], [11], [12] and [13] To reduce the possibility of these reactions, which usually occur shortly after the first treatment, it is advisable to turn the first treatment exposure into a second test. This second skin test is administered 2 to 4 weeks after the first, in either the contralateral arm or in a cosmetically inconspicuous area of the face. Treatment is then begun 2 to 4 weeks after a negative second test. [2], [14], [15] and [16] If a patient has not been treated or tested within a 12-month period, it is advisable to retest once to reduce the possibility of a treatment reaction.

Zyderm collagen is implanted in the superficial dermis by serial punctures of the skin with syringes prefilled with the

material. With ZC-I a 30- or 32-gauge needle is used. Many experienced practitioners prefer the 32-gauge metal hub needle that produces less trauma to the skin and ultimately has a better cosmetic result. With more viscous ZC-II, a 30-gauge needle is used. When implanting ZC-I and ZC-II, a serial puncture technique is employed with the syringe held almost parallel to the skin surface. Barely penetrating the skin with the needle tip, one must “flow” the material in the superficial dermis observing a flat yellow blanching of the skin. While injecting, each subsequent injection volume should be placed at the advancing edge of the previously injected quantity, generating a continuous “flow” of material that smoothly fills in defects. Because ZC-I and ZC-II contain bovine collagen in the form of microfibrils, it has excellent flow characteristics. “As superficial as possible” placement of ZC-I and ZC-II is no longer employed, nor is excessive overcorrection in that persistent whiteness at the injection site and elevation can be observed. [17], [18] Nevertheless, a slight overcorrection (25 percent) should still be sought when injecting ZC-I and ZC-II.

With ZP, a 30-gauge needle is used to create a mid-dermal flow of material, again by using a serial puncture technique. Zyplast should be placed neither too superficially nor in the subdermal space. In the former location, it will result in persistent overcorrection with beading; in the latter location, it will not provide lasting correction. With ZP, the syringe is held at a 45-degree angle during the injection process and the material placed slightly deeper than ZC-I or ZC-II. While implanting ZP the resistance of the dermal matrix is felt against the injecting hand and the plane of the injected site should elevate as the material is being placed. Deliberate overcorrection should be avoided. With Zyplast there is a greater resistance to flow upon implantation than with ZC-I and ZC-II because of its more robust nature (cross-linking) and the absence of microfibrils. Increased longevity of correction and improved aesthetic results can often be achieved by the “layering” technique wherein ZC-I or ZC-II is immediately implanted over Zyplast injection sites. Full correction can be achieved at one treatment session if enough material is employed.

Correction with all forms of bovine collagen is temporary and requires periodic maintenance at 4- to 12-month intervals. [19] In humans, while histologic studies of ZP (as opposed to ZC-I/ZC-II) have revealed some deposition of host collagen, there is no convincing evidence that this deposition contributes to longevity of correction. [20], [21] Indeed, correction with all forms of bovine collagen appears to be lost as the material is displaced from its site of implantation in the dermis into the subcutaneous space. [22]

Indications for ZC-I/ZC-II include horizontal forehead lines, glabellar lines, crow's-feet, nasolabial lines, fine lip lines, marionette lines, acne scars, excisional scars, and the like. Deep nasolabial folds, marionette grooves, deep acne scars, and the like respond best to ZP with or without ZC-I/ZC-II overlay. ZP is also best suited to resurface the vermilion border between the lip and skin for lip enhancement. Additionally, true “mucosal” injection of ZC-I, ZC-II, and ZP, is often employed in the lip enhancement process, although the mucosal location is not an FDA-approved site for collagen implantation. As one gains more experience, the practitioner will realize that while ZC-I is the most forgiving, it is also the most technique sensitive and versatile. Furthermore, as one's implantation techniques evolve, ZC-I rather than ZC-II will be the preferred filler for shallow defects in that, as one becomes more proficient at superficial placement, ZC-II can often be associated with whiteness at the injection site. The injection of bovine collagen in the circumoral area is the largest single indication for which these products are used. Even a small volumetric increase in the size of the lips in selected individuals can produce a most pleasing cosmetic result. Lip augmentation thus addresses both the age-related contour loss found in the lips and, by enhancing their size, the radial grooves. The ideal technique for lip enhancement is variable, and is certainly not uniform between physicians or even from patient to patient.

Adverse treatment responses to injectable collagen can be divided into nonhypersensitive and hypersensitive. Nonhypersensitive reactions include bruising and reactivation of herpetic eruptions, as well as bacterial infection. Additionally, local necrosis caused by vascular interruption at the treatment site has been noted with ZP and rarely ZC-I/ZC-II. [23] Because 56 percent of these locally necrotic events occur in the glabellar area, physicians are cautioned against using ZP at this site. If, upon injection, there is severe blanching of the area and pain, the procedure should be stopped immediately, as local necrosis may have occurred. The value of massage, cool compresses, or nitroglycerin gel in this situation is, as yet unsubstantiated. Two reports of partial vision loss after Zyderm collagen therapy have been noted. [24] These are probably the result of an occlusive event involving the retinal artery. These serious consequences of a cosmetic procedure underscore the need to ensure the dermal site is the proper locale for collagen implantation.

Treatment associated hypersensitivity reactions to bovine collagen implants are, for the most part, cosmetic problems consisting of redness and swelling at the treatment site. It is rare, but mild systemic symptoms can accompany these reactions. Hypersensitive reactions are almost uniformly associated with anti-Zyderm antibodies. These antibodies do not cross-react with human collagen. [13], [25] “Cyst–abscess” formation is a rare but severe hypersensitivity response occurring at a rate of 4 per 10,000 treated individuals. [23] Clinically, individuals develop painful, swollen cysts at the sites of treatment. These reactions are usually associated with ZP and rarely with ZC-I/ZC-II. Eighty-six percent of these individuals have associated antibovine antibodies. Incision and drainage, as well as intralesional glucocorticoids, have been advocated to manage this most undesirable sequela. This is a long-lasting, severe hypersensitivity response that can persist for more than 2 years. Analysis of extruded material from these abscesses has revealed bovine collagen implant. As to the possibility of bovine collagen inducing connective tissue disease in the human host, retrospective studies as well as an expert panel convened by the FDA have found no supporting evidence. [25]

FAT TRANSPLANTATION

Injectable fat, or autologous fat transplantation, is the oldest material used for tissue augmentation. Indeed, Neuber reported almost l00 years ago the technique of free fat grafts for tissue augmentation. [26] Although Brunings, in 1919, reported fat injection as a technique for soft-tissue augmentation, fat injection or transplantation was ignored in favor of pedicle flaps and the use of paraffin and silicone as filling agents. [27] In the 1980s, a dramatic change occurred. With the advent of liposuction, and especially tumescent liposuction, it was possible to return the viable fat to the body. A new age of fat transfer had begun, but its methodology was marked more by physician to physician variability than by uniformity.

Clinical experience has clearly supported the assumption that fat grafting is most successful when cellular transfer is

placed in areas already occupied with adipocytes. Simply stated, fat works best when injected into the fat. The vast majority of surgeons reporting success in fat-grafting procedures have selected the low-pressure harvest with a syringe system technique. Autologous fat has long been tried as a material for soft-tissue augmentation in aesthetic and reconstructive surgery. [26], [27], [28], [29], [30], [31] and [32] The harvest is relatively easy and there are numerous, easily accessed, donor sites. The avoidance of allogeneic or alloplastic materials and the potential antigenic and/or inflammatory responses inherent with such agents is also of great benefit. Nevertheless, the persistence of clinical augmentation with adipose transplants remains controversial. [33], [34]

Freezing fat for use at a later time is considered by many to be a useful adjunct to autologous fat transfer. After harvesting, some of the material is injected into the recipient site and the rest is fast frozen in liquid nitrogen and kept frozen until subsequent injections are necessary, but not longer than 6 to 12 months. Whether the fat cells remain viable after freezing, thawing, manipulation, and reinjection through 18-gauge or smaller needles is open to question. [35] While many physicians prefer to gently harvest the fat in a syringe, others prefer to remove fat by liposuction. [35], [36]. Whether the size of the lipocyte, the metabolic rate, the site of removal, or washing and stabilizing agents are important in the application of fat transplantation is as yet unclear. [36] Similarly, the most amenable sites for transplantation have not been totally defined. [35] In regards to longevity, additional controversy still exists. In an excellent subjective evaluation of autologous fat transplantation follow-up, Pinski and Roenigk revealed that only 25 to 30 percent of the original transplanted fat remained at 1 year in the forehead, nasolabial folds, and cheeks. [35] In another excellent study, Gormley and Eremia found microlipoinjection of fat unpredictable, yet a good result at 6 months usually was maintained at 1 year. [37] Other authorities have found fine rhytides not amenable to correction with injectable fat, although the fat may be used to fill in hollow cheeks, the perioral area, the glabellar area, facial hemiatrophy, depressed temples, and hands, and for lip augmentation. In an attempt to use autologous fat to correct fine wrinkles, the process of “lipocytic dermal augmentation” was developed. In this technique, centrifuged fat is mechanically manipulated and injected at the level of the dermis through a 25-gauge needle. Indeed, Coleman et al. presented histologic evidence in two patients at 3 months, and other anecdotal clinical subjective evaluations support their hypothesis that this technique of fat injection elicits host collagen deposition and results in the correction of dermal defects. [38]

Despite what appears to be a confusing area, a consensus appears to be evolving. [36], [37], [39], [40] The thighs, buttocks, knees, and abdomen appear to be the donor sites most often used. Individual preference and donor fat availability appear to be directing forces in choosing the proper donor site. After adequate anesthesia, the fat is removed as atraumatically as possible either by syringe extraction or by a machine-assisted method. In the former, almost any size syringe is employed with either a 1.5-inch 14- to 16-gauge needle or microcannula. Once extracted, treatment of the fat appears to vary greatly, but, in general, individuals appear to either use gentle centrifugation or gravity to separate the extracted fat from the fluids. While some individuals continue to wash the extracted lipocytes, others have abandoned this portion of the process. To place the fat, appropriate anesthesia is used and a 16- to 18-gauge needle is attached to the injecting syringe. An 11-gauge scalpel is employed to prick the skin and the syringe containing the fat is then inserted at this recipient site and the material injected at the level of the subcutaneous space. Molding after implantation is frequently used. Sites most amenable for correction with microlipoinjection, by consensus, appear to be the dorsal hand, depressed temples, hollow cheeks, deep nasolabial grooves, and defects caused by liposuction or lipodystrophy. Fat implantation has also been advocated for malar and chin augmentation. [35], [39], [40]

While swelling and bruising are fairly common and usually minor at the recipient site, occasionally persistent edema, asymmetry, punctate scarring, lumping, and bleeding occur. On the other hand, infection is a rare occurrence. There has been a single case of unilateral blindness reported following autologous fat transplantation. This is the most serious adverse consequence reported to date. [41]

OTHER MATERIALS

In addition to the above agents, there are numerous products and techniques whose position in the field of soft-tissue augmentation has not yet been fully defined. Fibrel, Autologen, Dermalogen, Isolagen, and Softform are no longer available.

AcHyal is a 1% solution of the sodium salt of hyaluronic acid. It is provided in 2.5 cc prefilled syringes with 30-gauge needles. It can be stored at room temperature and has a shelf life of 3 years. Indications are for wrinkles, scars, lip, and contour deformities. Adverse reactions are listed as reddening, inflammation, or bruising which dissipate in 2 to 3 days. There is no experience with the material in the United States.

Alloderm is a decellularized, processed, nonimmunogenic human dermal allograft that is inserted through dissected dermal tunnels for soft tissue augmentation. It is a protein framework without cells. It has been used since 1992 on more than 3500 patients. Alloderm is available in solid sheets for grafting or implanting.

Artecoll is a suspension of 20% PMMA (polymethylmethacrylate) microspheres of 30 to 42 µm diameter in 80% collagen solution. The collagen is degraded following injection with the resultant permanent deposition of PMMA. Artecoll is supplied in 0.6 mL syringes and designed for implantation into the deep reticular dermis. Artecoll is distributed worldwide, except in Japan and the United States. Clinical trials in the United States have been conducted. [42], [43] Because of its long lasting effect, Artecoll is not forgiving. Uneven distribution, long lasting itching and redness are common side effects.

Artecoll was preceded by Resoplast and Arteplast, and is basically a combination of these two products. Gottfried Lemperle published results of a prospective study in 118 patients. [44] Other studies [45], [46] have disputed Lemperle's results, and some authors claim that particles of this size are phagocytized, with the subsequent death of the engulfing macrophage and release of enzymes leading to a chronic inflammatory response. Lemperle [45] states that this is less likely given the smooth surface of PMMA microspheres. There have also been problems reported with the collagen

vehicle used for this product. [46] Other impurities were also found in the vehicle.

Biocell Ultravital is also called Biopolymere III. It is a biopolymer developed in Switzerland and contains Silicium (a derivative of silicon). According to the manufacturer, there is no need for allergy tests prior to treatment and results may be permanent. It is commonly used in South America.

Bioplastique is a suspension of textured composite silicone polymer of solid, vulcanized methylsiloxane rubber particles from 100 to 400 µm in size in a carrier vehicle (biocompatible plasdone hydrogel). [47] It is an investigational material for soft-tissue augmentation with a controlled foreign-body response. The size of the particles reportedly reduces migration. There are several reports of granulomas requiring excision. Because of the controversy and resultant bad press surrounding silicone gel implants, it is unlikely to be FDA approved and thus studies have been largely abandoned.

Cosmoderm and Cosmoplast are new products that are not yet on the market. They are recombinant human collagen. They have the same consistency and injection properties as Zyderm and Zyplast bovine collagen. They are grown from a single tissue cell line to avoid the possibility of disease transmission. They are currently undergoing clinical testing. They should eliminate potential allergenicity to collagen injections and may not require skin testing.

Cymetra is micronized cryofractured Alloderm. The material in rehydrated with 1 cc of Xylocaine. No allergy prescreening or testing is required, according to the manufacturer. Donor screening and viral inactivation are performed. The material is obtained from American Association of Tissue Banks (AATB) guideline-compliant tissue banks. It is implanted with a 26-gauge needle into the subcutaneous space. Clinical studies on 200 patients to date evidenced no allergic or immunologic reactions. Adverse reactions are bruising, redness, swelling, and wrinkling of skin. Eye pain with temporary vision loss has been reported. All the adverse reactions are reported as transient and occur at a rate of 2.1 percent.

Dermal grafting is a very unique process championed by Dr. James Swinehart in which postauricular dermis is harvested and inserted in dermal tunnels for soft-tissue augmentation and correction of scars. [48]

Dermalive is composed of hyaluronic acid and acrylic hydrogel fragments. It is nonanimal in origin. The particle sizes are 45 to 65 µm. Skin tests are reportedly unnecessary.

Endoplast-50 is a new product of elastin-solubilized peptides with bovine collagen for intradermal injection. Two skin tests are performed at 15-day intervals prior to treatment. Test syringes are available. It is provided in 0.5 or 1 mL syringes. It is injected with a 30-gauge needle in a serial puncture technique in the reticular dermis and is then massaged. There is a rare possibility of hypersensitivity. After treatment, inflammation is expected for 24 to 48 h. The material influences proliferation of fibroblasts to produce collagen. Duration of correction is said to be 8 to 12 months.

Fascian is preserved, particulate fascia lata derived from screened human cadavers. The material is freeze-dried and typically preirradiated. This material can be injected when soft tissue augmentation is desired. In a clinical trial, Burres followed 81 subjects for 6 to 9 months after implantation without incidence of infection, allergic reaction, or acute rejection. [49] Soft-tissue augmentation was evident 3 to 4 months after grafting, or longer in most cases. Injectable material is supplied in particle sizes of <0.25 mm, <0.5 mm, or <2.0 mm. The Fascian particles are hydrated in 3 to 5 cc of 0.3% lidocaine solution prior to injection. The injected area is pre-undermined with a 20-gauge needle and the material injected into the preformed tunnel with a 16- to 25-gauge needle, depending on the size of the particles used.

Gore-Tex is expanded polytetrafluoroethylene (ePTFE) that has been in medical use in general, cardiovascular, urologic, and reconstructive surgery since 1971. In 1993, it was approved by the FDA for facial plastic and reconstructive surgery. This solid material is inserted under the skin as tied strips, strings, or through a trocar that contains the product. Indications are for nasolabial folds, glabellar folds, lip lines, and lip augmentation. Adverse reactions are infection (0 to 3 percent), foreign-body extrusion, and three-dimensional elevation.

Maas et al. [46] performed studies in the porcine model comparing the implantation of solid strips, rolled sheets, and tubular implants of ePTFE. This work led to the development of the version of ePTFE marketed as Soft-Form, approved by the FDA, and made available in 1997. Softform is no longer available but the material is still available as Conform and Ultrasoft.

Hyaluronic acid derivatives are exciting new materials for soft tissue augmentation with great future potential. Hyaluronic acid is a mammalian polysaccharide found naturally in the dermis. Its ability to bond water assists in hydration and provides skin turgor. Unlike collagen, it is identical across all species and is produced by many types of cells. Hyaluronic acid itself is broken down quickly within the dermis, then eliminated by the lymphatics and eventually the liver. Hylan gels are cross-linked derivatives and have longer dwell times in tissues, but are eventually broken down into their original molecules and eliminated in the same fashion. [51]

Hylaform gel is processed from the cock's combs of domestic fowl. In clinical trials in wrinkles and scars, 80 percent of patients reported moderate or greater satisfaction at 12 weeks. Hylaform is used for facial augmentation throughout most of the world. It is especially popular for volume augmentation of the lips. However, it is not available for this purpose in the United States. It is available in a more concentrated form as Synvisc for use in osteoarthritis of the knee. There is reportedly no immunologic activity, although there have been some reports of redness that persisted at the sites of implantation. Reported adverse reactions are less than 2 percent and include erythema, ecchymoses, and acne. While the major problem reported has been the occurrence of a certain degree of redness, others have reported severe hypersensitivity-like reactions. Recently, two new forms, Hylaform-Fine and Hylaform-Plus became available.

The hyaluronic acid derivative Restylane has been available for soft-tissue augmentation in Europe for more than 5 years. Restylane is stabilized, partially cross-linked hyaluronic acid created via bacterial fermentation from streptococci bacteria and, thus, this is not animal material. It is biocompatible and biodegradable. It has a higher concentration of

hyaluronic acid than Hylaform gel increasing the filler's solubility. Restylane is provided in 0.7 cc preloaded syringes containing 20 mg/cc of stabilized hyaluronic acid. Initially the investigators recommended a linear threading, not a serial puncture technique, but now the serial puncture technique is being used with a 30-gauge needle and no overcorrection. With the second generation of this product, problems with intermittent swelling of the lips apparently have been eliminated. However, there are recent reports of patients developing acute hypersensitivity reaction to Restylane with facial extrusion of the material. It is indicated for rhytides and depressions, but the best indication is for lip augmentation, putting it into the potential space and then actually the mucosa itself, creating excellent volume lip enhancement. Restylane-fine is a new, less viscous form of Restylane for use with a 32-gauge needle. Perlane is a more robust form of Restylane for use with a 27.5-gauge needle. It is placed at the subcutaneous–dermal border.

Hylan Rofilan Gel is hyaluronic acid cross-linked with a natural acid instead of a chemical compound.

Koken Atelocollagen implant is a 2% monomolecular solution of collagen of Japanese origin. It is supplied in cartridges to be injected with a dental syringe through a 30-gauge needle. The indications, contraindications, testing, and injection techniques are the same as those for Zyderm collagen implant. Unlike, Zyderm, Koken Atelocollagen does not contain lidocaine. It is a 2% aqueous solution of monomolecular collagen molecules, whereas Zyderm is a suspension containing molecules, fibers, and fibrils of collagen.

Meta-crill is composed of microspheres of methacrylate in a colloidal suspension without protein. It is similar to Arteplast.

New-fill is a polylactic acid, and is not of animal origin. It is provided as freeze-dried material and can be stored at room temperature. After reconstitution with water, it is 4.45% polylactic acid. The material is biocompatible, biodegradable, and immunologically inert. It is injected into the superficial dermis or subdermally, using a 26-gauge needle. Indications are for nasolabial folds, lips, lipodystrophy of cheeks, acne scars, wrinkles, hands, and liposuction contour deformities.

Permacol is a permanent, cross-linked, solid porcine collagen implant (not injectable), presently available only in sheets. It allows ingrowth of host tissue cells and blood vessels. In Europe it is a CE Mark Class III and is thus approved for implantation. No US studies exist on this porcine product. It is available in 5 × 5 cm and 5 × 10 cm sheets in two thicknesses, 1.5 and 0.75 mm.

Plasmagel is an autologous, blood-derived augmenting material. Ascorbic acid and lidocaine are added to blood plasma. The material is heated to form a gel and injected. It is applicable for wrinkles, contour defects, acne scars, and lip augmentation. [52]

PMS-350 achieved CE certification in Europe after 15 years. It is silicone with a viscosity of 350 centistokes. It is indicated for glabellar lines, nasolabial folds, perioral lines, lip augmentation, atrophic disorders and scars.

Profill is provided as a translucent gel. It is a block copolymer of polyoxyethylene and polyoxypropylene with mineral salts, amino acids and vitamins. The material contains no animal proteins. It is a liquid that can be refrigerated until used. No skin test is required. The liquid material turns to gel upon implantation and can, therefore, be molded after implantation. It is provided in 1 mL syringes and injected with a 30-gauge needle in a serial puncture fashion. Several hours of redness are expected postimplantation. Correction reportedly lasts 6 to 9 months. Profill is frequently used in concert with Endoplast-50.

Reviderm-intra contains 40 to 60 µm dextran beads of the Sephadex type in hylan gel. It is of nonanimal origin. The material is nonimmunogenic, biocompatible, and biodegradable. Intradermal injection is used with a 30-gauge needle. EMLA or a topical anesthetic can be used. No overcorrection is necessary. The material can be molded after injection to disperse the beads. In a clinical study of 274 patients, the material was resistant to resorption and migration.

Silicones are synthetic compounds that do not occur naturally. The liquid silicones used for medical purposes are long polymers of dimethylsiloxanes. [53] Siloxane is an acronym used to describe compounds containing repeating units of silicon, oxygen, and methane. During the 1940s, there was significant German, Swiss, and Japanese experience with injectable silicone. There have been two major American protocols involving the use of highly refined, liquid silicone.

Silicone has a very high use potential, providing pleasing aesthetic results in many patients, but, unfortunately, it also has a high abuse potential. Numerous disastrous complications have resulted from the use of adulterated or impure silicones. Foreign-body–type silicoma can occur up to 11 years after implantation, even with the highly refined, medical grade silicon. Other adverse reactions which have been reported are movement or drift of the implant, peau d'orange, beading, discoloration, site reactions in 12 to 14 percent of patients, and immunologic reactions. [54] While injectable silicone has a long history of use in the United States, its use for soft-tissue augmentation was declared illegal by the FDA. Nevertheless, two forms of silicone—Adatosil-5000 and Silikon-1000—were recently approved as ophthalmic devices for injection into the eye for use as a prolonged retinal tamponade in selected cases of complicated retinal detachment. These are highly viscous agents. Some physicians are injecting this high-viscosity material into the face, but this may not be legal in some states in the United States.

Surgisis is derived from porcine small intestine submucosus. All cells are removed but the complex acellular matrix is retained. It works as a scaffold for host cells and tissue remodeling. It is available in sheets of various sizes and strengths. No immunologic human rejections or sensitization have been seen, although it is not applicable for patients with a known hypersensitivity to porcine products.

On April 15, 2002, the Federal Food and Drug Administration granted Allergan, Inc. (Irvine, California) approval to Botox Cosmetic (botulinum toxin type A) for the “temporary improvement in the appearance of moderate to severe glabellar lines in adult men and women 65 or younger.” This is the first approved indication for elective cosmetic use of any commercially available botulinum toxin in the US market. However, the FDA's approval merely gilded the lily because off-label usage of the toxin had already propelled annual sales to a quarter of a billion dollars a year in 2002.

HISTORY

The Napoleonic wars eroded rural hygiene and spread poverty throughout southern Germany from 1795 to 1813. [1] A 29-year-old health official, Justinus Kerner, observed a connection between sausage fat and a paralytic illness, which he reported to medical authorities in 1815, and published as a monograph in 1820. His observations provided compelling epidemiologic evidence for causation of a disease eventually known as botulism, after *botulus,* the Latin word for sausage. In 1822, he published a series of experiments, first on animals and later on himself, in which he demonstrated that a poison could be extracted from affected sausage that would induce weakness and anhidrosis. In a fascinating example of forward thinking, Kerner speculated that minimal doses of the toxin might be useful to treat a variety of disorders of the nervous system. Seventy-five years later, Emile-Pierre van Ermengen published the initial description of the causative organism, *Clostridia botulinum,* demonstrating production of a toxin that produced weakness in animals.

In 1944, Schantz began purification of botulinum toxin A in crystalline form, and in the 1950s, Brook first demonstrated that botulinum toxin A blocked release of acetylcholine from motor neurons at the neuromuscular junction. [2] In the early 1970s, Scott, with Schantz, sought a biologic toxin that would be useful in paralyzing muscular action around the eyes. He identified botulinum toxin as an agent useful in treating human strabismus, [3] and predicted it would be used in other conditions of muscle spasm or hyperactivity.

In 1987, Dr. Jean Carruthers, an oculoplastic surgeon visiting Scott's laboratory, and her husband, Dr. J. Alastair Carruthers, a dermatologist, noticed the smoothing effect of the toxin on the glabellar brow furrow when treating a patient for blepharospasm. They pursued their observations on the cosmetic effectiveness of botulinum toxin, which they first published in 1992. [4] By this time the toxin was in use for blepharospasm, strabismus, torticollis, hemifacial spasm, and other focal dystonias. [5] Other therapeutic uses for botulinum toxin have evolved since 1992, including hyperhidrosis, [6] migraine headaches, [7] and low back pain. [8]

PHARMACOLOGY

Toxin Structure

Botulinum neurotoxins are currently categorized into eight distinct serotypes: A, B, Ca, Cß, D, E, F, and G. [9] The molecules vary in their biosynthesis, size, cellular sites of action, binding kinetics, duration of effect, and stability. The two currently available serotypes, A and B, are derived from different strains of *C. botulinum*. They both have 150 kDa dichain polypeptides with a heavy chain and light chain linked by disulfide bonds. During biosynthesis, the molecules of A and B are surrounded by proteins to form a neurotoxin complex, ranging from 500 kDa to 900 kDa.

Mechanism of Action

The toxin enters the nerves by binding to surface protein receptors and undergoing endocytosis into internalized vesicles. The light chain is released into the nerve cytosol, and the SNARE protein complex is cleaved to inhibit exocytosis of the neurotransmitters such as acetylcholine. Type A toxin cleaves SNAP-25, while type B cleaves vesicle-associated membrane protein (VAMP), also called synaptobrevin.

There were three commercially available preparations of botulinum neurotoxin on the market at the time this chapter was written. Type A is available worldwide as Botox or Botox Cosmetic and in Europe as Dysport. Type B is marketed in the

US as Myobloc. Botox and Dysport are sold in lyophilized form and must be reconstituted with normal saline. Myobloc is sold in aqueous solution at pH of 5.6. While the molecule complexes are unique, very approximate equivalencies have been derived from clinical observations. One mouse unit of Botox is equal to approximately 3 to 4 units of Dysport and 100 units of Myobloc. In dermatologic uses, Botox Cosmetic is usually diluted with 1.0 or 2.5 mL saline, producing concentrations of 40 U/mL or 100 U/mL. Contrary to the package insert instructions, clinicians find that the toxin is stable at room temperature, and when diluted, it remains stable at refrigeration for extended periods of time without significant loss of potency. The use of preserved saline lessens the sting of injection with Botox Cosmetic. Myobloc causes more discomfort on injection because of its low pH, but it is stable in liquid form at room temperature for many months.

Immunology

The possibility of antibody-mediated resistance appears to be largely theoretical. Original Botox batch #79-11, widely used in ophthalmology and neurology for years, produced rare cases of nonresponders in torticollis and blepharospasm. Newer batches introduced in 1997, #91223US and #BCB2024, have significantly less protein load. Although the occasional primary nonresponder may be encountered, clinical resistance to Botox/Botox Cosmetic does not appear to be clinically relevant in dermatology, even with the doses used in hyperhidrosis, which can average 400 units per treatment session. In addition, the treatment interval does not appear to be a significant factor in clinical resistance with the use of the newer batches.

INDICATIONS

Botulinum toxin is used primarily in dermatology for treatment of the dynamic expression lines of the upper third of the face: glabellar brow furrow, the horizontal frontalis forehead lines, the periocular crow's-feet rhytides, and axillary hyperhidrosis. Less common and therapeutically more challenging indications are platysmal banding in the neck, perioral rhytides, marionette lines at the corners of the mouth from the action of the depressor anguli oris, and postsurgical synkinesis in the lower face.

TREATMENT

The Glabellar Brow Furrow

A firm understanding of the underlying facial anatomy is the sine qua non of successful aesthetic therapy with botulinum toxin. Depending on the muscle mass present and degree of atrophy from prior treatment, 25 to 35 U of Botox Cosmetic is placed in five separate injection points to treat the corrugators and procerus muscle in the average brow (Fig. 276-1). A 30-gauge needle and a tuberculin or diabetic syringe are used to minimize the trauma of the intramuscular injections. The corrugator injections are placed just at or above the medial brow and in or just lateral to the mid-pupillary line, 1 cm above the bony orbital rim. The fifth injection is placed in the procerus at the midline. Patients are instructed to remain upright for 2 to 3 h to limit incidence of eyelid ptosis, which occurs with diffusion of the toxin down into the levator muscles of the lid. With experience, incidence of ptosis following injection of the brow should be less than 2 percent. Temporary stimulation of Müller's muscle in the lid can be achieved with 0.5% apraclonidine or 2.5% phenylephrine eyedrops. These will produce 2 to 3 mm of elevation of the lash margin and may be repeated at intervals until the distant diffusion effect of the botulinum toxin on the levator muscle disappears, usually in 2 to 3 weeks.

FIGURE 276-1 The corrugator and procerus muscles are weakened by carefully positioning five injections of Botox Cosmetic of 5 units each. Forceful knitting of the brow is prevented. Before treatment (*upper figure*) and 1 week posttreatment (*lower figure*).

Horizontal Forehead Lines

The frontalis is treated at the horizontal equator of the forehead or above to avoid inactivation of the lower third of the frontalis muscle, which is responsible for suspension and movement of the eyebrows (Fig. 276-2). Twelve to 20 U of Botox are placed in four or five divided doses along the forehead equator equidistant. If too large a dose is applied, or injection sites placed too low, brow ptosis and loss of brow arch are produced, giving an unpleasant heavy sensation to the brow, as well as an aesthetically unattractive appearance.

FIGURE 276-2 The upper half of the frontalis muscle is weakened by injecting four or five sites equidistantly along the equator of the forehead, totalling 16 to 20 units of Botox Cosmetic. Before treatment (*upper figure*) and 1 week posttreatment (*lower figure*).

Unlike the treatment of eyelid ptosis, there is no comparable adrenergic agent available to reverse brow ptosis induced by botulinum, and the patient must wait several weeks for the effect to wear off. In the patient who has never received Botox before, it is wise to separate the glabellar area from the forehead area, giving a couple of weeks interval between the two to avoid the possibility of overtreatment and brow ptosis.

Crow's-feet

The rhytides at the corners of the eye will respond favorably to injections of toxin at an injection point approximately 1 cm lateral to the lateral canthus. Great care must be taken to make the injections into the skin only, raising wheals or blebs that can be gently massaged down. Intramuscular injection in this area will reliably produce unwanted bruising because of the rich venous plexus underlying the skin in this area. The toxin will readily diffuse from the blebs into the underlying orbicularis muscle, relaxing the grip on the overlying skin and smoothing out the wrinkles. Care must be taken to avoid injecting too low down onto the malar eminence where diffusion may affect the zygomaticus major muscle and disrupt the symmetrical movement of the corner of the mouth in smiling. In addition, the patient must have good lower eyelid tarsal tone to avoid the appearance of senile ectropion from too much laxity of the lower eyelid. Pretreatment of the crow's-feet area is very useful as an adjunctive technique prior to laser resurfacing, preventing the problem of rhytides being readily reformed by repeated squinting during the postoperative healing period.

Hyperhidrosis

Focal axillary hyperhidrosis is successfully treated with botulinum toxin by using Minor's starch iodine test to map out the extent of surface area in the axillary vault that is affected and then placing 2.5 to 4.0 U of Botox every 1 to 2 cm as intradermal injections in axillary skin. Reliable anhidrosis is produced within 72 h, which will last for 8 to 12 months with doses of 50 U per axilla. The duration of effect appears to be dose related, and doses up to 200 U per axilla have been reported to produce dryness up to 29 months. [10] Aside from insignificant bruising from the needle trauma, there are no apparent side effects.

Palmar hyperhidrosis is more challenging because of (1) more limited diffusion of the toxin in palmar skin, (2) pain on injection, and (3) the generally predictable incidence of temporary weakness in the hand. Anesthesia is achieved with wrist blocks of the median, ulnar, and radial nerves. Approximately 100 to 150 U of Botox are needed for a single palm, divided into 50 to 60 intradermal injection sites of 2 to 3 U each. Onset of anhidrosis peaks in about 5 to 7 days, and is accompanied by minor weakness of the intrinsic muscles of the hand, which makes tasks requiring strength and stability difficult, for example, pushing a button through a button hole. The weakness usually subsides within 3 weeks, while the anhidrosis persists for several months. There is a wider variety of response to palmar treatment with durations lasting from 4 to 12 months, probably mirroring the technical difficulties in achieving even dispersion of the toxin through the palmar skin.

SIDE EFFECTS AND COMPLICATIONS

Minor needle trauma and bruising upon injection with a 30-gauge needle are insignificant short-term complications. The more problematic complications to consider are eyelid ptosis, which can occur with injections in the glabellar brow; headaches with injections anywhere in the upper third of the face; and palmar weakness following injections for hyperhidrosis. Antibody-mediated resistance appears to be an exceedingly rare event and of little clinical consequence in dermatologic uses of botulinum toxin.

REFERENCES

The first written account of autografting of hair was a doctoral thesis by Dieffenbach, in 1822, in Konigsberg, Germany. [1] However, the concept did not really capture the medical profession's imagination or the general public's enthusiasm until 1959, when Norman Orentreich published an article including an account of successful hair transplantation in male-pattern baldness (MPB). [2] In addition, in the late 1970s, the concept of alopecia reduction (AR) or serial excision of areas of MPB was introduced by the Blanchards and Ungers. [3], [4] This chapter summarizes the present state of graft hair transplantation and AR. Controversial aspects and alternative approaches for hair restoration cannot be dealt with here because of space constraints, but are available in detailed form elsewhere. [5]

HAIR TRANSPLANTATION

Patient Selection and Planning

Hair transplantation is based on the concept of “donor dominance” in MPB. [2] If a graft is taken from an area destined to be permanently hair-bearing and transplanted into an area of MPB or future MPB, it will, after an initial short effluvium, continue to grow in its new site for as long as it would have in its original one. Thus, all planning is predicated on an accurate assessment of the eventual extent of MPB and the size and characteristics of the permanent donor rim. A careful family history, physical examination, and consideration of the patient's age are all important factors to consider as this assessment is made.

Conceptually, the recipient area is now dealt with in thirds [6] (Fig. 277-1A). The anterior third, or “frontal” area, frames the face and extends from the chosen hairline to a line drawn perpendicularly from the tragus. The middle third or “mid-scalp” area extends from the posterior point of the anterior third to the region where the scalp changes from its more horizontal orientation to a more vertical one. The posterior third or “crown” area extends from the posterior border of the mid-scalp to the superior border of the permanent rim hair. If one transplants the anterior two thirds, the patient will appear to have a full head of hair when viewed from frontally and laterally. The crown area is usually not treated unless the individual is not going to treat the frontal third or is also willing to undergo AR or scalp extension and the long-term donor/recipient area ratio is thereby converted to one that is satisfactory for this objective.

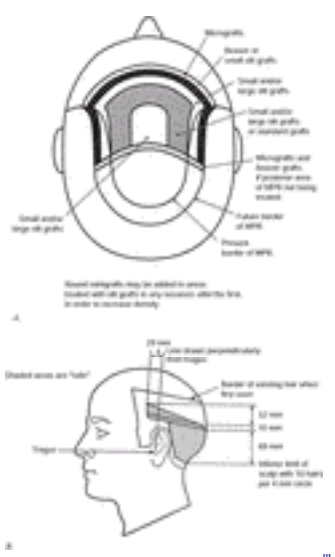

FIGURE 277-1 *A.* Schematic of the distribution of various types of grafts used in hair transplantation. The periphery of this area is always composed of small grafts. If MPB progresses beyond its anticipated extent, one can either treat the new areas or leave them as empty “alleys” adjacent to a relatively large “isolated frontal forelock.” Round mini-grafts and/or slot grafts may be added to any area treated with slit grafts, after the first session, to add greater density. *B.* A safe donor area for 80 percent of patients younger than 80 years of age. The hair density within this zone is greater than or equal to 8 hairs per 4 mm circle and it is approximately 69 mm high in the occipital midline. These boundaries were arrived at by studying 328 men, 65 years of age or older.

If one wants to be sure of *never* overestimating how large an area can be treated, one can create only an “isolated frontal forelock” (IFF), which will look natural standing on its own as long as the periphery is completed with small grafts. [7] This latter objective avoids any need for an accurate prognosis of the eventual boundaries of the area of MPB and is most suitable for those who are likely to develop type VI or VII MPB (see also Chap. 71). However, it appears that less than 24 percent of men who reach the age of 80 years will develop type VI or VII MPB. [8], [9] In addition, a “safe” donor area that is only 50 to 60 mm wide, extending approximately from ear to ear, is usually sufficient to produce enough grafts for four to five relatively large hair transplant sessions (see below). Even men with type VI MPB maintain “safe” donor areas of that width (Fig. 277-1B). In this light, limiting most patients to an IFF seems excessively conservative. A more reasonable course is to attempt to transplant all present and future areas of at least the anterior half to two-thirds of the area of MPB. The transplanted area should have a hair density that is appropriate given the expected donor/recipient area ratio and the borders of the entire area should be completed with small grafts (Fig. 277-1A). If hair loss does eventually exceed the originally estimated extent of MPB, one can treat the new areas or leave them as empty “alleys” adjacent to a relatively large IFF. With today's techniques, few patients are totally unacceptable candidates.

It is not necessary, nor advantageous, to wait until an area is totally alopecic before transplanting is initiated. Existing hair in a patient with relatively “early” androgenetic alopecia, allows for better postoperative camouflage with longer and more convenient intervals between sessions that are timed to keep pace with the rate of hair loss (Fig. 277-2). Transplanting does not, in our opinion, accelerate future hair loss, but the more hair that is present, the more skill is required; incisions must be made in the same direction and at the same angle as the original hair or MPB *will* be accelerated. [6] Similarly, no absolute rules apply to the correct age at which to begin—experience and skill extend the limits, although it is very uncommon to begin before age 21 or after age 80. [6]

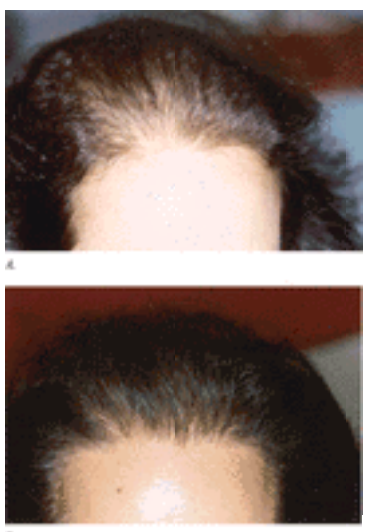

FIGURE 277-2 *A.* A female patient with androgenetic alopecia before transplantation. *B.* Nine months after one session of micrografts, mini-slit, and slit grafts. In our experience, transplanting into hair-bearing areas does not accelerate hair loss, whether in a female or a male with relatively “early” MPB. Subsequent additional transplant sessions may be carried out in pace with the rate of future hair loss.

Women now represent a larger percentage of hair transplant patients, as newer techniques perfected over the last 10 years are ideal for their treatment. Because of these advancements, most women we see are now felt to be acceptable candidates (Fig. 227-2). [10] A minority of women develop diffuse thinning that affects all areas of the scalp hair and are therefore not candidates for hair transplanting. Hair transplantation can also be used to treat cicatricial alopecia, including those from cosmetic surgery, and for the creation of eyelashes and eyebrows.

The less contrast between the color of the hair and skin, the better. Other advantageous hair characteristics are good density, frizziness, and curl or wave. Fine-textured hairs allow transplanted hair to blend in less perceptibly in areas of moderate or advanced thinning, without contrasting too much against hair that gradually becomes finer as MPB progresses. It is also ideal for the creation of very natural looking hairlines. Coarser hair produces more hair bulk and is best used in areas where high hair mass is the objective. An increase in hair diameter of only .01 mm increases hair bulk by an astounding 36 percent.

AR can be used to decrease both the width of an area of MPB and its length by making more superior hairlines cosmetically acceptable, and will therefore result in substantial graft savings. [6] Potentially negative sequelae of AR, such as significantly decreased hair density in future donor areas, disorientation of hair direction, permanently noticeable and/or poor scars, and partial loss of initial gains or “stretch-back” are minimal or can be totally avoided by appropriate planning and technique. [11], [12] and [13] AR can usually be done prior to any transplanting or between sessions.

Graft Types

Grafts are defined by the number of follicular units (FU) they contain, and the instruments used for making their recipient site. FU, first described by Headington, are single follicles or small groups of two to five closely spaced follicles, that are separated from other similar groups by slightly larger alopecic spaces (Fig. 277-3A). [14] Table 277-1 summarizes the definitions of the types of grafts that can be used in hair transplanting (see also graft preparation below).

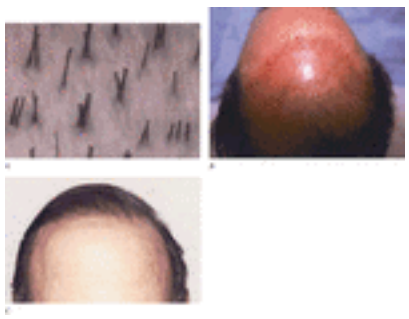

FIGURE 277-3 *A.* Densitometry illustrating the natural follicular groupings in the donor area of a patient with average hair density. Note that only 15 to 20 percent of hairs emerge singly, most are in groups of two and three hairs. *B.* Pattern of a follicular unit transplant (FUT) on a bald scalp. *C.* Frontal view of the same patient 5 months after one session of micrografts; the result will become thicker over the next 5 months.

Micrograft (always a single follicular unit)	1–4	Puncture hole	1 or less	No
Mini-slit graft	3–5	Beaver mini-EL Sharpoint or stitch knife	2	No
Mini-graft "small"	5–8	Hole or slot	3	Yes
Mini-graft "large"	6–12	Hole or slot	3–4	Yes
Slit graft "small"	5–8	Blade slit	3	No
Slit graft "large"	6–12	Blade slit	3–4	No
Standard graft	8–30	1.0+ mm Hole	6–12	Yes

TABLE 277-1 **Graft Terminology**

Three variables are considered in choosing the type of graft to be employed: hair characteristics, density objectives, and the amount of persisting recipient area hair.

The finer the hair texture, the less skin/hair color contrast, and the more hair wave or curl, the less plugginess will be noticed with grafts containing more than one FU. Sessions composed exclusively of FU [follicular unit transplant (FUT)], should be used if density objectives are not high. FUT is also ideal for the first session in a totally alopecic patient, as it produces the most even and natural distribution of hair in such individuals (Fig. 277-3). In addition, FUT is sometimes used as a last session in individuals with coarse hair and/or greater degrees of hair to skin color contrast. FUT is the least efficient way of producing substantial hair density.

Transplanting with mixtures of micrografts, mini-slit, and slit grafts is ideal for producing moderate density, while slot grafts (Fig. 277-4) and round grafts are better for creating greater density. It is popular to assume that round grafts will always produce noticeable "plugginess." This is not so if patients are properly selected and a combination of grafts of proper types and sizes are skillfully used.

FIGURE 277-4 *A.* Intraoperative pattern of a first frontal session. A mixture of micrografts, mini-slit, slit, and slot grafts has been used. *B.* The same patient shown after three sessions. *C.* A critical close-up lateral view of the hairline. Note the absence of any "plugginess" despite the use of some larger grafts.

Initially, micrografts, mini-slit, and slit grafts of whatever type will produce a greater increase in hair density than will slot or round grafts in a recipient area with persisting hair. With micrografts, mini-slit, and slit grafts, the net gain will be equal to the number of hairs being transplanted, as no hair is removed when micrograft holes and slits are correctly made between them. In the long-term, however, the more slot and round grafts that are used, the greater the density that will be achieved. This is the case because alopecic or potentially alopecic skin is also being removed, and because the hairs in the slot and round grafts are closer together than FU or slit grafts can ever be placed.

From the preceding discussion it should be clear that each graft type has advantages as well as disadvantages. Using only one or two types of grafts for all patients and circumstances unnecessarily limits the artistic options available to the hair restoration surgeon and the eventual density a patient can attain.

"Megasessions" consisting of several thousand FU and "dense packing" of the FU (e.g., 40 to 50 FU/cm ^{2}) in a single session were once suggested as a means of producing more coverage and density in fewer sessions and therefore less

time. [15], [16] Unfortunately sessions of 8 h or longer are necessary and may be medically unwise for some individuals. There is also considerable concern as to whether hair survival is as good as it is with smaller sessions and lower FU densities. [17], [18], [19] and [20] Nearly all hair restoration surgeons now limit the number of FU they will transplant in a single session to 1500 to 2000, and FU densities to 20 to 25 FU/cm ^{2}.

TECHNIQUE

Anesthesia

Diazepam 20 mg is given orally 30 min before surgery to minimize anxiety and, more importantly, the possibility of anesthetic toxicity. Oral meperidine hydrochloride (Demerol) 50 mg can be added to the diazepam for patients with low pain thresholds. For patients with extreme anxiety, premixed and self-administered 50% nitrous oxide and 50% oxygen, or intravenous propofol—the latter administered by a fully qualified anesthetist—can also be employed for 10 to 15 min as the local anesthetic is being injected. Field blocks are used in both donor and recipient areas and are produced, respectively, with buffered 1 to 2% lidocaine with 1:100,000 epinephrine and unbuffered 2 to 4% lidocaine with 1:50,000 epinephrine. [21] The buffering minimizes the stinging associated with the initial donor area injections. A tumescent anesthetic technique is used superior to the donor area field block.

For the frontal recipient area, 2 to 4% lidocaine with 1:50,000 epinephrine is used to produce three wheals along the proposed hairline: one in the midline and two midway between the midline and the left and right lateral ends of the hairline. The unanesthetized gaps between these wheals are gradually anesthetized by periodically inserting a needle into the anesthetized sections and injecting more lidocaine bilaterally, until a solid line of anesthesia is created. This field block is produced very slowly, over a period of at least 30 min. Injections are made superficially and the block is not started until 30 to 45 mins after the donor area is anesthetized, thus minimizing the potential for lidocaine and epinephrine toxicity. [21] Approximately 15 to 20 min after the recipient area block is completed, 1:50,000 epinephrine solution is infiltrated superior to it in order to minimize intraoperative bleeding.

The Donor Area

Improved donor area harvesting technique has revolutionized what can be accomplished with hair transplanting even in patients who have a very limited “safe” donor area (SDA). [9] Conceptually, one excises a donor area of appropriate size and sections it into the desired number and types of grafts. The authors employ two donor zones in most patients: one inferiorly in the occipital area and the other on the contralateral side more superiorly, extending from the midline into the parietal area and as far as 28 mm anterior to a line drawn perpendicularly from the tragus. The former is taken from an area with the finest caliber hair that is judged to be permanent and is ideal for use in the hairline zone. The superior donor zone contains hair that is coarser and can be used to produce greater density posterior to the hairline zone. It also contains temporal hair that will become gray or white earlier than that from occipital and parietal areas, and will therefore result in a sprinkling of gray hair in the frontal recipient area in pace with similar changes in the temporal area. During the second session, donor strips are taken contralateral to those obtained in the first session. If the SDA is narrower than usual, only one long donor strip is employed and one attempts to find the different hair textures along different areas on the same strip. Using figures obtained in a study of 328 men 65 years of age or older, a donor area of acceptable density and one that is “safe” to use in 80 percent of the patients younger than the age of 80 years was established. It is shown in Fig. 277-1B. [9] It is not uncommon to be able to excise 7- to 10-mm–wide strips of donor tissue bilaterally in four to six separate sessions, without the rim hair density appearing to be significantly decreased. Each session typically consists of 1500 to 1750 FU or 700 to 900 grafts of various types.

Incisions in the donor areas are made into the mid-subcutaneous tissue and the blades are always held parallel to the angle of exiting hair. Tissue harvested with a multibladed knife is used to prepare all types of grafts, while a strip excised with a two-bladed knife is used to obtain FU. Donor sites are usually closed in a single layer employing a 2–0 Supramid suture; these are removed in 7 to 10 days. Appropriate spacing of blades and donor sites is an important consideration. [9] Overzealous “harvesting” can lead to larger than necessary scars in the donor area. Scars from previous donor harvests are usually excised as part of any new donor areas, so that only one or two scars will ultimately be left no matter how many operations are carried out. Wide scars and needless patient discomfort are usually the result of overestimating what can be removed, or being too zealous in producing large numbers of grafts in a single session.

Graft Preparation and Insertion

After the donor strips obtained with a multibladed knife have been excised, they are separated from each other and oriented on a moistened piece of plastic sheeting with a good back light so that a clear view of the hair follicles is possible. These multiblade strips are used to create primarily slit grafts, slot grafts, and round grafts, but also are a source for additional micrografts. Elliptical blocks of donor tissue, obtained with the two-bladed knives, are first carefully slivered into sections that are one FU wide. [22], [23] These “slivers” are then further divided into pieces containing one, two, or three FU for, respectively, micrografts, mini-slit, and slit grafts. All grafts are immediately placed into saline-filled petri dishes that sit on a cup filled with ice. Most technicians use 6 to 10× stereo microscopes for creating the “slivers” and FU and 1 to 2× magnifying glasses for all other grafts. Although we currently expend considerable effort on keeping FU intact, the importance of this practice is far from certain. Transected follicles often grow hair—although sometimes of smaller caliber—and may, in fact, produce more hair than was originally transplanted.

The grafts are sorted according to hair texture, color, and size and must be kept moist at all times. They are gently eased into the recipient sites using small serrated forceps or jewelers' forceps. They are positioned flush with or slightly above the surrounding skin.

The Recipient Area

The hairline should begin and end at the *ultimate* anterior–superior points of the temporal hair. The midline point should be placed such that (1) the hairline runs approximately parallel to the ground when viewed laterally, and (2) it is situated in the transition area between the more or less vertical forehead and the horizontal caudal plane of the head. Approximately 500 to 600 micrografts are used in the hairline zone, which should always have a very irregular anterior border. Posterior to the micrografts, a zone of mini-slit grafts is usually used, with micrografts scattered between them. Although one is ultimately looking for a random and therefore natural-looking distribution of hair in the hairline zone, the authors have found that a careful “organized disorganization” produces a better short-term as well as long-term appearance. [24] Mini-slit, small and/or large slit grafts are employed for the rest of the recipient area in most patients, excepting the center of the whorl of the vertex, where only micrografts are used (Fig. 277-1A).

After 4 or more months have elapsed, similar grafts are placed between those transplanted during the first session. However, if hair characteristics are good and greater density is preferred, some large slit grafts and/or slot or small round minigrafts may be used during the second session. Six or more months later, a third session may be done. It is common to carry out three sessions in an alopecic frontal area, although some patients are content with two and a few require four sessions to satisfy their density objectives. In the mid-scalp and vertex areas no more than two sessions are usually necessary to produce cosmetically satisfying results. The size of the grafts can be increased from session to session to increase density without increased graft noticeability. The combination of micrografts, mini-slit grafts and slit grafts described above is used for a large majority of patients. However, as noted earlier, if the recipient area is initially alopecic, a first session of FUT may be used. FUT may also be employed for patients who do not want to commit to more than one session.

In 10 to 15 percent of male patients, if the objective is greater hair density, an organized pattern of square grafts placed into round holes may be employed in a zone that is approximately 2 to 2.5 cm posterior to the hairline and medial to the most lateral frontal area grafts (Fig. 277-1A). Generally the square grafts are prepared from 2- or 3.5-mm–wide strips and are placed into holes made respectively with a 2- or 3- to 3.25-mm trephine. Any given area of alopecia can be solidly filled with either three or four sessions of round grafts. [25] The intervals between sessions of round grafts should be the same as those employed for slit grafts. In the authors' view, reports of the demise of the round graft are premature. Such grafts are appropriate for most patients who want more than moderate hair density.

In women, nearly all grafts used are FU or mini-slit grafts. For African American patients, a combination of micrografts and slit grafts for the hairline zone and round or slot grafts of various sizes posterior to the hairline zone should be used. For all other races, the use of this combination of graft types is optional.

The need for consistent direction and angling of recipient sites (mimicking the original direction and angle of hair in the area) cannot be overemphasized. Slight changes in the angle at which one prepares a recipient site, especially for slot and round grafts, can result in injury to or excision of adjacent original or previously transplanted hair matrices and the creation of new small areas of alopecia.

Laser Transplanting

A variety of carbon dioxide lasers were tried and reported on by one of the authors over a period of 5 years. [26], [27] The main objective was to produce slotlike recipient sites that would result in an appearance that was cosmetically superior to that created with micrografts, slit grafts, or round grafts. Unfortunately, the problems of inconsistent degrees of lateral thermal damage, increased postoperative crusting, delayed hair regrowth, and variable rates of hair survival were never overcome. More recently, erbium lasers and combination erbium-CO_2 lasers have shown lesser amounts of all the preceding problems; however, they have thus far been used only for the production of round recipient sites. [28] Therefore, while these lasers allow for better control of bleeding than do trephines and blades, they do not result in better cosmesis, especially when compared to the new “slot” punches. If and when a laser is perfected that combines minimal thermal damage and the rapid production of “slot” sites—especially if it were combined with a scanner to create those sites in a specific pattern with consistent spacing between the sites—then lasers might finally enjoy the potential that the technology has always promised.

Bandaging

Most physicians continue to use a small turban-like postoperative overnight dressing. However, if FUT or micromini-grafting is employed, and if there is no more than the usual amount of bleeding, many patients can leave the office 30 to 120 min after completion of the surgery without a bandage. All patients should ideally return the next day to confirm that the grafts are still positioned properly as well as to carefully clean away any blood clots that may have developed overnight. Properly trained assistants then carefully wash, style, and dry the hair.

Postoperative Course

Patients are supplied with three analgesics to be used as required: acetaminophen tablets with 30 mg of codeine, oxycodone, and meperidine hydrochloride 50 mg. Most patients use only the acetaminophen and codeine tablets and only for the first night. Unless it is contraindicated, patients are also given an intramuscular injection of ketorolac tromethamine, 30 to 60 mg, which generally eliminates all postoperative pain for 6 to 8 h. Nearly all hair restoration surgeons administer an intramuscular glucocorticoid, such as 80 mg of methyl prednisolone acetate, to reduce postoperative edema.

A small amount of crusting forms over the grafts. Most of this is removed during the first cleaning and washing the day after surgery, and it is gone in 7 to 14 days. The grafts will usually lose their hair in 2 to 6 weeks while new hair growth

normally begins 10 to 20 weeks after surgery. The ultimate cosmetic effect of any given session is seen 9 to 12 months after surgery. A 3% solution of minoxidil used twice daily for 5 to 6 weeks postoperatively will often accelerate regrowth and decrease the chance of postoperative telogen effluvium of existing hair in the recipient area. Some hypoesthesia of the scalp can be expected to occur postoperatively in nearly everyone. This is usually temporary, but it may sometimes persist in one or more small areas.

Complications

True infection in the recipient area occurs in fewer than 0.1 percent of patients, while a few usually self-resolving ingrown hairs are seen in 1 to 5 percent. Hot compresses and topical, as well as systemic, antibiotics are prescribed if pathogens grow from the exudate or if there is clearly infection present. Grafts may be slightly elevated ("cobblestoning") or slightly depressed, although both are very uncommon with FU, mini-slit, and slit grafts. Cobblestoning can be treated with light electrodesiccation, while depressed grafts should be excised and repositioned at that site or replaced with new grafts that lie flush with the skin. Other complications include epidermal cysts; keloids; hypertrophic scars; poor hair survival; arteriovenous fistulae; osteomyelitis; telogen effluvium; chronic folliculitis; accelerated hair loss; temporary curly or lusterless hair; indented skin or "grooves" in the recipient area; "hyperfibrotic" healing; and wound dehiscence. All of the above potential complications are either rare, temporary, minor, or avoidable sequelae of hair transplanting, and should be viewed from that perspective. [5] There has, however, been one reported case of an arteriovenous fistula in the donor area leading to septic pulmonary emboli.

ALOPECIA REDUCTION

AR, or scalp reduction, can be defined as the excision of an area of alopecia or future alopecia. The larger the area that can be removed, the smaller the remaining area of alopecia will be, with the result that fewer grafts will be required to treat the reduced area or produce the same hair density in the reduced area. In general, the authors recommend that one or more ARs be employed any time the objective of the patient is maximum coverage of frontal and vertex alopecia.

Technique

AR is usually carried out on an outpatient basis using only local anesthesia but under sterile conditions. [29] If the excision pattern is an ellipse, a variant of an ellipse, or shaped like a "lazy S," an incision is made down to and through the galea along one side of its entire length, usually in a staged fashion, stopping to control bleeding with cautery where required. Care is taken to angle the blade so as to not injure any adjacent follicles. Mayo scissors and blunt finger dissection are used to undermine between the periosteum and galea aponeurotica. Recent studies by Raposio and Seery suggest that 5 cm of undermining will allow the surgeon to excise the same width of tissue when compared to more extensive undermining. [30]

The amount of redundant scalp tissue is estimated by overlapping the tissues, followed by perpendicular incisions made through the top flap, stopping at the points where the flaps meet. The ends of the perpendicular cuts are then joined by a long incision parallel to the original one, and the excess tissue is thereby removed. If the AR is done in the shape of an inverted Y, each "arm" of the Y is treated as a separate ellipse. ARs are closed in two layers—galea and skin—and an overnight dressing is applied.

Complications

Complications of AR include postoperative bleeding, infection, nerve damage, persistent hair thinning or loss in the fringe areas, disorientation of hair direction, and poor scars. All of these rarely occur.

Major Reductions

Major reductions have been described by numerous authors. Brandy suggested calling them bilateral occipital parietal flaps and bilateral temporal flaps. [5] Major reductions are distinguished from standard ARs by more extensive undermining involving the severing of temporal and/or postauricular and/or occipital arteries and nerves bilaterally. The efficacy of these procedures in excising substantial areas of alopecia is beyond question. However, potential complications include wound dehiscence, permanent hypoesthesia, persisting marked thinning of existing scalp hair, and necrosis of large areas of the scalp. Although they are infrequent, they are serious enough that the authors are not aware of anyone presently doing these types of reductions.

Scalp Extension

Scalp extension was first described by Frechet in 1993. [31] As part of a conventional AR, he inserted a thin stretched sheet of silicone elastomer in the subgaleal space. Rows of titanium hooks attached to the lateral ends of this "extender" were hooked into the galea. The wound was then sutured closed in two layers. The extender has a natural tendency to return to its original size, thus stretching the tissue located lateral to the hooks and contracting the scalp between them. After a period of approximately 30 days, the extender is removed. Substantial scalp laxity is then present and another AR is carried out. Frechet's studies revealed that if the extender had been stretched to twice its original length, approximately twice the expected area of alopecia could be removed on this second occasion, and as soon as 30 days after the first (instead of the more usual 2 to 3 months between ARs). Another extender can be inserted at the time of the second, so even a third AR can be carried out. Remarkable results can be achieved very quickly (Fig. 277-5). Disadvantages include substantial discomfort during the postoperative period that lasts from 1 to 2 weeks, an infection rate of approximately 0.5 percent, and a "slot" defect that must be repaired if the entire area of alopecia is excised.

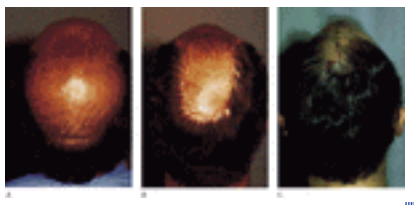

FIGURE 277-5 *A.* Before reduction. *B.* Immediately after the second alopecia reduction (AR), 30 days after the first AR, during which a Frechet extender was inserted. *C.* Immediately after a third AR, which was done 60 days after the first and 30 days after the second, and included a three-flap corrective procedure for the slot that would have otherwise been present. (*Photos courtesy of Dr. Patrick Frechet*)

Alopecia Reduction Preceded by Soft-Tissue Expansion

Tissue expansion has been used prior to AR for more than two decades. In brief, a specially designed surgical “balloon” is inserted as a separate procedure prior to a planned AR. It is gradually inflated with injections of saline every 1 or 2 weeks for 6 to 12 weeks. The expander is then removed and an AR is carried out. The use of such expanders enabled physicians to excise as much as 10 to 12 cm of alopecia in one AR. An infection rate of less than 0.5% is the only additional complication over those that can occur with modified major AR. Anderson described elegant procedures that use soft-tissue expansion prior to bilateral advancement transposition (BAT) and triple advancement transposition (TAT) flaps that produce excellent cosmetic results. [5] Despite this, the cosmetic disability caused by the gradually inflated expanders, which produce a hydrocephalic appearance toward the end of the inflation period, has to a large extent limited this technique to individuals with cicatricial alopecia. Unger recently described the use of what he terms prolonged acute tissue expansion (PATE) during the course of a conventional modified major AR. [29] A U-shaped expander is inserted under the hair-bearing skin and is expanded over 2 to 3 h while the patient remains in the operating room under local anesthesia. The AR is then carried out and generally will result in the removal of approximately twice the area that would have been removed with a conventional modified major AR. This technique offers a reasonable compromise approach to the advantages of tissue expansion while eliminating most of its disadvantages.

HISTORY

Cold has been an important adjunct in medicine since the Egyptians used it to treat injuries and inflammation around 2500 B.C. [1] Similarly, Hippocrates used cold to relieve the pain of injury and illness from 460 to 370 B.C. [2] Baron Dominique Jean Lorrey used cold to stop hemorrhage after amputations done in Napoleon's historic retreat from Moscow. [3] Using a brine solution, Arnott, [4] a London physician, lowered temperatures to –24°C (–11.2°F) for treatment of neuralgia and as palliation in terminally ill cancer patients.

New York became the “cradle of cryosurgery” in the United States in 1899, when White, a dermatologist, first dipped a cotton-tipped applicator into liquid air and successfully treated warts, nevi, keratoses, and skin cancers. [5] Whitehouse, another New York dermatologist, developed a spray from a laboratory wash bottle in 1907. [6] In the mid-1960s, Zacarian used this concept to develop a spray of liquid nitrogen after first working with copper probe tips. [7] Around the same time, another New York dermatologist, Torre, treated multiple types of skin lesions with an instrument originally designed by Cooper for use in the brain. [8]

Carbon dioxide was the primary cryogen used from the early 1900s until Allington introduced liquid nitrogen applied with a cotton swab in 1948. [9] This technique is still widely in use.

Cryosurgery is effective in treating a wide array of skin conditions including many benign, premalignant, and malignant lesions. Because it also offers partial anesthesia, numerous lesions may be treated at one sitting. This efficient, effective, and economical method is now widely used by physicians who manage skin lesions.

PATIENT SELECTION

Dermatologists now have a variety of treatment methods available for benign and malignant skin lesions including excision, electrodesiccation, chemical peeling, laser, the Mohs technique, radiation, and topical agents such as 5-fluorouracil, glycolic acid, and retinoids. The selection of treatment depends on the patient as well as his or her skin type, general health, and overall expectations. Not all methods are available in every office, but freezing and

electrodesiccation are extensively used by many dermatologists.

Cryosurgery is unique in its versatility for treatment of multiple warts or keratoses in fair-skinned patients. Patients who are allergic to local anesthesia, take anticoagulants, or have anticipated poor wound healing are excellent candidates for the procedure. Cryosurgery is often selected for lesions larger than 3 to 4 mm, while for multiple 1- to 2-mm lesions, electrodesiccation may be preferable. Laser is usually preferred over freezing for port-wine stains and some other vascular lesions, but freezing may be more cost-effective than laser for treatment of multiple lentigines. [10] For physicians managing patients infected with HIV, the “blood-free” aspect of cryosurgery is a unique advantage, especially in the treatment of warts, molluscum contagiosum, and Kaposi sarcoma. [11]

CRYOBIOLOGY

Cryosurgery is a technique that removes heat from the skin by applying a cryogenic agent. The mechanism of injury involves direct cellular freezing as well as vascular stasis, which develops after thawing. These changes depend on several factors, including the rate of temperature fall, the rate of rewarming, the solute concentration, the length of time cells are exposed to a temperature in the 0°C to –50°C (32°F to –58°F) range, and the coldest temperature reached in the target tissue. [12] Slow cooling produces extracellular ice formation, whereas rapid cooling leads to intracellular ice formation. The latter results in more cellular damage, because the cells are ruptured during the thawing process. Slow thawing also causes an increased concentration of electrolytes. The recrystallization that takes place is damaging to cells. [13] The local inflammatory response contributes to the final cellular destruction [14] and consequent vascular stasis assures greater cell destruction.

EQUIPMENT

Cryosurgery can be performed with a number of cryogens (Table 278-1) and various forms of equipment. The Kidde apparatus uses carbon dioxide to freeze tissue. It is rarely used today, but some offices still use a combination of pulverized carbon dioxide, sulfur, and acetone, which forms a dry ice slush. The application of liquid nitrogen with a cotton swab is still in use, but most physicians in the United States, as well as in numerous foreign countries, frequently apply it using a small hand-held spray unit. These units come equipped with interchangeable apertures and probe tips of varying size. Some of the units available include the Frigitronics Cryo-Surg, Brymill Cry-AC units, Nitrospray, and Wallach Ultra Freeze. Liquid nitrogen may be purchased from many welding supply companies at a cost of approximately $1.50 to $2.40/L. It is stored in 20- to 30-L Dewar flasks.

Cryogens	Boiling Point STP (C°)
Carbon dioxide (solid)	−78.5 (−109.3°F)
Nitrous oxide (liquid)	−89.5 (−129.1°F)
Liquid nitrogen	−195.8 (−320.4°F)

TABLE 278-1 **Cryogens and Their Temperatures**

There is evidence that viral contamination of liquid nitrogen may occur when warts are treated by the dipstick method. [15] Use of a Styrofoam or stainless steel cup is recommended for holding liquid nitrogen prior to dipping the cotton swab in order to avoid this possible complication.

TREATMENT OF BENIGN LESIONS

Many benign tumors and conditions may be managed by cryosurgery. A number of factors must be considered before deciding that cryosurgery is the treatment of choice. These include the depth and location of the lesion, the patient's skin type, the total number of lesions being treated, the desired cosmetic result, and the anticipated discomfort that might result from treatment of lesions in certain locations such as the plantar surface of the foot.

Technique

In general, it is sufficient to freeze a benign tumor until a 1- to 2-mm rim of normal tissue has been frozen around it. Some lesions, such as the seborrheic keratosis, may be especially stubborn to eradicate and need longer freeze times (Table 278-2). The use of intermittent freezing allows for better control than one would have using a continuous spray, especially for small lesions. Probes are advantageous for small vascular lesions and sebaceous hyperplasia. The approximate freeze times for eradication of common benign lesions and the anticipated cosmetic results are given in Table 278-3.

TABLE 278-2 **Treatment Chart***

Lesion	Freeze Times seconds	Range of Expected Cosmetic Results
Acne scarring	10	Good to fair
Actinic keratoses	5–10	Excellent to good
Cherry angioma	15–20 (probe)	Good to fair
Chondrodermatitis	30	Good to fair
Granuloma faciale	30	Good to fair
Hemangioma	60+	Good to fair
Hypertrophic scarring	20	Good to fair
Keloidal scarring	30	Excellent to good
Keratoacanthoma	30	Excellent to good
Lentigines	10	Excellent to good
Lentigo maligna	60–120	Good to fair
Morphea-type basal cell	90–120	Good to fair
Nevi	10	Excellent to good
Nodular basal cell	60–90	Excellent to good
Sebaceous hyperplasia	5–10 (spray or probe)	Good to fair
Seborrheic keratoses	10	Excellent to good
Superficial basal cell	60	Excellent to good

*Using intermittent spray, unless otherwise specified.

TABLE 278-3 **Comparison of Freeze Times for Benign and Malignant Lesions and Range of Expected Cosmetic Results***

PREMALIGNANT LESIONS

The actinic keratosis is one of the most common lesions treated by cryosurgery. The specific type of keratosis and its size determine the duration of freeze. A relatively macular lesion with a thin scale may be eradicated by a 5- to 7-second freeze, whereas a thicker hypertrophic lesion may require up to 20 or 30 seconds of freezing (Table 278-2). The comedonal type of actinic keratosis may require at least 20 seconds. Outlining the lesion with a marking pen prior to freezing is helpful in making certain the entire lesion is treated adequately. A cryopattern develops as a keratosis is frozen, and this is useful in determining lesion size. In some patients, prethinning of lesions with emollients (especially glycolic acid compounds) results in lesions that necessitate an even shorter freeze time of 4 to 6 seconds.

A 2- to 4-mm margin of freeze around the lesion should be sufficient. Thermocouple monitoring for determining depth of cold is not necessary when treating benign lesions.

MALIGNANT LESIONS

Sufficient experience has been gained by numerous cryosurgeons who agree that a freeze time of approximately 60 seconds using an intermittent spray is adequate treatment for a malignancy such as a basal cell carcinoma (BCC) or squamous cell carcinoma (SCC), especially a SCC arising from an actinic keratosis. To measure the depth of freeze by thermocouple monitoring requires inserting a needle beneath the tumor. While many experienced cryosurgeons no longer do this, it can be quite advantageous for learning the proper technique.

Technique

The tumor is frozen with an intermittent spray until a zone of approximately 5 mm of frozen tissue is reached around the lesion (Fig. 278-1, Fig. 278-2 and Fig. 278-3). This usually requires about 60 seconds of freezing. If a neoprene or other type of cone is used, this may shorten the freeze time to 45 seconds or less. The halo thaw time will be approximately 60 seconds, and the complete thaw time for the entire lesion is 2 to 5 min. If a thermocouple needle is used, freezing should continue until the monitor registers around –50°C (–58°F). The thaw time to 0°C (32°F) is often around 1 min. For the greatest destruction, a double freeze–thaw cycle is used.

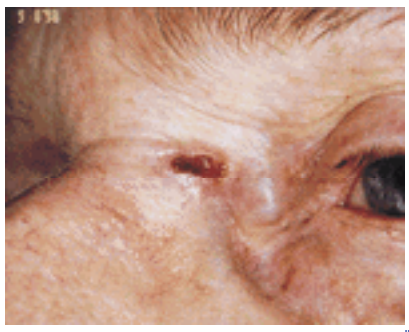

FIGURE 278-1 Basal cell carcinoma on the nasal bridge.

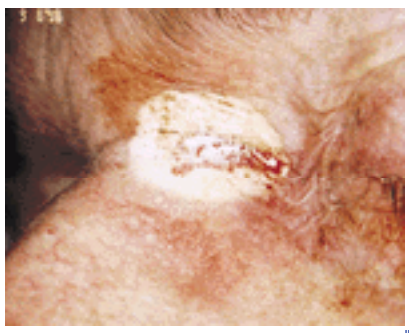

FIGURE 278-2 A double freeze–thaw cycle was used after biopsy confirmation. Freeze time was 1 min for each cycle. Halo around tumor is 5 mm. Halo thaw time was 90 seconds.

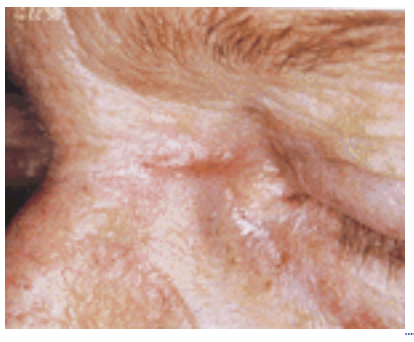

FIGURE 278-3 The site has healed with a linear scar.

Mallon and Dawber [16] found that for facial lesions, a double freeze–thaw cycle yields a higher cure rate; but for superficial basal cell carcinomas on the trunk, a single freeze–thaw cycle is sufficient to yield a 95.5 percent cure rate. Freeze and thaw times should be recorded in the medical record.

Many physicians prefer to debulk the tumor by curettage or razor blade saucerization prior to freezing. [17] This provides an adequate specimen for the pathologist and allows for better judgment in terms of tumor depth and lateral extent of the tumor. Freezing is then performed on the tumor bed. Lesions 3 to 4 cm in size may be divided into 1- to 2-cm portions but may be treated at one visit. More extensive lesions may be treated over several months.

When treating lesions on the ear, the external auditory canal should be protected with a cotton pledget or with one's hand. When treating the nose or eye, protection with a tongue blade or a Jaeger retractor (for the eye) is useful. When proper technique is used, cryosurgery is especially effective in treating lesions overlying cartilage.

Postoperative Management

While simple, the care of the cryosurgical wound requires specific instructions to the patient. Washing the lesion with soap and water once to twice daily is the most useful approach. Although some locations will need a dressing because of the bullous reaction and drainage that freezing can induce, most sites may be left open. These wounds actually seem to heal better this way, because the eschar is not inadvertently removed by adherence to dressings. The cryowound is its own biologic dressing and is wet from its inception (Fig. 278-4). Benign and premalignant lesions heal in 10 days to 2 weeks, although the final eschar separates and comes off at about 1 month postoperatively for most skin cancers. Those on the back and leg, especially if over 1 to 2 cm in diameter, may require 6 weeks to 3 months to heal. If the eschar becomes dry and adherent, it may be removed and the base treated with antibiotic ointment twice daily until healed. If an ulcer is present upon the removal of the eschar, DuoDERM or a similar dressing may be used.

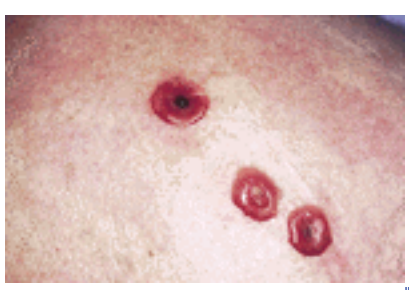

FIGURE 278-4 The bulla resulting from freezing is its own biologic dressing and heals in 10 to 14 days when 10 to 20 seconds of intermittent freeze time is used.

SIDE EFFECTS AND COMPLICATIONS

The expected effects following freezing are edema, vesicles, bullae, weeping, and eschar formation. Periorbital edema may be lessened by the use of systemic glucocorticoids [18] or potent topical glucocorticoids twice daily [19] for 3 to 4 days. Pain following freezing is more likely to occur when lesions on the palms, soles, fingers, toes, scalp, and temple are treated. Rarely are analgesics other than aspirin or acetaminophen required. Bleeding following freezing is uncommon, but should be considered while treating patients who take anticoagulants.

Infection

The incidence of infection following freezing is very low, probably because of destruction of skin flora, maintenance of the basement membrane, and the rapid reepithelialization that occurs after treatment. Patients should be cautioned that if increased heat, redness, or purulent drainage develops, they should return to see the physician promptly.

Abnormal Scarring

The maintenance of a normal dermal fibrous network after freezing allows many wounds to heal with little or no scarring. The most common scar is soft and hypopigmented. Linear hypertrophic scarring may be seen following treatment of cancers on the nose, upper lip, and chest. Ectropion may result following freezing of eyelid carcinoma, but this is rare. Loss of eyelashes is routine after such treatment. Notching of the ala of the nose and helix of the ear is seen when large tumors are treated.

Pigment Alteration

Pigment loss due to sensitivity of the melanocytes, which are destroyed at –4°C (24.8°F), is common after freezing, [20] but when freezing times under 20 to 30 seconds are used, this pigment loss is often temporary. Peripheral hyperpigmentation may be noted especially on the leg and back. Use of topical steroids, glycolic acids, and retinoids as well as hydroquinones may decrease this effect.

Nerve Damage

Damage to nerves is rare following the freezing of benign and premalignant lesions and is also uncommon after freezing malignancies. Digital neuropathy after treating a wart on the finger has been reported. [21] Sensory loss following freezing usually resolves in 6 to 12 months. The sense of touch recovers more quickly than the sensations of pain and cold. [22]

Insufflation of Soft Tissue

Nitrogen gas may escape into perilesional skin when freezing follows a biopsy. Pressure on the crepitant area will result in expulsion of the gas. The use of a cone surrounding the biopsy site can prevent this from occurring.

Alopecia

Freeze times longer than 20 seconds may result in alopecia of the scalp hair, eyebrows, eyelashes, or beard. Alopecia is more common after freezing skin cancer than after treating benign lesions.

Loss of Mucosa

Adherence of probes to mucous membranes can result in loss of mucosa upon removal of the probe. This can be prevented by prechilling the probe or by applying K-Y jelly. If the probe does adhere, it should be allowed to defrost so that it pulls away from the mucosa without tearing it. [17] Pseudotumor recidive and exuberant granulation tissue are occasionally seen.

Reactive Changes

Formation of a pyogenic granuloma after using liquid nitrogen to treat a venous lake on the lip has been reported. Pyogenic granuloma formation has also been noted after freezing basal cell carcinomas and actinic keratoses. [23] Erosive pustular dermatosis of the scalp following cryotherapy for actinic keratosis has been documented, [24] as well as the development of a keratoacanthoma following treatment of prurigo nodularis with cryotherapy. [25]

Cartilage Necrosis

This complication is rare but occurs most frequently on the helix of the ear. Cartilage necrosis is seen most commonly after treating a malignancy because of the deeper cold penetration achieved from longer freeze times. [17]

Syncope

Syncope occurs infrequently but should be anticipated after freezing warts on the digits. A patient who experiences syncope should be cared for with standard supportive measures.

OTHER INDICATIONS FOR CRYOSURGERY

Full-Face Cryosurgical Peels

Full-face cryopeeling was carried out for more than 40 years by using a mixture of carbon dioxide, acetone, and sulfur to create a dry ice sludge that was applied with a gauze ball. Graham first used liquid nitrogen for spraying acne and acne scarring, and performed full-face peeling in lieu of dermabrasion for scarring. [26]

Chiarello used a similar but modified technique called the “cryopeel” for the treatment of sun-damaged skin, actinic keratoses, seborrheic keratoses, lentigines, and wrinkles. [27] He has since combined freezing and “derma sanding” with tumescent anesthesia. With this technique he reports excellent, consistent, and reproducible results with minimal complications in the treatment of rhytids. [28]

Ultrasound

The use of ultrasound in determining the depth and lateral extent of a tumor aids in the decision-making process with regard to the type of procedure to be used for the treatment of a particular cancer. If the tumor has indefinite margins, a procedure such as Mohs surgery should be selected over cryosurgery. The dermatopathologist can aid in this determination by describing the location of the tumor on biopsy, that is, upper, mid, or lower dermis. [17], [29]

Abramovits et al. [30] found ultrasound useful for the accurate placement of thermocouples. They located the thermocouples by using ultrasound and accurately measured their distance from the skin surface. The use of ultrasound significantly benefits the cryosurgeon who uses thermocouples routinely for the treatment of skin malignancies.

Granuloma Annulare

Although cryosurgery has been used for years in the treatment of granuloma annulare, a prospective trial carried out in Germany, in 1993, found that applying liquid nitrogen or nitrous oxide for one freeze–thaw cycle for 10 to 60 seconds produced excellent results. Twenty-five of 31 lesions (80.6 percent) resolved after one treatment. One patient relapsed during a 2-year follow-up. [31]

Lentigines

These common, hyperpigmented macules on the hands and face may be satisfactorily removed by freezing. Pretreating the skin with topical tretinoin, hydroquinone, or glycolic acid helps to thin these lesions prior to freezing and makes the final cosmetic result much better. Approximately 5 to 7 seconds of intermittent freezing will clear a significant portion of the lesions. Cryopeeling also works well on these. [27]

Stern et al. compared laser therapy with cryotherapy and found that freezing worked as well as or better than laser and was more cost-effective in the treatment of lentigines. [10]

Keloids

Freezing may be very effective in some keloids. [26] The variability in size, age, consistency, skin color, and location play a role in deciding which treatment to use. Numerous modifications have been added, such as freezing in conjunction with intralesional steroids with or without prior debulking. The addition of an Epiderm dressing for a few weeks prior to the freezing is helpful. Some have used radiation therapy for treatment prior to freezing. Comparison of intralesional steroid and cryosurgery in acne keloids was carried out by Layton et al. [32] and showed an average of 80 percent improvement in early lesions treated with cryosurgery.

Psoriasis

Although there are few publications attesting to its effectiveness, freezing is used widely by clinicians in treating small and medium-sized plaques of psoriasis. [17], [33]

Nouri [34] reported success in using average freeze times of 12 seconds/cm ^{2}. There was complete resolution of lesions in 5 of 9 subjects. Two others improved substantially and one worsened. Graham [17] has noted Koebnerization in one patient with a brief freeze of only 5 seconds on an elbow. With freeze times of 10 to 15 seconds, this did not occur.

Seborrheic Keratosis

Cryosurgery alone or followed by curettage is an effective form of therapy for this lesion, whose treatment is covered by only a few insurance companies. Some patients experience disabling pruritus but may be helped by using an a-hydroxy body cleanser applied with a polyethylene sponge followed by an a-hydroxy lotion. Castor oil applications are also helpful. Thin lesions are treated with 10 to 15 seconds of freeze. Some very thick lesions may be treated successfully by curettage and cryosurgery. [17]

Prurigo Nodularis

Cryosurgery is one of the treatments of choice for recalcitrant lesions. The C fibers of the nerves are altered by freezing, thereby decreasing pruritus and ameliorating the itch-scratch cycle. [17] Because of differences in lesion size, shape, and thickness, freeze times vary from 15 to 30 seconds. Spray or a contact probe may be used. Topical and oral antipruritic agents and topical steroids help to prevent recurrence. [35]

Myxoid Cyst

There are numerous reports of resolution of myxoid cysts following cryosurgery with one double freeze–thaw cycle. [36] Healing occurs in 2 to 3 weeks with good cosmetic results.

Verruca

The treatment of verruca can be frustrating. [37] Combined treatment of warts with topical salicylic acid and cryotherapy results in an improved cure rate. [38] Pain experienced after the procedure can be minimized by administering aspirin or acetaminophen before freezing. The dipstick method is preferred by some, while many others prefer the spray technique. Kuflik [39] was able to eradicate 97.4 percent of 80 periungual warts with the dipstick technique. Although the spray technique alone will cure some plantar warts, combining spraying with salicylic acid pads and paring will clear more. Failures may respond to bleomycin. [40]

Condylomata Acuminata

Complete cure of these lesions is quite difficult if not impossible despite the use of freezing, surgical excision, laser surgery, and interferon. The use of podofilox or imiquimod on reliable patients enhances resolution of the lesions. The safety of such agents used by pregnant women has not yet been established. [41] Damstra and Van Vloten [42] did a controlled study of 64 patients with small penile and vulvar condylomas. They used a fine needle-spray technique and achieved 92 percent remission rate after 3 months.

Kaposi Sarcoma

Cryosurgery is frequently used to treat Kaposi sarcoma. Tappero et al found treatment using a double freeze–thaw cycle every 3 weeks for three treatments to be effective. [11] Freezing may be combined with vinblastine or other therapies. [11]

Basal Cell Carcinoma

Mallon and Dawber studied the virtues of one versus two freeze–thaw cycles for treatment of basal cell carcinoma (BCC). [16] They treated 84 facial BCCs with a single or double 30-second freeze–thaw cycle. The double freeze–thaw cycle on the face achieved a 95.3 percent cure rate, while the single cycle had a 79.4 percent cure rate. Twenty-nine superficial BCCs on the trunk achieved a 95.5 percent cure rate with the single freeze–thaw cycle. Graham et al. [43] and Torre [44] have used a single freeze–thaw cycle successfully for BCCs 3 mm or less in depth, whether on the trunk or face. The size and depth of the lesions should be defined with reasonable certainty. Kuflik and Gage reported a 5-year cure rate of 99 percent for 628 BCCs ranging from 0.5 to 2 cm in diameter by using a double freeze–thaw cycle. [45]

Over 32 years of performing cryosurgery, Zacarian consistently achieved cure rates around 97.3 percent. [46] He maintained that double freeze–thaw cycles were necessary. Graham [43] compared shave excision or curettage plus cryosurgery with single and double freezes, achieving a higher cure rate with the combination. A double freeze coupled with curettage yielded a 98.4 percent cure rate. Her freeze times are usually 60 seconds or longer, whereas Dawber's were for 30 seconds. [43] This may account for the lower cure rate in his series.

The use of ultrasound for depth determination and placement of a thermocouple needle would probably improve the cure rates in most series. [29], [30] Patient selection is of paramount importance. The cure rate in our series [43] improved over a 30-year period, especially after a Mohs surgeon became available in North Carolina for referral of larger, more difficult tumors. Despite the severe sun damage seen in many of our patients who spend their lives in the sun during the entire year, healing after freezing has been remarkable. Treating tumors with indefinite borders is discouraged unless the treatment is used in a palliative way, as may effectively be done in the nursing home setting.

There is increasing use of cryosurgery in the management of some larger tumors. Biro, [47] Kuflik, [48] Gage, [49] and Goncalves [50] reported on the eradication of large tumors by freezing. Stolar and Turjansky in Argentina have managed many large tumors effectively, and their series supports the effectiveness of this procedure for both therapy and palliation. [51]

Mohs Micrographic Surgery

HISTORY
TECHNIQUE
INDICATIONS
Basal Cell Carcinoma
Squamous Cell Carcinoma
Melanoma
Other Cutaneous Malignancies

REFERENCES

Mohs micrographic surgery (MMS) is a precise method of treating skin cancer that results in the highest cure rate with maximal tissue conservation. Developed by Dr. Frederic E. Mohs, the procedure combines microscopic evaluation of tumor margins (“micro”) with detailed mapping of the tumor orientation (“graphic”). The hallmarks of MMS are tangential excision that allows theoretically 100 percent of the tumor margin to be examined and the surgeon serving a dual role as surgeon and pathologist. Commonly referred to as Mohs surgery, other names have been used to describe the procedure, including chemosurgery, microscopically controlled excision, and microscopically oriented histographic surgery.

HISTORY

In the 1930s Dr. Mohs, a general surgeon at the University of Wisconsin discovered that 20% zinc chloride paste was a good in situ fixative. He applied a thin layer of the preparation to skin cancers under an occlusive dressing for 12 to 24 h. The tissue was then excised, mapped, marked, and color-coded. It was sectioned horizontally so that the epidermis as well as the entire undersurface could be evaluated simultaneously under the microscope. If tumor remained at the excision margins then the fixation process was repeated. Tumor-free wounds were allowed to heal by second intention as the zinc chloride caused tissue sloughing. While the procedure yielded high cure rates, the technique was labor and time intensive and quite uncomfortable for the patient.

Mohs first published “Chemosurgery, microscopically controlled method of skin cancer excision” in 1941. [1] Despite the high cure rates, it was not well accepted within general surgery, but became adopted and advanced by the field of dermatology. To this day, MMS is recognized as a procedure unique to dermatology.

A key advancement in MMS was the change to the fresh tissue technique using frozen-section processing. Mohs had initially used frozen sections only on a few eyelid tumors. It was not, however, until 1970 that Dr. Theodore Tromovitch presented a more widespread use of the fresh tissue technique eliminating the use of zinc chloride paste and the associated disadvantages. Tromovitch and Stegman subsequently published their results of long-term follow-up of patients having basal cell carcinomas (BCCs) treated with cure rates comparable to the previous fixed tissue technique. [2] With a faster turnaround time and lack of tissue slough allowing for same day reconstruction, the fresh-tissue technique was adopted and represents the standard of MMS today. Although the original “chemosurgery” is rarely used today, Mohs' original concepts of tangential excision and the surgeon serving as the pathologist are still an integral part of the technique which carries his name.

TECHNIQUE

The MMS set up requires an appropriately equipped procedure room, well-trained nursing staff, and a laboratory with a histotechnician trained in the specialized MMS tissue processing. The latter cannot be overemphasized as the quality of the microscopic slides and the efficiency in which they are produced are paramount in order to perform MMS at its highest level.

MMS is usually performed on ambulatory patients in an outpatient setting (Fig. 279-1). [3] The tumor is initially identified, marked, and infiltrated with local anesthesia. It is then debulked using a curette, which further delineates the size. The scalpel blade is held at approximately 45 degrees to the skin surface and the tumor is excised 2 to 3 mm beyond the curetted margin, producing a saucer-shaped piece of tissue. Anatomic orientation is carefully maintained. The remaining skin edge, as well as the surface of the removed tissue, is scored to preserve this orientation. The depth of the excision usually encompasses the entire dermis but can vary depending on the depth of the curettage. The wound is bandaged and the patient waits for the processing which usually takes 30 to 45 min.

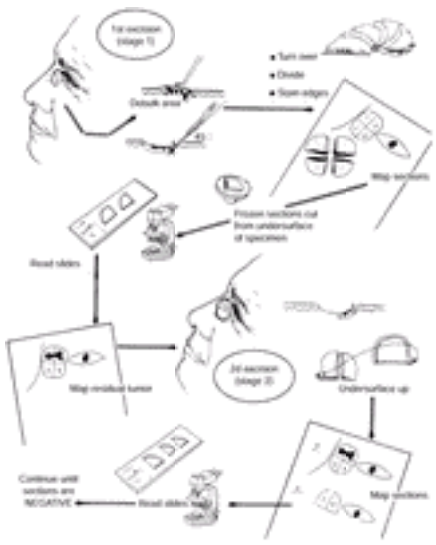

FIGURE 279-1 Schematic of Mohs micrographic surgery technique. See text for detailed explanation.

The tissue is sectioned into smaller pieces along the scored lines, turned over and inked with two to three different colors for precise orientation. An anatomic map is drawn with markings correlating with the scored lines and inked margins. The tissue is then laid flat on a cryostat chuck so that the epidermis and the deepest margin are on one plane (allowing for theoretically 100 percent of the tumor margins to be visualized). The tissue is then frozen, sectioned horizontally, placed on a slide, and stained, usually with hematoxylin and eosin.

A unique aspect of MMS is that the surgeon has a dual role as the pathologist; therefore, the clinicopathologic correlation is precise. This leads to accuracy that is difficult to duplicate when there is a separate surgeon and pathologist. The Mohs surgeon examines the slides microscopically, correlating them with the anatomic map he or she has drawn. If there is persistent tumor on the margin(s), it is marked on the map and the patient is brought back into the procedure room for the second stage. Additional section(s) are again tangentially excised but limited only to the area(s) of persistent tumor. This process continues until the margins are tumor free.

In comparison, with traditional excisions the scalpel blade is placed perpendicular to the skin surface, the tissue is processed in a “bread loaf” fashion and sectioned through the center of the tumor. Less than 1 percent of the tumor margin is visualized. In MMS, the goal is to visualize the outer as well as deep margins, and therefore only the tumor on the margins is represented on the slide. The tumor in the center is not seen unless it extends to the margins.

Since the introduction of the fresh-tissue technique, MMS has been refined to an efficient, highly successful surgery. Reconstructive surgery has become an important and integral aspect of the specialty. The original chemosurgery defects healed by second intention, whereas today's Mohs surgeon also uses side-to-side closures, flaps, and grafts (Fig. 279-2). As a result, advances in reconstructive surgery have been significant in the evolution of MMS.

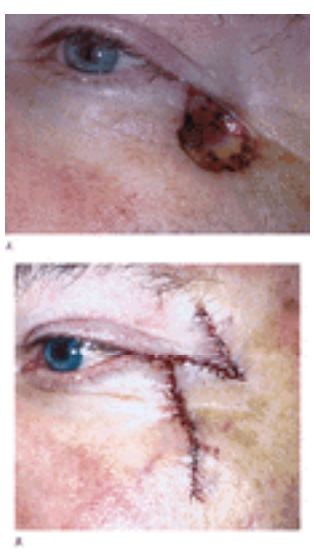

FIGURE 279-2 *A.* Postoperative defect after two stages of MMS. *B.* Reconstruction with rhombic transposition flap.

INDICATIONS

MMS has been used for different types of skin cancers. The overwhelming majority of the cases, however, are BCCs and squamous cell carcinomas (SCCs). MMS is not needed for all skin cancers and should be reserved for those cases that meet specific indications. The American Academy of Dermatology has outlined specific guidelines, which broadly include (1) high risk of local recurrence, (2) areas of tissue preservation, and (3) high risk of metastasis. [4] There are other treatment modalities such as simple excision, electrodessication and curettage, cryosurgery, topical chemotherapy, and irradiation that may be appropriate for other situations. Conversely, MMS should not be employed as the only treatment for some complex cancers. A multidisciplinary approach may be more appropriate for these cases.

Basal Cell Carcinoma

BCC is the most common skin cancer in the United States. Although the potential for metastasis is very low, it can cause significant local destruction. Four important factors that determine the successful treatment of primary BCCs are histologic characteristics, location, size, and clinical nature (Fig. 279-3). Histology ranges from less-aggressive patterns,

such as nodular and superficial, to more-aggressive patterns, such as infiltrative, micronodular, and sclerosing (morpheaform). Perineural involvement also constitutes an aggressive pattern. The aggressive subtypes typically are more ill-defined clinically with less predictable radial growth patterns leading to a greater subclinical extension of tumor. When viewed in the traditional “bread loaf” fashion, these areas of tumor extension can be missed leading to a false negative result. [5] MMS is ideally suited for visualizing these extensions as 100 percent of the margins are inspected.

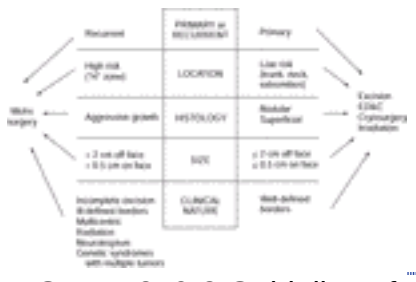

FIGURE 279-3 Guidelines for consideration for Mohs micrographic surgery. The *right* side of the figure represents less-aggressive presentations of BCCs that can be treated with standard treatment regimens. The *left* side of the figure represents more-aggressive presentations for which Mohs micrographic surgery should be considered.

BCCs located on the ear, nose, eyelid, and lip are part of the “H” zone where MMS is indicated because of the high recurrence rate (Fig. 279-4). [6] In these locations, tumors tend to be more destructive and invasive and are in close proximity to vital structures. Tumors spread along perichondrium, periosteum, perineurium and fascial planes. They also spread along embryonic fusion planes to unexpected depths in areas such as the nasal ala/nasolabial fold junction, preauricular sulcus, and columella, as well as penetrating deeply in areas like the medial canthus where there is minimal deep structural support. Furthermore, MMS is important in maximally preserving normal tissue in these cosmetically and functionally sensitive regions.

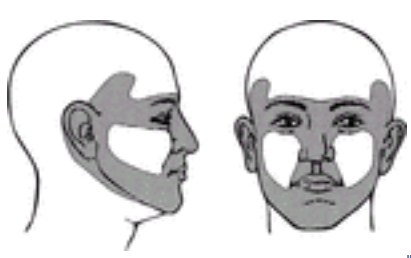

FIGURE 279-4 “H” zone on face. Shaded regions represent high-risk areas where Mohs micrographic surgery is indicated. These areas typically have higher recurrence rates from standard treatment modalities.

Size and clinical nature are also important considerations in determining the appropriate treatment. BCCs greater than 2 cm are more likely to recur or be incompletely excised. Ill-defined clinical borders also make simple excisions more difficult. [7] Overall, MMS has a 99 percent cure rate for primary BCCs, compared with 91.3 percent for all other treatment modalities previously mentioned. [8]

Beyond primary BCCs, MMS is even more significant in the treatment of incompletely excised and recurrent BCCs. MMS is indicated irrespective of histologic subtypes or location as the other treatment modalities have already failed. Incompletely excised BCCs recur between 12 and 41 percent of the time on the face if left untreated. [9] These can be readily treated with MMS by narrow margin excision around the previous scar. This results in precise localization of the persistent tumor.

Recurrent BCCs, by their very nature, are more aggressive and difficult to treat. Clinically, they can be subtle and therefore the diagnosis is usually delayed. By the time the recurrence is noted on the skin surface, there may be large tumor burden buried in the scar. For these recurrences, MMS yields the best cure rate of 94.4 percent, compared to all other modalities, which average only 80 percent. [10]

Squamous Cell Carcinoma

SCC is the second most common skin cancer in the United States. Although SCC and BCC are treated similarly, it would be dangerous to think that they are biologically the same. SCC metastasizes at a much higher rate and accordingly has a higher mortality rate. The indications for MMS are similar to BCC, but additionally involves identifying and reducing the risk for metastasis. As with BCC, histologic pattern is important in determining the potential aggressiveness. Tumors that are poorly differentiated and/or have perineural involvement have a worse prognosis. Locations such as the ear, penis, lip, and digits, lesions greater than 2 cm, deeper lesions, and those occurring in scars carry a higher risk of metastasis and local recurrence. Five-year cure rate for primary SCC of the skin is 96.9 percent with MMS versus 92.1 percent for all other modalities combined (irradiation, curettage and electrodessication, and excision). The difference is greater for primary SCCs of the lip (97.7 percent versus 89.5 percent) and ear (94.7 percent versus 81.3 percent). For recurrent tumors, it is 90 percent with MMS versus 77.7 percent with excision. [11] Immunosuppressed transplant patients have a disproportionate number of SCCs and also carry a greater risk of more aggressive disease.

MMS is an integral part of SCC management and can be especially valuable in special situations like tracking perineural involvement. It is important to note, however, that radiation therapy and surgical lymph node assessment may also be needed for proper management of more aggressive disease.

Melanoma

MMS for treatment of melanoma is controversial. Two issues have given rise to this controversy: interpretation of melanocytes by frozen section and determination of proper excision margins for melanoma. MMS is most useful for lentigo maligna type melanoma in situ and melanoma on the head and neck region, which are notorious for significant subclinical spread that often extends beyond the standard recommended excision margins. Although there have been reports of successful treatment of melanoma with MMS, the variability in the frozen section quality and interpretation places a limit on consistency and accuracy. The method that is commonly employed at many centers is a modified MMS in which a 2- to 3-mm margin is excised beyond the final frozen section margin and submitted for permanent paraffin embedded sections. These sections are processed in the MMS style so that 100 percent of the peripheral margins are visualized. The obvious disadvantage of this method is significant increase in the turnaround time delaying the final closure of the wound. [12], [13]

A newer method that potentially improves both the speed and accuracy is the use of immunohistochemistry stains. S-100 and HMB-45 have traditionally been used to mark melanocytes with variable sensitivity and specificity. Melan-A is a newer addition with better consistency and easier interpretation. [14] Although the turnaround time is shorter than with paraffin sections, it is still more labor intensive than traditional hematoxylin and eosin (H&E)-based frozen sections. Long-term studies determining efficacy are still needed.

Other Cutaneous Malignancies

MMS has been used on many different cutaneous malignancies. The consensus indications outlined by the American Academy of Dermatology include verrucous carcinoma, keratoacanthoma, dermatofibrosarcoma protuberans, atypical fibroxanthoma, malignant fibrous histiocytoma, leiomyosarcoma, adenocystic carcinoma of the skin, sebaceous carcinoma, extramammary Paget's disease, erythroplasia of Queyrat, oral and central facial paranasal sinus neoplasms, microcystic adnexal carcinoma, apocrine carcinoma of the skin, certain aggressive locally recurrent benign tumors, and Merkel cell carcinoma. All cutaneous malignancies that exhibit a contiguous pattern of radial growth and that can be interpreted on frozen section should theoretically be amenable to MMS.

Taken together, MMS is cost-effective although it should be reserved for those cases that meet appropriate indications. [15] It is a highly technical field that requires meticulous attention to detail and considerable training and experience in order to achieve the expected high cure rates.

The main objectives of nail surgery are to aid diagnosis by biopsy, to treat infection, to alleviate pain, to remove local tumors, and to ensure the best cosmetic results in acquired and/or hereditary and congenital abnormalities. Many of the problems that require nail surgery are discussed in Chap. 72; nail biology is also described in Chap. 72.

An exact illustration of the operation is helpful to give the patient insight into the procedure and its expected outcome. A thorough discussion regarding postoperative morbidity is essential. Preoperative photographs as well as any taken during surgery may be useful medicolegally. A careful history may reveal systemic disease such as diabetes mellitus, blood dyscrasias, vascular disease, collagen disease (scleroderma), allergy, chronic pulmonary disease and immune impairment. Any of these may at times be contraindications to surgery, or may alter the technique to be performed. Surgery of the nail is not recommended in high-risk patients. A history of concomitant administration of drugs may be relevant because these may affect anesthesia (monoamine oxidase inhibitors or phenothiazines), prolong bleeding (aspirin and anticoagulants), delay healing (glucocorticoids) or have toxic effects on the nail apparatus (retinoids). There may be a history of allergy to lidocaine or mepivacaine (Carbocaine) or parabens (contained in both as a preservative). A knowledge of previous antitetanus immunization is important because tetanus toxoid may be advisable in association with surgery in the toenail or in traumatic lesions that come into contact with soil.

A magnifying lens may be useful to observe the color, surface, and structure of the periungual tissue and to compare the unaffected contralateral digit. It may be necessary to probe in order to localize pain, to obtain an x-ray to rule out underlying bone involvement, or to ask for sonography and MRI when a tumor is suspected.

The basic requirements for nail surgery include a detailed knowledge of the anatomy and physiology of the nail apparatus. Full aseptic conditions, regional block anesthesia, and local hemostasis are indispensable.

ANATOMY AND PHYSIOLOGY

The nail plate (NP) is the permanent product of the nail matrix. Its normal appearance and growth depend on the integrity of several components; the surrounding tissues, or perionychium, and the bony phalanx all form parts of the nail apparatus (Fig. 280-1). The nail is a semihard horny plate covering the dorsal aspect of the tip of the digit. The nail is inserted proximally in an invagination that is practically parallel to the upper surface of the skin and laterally in the lateral nail grooves. This pocket-like invagination has a roof, the proximal nail fold, and a floor, the matrix from which the nail is derived. The matrix extends approximately 6 mm under the proximal nail fold and its distal portion is only visible as the white semicircular lunula. The general shape of the matrix is a crescent, concave in its posteroinferior portion. The lateral horns of this crescent are more developed in the great toe and located at the coronal plane of the bone. The ventral aspect of the proximal nail fold encompasses both a lower portion, continuing the matrix, and an upper portion (roughly

three quarters of its length), called the eponychium (Fig. 280-2A). The germinal matrix forms the bulk of the NP. The proximal element forms the superficial third of the NP, whereas the distal element provides its inferior two-thirds (Fig. 280-2B).

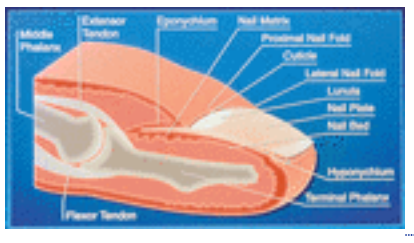

FIGURE 280-1 Sagittal section of the nail unit.

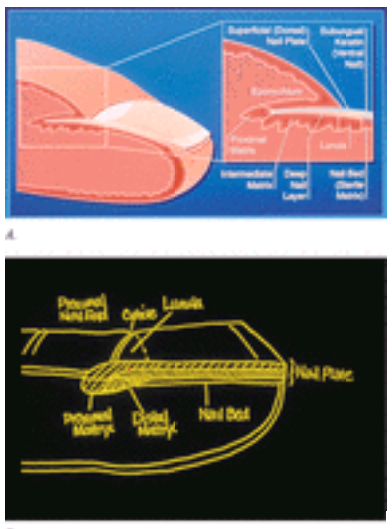

FIGURE 280-2 *A.* Origin of the nail layers. *B.* Origin of the nail plate itself.

The ventral surface of the proximal nail fold adheres closely to the nail for a short distance and forms a gradually desquamating tissue, the cuticle, made of the stratum corneum of both the dorsal and the ventral sides of the proximal nail fold. The cuticle seals and protects the “ungual cul-de-sac.”

The nail plate is bordered by the proximal nail fold, which is continuous with the similarly structured lateral nail fold on each side. The nail bed extends from the lunula to the hyponychium. It presents with parallel, longitudinal rete ridges.

In contrast to the matrix, the nail bed has a firm attachment to the nail plate. Colorless, but translucent, the highly vascular connective tissue, containing glomus organs, transmits a pink color through the nail. Avulsion of the overlying nail plate denudes the nail bed.

Distally, adjacent to the nail bed, the hyponychium, an extension of the volar epidermis under the nail plate, marks the point at which the nail separates from the underlying tissue. The distal nail groove, which is convex anteriorly, separates the hyponychium from the finger tip.

The circulation of the nail apparatus is supplied by two digital arteries that course along the digits and give off branches to the distal and proximal arches. The sensory nerves to the distal phalanx of the three middle fingers are derived from fine, oblique, dorsal branches of the volar collateral nerves. Longitudinal branches of the dorsal collateral nerves supply the terminal phalanx of the fifth digit and also the thumb.

Among its multiple functions, the nail provides counterpressure to the pulp that is essential to the tactile sensation involving the fingers and to the prevention of the hypertrophy of the nail bed. With the loss of the nail plate, the overgrowth of the anterior nail bed forms a distal wall ahead of the advancing, regenerating new nail particularly on the great toe. Histological examination reveals that the nail matrix and nail bed are devoid of a granular layer, in contrast to the upper ventral aspect of the proximal nail fold and the hyponychium.

INSTRUMENTS AND DRAPING

The instruments used in nail surgery are, in general, the same as those used in cutaneous surgery with the addition of nail elevators (dental spatula, Freer septum elevator), single- or double-pronged skin hooks (flexible retractors), double-action nail splitter (bone rongeur), clippers, nail-splitting scissors, English nail splitter, pointed scissors (Gradle scissors), curved iris scissors, small-nosed mosquito hemostats, disposable biopsy punches (2, 3, 3.5, and 4 mm), Penrose drains, Luer-Lok syringe, and 30-gauge needles.

Draping is accomplished with a sterile glove on the involved hand. The tip of the glove is cut off from the finger to be operated on; the open finger residue is then rolled back down the digit. This exsanguinates the digit and provides a tourniquet when it reaches the proximal part of the finger. For toenail surgery, the foot is draped in the usual aseptic manner with sterile towels secured by towel clamps.

ANESTHESIA

Local anesthesia should be administered while the patient is reclining or in a supine position. Lidocaine is widely used because the incidence of allergy to this agent is very low. As the use of epinephrine is still debatable, it is preferable to use 2% lidocaine alone; a tourniquet can provide prolonged hemostasis when a bloodless operative field is required. It has been claimed that using tepid lidocaine minimizes the burning sensation associated with its administration; one part 7.5% bicarbonate with nine parts lidocaine has also been advocated for the same purpose. One should allow 5 to 10 min for the anesthesia to take effect.

Anesthetics are administered via a 30-gauge needle on a Luer-Loc syringe using either a proximal digital block or a distal digital block (wing block). Other techniques, such as median distal anesthesia or transthecal block, have not replaced the classical routes of anesthesia. Although emergencies related to minor surgery occur rarely, the ready availability of resuscitative equipment and expertise are essential.

Proximal Digital Block (Fig. 280-3)

FIGURE 280-3 Proximal digital block.

The proximal digital block procedure is less painful than the distal block but the anesthesia takes 5 to 10 min to become established. The hand is laid down flat, with the fingers spread, in order to inject 1 to 2 mL of anesthetic by a dorsal injection, with a thin needle inserted and directed tangentially to the sides of the bony phalanx at the base of the finger involved and as far as the lateral side of the flexor tendon. Avoid a tourniquet effect, which may inadvertently be produced by injecting more than 5 mL of anesthetic. Verify the absence of blood reflux in the syringe before the injection if using a nondental syringe. When the operation is strictly localized in a lateral region, a block limited to the ipsilateral nerves to the lesion suffices, as in the case of a partial distolateral nail avulsion.

Distal Digital Block (Fig. 280-4)

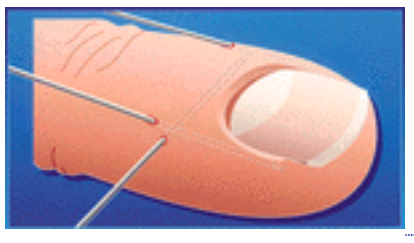

FIGURE 280-4 Distal digital block.

This procedure is more painful than the proximal block, but immediately effective. However, it is absolutely contraindicated when handling bacterial infection in the region. The latter requires wrist block or general anesthesia.

To perform a distal digital block, the needle is inserted just behind the junction of the proximal nail fold and a lateral nail fold, injecting a few tenths of a milliliter of anesthetic, which whitens the region. The injection is continued by aiming the needle toward the pad. One then returns to the initial area in order to inject the proximal fold transversely, then, at its junction with the lateral fold on the opposite side, one proceeds as described above. The anesthesia is almost immediate and when done correctly, it rarely has to be extended to the distal area of the finger.

Median distal administration is relatively simple and quick (Fig. 280-5). The needle is introduced at a 30-degree angle into the middle of the proximal nail fold and advanced distally into the underlying matrix. Anesthetic is injected slowly as the needle first pierces the nail plate, then the matrix, and, finally, the adjacent nail bed. The nail plate is soft and offers little resistance. Blanching confirms the delivery of anesthetic to the nail matrix and bed. Pain is brief and anesthesia nearly instantaneous. This method is suitable for most procedures performed on the proximal half of the nail unit; it is not suitable for matricectomy or complete nail avulsion.

FIGURE 280-5 Median distal block.

Transthecal Block

The flexor tendon sheath may be used as an avenue for introducing anesthetic to the core of the digit. Through centrifugal anesthetic diffusion all four digital nerves are anesthetized rapidly. This technique involves palmar percutaneous injection of 2 mL of lidocaine into the potential space of the flexor tendon sheath at the level of the palmar flexion crease with a 3-mL syringe and a 25-gauge hypodermic needle.

Wrist Block

There are several instances when it is useful to have anesthesia of more than one digit at the same time. A wrist block may be appropriate in the surgical treatment of numerous warts and the infiltration of more than one finger with triamcinolone in the treatment of nail unit psoriasis. This should be undertaken with the guidance of an experienced clinician.

TOURNIQUETS

For brief intraoperative hemostasis (nail avulsion, punch biopsy of the nail bed, for instance), squeezing the sides of the digits is effective. If a prolonged bloodless field is required, a Penrose drain may be placed around the base of the digit and used as a tourniquet secured with a hemostat. It is preferable not to leave it on for more than 15 to 20 min; the tourniquet application can be interrupted for a few minutes during longer procedures.

To complement anesthesia and facilitate a bloodless field, an “exsanguinating” tourniquet is recommended. [1] A wide Penrose drain is wound tightly in loops that overlap in a distal to proximal fashion, leaving an exposed loose end distally (Fig. 280-6). This “milks” the blood from the digit. The loose end is then grasped and unwound, again working distal to proximal until the nail unit is exposed with the final proximal loop.

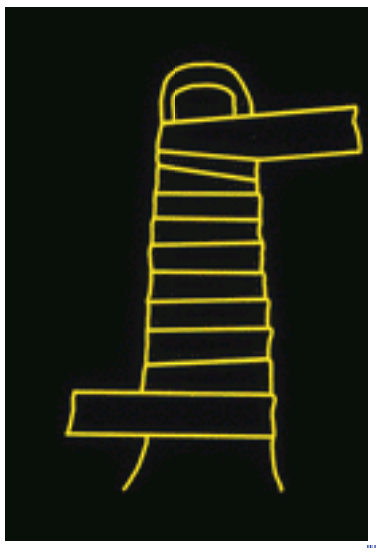

FIGURE 280-6 Exsanguinating tourniquet.

DRESSING AND POSTOPERATIVE CARE

At the end of the operation, the digit is either cleansed with sterile 10% hydrogen peroxide solution and sprayed with a colorless disinfectant, or with an antiseptic with hemolytic action. The nail area is then covered with an antiseptic or antibiotic ointment on gauze or pads. Dressing must be done in a way that takes oozing, pain and sensitivity into account. A bulky dressing gives a cushion against local trauma.

Dressings should be done every other day, or daily if there is infection. Several layers of sterile gauze should be kept in place by Micropore (2.5 cm) tape placed first on the dorsal, then on the ventral aspects of the finger or toe, and lastly on the lateral edges in a U-shape (never make a circular dressing in the first week). Finally, an X-span tube dressing or Surgitube will give the patient more freedom to use the hand. During the first 48 h, the arm must be kept in a sling.

Stitches are removed after 7 to 12 days.

When treating the feet, daily chlorhexidine baths precede the care described above.

For all operations involving the toes, the patient should wear an appropriate shoe or sandal, after the dressing has been applied. The patient should be recumbent for 24 to 48 h with the foot elevated to 30 degrees.

POSTOPERATIVE COMPLICATIONS

Bleeding

Bleeding is seen after the tourniquet is removed but can be stopped by compressing the lateral edges of the distal inter-phalangeal joint. In cases of persistent bleeding, 35% aluminium chloride solution or a cellulose application (Gelfoam) should be applied.

Pain

Pain threshold varies from patient to patient. Postoperative pain can be almost nonexistent if, in the absence of infection, the operation is followed by a periungual injection of 0.6 mL 0.5% bupivacaine with 0.4 mL of 4 mg/mL dexamethasone. While the dressing is put in place, the patient must be told what precautions to take. A supply of moderately potent oral analgesics will help the patients to feel in control of their pain, even if they choose not to take the tablets. Sometimes postoperative pain may be severe and it is alleviated by elevating the extremity as much as possible for two days. Pulsating pain beginning after 36 to 48 h may indicate an infection that should be treated according to the results of bacterial culture of the organism. Any bulky dressing, blood-stained after 24 h, should be changed.

Infection

Prophylactic antibiotic treatment is mandatory for patients with valvular heart disease, including a prosthetic valve. Peripheral vascular disease and childhood (when the nail matrix is extremely fragile and behavior less sanitary) are further indications. If there are ragged surfaces to the nail, making thorough preoperative cleaning difficult, antibiotics may prevent wound infection.

Postoperative infection may be caused by preoperative colonization or infection. Preoperative swabs will indicate the best choice of drug after initial coverage with a broad spectrum antibiotic.

Attention to detail is important. Carelessness may result in serious infectious complications in the soft tissue and occasionally bone. Routine or preoperative nail cleansing softens the nail plate and keeps contamination to a minimum.

Misaligned Nail

Misaligned nail may result from a lateral longitudinal nail biopsy especially if the routine 3-mm width is exceeded.

Relapse

Relapse will depend on the nature of the lesion treated. Warts, ingrown nails, and myxoid cysts can be difficult to eradicate.

Residual Dystrophy

Residual dystrophies are not unusual when surgery involves the proximal area of the matrix.

Unpredictable Complications

Implantation epidermoid cysts can occur in operation scars; malalignment of the nail may occur after lateral longitudinal biopsy; reflex sympathetic dystrophy, although exceptional, following nail biopsy, has been reported.

NAIL AVULSION

The removal of the nail plate can be carried out using distal or proximal approaches. In both techniques, inserting the blunt instrument back and forth between the horny layer of the proximal nail fold and the nail plate, loosens the proximal nail fold adherence.

Distal Approach (Fig. 280-7A)

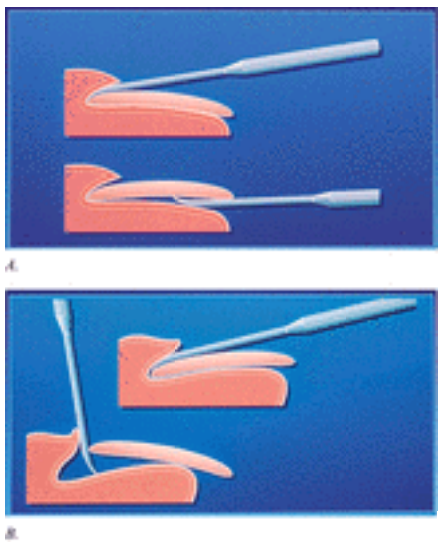

FIGURE 280-7 *A.* Distal nail avulsion. *B.* Proximal nail avulsion.

In the more commonly used distal approach, a Freer septum elevator or a dental spatula is inserted between the nail plate and nail bed. The nail is separated from its nail bed attachment using proximal force applied in anterior–posterior movements so as not to injure the longitudinal ridges of the nail bed. The detachment is completed by firmly pushing the instrument into the posterolateral corners of the nail plate. Then, one of the lateral edges is grasped with a sturdy hemostat, and extracted with an upwards and circular movement to accomplish the removal of the nail plate.

Proximal Approach (Fig. 280-7B)

The proximal approach for nail avulsion is advisable when the subungual distal area adheres strongly to the nail plate and where the hyponychium may be injured by the subungual introduction of the spatula. The proximal nail fold is freed as described above. The spatula is then used to reflect the proximal nail fold, and is delicately inserted under the base of the nail plate where adherence is normally weak. The instrument is advanced distally following the natural cleavage plane, and this operation is repeated on the entire width of the subungual region. After the last attachments are freed, the nail plate is easily pulled out.

Total surgical removal however should be discouraged; the distal nail bed may shrink and become dislocated dorsally. In addition, the loss of counterpressure produced by the removal of the nail plate allows expansion of the distal soft tissue and the distal edge of the regrowing nail then embeds itself. In the management of high-risk patients, nonsurgical removal of the NP should be considered when necessary. This can be affected by the use of 40% urea paste applied directly to the nail after protecting the surrounding skin. Urea acts on the bond between nail keratin and diseased NP, sparing only the normal nail tissue.

Partial Nail Avulsion

The problems that can arise following total nail avulsion may be overcome by partially avulsing the nail. Partial distal avulsion only requires separation of the nail from the distal nail bed. This procedure can be performed under local anesthesia in selected patients, when the fungal infection is of a limited extent. An affected portion of the nail plate may be removed in one session, even when the disease has reached the deeper regions of the subungual tissue beneath the proximal nail fold. Commonly, an English anvil nail splitter or a double-action bone rongeur is used for this procedure.

Partial surgical section of the lateral and/or medial segment of the nail plate may be sufficient for the treatment of distal lateral subungual onychomycosis. Enough normal nail is left to counteract the upward forces exerted on the distal soft tissue when walking and this will prevent the appearance of a distal nail wall.

In proximal subungual onychomycosis, removal of the nonadherent base of the nail plate, cut transversely, leaves the distal portion of the nail in place (Fig. 280-8), which decreases discomfort. Similarly, an acute paronychia that does not respond to appropriate antibiotics within 48 h should be treated surgically by removing the base of the nail plate.

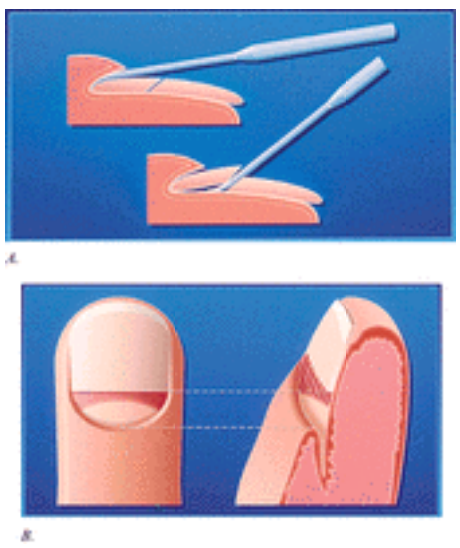

FIGURE 280-8 *A* and *B*. Technique of removal of the base of the nail plate.

Where *Candida* infection or, more rarely, dermatophyte infection result in onycholysis, the detached portion of the nail plate should be thoroughly clipped away. This facilitates the daily application of a topical antifungal drug until nail regrowth is complete. *Candida* lateral nail edge involvement associated with paronychia should be surgically sectioned and the affected nail keratin removed. Recalcitrant *Candida* paronychia with secondary nail plate invasion may be treated by surgical excision of a crescent of thickened nail fold followed by partial or total nail avulsion.

In any type of surgically treated onychomycosis, the avulsed nail segment must always include a margin of normal nail.

SURGICAL APPROACHES TO THE DIFFERENT TISSUES OF THE NAIL APPARATUS

Surgery of the Nail Matrix

When surgery involves the nail matrix, there are four primary approaches, including a reduction in its width or its length for removal of tumors, for instance, by using cold steel procedure or a 2- to 3-mm punch biopsy. In contrast to the three previously discussed procedures, complete matricectomy, that is, ablation of the nail-forming tissue, is rarely performed as the nail is permanently lost.

After reduction of the width, one is left with a narrower nail and after reduction of the length, with a diminution in the thickness of the nail. Reduction of the matrix width is a useful and/or necessary procedure in six major circumstances:

(1) lateral-longitudinal biopsy;
(2) lateral nail splitting;
(3) benign or malignant tumor in the lateral third of the nail apparatus;
(4) longitudinal melanonychia in lateral location;
(5) ingrown nail; and
(6) racquet nail.

Reduction of the matrix length has limited indications: crescent or transverse ellipse biopsy, tumors equal to or greater than 3 mm in width, and thick nails in dystrophic congenital and/or hereditary disorders.

BIOPSY [2] Biopsy of the nail matrix is performed to obtain the histopathology of any lesions or to clarify dubious clinical diagnosis. A 3-mm punch biopsy may be performed through the nail plate into the matrix. Three millimeters is the maximum size that does not produce serious dystrophy except when it is performed in the most proximal portion of the nail matrix. When a punch biopsy is used for longitudinal *melanonychia* of less than 3 mm in width, the circumferential incision is made around the origin of the band, through the NP (Fig. 280-9). This may be distal enough to be reached by pushing back the cuticle, but if it is more proximal, the proximal nail fold (PNF) may have to be reflected using a posterolateral incision. The next step consists of removing the proximal third of the nail plate, but leaving the cylinder of tissue containing the origin of the longitudinal melanonychia still in place. This technique enables the surgeon to inspect the surrounding nail matrix and bed with a magnifying lens to determine whether pigment extends around the punch incision and to facilitate the removal of the biopsied cylinder of tissue with a Gradle scissors.

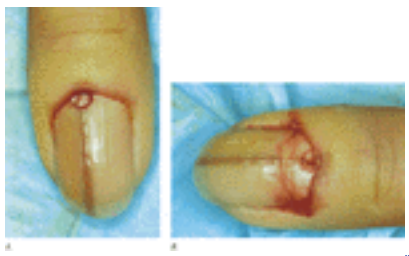

FIGURE 280-9 *A.* Punch biopsy for longitudinal melanonychia of less 3 mm in width. *B.* Removal of the base of the nail plate allowing easy removal of the biopsied cylinder of matrix tissue and pigment left distally.

For lateral longitudinal biopsy (Fig. 280-10), an elliptical incision may be made on either side of the nail plate and proximal nail fold. For the most part, the incisions parallel the lateral edge of the nail plate. Beginning in the lateral nail groove, the incisions should include a 3- to 4-mm nail segment reaching to the bone. This ensures that a full-thickness fragment of the matrix with its lateral horn is obtained. Slightly curved iris scissors are useful for separating the tissue from the bone. Starting at the tip of the digit, one proceeds proximally while maintaining contact with the bony phalanx. Lateral longitudinal biopsy is the advised procedure when longitudinal melanonychia [3] is located in the lateral part of the nail plate.

FIGURE 280-10 Lateral longitudinal biopsy for longitudinal melanonychia located within the lateral third of the nail plate.

For transverse biopsy (Fig. 280-11), two small oblique incisions are made on each side of the PNF; the fold is then reflected in order to expose the matrix area. The proximal third of the nail plate is avulsed. Then, the lesion is removed by an elliptical or a crescent-shaped wedge of tissue with the convex portion of the crescent paralleling the anterior border of the lunula. When longitudinal melanonychia lies within the midportion of the nail plate, the potential for postoperative dystrophy is great and selection of the optimal biopsy method is difficult. It is important to establish preoperatively the matrix origin (proximal or distal) of longitudinal melanonychia because the more proximal the origin, the greater the risk of

nail dystrophy. [3] The origin of pigmentation may be determined by microscopic examination of Fontana-Masson stained clippings from the free edge of the nail.

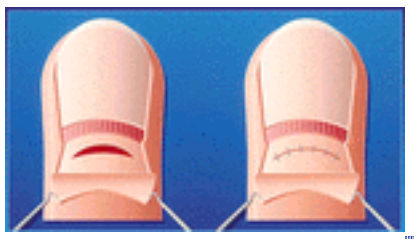

FIGURE 280-11 Transverse biopsy of the nail matrix.

For bands between 3 and 6 mm wide that involve the distal two-thirds of the matrix, a transverse elliptical excision is indicated. Although the potential for postoperative dystrophy is significant, an effort should be made, depending on the clinical circumstances, to completely excise the origin of the band, not only to prevent postoperative recurrence of longitudinal melanonychia, but also to ensure that representative tissue is submitted for study. Because the proximal matrix remains intact, a thinned nail plate will regenerate postoperatively. Tangential matrix biopsy for longitudinal melanonychia is also effective. The scalpel is held parallel to the matrix surface and the entire lesion is removed by cutting horizontally. This leaves a wound area about 1 mm deep.

SURGERY OF SPLIT-NAIL DEFORMITY [4] The common causes of split-nail deformity include trauma, operations, lichen planus, and tumors. Split-nail deformity may occur in either the lateral or the median region. The appropriate surgical technique varies correspondingly. If the split is located within the lateral third of either portion of the nail, especially when it is close to its lateral margin, the best method is the technique recommended for the lateral longitudinal nail biopsy, that is, the removal of the lateral portion of the nail with the defect. If the split is located in the middle region of the nail (Fig. 280-12) and involves its whole length, the PNF, carefully freed from the underlying nail plate, is obliquely incised at both sides and reflected to expose the whole matrix area. The nail plate bordering the split is cautiously cut as a rectangular block about 1 mm wider than the scar that has to be excised. The nail bed and matrix of the defective tissue are dissected from the bone to allow an exact approximation of the remaining bed and matrix, which are sutured with 6–0 monofilament resorbable sutures. To prevent the sutures tearing the tissue, 3–0 sutures are put through the nail plate. When these threads are knotted firmly, the matrix and nail bed are further approximated, relaxing the 6–0 sutures.

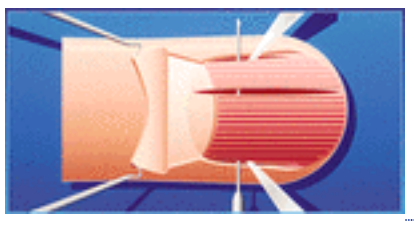

FIGURE 280-12 Treatment of “split nail” in the middle region of the nail plate.

If the scar is too wide to allow primary closure of the defect, relaxing longitudinal incisions along the lateral nail grooves down to the bone usually permit suturing. An alternative approach is the formation of Schernberg's nail bed–matrix flap with an L-shaped incision of the lateral aspect of the finger. The secondary defect below the distal lateral nail fold heals readily by secondary intention.

RACQUET NAIL In this condition, which is caused by an abnormally short and broad terminal bony phalanx, the nail is very short and wide; the lateral nail folds are usually narrow or lacking. Racquet nail usually affects the thumb and is inherited as an autosomal dominant trait. Treatment of racquet nail is aimed at narrowing the soft tissues of the terminal phalanx to about the normal length-to-breadth ratio by using the technique described for lateral longitudinal nail biopsy. This is performed on both sides of the thumb nail. The lateral soft aspects of the distal phalanx are dissected from the bone, and back-stitches are used to create lateral nail folds. The needle is run into the lateral aspect about 2 to 3 mm volar to the plane of the nail bed–bone interface, through the nail bed and plate, and back again through the lateral thumb skin, which, upon knotting, will be elevated, thus forming a lateral nail wall. Sulcus epithelium develops secondarily.

THINNING OF A HYPERPLASTIC NAIL As the thickness of the nail is proportional to the length of the matrix we remove one-third of the distal matrix. This is achieved by two parallel, transverse incisions; one located a third of the way along the distal matrix, and the second at the level of the distal border of the lunula.

NAIL ABLATION AND ISOLATED MATRICECTOMY Nail ablation means the definitive removal of the entire nail organ and matricectomy, the complete extirpation of the nail matrix, resulting in permanent nail loss. The principle of nail ablation is the complete removal of the nail unit with hyponychium, nail bed, matrix, lateral, and proximal nail folds. Except for malignant tumors of the nail apparatus, nail ablation is rarely indicated. It may be necessary in an excessively painful nail treated several times in vain, but this should be an exception. Scalpel excision is strongly advocated whenever the surgical specimen needs a histopathologic examination. If periungual pigmentation is associated with longitudinal melanonychia or if the latter is wider than 6 mm or if the full thickness of the nail is pigmented, a large portion of the matrix would necessarily be involved. Under these circumstances, the underlying disease process in unlikely to be benign. The entire portion of the involved nail apparatus has to be excised en bloc. The nail plate may be left in place as a guiding structure or may be avulsed prior to nail ablation; a sterile staining solution such as methylene blue may be painted into the matrix space and then dried. The matrix surface will then be stained, remaining clearly visible throughout the surgical procedure and helping the surgeon to dissect the matrix horns as well as the lateral and proximal nail grooves, which are often not completely extirpated, giving rise to nail spicules. An incision is carried down to the bone, around the tip of the digit 3 to 5 mm below the hyponychium, along both lateral aspects of the terminal phalanx until the distal dorsal crease of the distal interphalangeal joint, and across the dorsal aspect of the distal phalanx at least 3 mm proximal to the beginning of the matrix. The latter may be made visible by pressing on the free border of the nail plate, which makes a light transverse furrow appear at the base of the proximal nail fold or along the distal joint crease. The nail unit is then dissected from the bone. This is easier using blunt-tipped scissors than a scalpel, especially at the beginning when the nail bed has to be separated from the dorsal tuft of the tip of the terminal phalangeal bone. The nail bed is then removed, with the periosteum, to the base of the phalanx. Particular attention has to be paid to the extensor tendon insertion; this can be severed if a pointed scalpel is used, but this risk is minimized with blunt-tipped curved scissors. The dissection is then directed to the lateral matrix horns; this is easy on fingers and toes but it may require the dissection of

the entire dorsal distal half of the first toe, particularly in patients with pincer nails or ingrown nails. Nail ablation cuts the arteries feeding the nail organ. These arteries should be ligated or electrocoagulated because they are visible, even under regional ischaemia. The defect from nail ablation may be covered with a free graft (split-thickness, full-thickness, reversed dermal graft), which usually takes on the bone in this particular location. A cross-finger flap is a very useful alternative for a free graft; the use of the skin from the intermediate phalanx of a neighboring finger is more convenient for the patient than skin from the thenar area of the palm. If only permanent nail plate removal is necessary, the procedure is less extensive. The proximal third of the nail is avulsed and the proximal nail fold is incised on both sides to allow this fold to be reflected. An incision is made from the nail bed distal and parallel to the lunula border to the lateral aspects of both lateral nail grooves, carried along the lateral nail folds to meet the incisions of the proximal nail fold. Another incision is made along the underside of the proximal nail fold to remove the eponychium and proximal matrix. The entire matrix is then dissected from the bone. The remaining portion of the proximal nail fold may be sutured onto the matrix defect so that only a small defect will be left, which usually is even smaller than the lunula was before operation. The average time away from work is 2 weeks. Where pathologic examination is unnecessary, phenol cautery is, however, the preferred technique for matricectomy. Most patients return to normal ambulation and activity as early as one day after the operation.

Surgery of the Nail Bed

Nail bed surgery is performed for biopsy, removal of tumors and for treating dystrophic nails such as onychogryphosis.

BIOPSY OF THE NAIL BED Biopsy may be useful in any pathologic condition involving the nail bed. Punch biopsy is done with a 3- or 4-mm diameter punch, driven perpendicularly into the nail plate in a circular motion, down to the bone. However, it is not always easy to extract the cylinder cut in this small area. A useful technique consists of perforating the nail with a 6-mm punch, without injuring the underlying tissue. The covering nail is then detached by using the tip of the scalpel to remove the disk of nail and the biopsy is performed easily by using the 4-mm punch to the bone. The tissue can then be released from its tether with fine scissors. It is advisable to replace the 6-mm disk of nail keratin, after cleaning with 10% hydrogen peroxide, to cover the hole. If the nail plate is thick, using rotating grinders will thin it down and facilitate the transungual biopsy. If a larger nail bed fragment is needed, fusiform biopsy with a major longitudinal axis can be done after partial avulsion of the lateral half of the nail or, after total avulsion, if the fragment is central. After excision, the nail bed is undermined to facilitate reapproximation of both sides. The suture needle is used generously on these fragile subungual tissues. The wound is stitched with resorbable thread (Dexon 7–0). It is sometimes useful to make relaxing incisions at the most lateral margins of the nail bed.
SUBUNGUAL HEMATOMA Acute trauma with severe pain is always remembered by the patient. Depending on the site and the intensity of the injury, the hematoma may be visible almost immediately or it will grow out from under the proximal nail fold within a few weeks. When the hematoma is partial (less than 25 percent of the visible portion of the nail), it should be drained with a pointed scalpel or by hot paperclip cautery over the center of the dark spot. This will produce relief from pain. Sometimes the nail sloughs as the new nail regenerates beneath the old one. Small hematomas may be included in the nail but they cannot be degraded to hemosiderin and the Prussian blue test will be negative. Therefore, to demonstrate the nature of the blackish pigment, scrapings are boiled in a small test tube with hemostix, which gives a positive benzidine result. A hematoma involving more than 25 percent of the visible portion of the nail is a sign of significant nail bed injury. An x-ray is mandatory because the phalanx may be fractured. The nail is carefully removed and the hematoma evacuated. Traumatic nail bed laceration or wounds need a surgical approach to avoid delayed complications. Nail bed lacerations can be sutured after thorough cleaning with antiseptics, using 6–0 resorbable monofilament material. The avulsed nail plate should be put back to cover the wound, then kept in place by suturing to the lateral nail folds or the finger tip. Nail bed defects larger than 4 mm can be repaired by using a split-thickness graft taken either from the nail bed of the same digit or from the nail bed of a great toenail. The torn nail bed should be sutured with Dexon 6–0 and large bites of tissue should be taken so that the suture material does not pull through when it is tied. The nail plate is cleaned, shortened, and slightly narrowed, and then replaced with sutures into the lateral nail folds. The stitches are left in for 2 weeks. Chronic hematomas are usually painless and mainly caused by repeated microtrauma from either ill-fitting footwear or sporting activities. A notch is made with a scalpel blade at the distal and proximal border of the pigmented area. Observation over a 3-week period will delineate whether the nail grows independently of the pigmentation or with it. However chronic hematoma may resemble subungual melanoma and pose a distressing problem and nonmigrating hematoma should be ruled out.

Surgery of the Proximal Nail Fold

BIOPSY

- A 2- to 3-mm punch may be used for biopsying a tumor.
- A blister may be completely removed by a shave biopsy using half a razor blade.
- A 3-mm crescent-shaped tissue excision ending in the proximal region of the lateral nail folds may be helpful in the study of collagen diseases.

SURGERY OF A RECALCITRANT CHRONIC PARONYCHIA A foreign body (hair, for instance) under the proximal nail fold is the main cause. A recalcitrant chronic paronychia manifests as a red, painless swelling, except when pressed, with secondary retraction of the paronychial tissue whose cuticle has disappeared and with recurrent episodes of acute paronychial inflammation.
Crescent excision of the PNF A Freer septum elevator is inserted under the proximal nail fold to protect the matrix and extensor tendon. A No. 15 Bard-Parker blade is used to excise, en bloc, a crescent shaped, full-thickness skin segment, 4 mm at its greatest width, which extends from one lateral nail fold to the other. A bevelled incision prevents accidental damage to the proximal nail matrix and the most proximal portion of the PNF, responsible for the normal shine of the nail plate. In patients who experience repeated acute flares associated with a chronic paronychia, additional removal of the base of the nail is useful.
SURGERY OF TUMORS OF THE PROXIMAL NAIL FOLD Different techniques can be used according to the nature of the tumor, its location and the length of its long axis.
Crescentic excision Useful for small distal tumors, the crescent should not exceed 4 mm at its greatest width. Tumors of

the proximal nail fold situated in a median position (Fig. 280-13) and with a longitudinal axis greater than 4 to 5 mm can be excised with a wedge of PNF whose base is located at the free margin and whose apex points proximally. Two relaxing lateral incisions of the PNF then allow suturing of the wedge-shaped defect after the undersurface of the PNF has been released from the nail plate.

FIGURE 280-13 Tumor of the proximal nail fold in median position.

The resulting symmetric narrow defects on both sides heal rapidly by secondary intention. A small tumor on the lateral part of the PNF may be treated with a wedge-shaped excision. Only one lateral relaxing incision is made at the opposite region of the PNF. To obtain better healing of the secondary defect, which is wider than in the procedure using two relaxing incisions, the operation may be supplemented by a relaxing, crescent shaped incision in the PNF. A dorsal flap can be raised from the PNF by using two dorsolateral incisions and a horizontal one, proximal to the cuticle. This gives complete exposure of subcutaneous tumors.
Reconstruction of the proximal nail fold This may be necessary after any injury (accident, burn, avulsion caused by rapidly rotating belts and sanders, etc.). If the irregular tissue is excised, it is sometimes possible to recreate the distal curve of the PNF, which may produce a near perfect restoration. The PNF may also be restored by using two long, narrow, V-shaped transposition flaps from the lateral aspects of the terminal phalanx.

Lateral Nail Fold

A 2- to 4-mm punch can remove a tumor of the lateral nail fold (LNF). Benign tumors may be removed by an elliptical wedge of tissue taken for the LNF and lateral nail wall. Malignant tumors, such as Bowen's disease, are treated by excision of the whole LNF or by Mohs micrographic surgery followed by healing by second intention.

INGROWN NAILS

Ingrown nail is a condition that mainly occurs in the great toe. It is created by impingement of the nail plate into the dermal tissue, distally, or into the distolateral nail groove. Irrespective of the initial cause, the condition finally presents with a nail bed that is too narrow for its nail plate. Logical treatment is therefore aimed at correcting this disparity.

Distal Toenail Embedding

Surgical avulsion, or the loss of the toenail from trauma such as tennis toe, may initiate the pathology. The distal subungual tissues released from the physiologic counterpressure of the nail plate become hypertrophic and the newly formed nail plate abuts this distal wall. A crescent wedge-shaped excision is carried out around the distal phalanx. The wedge should be 4 mm at its greatest width and has to be dissected from the bone. The defect is closed with 5–0 monofilament sutures, which should be removed after 12 to 14 days.

Juvenile (Subcutaneous) Ingrown Nails

This is the most common type of ingrown nail. The nail is usually embedded medially, but both sides are often affected. In an effort to relieve the pain, the patient often tries to cut off the offending corner under the inflamed swollen soft tissue. The remaining portion will give rise to a nail spicule piercing through the epithelium of the lateral nail groove, which produces secondary infection and excessive granulation tissue.

Treatment of the early stage must be conservative but demands a high degree of compliance. The foot is soaked in warm water with povidone-iodine soap, then, under local anesthesia, the nail spicule is removed and a wisp of cotton wool is placed between the nail and the lateral nail groove. It should be moistened repeatedly with a disinfectant.

For definitive cure, surgical excision, or better chemical suppression of the lateral horn of the nail matrix, permanently narrows the nail. The lateral fifth of the NP is freed with a nail elevator from the PNF and the subungual tissues. It is then cut longitudinally with an English nail splitter or nail-splitting scissors and extracted with a sturdy hemostat. The lateral matrix horn is cauterized with a freshly made solution of liquefied phenol (88% solution). Above all, a bloodless field is needed, because blood inactivates phenol. Hemostasis is therefore accomplished with a tourniquet, and the blood is carefully cleaned from the space under the PNF using sterile gauze. The surrounding skin is protected with petroleum jelly. The phenol is rubbed onto the matrix epithelium for 3 min with a Q-tip changed two or three times. Postoperative pain is minimal because phenol has a local anesthetic action and is antiseptic. The matrix epithelium is sloughed off and oozing is usual for 2 to 6 weeks. Daily warm foot baths with povidone iodine soap accelerates healing.

Pincer Nail [5]

Overcurvature of the nails may affect the great toe alone or all the digits. This condition may be so painful that even the bed sheet becomes unbearable.

When the condition is mild, the nail brace technique is aimed at correcting the inward distortion of the nail by maintaining continuous tension on the nail plate. A stainless steel wire brace is fitted to the NP. A series of adjustments adapted to the gradual decrease of curvature is made over a period of 6 months and results in a painless correction of the pincer nail. However, because the underlying bone pathology remains untreated, relapse is usual. Therefore, the definitive cure,

using phenol cautery on the lateral matrix horns is, undoubtedly, the simplest effective treatment modality.

Hypertrophy of the Lateral Nail Fold

Hypertrophic lateral nail folds are usually the result of long-standing ingrown nails. Inflammation may range from the subclinical to the severe. Approximately one-fifth of the nail digging into the lateral nail fold is removed. Then an elliptical wedge of tissue is taken from the lateral nail wall of the toe, down to the bone. Suturing the defect pulls the lateral nail fold away from the offending lateral nail edge. In severe cases, this procedure may be combined with phenol cautery of the lateral horn of the matrix. In contrast to the adult-acquired hypertrophy of the lateral nail fold, congenital lateral hypertrophic lips disappear progressively and spontaneously within 12 months.

Congenital Malalignment of the Big Toenail

Typically, the nail is laterally malaligned, with transverse furrows on a thick brownish or greenish nail. This appearance may correct itself without therapy in 50 percent of cases before the age of 10 years. If the appearance is extreme, surgery diminishes the risk of permanent dystrophy.
