
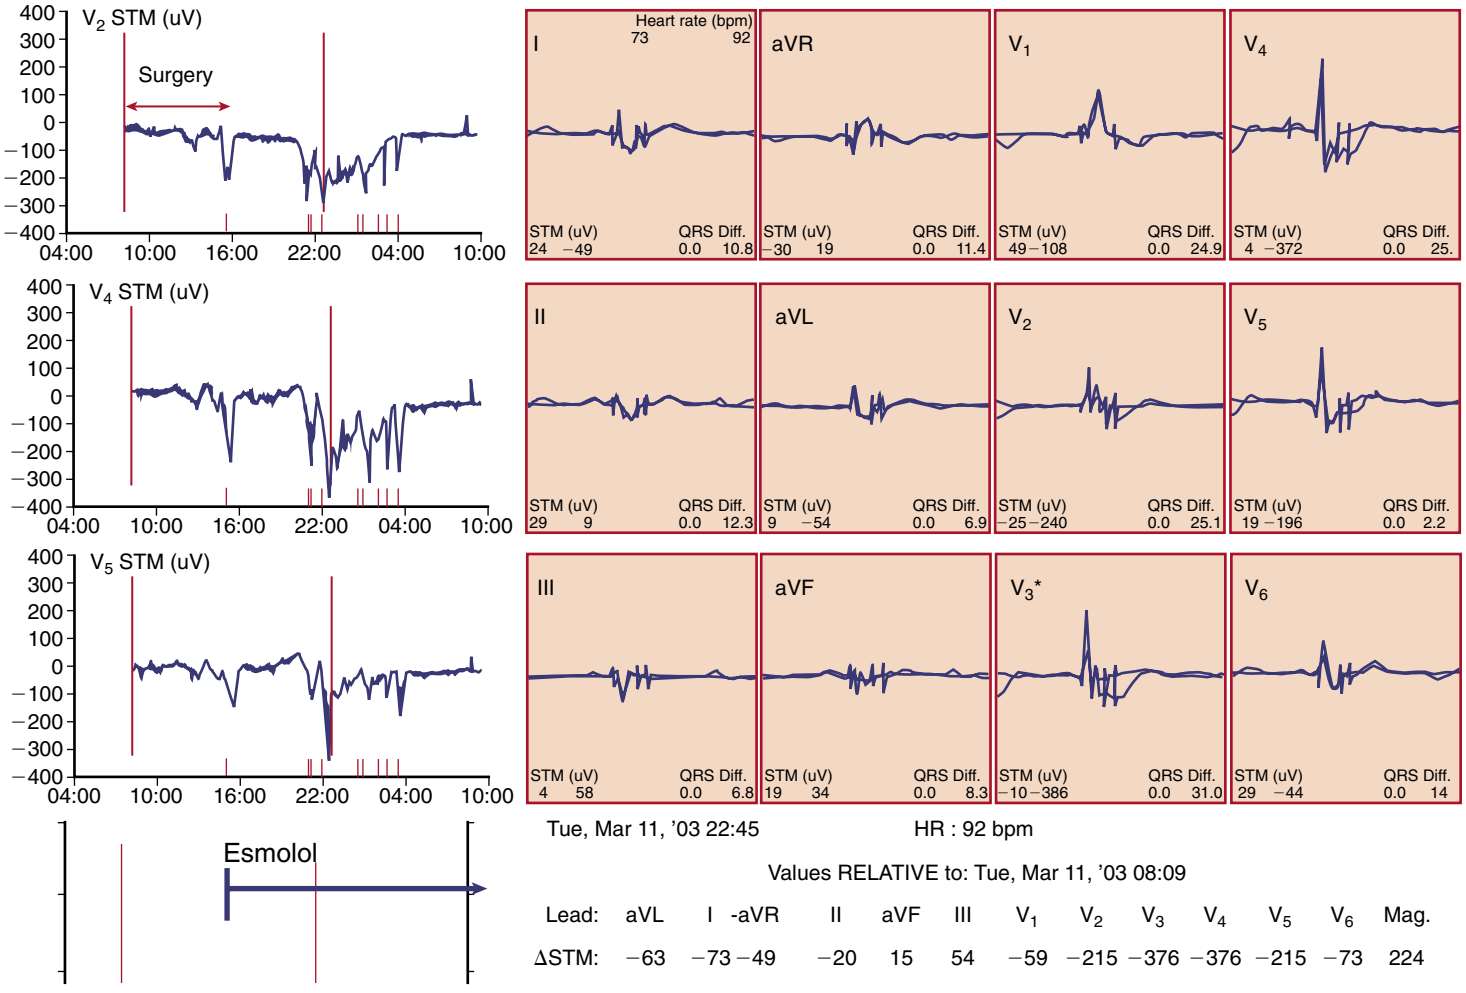

Figure 42-27 Perioperative ST-segment and heart rate trends are demonstrated in the *left panels*. All 12-lead electrocardiographic complexes during peak ischemia, superimposed over the corresponding baseline (preoperative) complexes, are demonstrated in the *right panels*. The ST-segment trends show two episodes of ST-depression–type ischemia: a short episode of 15 minutes immediately at the end of surgery, followed by a 5-hour period of no ischemia and then another long episode of ST depression lasting more than 5 hours. Ischemia is evident in all anterior leads but is maximal in V_3 and V_4.

infusion of packed red blood cells. Twenty-fours hours after the end of surgery, the ischemic electrocardiographic changes regressed almost completely to normal, yet serum troponin T levels increased to 0.64 ng/mL and remained elevated for another 5 days.

This unique case demonstrates that postoperative MI may occur as a result of prolonged stress-induced ST depression–type ischemia in the presence of stable CAD with chronic total coronary artery occlusion of one coronary artery and no rupture of coronary plaque.

43 Implantable Cardiac Pulse Generators: Pacemakers and Cardioverter-Defibrillators

Key Points

Preoperatively

1. Identify the generator manufacturer and whether the generator is a pacemaker or defibrillator.
2. Have the pacemaker or defibrillator interrogated by a competent authority shortly before administration of the anesthetic.
3. Obtain a copy of this interrogation. Ensure that the device will pace the heart.
4. Consider replacing any device near its elective replacement period in a patient scheduled to undergo either major surgery or surgery within 25 cm of the generator.
5. Determine the patient's underlying rate and rhythm, which then determines the need for backup (external) pacing support.
6. Identify the magnet rate and rhythm, if any.
7. Program minute ventilation rate responsiveness off, if present.
8. Program all rate enhancements off.
9. Consider increasing the lower rate limit to optimize oxygen delivery to tissues for major cases.
10. Disable antitachycardia therapy if a defibrillator is present.

Intraoperatively

1. Monitor cardiac rhythm with pulse oximetry (plethysmography) or arterial waveform analysis.
2. Ask the surgeon to operate without the monopolar electrosurgical unit (ESU).
3. Use a bipolar ESU if possible; if not possible, a pure cut is better than "blend" or "coag."
4. Place the ESU return pad so that electricity is prevented from crossing the generator-heart circuit, even if the pad must be placed on the distal part of the forearm and the wire covered with sterile drape.
5. If the ESU causes ventricular oversensing and pacer quiescence, limit the period or periods of asystole.

Postoperatively

1. Have the device interrogated by a competent authority immediately postoperatively. Some rate enhancements can be reinitiated, and the optimum heart rate and pacing parameters should be determined. Note that any patient with disabled antitachycardia therapy must be monitored until the antitachycardia therapy is restored.

Adapted from the ASA Practice Advisory for Perioperative Management of Patients with a Pacemaker or Defibrillator.

Battery-operated pacing devices were introduced by C. W. Lillehei (a cardiothoracic surgeon) and Earl Bakken (an electrical technician) in 1958, just 4 years after invention of the transistor. In 1960, Wilson Greatbatch, an engineer in Buffalo, New York, created the first implantable battery-powered device in his barn.[1] The natural progression of pacemaker (PM) developments led to invention of the implantable cardioverter-defibrillator (ICD*) around 1980 by Michael Morchower (of Baltimore). First approved by the U.S. Food and Drug Administration (FDA) in 1985, implantation of ICDs required a thoracotomy, a significant operation in a patient with poor heart function. Advances in electronic miniaturization, as well as improvements in battery technology, have led to the development of very small (10-mL volume), but electronically complicated, programmable pacing devices.

Technologic advances (transvenous lead placement, antitachycardia* pacing [ATP] capability, miniaturization permitting

*Although many authors and references identify this device as an "automatic implantable cardioverter-defibrillator or AICD," the term "AICD" is a brand name originally owned by CPI-Cardiac Pacemakers, Inc., which was acquired by Guidant Medical Corporation and is now a part of Boston Scientific (Natick, MA). The term "PCD" (for "Programmable Cardioverter-Defibrillator") belongs to the Medtronic Corporation (Minneapolis, MN).

*The terms *antibradycardia* and *antitachycardia* will be used throughout this chapter. Antibradycardia refers to pacing to maintain a minimum rate. Thus, conventional PMs are antibradycardia devices. Antitachycardia refers to therapy delivered in the setting of tachycardia, and it is designed to reduce the underlying heart rate.

pectoral pocket placement, and multiple-chamber, rate-responsive antibradycardia pacing) and numerous survival benefits[2,3] have led to increases in the use of ICDs. These changes in ICD implantation and indications have two important results for health care providers. First, a pectoral (rather than abdominal) pocket ICD with pacing capability might be mistaken, by virtue of pacing "spikes" on the surface electrocardiogram, for a (non-ICD) PM. At many centers, electrocardiograms are obtained from patients who have "PMs" with use of a magnet. Because some ICDs from Boston Scientific/Guidant Medical/CPI can undergo permanent deactivation of antitachycardia therapy with magnet placement, this mistake could leave a patient unprotected[4] and possibly result in death.[5] Second, pacing functions in an ICD often respond to external stimuli (magnet placement, electromagnetic interference [EMI]) differently than a PM does. These issues are addressed later in this chapter. Additionally, all ICDs now perform permanent cardiac pacing, so the issues in the sections on pacing will apply to ICD care as well. Distinguishing a conventional PM from an ICD can be accomplished by examining the right ventricular (RV) lead system on a chest radiograph (Fig. 43-1). A chest radiograph can also be used to identify the generator manufacturer (Fig. 43-2).

Pacemaking and defibrillation systems have a remarkable record for reliability, but they can and do fail. Maisel and colleagues reviewed FDA records for PM and ICD failures (death or explantation because of malfunction other than battery depletion) for the period 1990 to 2002. Even though the nature of this reporting scheme promotes under-reporting of problems, for these 12 years, 2.25 million PMs were implanted, with 8,834 (0.4%) confirmed (and reported) malfunctions and 30 deaths. For ICDs, 415,780 were implanted, with 8,489 (2%) confirmed malfunctions and 31 deaths.[6] Thus, every patient with a cardiac generator should undergo regular in-office follow-up. For appropriately selected devices, telephone checks can be used to identify battery depletion (PM and ICD) or detection of tachycardia (ICD), but telephone checks cannot ensure adequacy of pacing capture and sense safety margins at this time. For PMs, nationally published guidelines recommend at least a telephone check every 1 to 3 months, depending on implant duration.[7] No such guidelines exist for ICD follow-up, although most ICD manufacturers recommend follow-up periods not to exceed 4 months.

Issues also develop and lead to "notices," "product advisories," or "recalls" from the various manufacturers, which might affect perioperative care. For example, Guidant has 46,000 ICDs with potentially defective magnet sensors that could prevent delivery of shock or ATP. Their recommended action was to permanently disable the magnet switch by programming. An ICD thus programmed will therefore deliver a shock even with a magnet in place (Fig. 43-3).[8] The Sprint Fidelis ICD lead series from Medtronic will report ventricular activity in the absence of true electrical systoles (oversensing), which can result in failure to pace or inappropriate delivery of shock,[9] and Guidant has one such lead with similar issues (Model 0156) (Fig. 43-4).

The complexity of PMs and ICDs, as well as the multitude of programmable parameters, limits the number of generalizations that can be made about the perioperative care of a patient with an implanted pulse generator. Population aging, continued enhancements in implantable technology, and new indications for implantation of cardiac devices continue to drive the growing number of implants. The American Society of Anesthesiologists has taken note of these issues and is developing a Perioperative Practice Advisory[10]; the "Key Points" reflect this advisory. Practice guidelines have been issued by the American College of Cardiology (ACC) (hereafter called the ACC guidelines),[11] the American Heart Association (AHA), and the Heart Rhythm Society (formerly the North American Society of Pacing and Electrophysiology [NASPE]).[12] Reviews can also be found in a number of journals.[13-15]

Patients with an implanted cardiac pulse generator often have significant comorbid disease in addition to their cardiac rhythm disturbance. Our ability to care for these patients requires attention to both their medical and psychological problems. We also need an understanding of their pulse generator, its function, and its probable idiosyncrasies in the operating or procedure room.

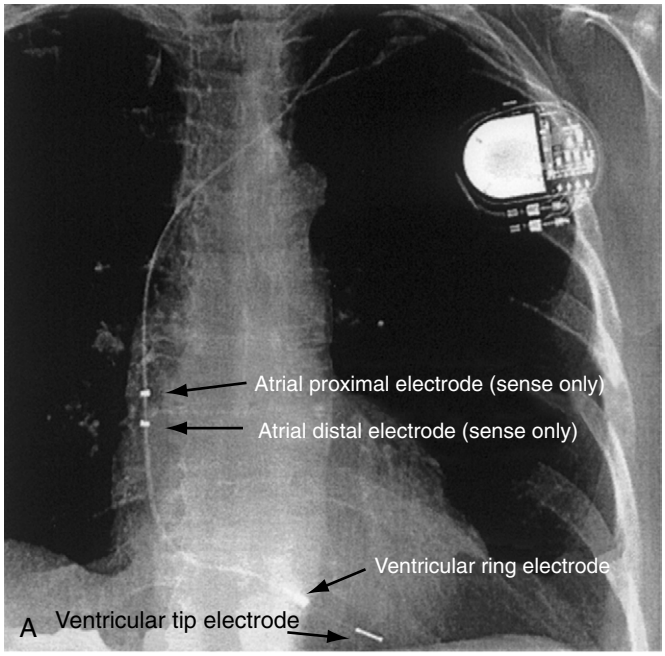
Finally, not all electronic generators implanted in the chest are cardiac devices, and devices resembling cardiac pulse generators are being implanted at increasing rates for indications unrelated to cardiac issues. When implanted in the pectoral position (the usual place for current cardiac generators), these noncardiac devices can be mistakenly identified as cardiac generators.[16] Pulse generator implantation has been approved by the FDA for pain control, thalamic stimulation to control Parkinson's disease, phrenic nerve stimulation to stimulate the diaphragm in paralyzed patients, and vagus nerve stimulation to control epilepsy and depression.[17] Vagus nerve stimulation is also under consideration for the treatment of heart failure[18] and perhaps obesity. Thus, when evaluating a patient with any pulse generator, one must now determine whether the pulse generator will be pacing the heart, stimulating the central nervous system, stimulating the spinal cord, or stimulating the vagus nerve.

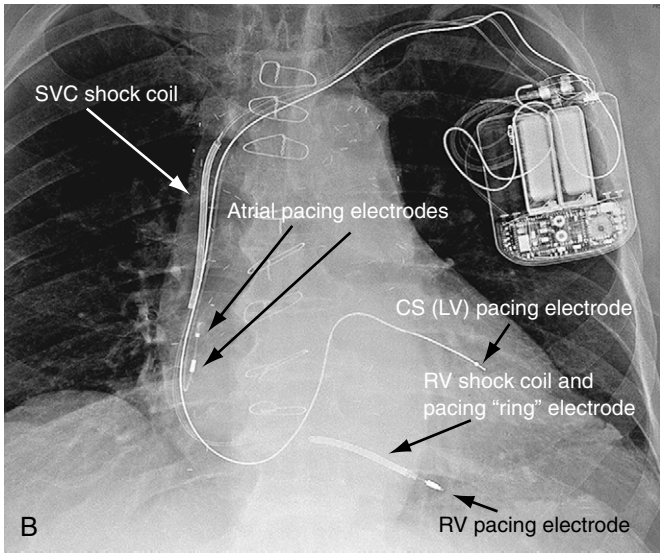
Pacemakers

PM manufacturers report that more than 2,500 generators have been manufactured by more than 26 named entities over the past 40 years. Currently, more than 250,000 adults and children in the United States undergo new PM placement each year, and nearly 2 million patients have PMs today. Many factors lead to confusion regarding the behavior of a device and the perioperative care of a patient with a device, especially since case reports, textbooks, and literature reviews have not kept pace with technologic developments.

A pacemaking system consists of an impulse generator and a lead or leads to carry the electrical impulse to the patient's heart. Leads are connected to the heart's chambers through the vena cava (transvenous leads) or are directly sewn onto the surface of the heart (epicardial leads). Leads can be unipolar (one electrode per lead), bipolar (two electrodes per lead), or multipolar (multiple electrodes and wires contained within one lead with connections in multiple chambers) (see Fig. 43-1A). Because two electrodes are required to complete a circuit, the second electrode in a unipolar configuration will be the metal generator case. Use of the case as an electrode requires that the generator pocket be devoid of gas, and electrical continuity has reportedly been disrupted by the use of nitrous oxide.[19]

PMs with unipolar leads seem to be more sensitive to the effects of EMI, and these systems produce larger "spikes" on an analog-recorded electrocardiogram. Most PM systems (except many Autocapture devices from St. Jude Cardiac Rhythm Management, Sylmar, CA) pace in bipolar mode because bipolar





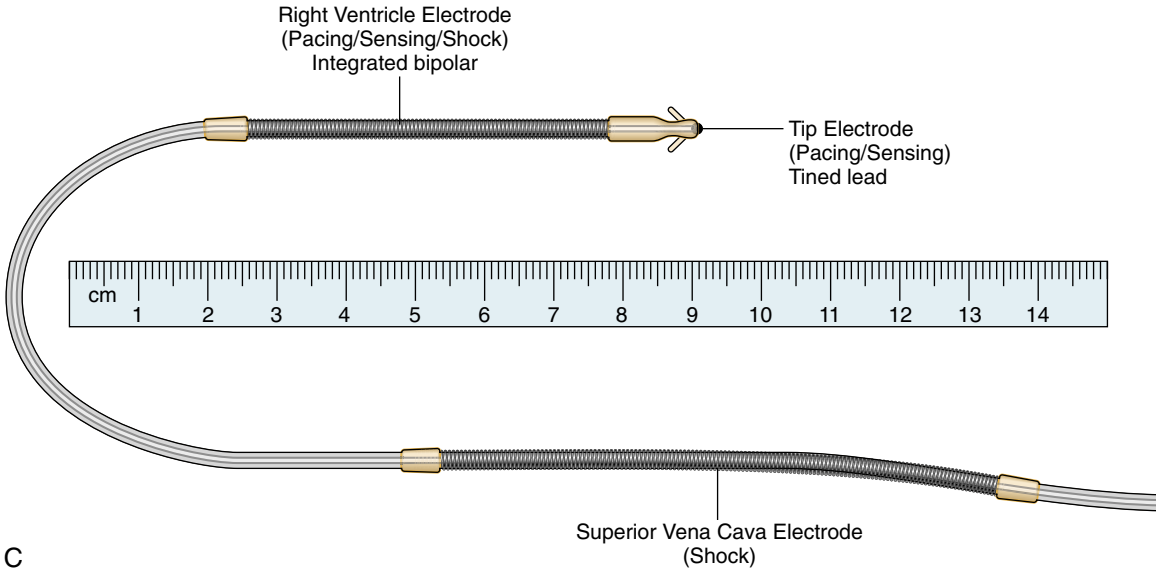


Figure 43-1 A conventional single lead pacemaker, an implantable cardioverter-defibrillator (ICD), and a right ventricular (RV) defibrillator lead are shown to assist in determination of the type of system on chest radiography. **A,** Conventional pacemaker with one quadripolar lead that provides atrial and ventricular sensing and ventricular pacing. This chest radiograph shows a number of features of a modern pacing system. The generator is located in the left pectoral region. The single lead enters the subclavian vein under the clavicle but superficial to the first rib (a common site for lead problems, although no problem is demonstrated here). This device has two electrodes positioned within the right atrium that can provide sensing to detect intrinsic atrial activity. The ventricular portion of the lead shows the classic bipolar pattern with a ring electrode just proximal to the tip electrode, and these electrodes can be used for sensing intrinsic ventricular activity, as well as depolarizing the ventricle. This particular system is a VDD pacemaking system, and this configuration is placed into patients with a functioning atrioventricular node. The system cannot be used to depolarize the atrium. Because the surface electrocardiogram will often demonstrate ventricular pacing that tracks the atrial activity, inspection of the surface electrocardiogram often produces an erroneous diagnosis of a dual-chamber (DDD) pacemaker. **B,** Defibrillator system with biventricular pacing capability. Note that three leads are placed: a conventional bipolar lead to the right atrium, a multipolar lead terminating in the right ventricle, and a unipolar lead to the coronary sinus (CS). The presence of a "shock" conductor in the right ventricle (called a "shock coil") distinguishes a defibrillation system from a conventional pacing system. Many ICDs have an additional shock coil in the superior vena cava (SVC). Typically, the SVC shock coil is electrically identical to the defibrillator case (called the "can"). When the defibrillation circuitry includes the ICD case, it is called "active can configuration." This particular system is designed to provide "resynchronization therapy" in the setting of dilated cardiomyopathy with a prolonged QRS interval (and frequently with a prolonged PR as well). The bipolar lead in the right atrium will perform both sensing and pacing function. Likewise, the tip electrode in the right ventricle along with the shock coil performs RV pacing and sensing function. When the second RV pacing electrode is merged with the shock coil, the lead is called "integrated bipolar" because unipolar RV pacing is not permitted in an ICD system. The lead in the CS depolarizes the left ventricle (LV). Failure to depolarize one of the ventricles might result in ventricular oversensing (and inappropriate antitachycardia therapy) in an ICD. **C,** Integrated bipolar RV defibrillator lead. The tip of this lead becomes enmeshed in the RV trabeculae (called a "tined" lead) rather than engaging the myocardial wall with a screw ("active fixation"). This particular lead has an SVC shock coil as well.

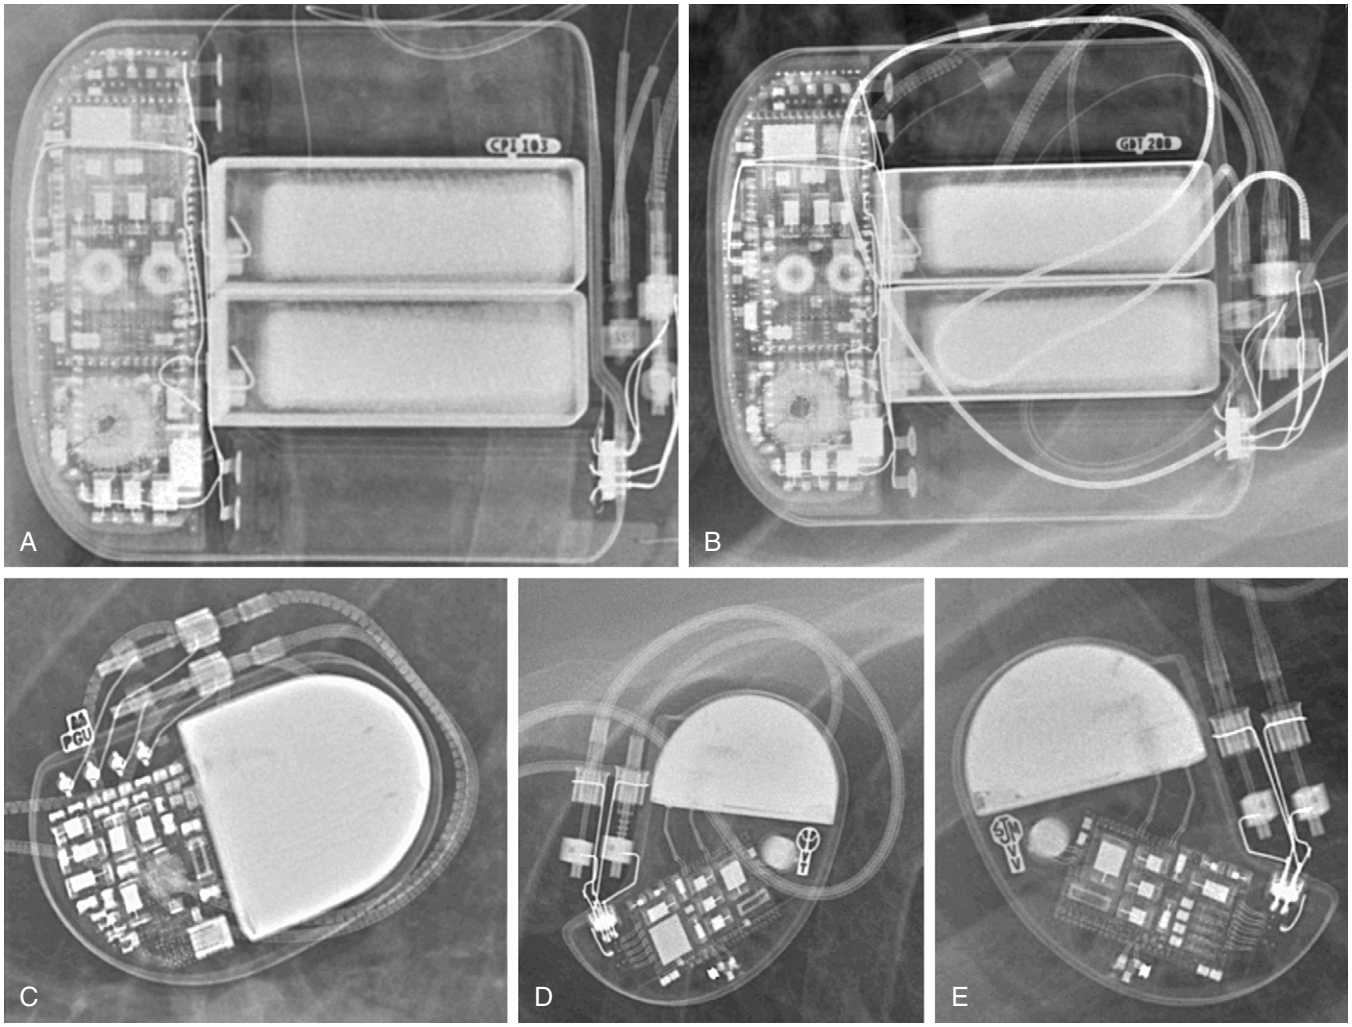

Figure 43-2 Radiographic identifiers for some generator manufacturers. Pacemaker and implantable cardioverter-defibrillator generators can be identified from operative dictations, patient cards, or some chest radiographs. Using digital x-ray equipment with postprocessing zoom capability, corporate x-ray logo identifiers from CPI (**A**), Guidant (**B**), Medtronic (**C**), Pacesetter (**D**), and St. Jude Medical (**E**) are shown. Not shown: BOS is the new Boston Scientific logo.

Figure 43-3 Magnet mode setup from a Guidant Contak Renewal 3 HE model H179. This implantable cardioverter-defibrillator (ICD) is part of an "Urgent Medical Device Safety Information and Corrective Action" letter to physicians from the Guidant Corporation on June 23, 2005, in which a magnet switch problem was announced. The corrective action was designed to permanently disable the magnet switch by programming. As a result, this ICD will not disable shock therapy in response to magnet placement. According to the notice, approximately 46,000 Guidant ICDs were affected and should have their magnet switch permanently disabled. Note the line below the magnet switch report called "Change tachy mode with magnet." With magnet function operative in many Boston Scientific/Guidant Medical/CPI ICDs, enabling this setting allows permanent deactivation of ICD function with the application of a magnet for more than 30 seconds (see text).

B

Figure 43-4 Ventricular oversensing from damaged leads. **A,** A real-time telemetry recording from a Guidant implantable cardioverter-defibrillator (ICD) with a Guidant 0156 right ventricular (RV) defibrillation lead reports a spontaneous ventricular (*arrow*) event that was not present on the surface electrocardiogram (ECG), termed ventricular oversensing. In this ICD, the pacing function was DDD (lower rate, 60 beats/min; atrioventricular delay, 180 msec), and this patient was dependent on the ICD pacing function for his ventricular systoles. The top tracing is the surface ECG, the second tracing is the intracardiac atrial electrogram (EGM), and the third tracing is the intracardiac ventricular EGM. Along the bottom is the "marker channel," which shows the pacemaker's interpretation of events—AP is atrial pace, AS is atrial sense, VP is ventricular pace, and the inappropriate ventricular sensed event is labeled "PVC" because it occurs after a ventricular event without an intervening atrial event. Note that this oversensing has prolonged the RR interval between the fourth and fifth ventricular systoles because this patient is dependent on the pacing function for his ventricular systoles. In a pacing-dependent patient, this type of oversensing can lead to asystole. It can also provoke inappropriate antitachycardia therapy (i.e., shock) in a patient with native ventricular activity because these oversensed events can increase the apparent heart rate count to the ICD. **B,** A patient with a single-chamber Medtronic ICD and a Medtronic Sprint Fidelis RV defibrillation lead was found to have a significant ventricular oversensing issue at interrogation 4/26/05 before his head and neck surgery. In this case the ICD is reporting 875 "short RR intervals" (note the *arrow*) since the previous interrogation 15 days earlier (4/11/05). These data are consistent with a lead fracture causing intermittent "make-break" contacts. In this case, new counts began accumulating 12 minutes after the previous interrogation was complete. More than 100 counts per month is considered a problem; indications to replace the lead include ventricular oversensing in a pacing-dependent patient or high rate detection triggered by this inappropriate oversensing.

Table 43-1 NASPE/BPEG Revised (2002) Generic Pacemaker Code (NBG)

Position I: Pacing Chamber(s)	Position II: Sensing Chamber(s)	Position III: Response(s) to Sensing	Position IV: Programmability	Position V: Multisite Pacing
O = none	**O** = none	**O** = none	**O** = none	**O** = none
A = atrium	**A** = atrium	**I** = inhibited	**R** = rate modulation	**A** = atrium
V = ventricle	**V** = ventricle	**T** = triggered		**V** = ventricle
D = dual (A + V)	**D** = dual (A + V)	**D** = dual (T + I)		**D** = dual (A + V)

The generic pacemaker code.[20] This code, initially published in 1983, was last revised in 2002 in an effort to keep current with technologic developments in the pacing field. The NBG code is a joint project by the North American Society of Pacing and Electrophysiology (NASPE) (the "N") and the British Pacing and Electrophysiology Group (BPEG) (the "B"). The "G" stands for generic.

pacing usually requires less energy. Bipolar sensing is more resistant to interference from muscle artifacts or stray electromagnetic fields. Frequently, bipolar electrodes can be identified on the chest film because they will have a ring electrode 1 to 3 cm proximal to the lead tip (see Fig. 43-1A). Note, however, that generators with bipolar leads can be programmed to the unipolar mode for pacing, sensing, or both.

Pacemaker Codes

No discussion of PMs can take place without an understanding of the generic PM code, which has been published by the NASPE and British Pacing and Electrophysiology Group (BPEG). This code (NBG*) was initially published in 1983 and was last revised in February 2002.[20] It describes the basic behavior of the pacing device (Table 43-1). PMs also come with a variety of terms generally unfamiliar to the anesthesiologist, many of which are shown in the glossary at the end of this chapter.

The first two positions of this code (chambers paced, chambers sensed) seem relatively straightforward. Although early PMs provided only ventricular support, current models can provide pacing in the atria and ventricles, and these devices can also be programmed to determine intrinsic activity in these chambers as well. The code does not describe the array of diagnostic data that can be accumulated by these devices.

Probably the most confusing aspect of the NBG code is the third position (response to the sensed event). Most PMs are programmed either to the DDD mode (dual-chamber pacing and sensing, both triggered and inhibited mode) or the VVI mode (for single-chamber, ventricular pacing in the inhibited mode). Two other modes frequently found are VDD (ventricular pacing with dual-chamber pacing in the triggered and inhibited mode) and DDI (dual-chamber pacing and sensing, but inhibited mode only). In the United States, atrial-only PM placement (AAI mode) is unusual, but these devices are implanted in patients with sinus node disease in other countries. This third position describes the following behavior:

D (**Dual**): DDD pacing provides atrioventricular (AV) synchrony. In the DDD setting, atrial pacing will take place in the "inhibited" mode; that is, the pacing device will emit an atrial pulse if no sensed atrial event (or intervening ventricular event because any ventricular event will reset atrial timing) takes place within the appropriate timeframe. In DDD or VDD devices, once an atrial event has occurred (whether native or paced), the pacing device will ensure that a ventricular event follows (up to the upper tracking rate [UTR, see "Glossary"]).

I (**Inhibited**): The appropriate chamber is paced unless intrinsic electrical activity is detected during the pacing interval. For the DDI mode, AV synchrony is provided only when the atrium is paced. If intrinsic atrial activity is present, no AV synchrony is provided by the pacing function.

T (**Triggered**): The pacing device will emit a pulse only in response to a sensed event. The triggered mode is used when the device is being tested.

The modes VDD and DDI deserve further comment. VDD pacing is used for a patient with AV nodal dysfunction but intact and appropriate sinus node behavior. VDD pacing is accomplished with a single lead that incorporates atrial sensing electrodes and ventricular conductors that can both pace and sense (see Fig. 43-1A). A VDD device has no atrial pacing capability. As a result, in a patient who depends on atrial contraction to augment cardiac output, events that result in VVI pacing (e.g., sinus rate below the programmed rate, battery depletion) or asynchronous ventricular pacing (e.g., magnet placement in many devices, EMI) can lead to deteriorating hemodynamics.[21,22]

DDI pacing is indicated for a patient who has a dual-chamber pacing device and also has episodes of paroxysmal atrial dysrhythmia (e.g., paroxysmal atrial fibrillation). DDI pacing prevents high ventricular rates (i.e., pacing at the UTR) that could result from attempted tracking of the atrial arrhythmia, and it provides AV synchrony only when the atrium is paced. Many DDD programs will enter the DDI mode on detection of high (programmable) atrial rates (called mode switch, automatic mode switch, or atrial tachy response, depending on the manufacturer). When the mode switches to DDI, perturbations (such as very high [>400/min] atrial rates, EMI from the electrosurgical unit [ESU], or magnet placement and removal) might revert the PM back to DDD pacing, with the resultant appearance of AV pacing or ventricular pacing at the UTR (see "Pacemaker Magnets").

Rate modulation (the fourth position) also remains a poorly understood concept. Because some patients cannot increase their heart rate in response to increased oxygen demand (chronotropic incompetence), PM manufacturers have devised a number of mechanisms to detect "patient exercise," such as sensors that detect vibration, respiration, and pressure (Box 43-1). As the sensor detects "exercise," it increases the pacing rate

*The NBG code is a joint project from the NASPE (the "N") and the BPEG (the "B"). The "G" stands for generic. NASPE reorganized as the Heart Rhythm Society (HRS) in 2004.

Box 43-1 Rate Modulation (Activity) Sensors Available or Under Investigation

Currently Approved in the United States
- Vibration sensor
- Motion sensor
- Minute ventilation (bioimpedance sensor)
- QT interval (Vitatron only)
- Right ventricular pressure (Biotronik only)

Under Investigation
- Right ventricular stroke volume
- Blood pH
- Blood temperature
- Mixed venous oxygen sensor
- Systolic time intervals
- Evoked response
- Intracardiac Impedance

Of the types of sensors used to detect exercise in a patient with a cardiac pacemaker, five are currently approved in the United States, although many others are under investigation. Some devices have two sensors and can be programmed for cross-checking to prevent increases in heart rate from spurious causes. Minute ventilation sensors are very sensitive to stray electromagnetic interference, and patients have been inappropriately treated for pacemaker-driven tachycardias as a result. There is very little perioperative experience with right ventricular pressure sensors at this time. Most pacemaker experts recommend that rate modulation be programmed to "OFF" in the perioperative period to prevent confusion between an intrinsic tachycardia versus a pacemaker-induced tachycardia (for example, see Schwartzenburg and colleagues[23]).

(termed "sensor-indicated rate"). As the exercise tapers, this sensor-indicated rate returns to the programmed lower rate. The sensitivity of these sensors to their exercise signals and the rates of change in pacing are programmable features in current generators. Activation of rate response algorithms resulting in an increased pacing rate in the operating room, whether from vigorous chest wall skin preparation, pressure on the generator, or EMI in a minute ventilation device, has led to inappropriate treatment and patient harm.[24,25]

With the 2002 revision of the NBG, the fifth column describes multisite pacing functionality (it had been used to describe antitachycardia functions, but this scheme has been abandoned and a generic defibrillator code has been established). Atrial multisite pacing might prevent atrial fibrillation,[26] and ventricular multisite pacing is an acceptable means of pacing patients with dilated cardiomyopathy (DCM).[27-29]

Pacemaker Indications

Indications for permanent pacing are shown in Box 43-2 and are reviewed in detail elsewhere.[30] Classically, antibradycardia pacing treats patients with sinus node disease (improper impulse formation) and AV node disease (improper impulse conduction). Pacing can be used to reduce the outflow tract obstruction in hypertrophic obstructive cardiomyopathy (HOCM) in both adults and children because paced ventricular conduction takes place in a left bundle branch pattern (the left ventricular [LV] septum depolarizes after the other segments rather than as an early systolic event).[31] Finally, in August 2001, devices were approved by the FDA for three-chamber pacing (right atrium, both ventricles) to treat DCM.[32] This pacing modality can also be called cardiac resynchronization therapy (CRT) or biventricular (BiV) pacing. To accomplish LV pacing, a pacing lead is placed into the coronary sinus (see Fig. 43-1B) or sewn onto the LV free wall. In patients with a significant RV-to-LV activation time, loss of capture in a ventricle can lead to ventricular overcounting with resultant inappropriate antitachycardia therapy in those with a DCM-pacing defibrillator.[33,34]

Pacing for HOCM and DCM requires careful attention to pacer programming. To be effective in these patients, the PM must provide the stimulus for ventricular depolarization, and AV synchrony must be preserved.[35] PM inhibition or loss of pacing (e.g., from native conduction, atrial irregularity, ventricular irregularity, development of junctional rhythm, or EMI) can lead to deteriorating hemodynamics in these patients.

BiV pacing might cause inappropriate lengthening of the QT interval in susceptible patients, and this lengthening has been reported to be associated with torsades de pointes.[36] As a result of this report, prudent anesthesiologists should ensure adequate access to rapid defibrillation for patients with BiV pacing accomplished without an ICD.

Pacemaker Magnets

Despite oft-repeated folklore, most PM manufacturers warn that magnets were never intended to treat PM emergencies or prevent the effects of EMI. Rather, magnet-activated switches were incorporated to produce pacing behavior that demonstrates remaining battery life and, sometimes, pacing threshold safety factors.

Placement of a magnet over a generator might produce no change in pacing because *not all pacemakers switch to a continuous asynchronous mode when a magnet is applied*. Moreover, not all models from a given company behave the same way. Possible effects of magnet placement are shown in Table 43-2.[37-39] In some devices magnet behavior can be altered by programming, whereas in others, magnet behavior can be completely eliminated by programming.

Box 43-2 Pacemaker Indications

Symptomatic diseases of impulse formation (sinus node disease)

Symptomatic diseases of impulse conduction (disease of the atrioventricular node)

Long QT syndrome

Hypertrophic obstructive cardiomyopathy*

Dilated cardiomyopathy*

Indications for permanent pacing are listed. Most patients with pacemakers currently fall into the first two categories (sinus or atrioventricular nodal disease).

*Requires 100% ventricular pacing to be effective. Thus, short atrioventricular delays (around 120 to 150 msec) are programmed.

Table 43-2 Pacemaker Magnet Behavior

Pacemaker Company		Magnet Mode Designation	Explanation
Biotronik (except INOS and DROMOS)		AUTO	If battery okay, 10 asynchronous events at 90 beats/min, then returns to original programmed mode, without rate responsiveness. Pacing is at the lowest available rate (LRL, sleep rate, or hysteresis rate). If battery at ERI, 10 asynchronous events at 80 beats/min in the VOO mode, then either VDD (dual-chamber) or VVI (single-chamber) pacing at 11% lower than the lowest available rate. For any dual-chamber mode (DDD, DDI, or VDD), the AV delay shortens to 100 msec while the magnet is in place
		ASYNCH	Asynchronous pacing at 90 beats/min if battery okay. At ERI, 80 beats/min (single-step change) in the VOO mode regardless of original programming. For any dual-chamber mode (DDD, DDI, or VDD), the AV delay shortens to 100 msec while the magnet is in place
		SYNCH	If battery okay, pacing in original programmed mode, without rate responsiveness. Pacing is at the lowest available rate (LRL, sleep rate, or hysteresis rate). If battery at ERI, either VDD (dual-chamber) or VVI (single-chamber) pacing at 11% lower than the lowest available rate. For any dual-chamber mode (DDD, DDI, or VDD), the AV delay shortens to 100 msec while the magnet is in place
Boston Scientific/Guidant Medical/CPI		ASYNCH	Asynchronous pacing at 100 beats/min if okay, 85 beats/min at ERI (single-step change). The Insignia model has an intermediate step at 90 beats/min at IFI. For Triumph and Prelude models, see Medtronic pacemakers, below
		OFF	No change, magnet is ignored. OFF is the magnet mode after a "power on reset," which can occur secondary to EMI
		EGM mode	No change in pacing. Magnet application initiates data collection
Medtronic			Asynchronous pacing at 85 beats/min if okay, SSI at 65 beats/min regardless of original programming if ERI detected (single-step change). Most Medtronic pacemakers emit one or more ventricular pulses during the first 3-7 asynchronous events (which might be at a rate of 100 beats/min) at a reduced pulse width or voltage to demonstrate the adequacy of ventricular pacing output. Also, Medtronic pacemakers default to SSI pacing at 65 beats/min, without rate responsiveness, on detection of ERI, regardless of whether a magnet is present
St. Jude Medical (not including Telectronics)	"SJM" x-ray logo	Battery Test	Asynchronous pacing at 98.6 beats/min gradually decreasing to <86.3 beats/min at ERI
		OFF	No magnet response
		Event snapshots	No change in pacing. Magnet application causes pacemaker to collect data. Identity and Entity models lack this feature
		Event snapshots + Battery Test	For a magnet placed 2 seconds, pacing mode and rate are unchanged and the device stores an EGM. If the magnet is placed ≥5 seconds, the Battery Test mode (see above) is activated. Identity and Entity models lack this feature
	Pacesetter x-ray logo (ψ)	Battery Test	Asynchronous pacing, with rate depending on the specific model. In general, a pacing rate of less than 90 beats/min should prompt further evaluation
		OFF	No magnet response
		VARIO mode (present in some models)	VARIO results in a series of 32 asynchronous pacing events. The rate of the first 16 paces reflects battery voltage, which gradually declines from 100 to 85 beats/min at ERI. The next 15 paces are used to document the ventricular pacing capture safety margin. The rate will be 119 beats/min with gradually declining pacing voltage. The 16th pace of this group is at no output. The next pace restarts the 32-event sequence. The 32-event sequence repeats as long as the magnet remains in place

The effect or effects of appropriately placing a magnet over a pacemaker are shown. Column 1 shows the pacemaker manufacturer. If the magnet response is programmable, column 2 shows the various programmable modes available. The first mode shown for a company is the default mode. Column 3 shows the effect on pacing therapy for the magnet mode shown in column 2. Unless otherwise specified, asynchronous pacing takes place, without rate responsiveness, in the chambers originally programmed. Thus, a dual-chamber program would result in DOO pacing, and a single-chamber program would result in VOO pacing (unless an atrial device is used, which would be AOO), and a biventricular, dual-chamber device would be DOOOV.

AV, atrioventricular; EGM, electrogram; EMI, electromagnetic interference; EOL, end of life—the device should be replaced immediately; ERI, elective replacement indicator—the device should be replaced promptly; IFI, intensified follow-up interval—the device needs monthly battery checks; LRL, lower rate limit—the programmed lower rate, or set point, of the pacemaker; SSI, single-chamber, inhibited mode—if implanted for ventricular pacing, SSI = VVI; for an atrial pacemaker, SSI = AAI.

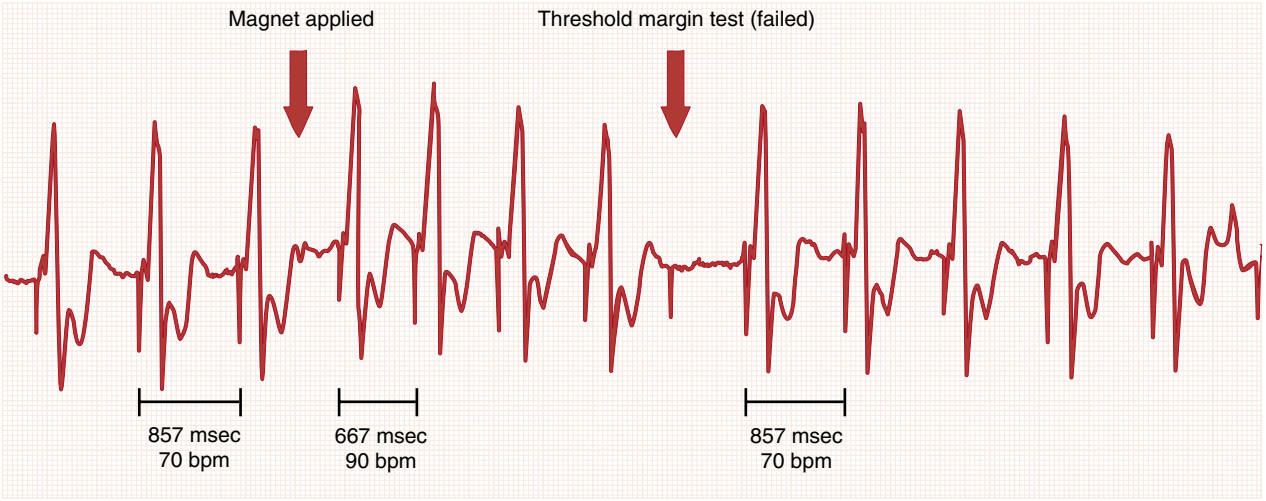

Figure 43-5 Threshold margin test (TMT) demonstrating an inadequate safety margin for pacing. Application of a magnet to some pacemakers will produce asynchronous pacing in which one or more pacing stimuli are emitted with reduced ventricular pacing voltage, pulse width, or both. This sequence is used to determine, without formal pacemaker interrogation, the adequacy of pacing energy settings. In this electrocardiographic strip from an Intermedics device, the patient was being paced in the VVI mode at a rate of 70/min (equal to 857-msec intervals). On application of the magnet, this pacemaker produced four intervals (five pacing stimuli) of asynchronous pacing at a rate of 90/min (667-msec intervals), thus demonstrating adequate battery voltage for this device (pacemaker response to magnet placement is dependent on the manufacturer and sometimes the programming). At the fifth pacing stimulus after magnet application, the pacemaker performs a TMT by reducing the stimulus pulse width to 50% of the programmed value (equal to 50% of programmed energy). Failure of this stimulus to produce ventricular systole (i.e., failure to capture) demonstrates a dangerously low safety margin for ventricular pacing because pacing pulse width should be at least three and generally four times the threshold for capture. After these five initial stimuli, Intermedics pacemakers then pace asynchronously at the programmed lower rate (70 in this case) for 60 additional cycles. On completion of these 64 cycles (65 stimuli), Intermedics pacemakers return to programmed values and ignore the magnet.

For all generators, calling the manufacturer remains the most reliable method of determining magnet response and using this response to predict remaining battery life (phone numbers for device manufacturers are shown in Appendix 2). As battery voltage falls, the magnet response can be used to detect the following:

IFI (Intensified follow-up required)—the device must be checked frequently (approximately every 4 weeks for most models).
ERI (Elective replacement indicator)—the device is nearing the end of its useful life and should be electively replaced.
EOL (End of life)—the device has insufficient battery power remaining and should be replaced immediately.

Upon application of a magnet, some devices perform a "threshold margin test" (TMT). In this test, one or more of the PM pulses are reduced in amplitude, pulse width, or both in an attempt to gauge the safety margin for pacing voltage. Loss of capture on these TMT pulses indicates an inadequate safety margin for pacing (Fig. 43-5). Some devices from St. Jude Medical (formerly Pacesetter) with the Siemens "Vario" feature will reduce the ventricular pacing energy over 16 cycles to demonstrate the pacing threshold. As a result, many pacing cycles can take place at insufficient energy for ventricular capture, which can produce periods of asystole while the magnet is applied.[40]

Occasionally, PM-mediated tachycardia (PMT) can ensue on removal of the magnet from a dual-chamber PM (Fig. 43-6). These PMTs result from retrogradely conducted P waves during asynchronous ventricular pacing, most commonly when the magnet rate is lower than the patient's intrinsic rate. These retrograde P waves are then "tracked" by a dual-chamber device (DDD, VDD modes only), which results in pacing at the UTR. Each paced ventricular cycle results in another retrograde P wave, thereby producing tachycardia. Should this behavior be observed, it can be subverted by reapplication and then removal of the magnet. Some devices can be programmed to recognize these PMTs and will periodically omit one ventricular pacing pulse or lengthen one AV delay cycle during UTR pacing.

In addition, as noted earlier, a patient with a dual-chamber device that has detected a rapid atrial rate and has "mode-switched" to prevent UTR pacing could have the mode switch reset upon application and removal of the magnet. These patients will then undergo UTR pacing until criteria are met to return to the mode-switch function. Distinguishing PMT caused by retrograde P waves from UTR pacing caused by rapid atrial rates (before mode-switch entry) can be very difficult. In general, though, mode switch secondary to rapid atrial rates will take place within 10 to 15 seconds, and PMT from retrograde P waves is quite persistent.

For generators with programmable magnet behavior (Boston Scientific/Guidant Medical/CPI, Pacesetter, St. Jude Medical, Telectronics, Biotronik), only interrogation with a programmer can reveal the current settings. Many manufacturers publish a generator reference guide, although not all of these guides list all magnet idiosyncrasies.

Preanesthetic Evaluation and Pacemaker Reprogramming

Preanesthetic management of a patient with a PM includes evaluation and optimization of coexisting disease (also see Chapter 34).

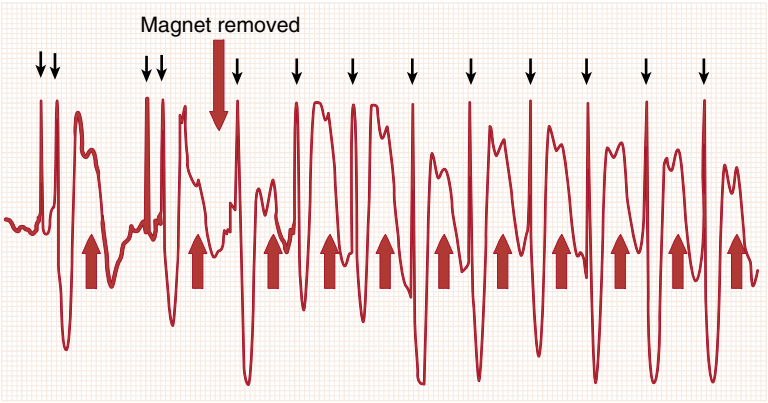

Figure 43-6 Pacemaker-mediated tachycardia (PMT) after removal of the magnet from a pacemaker. This patient had a dual-chamber pacemaker implanted for atrioventricular (AV) nodal disease, and she was pacemaker dependent for ventricular activity. She had a sinus rate of 75/min before application of the magnet with appropriate ventricular pacing (strip not shown). Her programmed AV delay is 200 msec. With magnet application, her pacemaker produced asynchronous AV sequential pacing (DOO mode) at a rate of 60/min. This strip is from an electrocardiographic recorder that enhances the pacemaker artifact with *black*, *downward arrows*. Because the asynchronous "magnet" rate of this device is lower than her intrinsic atrial rate, many of the atrial pacing stimuli were applied during an atrial refractory period (called functional noncapture). A consequence of atrial noncapture can be retrograde AV nodal conduction with depolarization of the atria after depolarization of the ventricle or ventricles. The retrograde P waves are shown with the *red upward arrows*. While the magnet is applied, this retrograde depolarization of the atria is ignored. Shortly after the magnet was removed (shown), there was a paced ventricular event, followed by retrograde AV nodal conduction. With the ensuing depolarization of the atria from this retrograde conduction, the pacemaker sensed an atrial event and responded by pacing the ventricle 200 msec later. Yet another retrograde P wave appears, and each pace in response to a retrograde P wave created yet another ventricular pace. The result is a PMT at the upper tracking rate (programmed here to 130/min) of the pacemaker. PMT from retrograde AV nodal conduction can occur in any DDD or VDD device with magnet removal, a premature ventricular contraction, or a noncaptured atrial pace. Treatment of this PMT should be reapplication of the magnet. Some pacemakers can be programmed to eventually delay one AV cycle when pacing at the upper tracking limit to "break" PMT.

ACC guidelines suggest that cardiac testing (stress tests, echocardiograms) be dictated by the patient's underlying disease, medications, symptomatology, interval from last testing, and planned intervention.[11]

No special laboratory tests or radiographs are needed for patients with a conventional PM. Chest films rarely depict lead problems, not all devices have radiographic markings, and a standard chest radiograph can exclude the generator or its markings. However, a patient with a BiV PM or ICD might need a chest film to document the position of the coronary sinus lead, especially if central line placement is planned. Currently, there are no data or guidelines regarding placement of a central line in the setting of a coronary sinus lead, and because these leads have no fixation, they might be more easily dislodged than a standard PM or ICD lead. In fact, in early studies, spontaneous dislodgement of the coronary sinus lead was detected in more than 11% of patients.[41,42]

Important features of preanesthetic device evaluation are shown in Appendix 1. Current NASPE and Medicare guidelines include telephone evaluation every 4 to 12 weeks (depending on device type and age) and at least one direct evaluation (i.e., device interrogation with a programmer) at least once per year.[7] In abstract form, Rozner and coauthors reported significant noncompliance with these guidelines in 161 consecutive patients, as well as the need to replace 5% of PMs preoperatively for battery depletion.[43] Telephone evaluation provides some assurance of battery longevity, but it does not provide rigorous evaluation of the pacemaking system. ACC guidelines recommend timely, preoperative interrogation of every PM.[11]

For current PMs, interrogation with a programmer remains the most reliable method for evaluating battery voltage, battery impedance, lead performance, and adequacy of the current settings. Special attention should be paid to patients from countries where PMs might be reused[44] because battery life (typically 5 to 7 years) might not be related to length of implantation in the current patient. For any PM with battery voltage less than 2.6 V or battery impedance (where available) greater than 3000 Ω, the company should be consulted about the possible need for elective replacement of the device before surgery.

Appropriate reprogramming (Box 43-3) is the safest way to avoid intraoperative problems, especially if monopolar "Bovie" electrosurgery will be used. Many PM manufacturers stand ready to assist with this task (see Appendix 2 for company telephone numbers). However, interrogation of any generator with or without reprogramming requires a medical prescription and supervision by an appropriately trained physician.[52] Hospital guidelines and policy should reflect the need for a competent physician to review and validate any care delivered by a company representative.

Reprogramming a PM to asynchronous pacing at a rate more rapid than the patient's underlying rate usually ensures that no oversensing during EMI will take place, thus protecting the patient. However, there is one case report involving a Telectronics device that would open its output circuitry (i.e., no pacing stimuli would be delivered) in the presence of high-voltage EMI.[53] Furthermore, at our institution we have observed two PMs in DOO mode decrease their rate during use of an ESU for monopolar coagulation, presumably because of high battery current drain.

Reprogramming a device *will not* protect the device from internal damage or reset caused by EMI. Additionally, setting a device to asynchronous mode causes the PM to ignore premature atrial or ventricular systoles, which could have the potential to create a malignant rhythm in a patient with significant structural compromise of the myocardium.[54]

In general, rate responsiveness and other "enhancements" ("afib" suppression [formerly dynamic atrial overdrive], hystere-

sis, managed ventricular pacing, sleep rate, AV search, and so on) should be disabled by programming to prevent misinterpretation of the cardiac rhythm.[46,55] Note that for many Guidant and CPI devices, Guidant Medical recommends increasing the pacing voltage to "5 V or higher" in any case in which an ESU will be used. Few cardiologists follow this recommendation, but there are reports of pacing threshold changes during both intrathoracic[56] and nonchest surgery,[57] as well as in patients with significant noncardiac acute disease.[58]

Special attention must be given to any device with a minute ventilation (bioimpedance) sensor (Box 43-4) because inappropriate tachycardia has been observed secondary to mechanical ventilation,[25,47] monopolar "Bovie" electrosurgery,[47,61,62] and connection to an electrocardiographic monitor with respiratory rate monitoring.[48-50,59,60,63] Sometimes this PMT has led to inappropriate, unsuccessful pharmacologic treatment of the tachycardia[25] with subsequent patient injury.[24]

Intraoperative (or Procedure) Management of Pacemakers

Although no special monitoring or anesthetic technique is required for a patient with a cardiac generator, attention must be given to a number of concerns (also see Chapters 40 and 60). First, electrocardiographic monitoring of a patient must include the ability to detect pacing discharges. Currently, most electrocardiographic monitors in both the operating room and the intensive care unit perform digital acquisition and analysis of electrocardiographic signals, and they are subject to considerable interference from a variety of sources.[64] In their default settings, these monitors often filter the pacing artifacts, and no pacing "spikes" will be shown. This filtering must be disabled so that the monitor will "paint" pacing spikes onto the display. Even with the filtering disabled, however, pacing artifacts do not always appear. Atrial signals are weak, and current monitors do a poor job detecting them. Moreover, because many digital monitors analyze only one lead for these signals (and then "paint on" artifacts on every lead), placement of the electrocardiographic leads can markedly affect the detection axis.* In practice, when a patient with known pacing is monitored, sometimes changing the "analysis" lead on the monitor will result in the appearance of pacing signals. Unfortunately, when the PM artifact filter is disabled, EMI, especially from use of a monopolar ESU, can lead to inappropriate "painting" of pacing artifacts on the monitor (Fig. 43-7).[65]

Second, patient monitoring must include the ability to ensure that paced electrical activity is converted to mechanical

Box 43-3 Situations Probably Requiring Pacemaker Reprogramming

Any rate-responsive device—see text (problems are well known[23,45] and have been misinterpreted with the potential for patient injury[46-49]; the Food and Drug Administration has issued an alert regarding devices with minute ventilation sensors[50]—see Box 43-4)

Special pacing indication (hypertrophic obstructive cardiomyopathy, dilated cardiomyopathy, pediatric patients)

Pacemaker-dependent patients

Major procedure in the chest or abdomen

Rate enhancements present that should be disabled

Special procedures (see text)

Lithotripsy

Transurethral resection

Hysteroscopy

Electroconvulsive therapy

Succinylcholine use

Magnetic resonance imaging (generally contraindicated by device manufacturers)[51]

In some situations and for certain patients, a pacemaker should be reprogrammed either to avoid potential patient injury or to prevent a pacemaker rhythm that could be confused with pacemaker malfunction.

Box 43-4 Pacemakers with Minute Ventilation (Bioimpedance) Sensors

- Tempo (1102, 1902, 2102, 2902)

Pacemakers with minute ventilation (bioimpedance) sensors frequently respond to electromagnetic interference (EMI) with pacing at the upper sensor rate.[48,49] These tachycardias can also be produced by connection to an operating room electrocardiographic monitor because many of these devices inject electrical signals through the electrocardiographic leads to determine the respiratory rate or lead disconnection.[59,60] In 1998, the U.S. Center for Devices and Radiologic Health issued a safety alert calling for the deactivation of any minute ventilation (bioimpedance) sensor before exposing a patient to a potential source of EMI or connection to medical devices.[50]

*Most monitors manufactured since 2005 have much improved capability to detect and display pacing artifacts, although they still filter these high-frequency signals in their default setup mode.

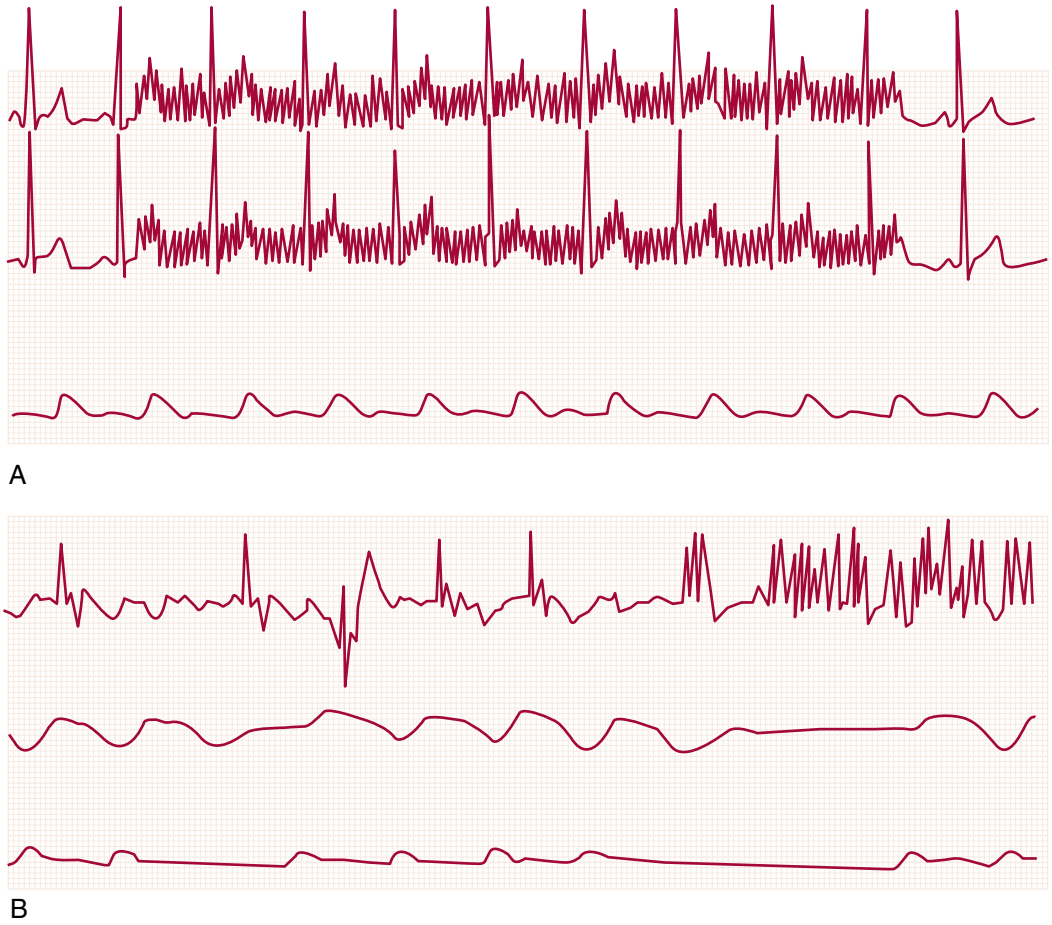

Figure 43-7 Disabling the pacemaker artifact filter on a digitally processed electrocardiographic monitor results in the "painting" of environmental noise (EMI) as pacemaker artifacts. **A,** Effects of "Cut" monopolar electrosurgical unit (ESU) application. Here, the patient's underlying rate exceeded the pacemaker's programmed lower rate limit, and no pacing took place. However, activation of the ESU in the "Cut" mode produced sufficient electromagnetic noise that the monitor began "painting" pacemaker artifacts at a rate of about 20 Hz. The *top tracing* is the electrocardiographic (ECG) lead II, the *middle tracing* is ECG lead V_5, and the *bottom tracing* is the invasive arterial pressure waveform. **B,** The effects of "Coagulation" ESU application produced ventricular oversensing with pacemaker inhibition and left this patient with compromised cardiac output. There is also evidence of inappropriate monitor "painting" of pacemaker artifacts from the EMI. The *top tracing* is ECG lead II, the *middle tracing* is the pulse oximeter plethysmogram, and the *bottom tracing* is the invasive arterial pressure waveform. *(From Rozner MA: Review of electrical interference in implanted cardiac devices. Pacing Clin Electrophysiol 26:923-925, 2003. Used by permission.)*

systole. Mechanical systole is best evaluated by pulse oximetry plethysmography, or arterial pressure waveform display.

Third, there remains limited published perioperative experience with intraoperative BiV pacing at this time. These patients often have ejection fractions of less than 30%, and they depend on pacing in both ventricles to improve their cardiac output. Loss of ventricular pacing from any cause (AV dyssynchrony [atrial fibrillation, atrial flutter, appearance of junctional rhythm], myocardial ischemia, acid-base disturbance, change in pacing threshold, ESU interference, etc.) can cause an immediate decrease in cardiac output. With the exception of transesophageal echocardiography, no beat-to-beat monitoring of cardiac output has demonstrated any utility in detecting loss of BiV pacing behavior. Patients with HOCM pacing can be dependent on ventricular pacing to limit LV outflow tract obstruction.

Fourth, some patients might need an increased pacing rate during the perioperative period to meet an increased oxygen demand. This subject is often not addressed. PM patients reportedly experience postoperative morbidity and mortality frequently,[66] and failure to address tissue oxygen demands and cardiac output needs might contribute to this problem.

Fifth, appropriate equipment must be on hand to provide backup pacing or defibrillation (or both) if needed. Cardiac generators, although hardy, occasionally perform some untoward maneuver or fail, even in the absence of EMI.[67] Acceptable, but inappropriate behavior of a PM or ICD can create an inhospitable situation. Even a properly working, dual-chamber PM can produce R-on-T pacing, especially in the setting of junctional rhythm or premature ventricular contractions (Fig. 43-8).

The medical team caring for a patient with an implanted cardiac pulse generator must understand that the patient has been deemed needy of this device by a physician who is an expert in the diagnosis and management of cardiac rhythm issues. Few anesthesiologists are qualified to contradict this diagnosis, yet some persist in providing an anesthetic without appropriate backup pacing and defibrillation equipment on hand.

Monopolar "Bovie" ESU use remains the principal intraoperative issue for patients with a PM. Between 1984 and 1997, the

Figure 43-8 Normal dual-chamber pacemaker timing can produce R-on-T pacing. **A,** This strip demonstrates functional ventricular undersensing of a premature ventricular contraction (PVC) with resultant R-on-T pace leading to torsades de pointes. This patient had a dual-chamber pacemaker in the DDD mode with a programmed lower rate of 70/min (R-R interval of 857 msec) and atrioventricular (AV) delay of 200 msec. With these parameters, the pacemaker will pace the atrium 657 msec after any previous ventricular event. Atrial pacing is labeled "A" and ventricular pacing is labeled "V." The *top tracing* is electrocardiographic (ECG) lead II, the *middle tracing* is ECG lead V_5, and the *bottom tracing* is the invasive arterial blood pressure waveform. Approximately 660 msec after the first QRS (1) on the strip (which was adequately sensed by the pacemaker), an atrial stimulus is emitted. At 200 msec after this atrial pace, a ventricular stimulus is emitted and appears to depolarize the ventricle (2). About 660 msec later (3), the patient experienced a PVC. Because the pacemaker was preparing to emit the atrial stimulus, it had disabled its ventricular sensing element and failed to sense this PVC (termed *functional undersensing*). At 200 msec after the atrial stimulus, no ventricular event had been sensed, so the pacemaker emitted a ventricular stimulus on the T wave. Because the ventricle was in a refractory period from the PVC, there was no depolarization of the ventricle (called *functional noncapture*). At 660 msec from this attempted V-pace, the pacemaker again paces the atrium (4), and it appears that the next V-pace captures the ventricle. At point 5 there is a repeat of the events at point 3; that is, the pacemaker disabled its sensing elements in preparation to pace the atrium and failed to detect the PVC. This time, however, the V-pace on the T wave produced torsades de pointes. **B,** This strip was obtained from a Medtronic programmer during interrogation of a Kappa 700 dual-chamber pacemaker. The *top tracing* is ECG lead II, and the *bottom tracing* is the "marker channel," which shows the pacemaker's interpretation of events. This pacemaker was programmed to the DDD mode with a lower rate of 60/min. The AV delay was 200 msec. As a result, after any ventricular event, the pacemaker will emit an atrial pulse at 800 msec if no intervening atrial or ventricular event takes place. This patient had a junctional rhythm at 75/min (corresponding to an R-R interval of 800 msec), so the pacemaker emitted an atrial pulse just as the junctional event occurred. Because the pacemaker disables its ventricular sensing element when emitting the atrial pulse, it failed to detect the ventricular event and emitted the ventricular pulse 200 msec later, on the T wave. This inappropriate pacing takes place every other cycle because every other junctional event is sensed around 600 msec after the previous ventricular pace. Decreasing the AV delay will decrease the likelihood of pacing during the vulnerable period of the ventricle. AP is an atrial pace, VP is a ventricular pace, and VS is a ventricular sensed event. The third complex deserves comment. The pacemaker sensed this ventricular event as it re-enabled its sensing element, and the pacemaker cannot tell whether the sensed event is a true ventricular depolarization or an "echo" of the atrial pace. When a signal from the ventricle is sensed within 30 to 90 msec after an atrial pace, many pacemakers immediately emit a ventricular pacing stimulus. Called a "ventricular safety pace," this pacing stimulus is designed to protect the patient from inappropriate sensing of the atrial signal by the ventricular channel, which would then inhibit the ventricular output. The safety pace is emitted at 110 msec to prevent R-on-T pacing. This feature is also called "nonphysiologic AV delay" by some manufacturers. R-on-T pacing can be appropriate (but not ideal) behavior of a DDD or DDI pacemaker in the setting of PVCs, as well as a junctional rhythm. It can also be seen with atrial or ventricular undersensing.

FDA was notified of 456 adverse events with pulse generators, 255 from electrosurgery, and a "significant number" of device failures.[68] A monopolar ESU is more likely to cause problems than a bipolar ESU, and PMs with a unipolar electrode configuration are more sensitive to EMI than those with bipolar configurations are.[69] The most common effect of an ESU on pacing function is ventricular oversensing, which causes pacing inhibition (see Fig. 43-7B). Sometimes the generator detects significant EMI and begins pacing asynchronously at the programmed lower rate. This behavior is called "noise reversion mode pacing," even though the PM does not actually change "modes." Noise reversion is not present in some ICDs and is programmable in others.

Magnet placement during electrosurgery might prevent aberrant PM behavior, and it might allow reprogramming of an older (pre-1990) generator. Note that some generators cannot be programmed in the presence of a magnet (for example, devices from Boston Scientific, Guidant, and CPI). Newer generators are believed to be relatively immune to spurious reprogramming as a result of EMI, although they can undergo a reset condition that will probably alter the programmed settings.[70]

If a monopolar ESU is to be used, the electrosurgical current-return pad (often misidentified as the "grounding pad") must be placed to ensure that the ESU current path does not cross the pacemaking system. Some authors recommend placement of this pad on the shoulder for head and neck procedures or on the distal part of the arm (with sterile draping of the wire) for breast and axillary procedures.[69,71] Procedures using only a monopolar ESU or with special EMI pacing ramifications include the following:

Lithotripsy—The cardiac generator must be excluded from the lithotripter field. If the lithotripter triggers its output on the sensed electrocardiographic "R" wave, atrial pacing should be disabled to prevent the lithotripter from inappropriately firing on the atrial pacing artifact (also see Chapter 65).

Transurethral Resection and Uterine Hysteroscopy—Transurethral resection of the bladder or prostate and hysteroscopic procedures generally use a monopolar ESU, and device reprogramming might be needed to prevent PM oversensing with resultant PM inhibition. A resectoscope that includes the current-return electrode on the shaft (the irrigation medium will be normal saline) might limit EMI to the generator but has not been carefully tested in this environment (also see Chapter 65).

Magnetic Resonance Imaging (MRI)—Without special care, MRI is contraindicated by most device manufacturers, and deaths have been reported. According to physicians' manuals from most manufacturers, MRI might lead to magnet switch closure (magnet mode activation), reprogramming, inappropriate high-rate pacing, generator damage, myocardial injury, or generator movement within the pocket causing pain, lead failure, or arrhythmia. Nevertheless, safe performance of MRI in qualified patients with PMs and ICDs has been reported[72,73] (also see Chapter 79).

Electroconvulsive Therapy—Electroconvulsive therapy might require a nonsensing (asynchronous) mode to prevent myopotential-induced oversensing with resultant PM inhibition.[74]

Nerve Stimulator Testing/Therapy—Nerve stimulators can cause PM oversensing with resultant PM inhibition[75] and cardiac arrest.[76] Nerve stimulators have been used intraoperatively to inhibit undesired cardiac pacing[23] or arrest the cardiac rhythm for placement of an endovascular stent.[77] In patients with an ICD, inappropriate detection of neuromuscular stimulators, transcutaneous electrical nerve stimulation, and chiropractic electrical muscle stimulation as ventricular tachycardia (VT) or ventricular fibrillation (VF) has been reported.[78,79] Nerve stimulators can also interfere with electrocardiographic monitoring of PM artifacts.[65] Like ESU current, the electrical path for nerve stimulator current should not cross the generator system or the chest[80] (also see Chapter 47).

Succinylcholine or Etomidate Use—Reports of myopotential problems on administration of succinylcholine[81] or etomidate[82] have been published. In the case of succinylcholine, muscle fasciculations might have caused ventricular oversensing with resultant PM inhibition, but this report is difficult to interpret. No electrocardiographic tracings were published, and the PM was damaged during a subsequent defibrillation. Using programmers, I have witnessed succinylcholine administration to more than 50 patients with PMs or defibrillators without finding any myopotential oversensing. The etomidate issue is also not clear because there were other issues with the particular PM.[83] However, myopotential oversensing (in the absence of succinylcholine) has been observed to interfere with PM function[84] or cause inappropriate ICD therapy[85] (also see Chapter 29).

Pacemaker Failure

PM failure has three causes: generator failure, lead failure, or failure of capture. Generator failure is rare in a device that has previously been evaluated and not near the end of useful battery life, unless the generator (or leads) is struck directly by the ESU. Lead failure, also unusual but reported during patient repositioning,[86] can result in undersensing (intrinsic activity is not detected), oversensing ("detection" of events unrelated to intrinsic activity), or failure to deliver sufficient energy to the myocardium to produce depolarization (termed loss of capture). Myocardial changes that lengthen the refractory period or increase the energy requirement for depolarization (failure to capture) can result from myocardial ischemia/infarction, acid-base disturbance, electrolyte abnormalities, or abnormal antiarrhythmic drug levels.

The response to PM failure depends on the clinical situation: a patient with a perfusing rhythm and stable vital signs can be observed while a plan is made to correct the problem. For a patient with inadequate perfusion, the following steps can be attempted (while cardiopulmonary resuscitation is in progress when appropriate):

1. A magnet can be applied if the PM is known to revert to an asynchronous mode, which will also eliminate sensing behavior in these devices. For many of the St. Jude Autocapture devices with magnet mode enabled, magnet application might increase pacing amplitude and restore capture. Devices from ELA Medical (Denver, CO) typically increase their pacing amplitude when a magnet is applied. Some PMs perform threshold margin testing upon magnet placement, which can further reduce pacing.[38]

2. Temporary pacing can be initiated, and it can be transthoracic (transcutaneous), transvenous, or transesophageal. Transesophageal (atrial) pacing requires a functional atrium and AV node for ventricular activation, so it is contraindicated in patients with atrial fibrillation or flutter. It is also generally contraindicated in the presence of a permanent PM (or ICD).

In the setting of external pacing, the electrocardiogram can be misinterpreted because the PM artifacts are large in comparison to the QRS complexes (Fig. 43-9A). Successful ventricular pacing has been reported with transesophageal PMs, but it remains unreliable[87] and produces inferior hemodynamics when compared with atrial pacing (Fig. 43-9B). Note that any external pacing might further

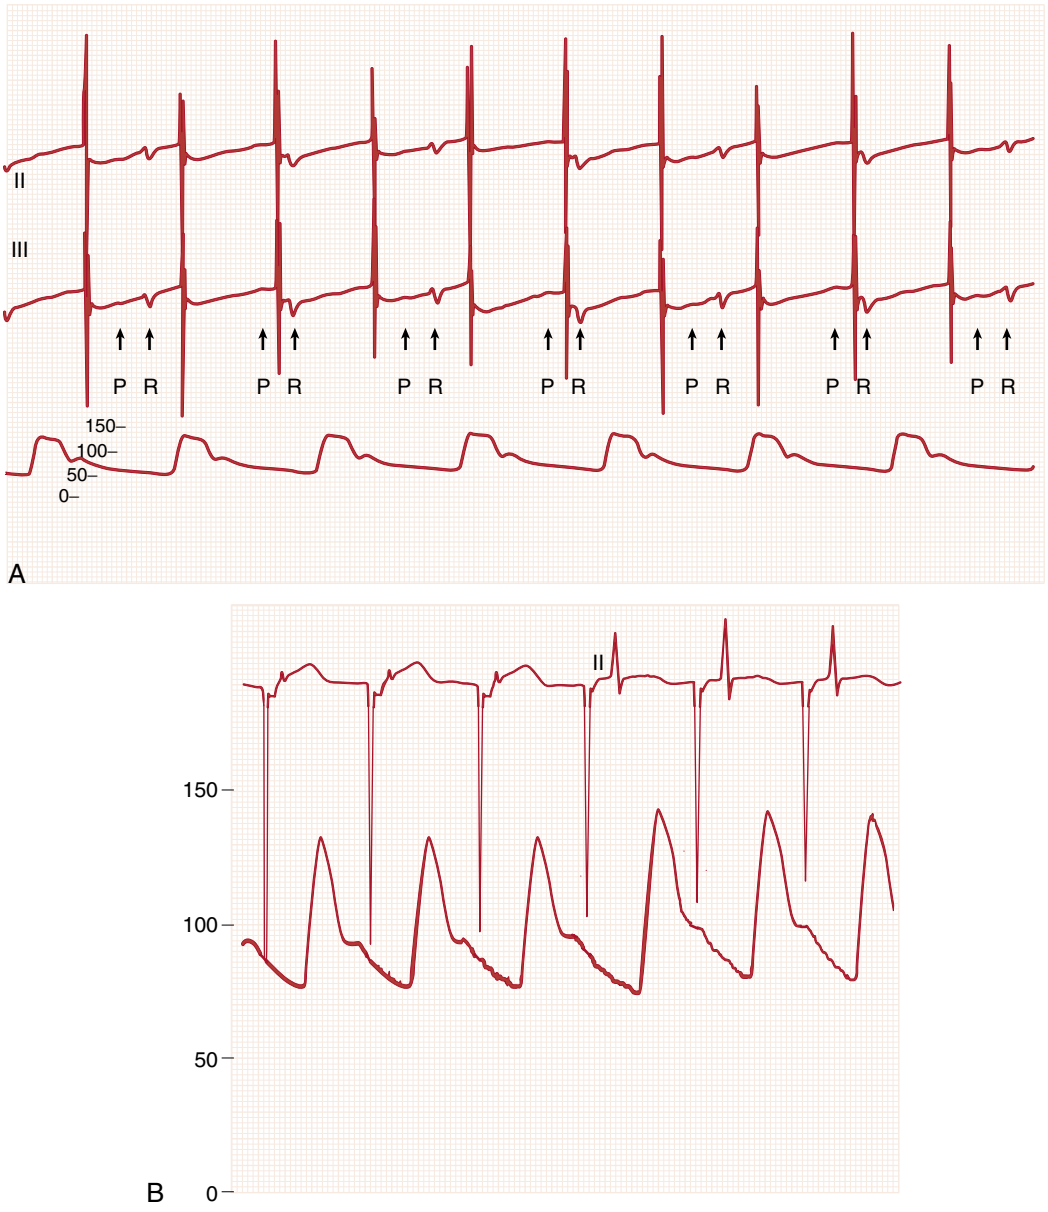

Figure 43-9 Issues with a transesophageal atrial pacemaker (TAP). **A,** Improper placement of a TAP demonstrating atrial noncapture. The *top recording* is electrocardiographic (ECG) lead II, the *middle recording* is ECG lead III, and the *bottom recording* is the invasive arterial pressure waveform. Sinus bradycardia with evidence of tissue underperfusion developed in this 72-year-old man. A TAP (CardioCommand, Tampa, FL) was placed, and the large ECG artifacts at 75/min were misinterpreted by personnel and the ECG monitor as ventricular systoles (capture). This patient has a sinus rate of 50/min with a first-degree atrioventricular block (PR interval of 280 msec). The patient's native atrial (P) and ventricular (R) depolarizations are noted. The arterial pressure waveform confirms pacing noncapture. **B,** Direct ventricular activation with a transesophageal pacemaker. The *top recording* is ECG lead II, and the *bottom recording* (enhanced vertical scale) is the invasive arterial pressure waveform. This strip is from an obese 61-year-old woman with diabetes and hypertension undergoing transsphenoidal hypophysectomy. Shortly after induction, sinus bradycardia at 37 beats/min and mild hypotension developed. A transesophageal pacemaker was placed but advanced too far into the esophagus. This strip was recorded during "pullback." The ventricle was directly activated in the first four events, with a resultant wide-complex QRS and average blood pressure of 135/75 mm Hg. On pullback, the atrium was activated, the QRS returned to a narrow complex, and blood pressure increased to 143/80 mm Hg. Except for the bradycardia, this patient had a normal heart and did not have a permanently placed generator.

inhibit PM output at energies that will not produce myocardial capture.[88]

3. Sympathomimetic drugs can decrease depolarization threshold or increase chronotropicity (or both). Epinephrine (0.5 to 1 μg/min) or dopamine (5 to 20 μg/kg/min) should be considered. Isoproterenol (0.5 μg/min) is often recommended but not widely available and is complicated by hypotension. Antimuscarinic drugs (atropine, glycopyrrolate) might be helpful.
4. Causes of myocardial ischemia should be sought and corrected. Myocardial ischemia can substantially increase the energy required for ventricular capture.[89]
5. Disturbances in electrolyte balance, antiarrhythmic drug levels, and acid-base equilibrium should be investigated and corrected. Potassium, calcium, and magnesium abnormalities can raise depolarization thresholds. In addition, potassium flux, ionized calcium levels, and acid-base equilibrium can be affected by hyperventilation and hypoventilation.
6. If none of the measures just presented succeed, consideration should be given to placement of epicardial leads by the surgical staff.

Postanesthesia Pacemaker Evaluation

A PM that was reprogrammed for the perioperative period should be reset appropriately. For non-reprogrammed devices, most manufacturers recommend interrogation to ensure proper functioning and acceptable remaining battery life if any electrosurgery was used. The ACC guidelines now recommend a postprocedure interrogation (also see Chapter 85).[11] Consideration should be given to increasing the lower paced rate in a chronotropically incompetent patient if increased cardiac output will benefit the patient during convalescence.

Implantable Cardioverter-Defibrillators

The development of an implantable, battery-powered device able to deliver sufficient energy to terminate VT or VF represents a major medical breakthrough for patients with a history of ventricular tachydysrhythmias. These devices reduce deaths in the setting of malignant ventricular tachydysrhythmias,[90,91] and they clearly remain superior to antiarrhythmic drug therapy.[92] Initially approved by the FDA in 1985, more than 60,000 devices will be implanted in the United States this year, and industry sources report that more than 250,000 patients have these devices today. Furthermore, results from the Sudden Cardiac Death–Heart Failure Trial (SCD-HeFT—showing that prophylactic placement of an ICD is superior to drug therapy in any patient with an ejection fraction less than 0.35 and *without* evidence of arrhythmic inducibility) have led to a significant increase in the number of patients for whom ICD therapy is indicated.[93]

A considerable number of technologic advances have been applied since the first ICD was placed, including substantial miniaturization (pectoral pocket placement with transvenous leads is the norm), as well as battery improvements that now permit permanent pacing with these devices. Thus, one could easily confuse a pectoral ICD for a PM.

Table 43-3 NASPE/BPEG Generic Defibrillator Code (NBD)

Position I: Shock Chambers(s)	Position II: Antitachycardia Pacing Chamber(s)	Position III: Tachycardia Detection	Position IV: Antibradycardia Pacing Chamber(s)*
O = none	**O** = none	**E** = electrogram	**O** = none
A = atrium	**A** = atrium	**H** = hemodynamic	**A** = atrium
V = ventricle	**V** = ventricle		**V** = ventricle
D = dual (A + V)	**D** = dual (A + V)		**D** = dual (A+V)

The NBD code is a joint project from the North American Society of Pacing and Electrophysiology (NASPE) (the "N") and the British Pacing and Electrophysiology Group (BPEG) (the "B").[94] The "D" stands for defibrillator.
*For robust identification, position IV is expanded into its complete NBG code. For example, a biventricular pacing-defibrillator with ventricular shock and antitachycardia pacing functionality would be identified as VVE-DDDRV, assuming that the pacing section was programmed DDDRV. Currently, no hemodynamic sensors have been approved for detection of tachycardia (position III).

Like PMs, ICDs have a four-place generic code (NBD*) to indicate lead placement and function, as shown in Table 43-3.[94] The most robust form of identification, called the "label form," expands the fourth character into its component generic PM code (NBG).

Newer ICDs (since 1993) have many programmable features, but essentially they measure each cardiac R-R interval and categorize the rate as normal, too fast (short R-R interval), or too slow (long R-R interval). When the device detects a sufficient number of short R-R intervals within a certain period (all programmable), it will begin an antitachycardia event. The internal computer will choose ATP (less energy use, better tolerated by patient) or shock, depending on the manifestation and device programming. If shock is chosen, an internal capacitor is charged. Charging time is dependent on the desired output, and it can be 6 to 15 seconds for a maximum shock. Charging time is lengthened by lower battery voltage, time from last charge,† and lower temperature.

Most ICDs can be programmed to "reconfirm" VT or VF after charging to prevent inappropriate shock therapy. Some ICDs can be programmed to begin ATP immediately on initiating a charge cycle. Typically, ICDs deliver 6 to 18 shocks per event. Once a shock is delivered, no further ATP will take place. Despite considerable improvement in detection of ventricular dysrhythmias, more than 10% of shocks are for rhythms other than VT or VF.[95,96] Supraventricular tachycardia (SVT) remains the most common etiology of inappropriate shock therapy,[97,98] and causes of inappropriate shock have been reviewed elsewhere.[99] Program-

*The NBD code is a joint project from the NASPE (the "N") and the BPEG (the "B"). The "D" stands for defibrillator.

†The capacitor in an ICD "deforms" during inactivity, which leads to increased time needed to charge the capacitor. To mitigate the effects of deformation, all ICDs perform nontherapeutic charging of their capacitor (called "reforming") at a programmable periodic interval (usually 1 to 6 months).

mable features in current ICDs to differentiate VT from a tachycardia of supraventricular origin (SVT) include the following[100]:

1. Onset criteria—in general, the onset of VT is abrupt, whereas the onset of SVT has a sequentially shortening R-R interval.
2. Stability criteria—in general, the R-R interval of VT is relatively constant, whereas the R-R interval of atrial fibrillation with rapid ventricular response is quite variable.
3. QRS width criteria—in general, the QRS width in SVT is narrow (<110 msec), whereas the QRS width in VT is wide (>120 msec).
4. "Intelligence" in dual-chamber devices attempting to associate atrial activity with ventricular activity.
5. Morphology waveform analysis with comparison to stored historical templates.

Note that once the R-R interval becomes sufficiently short for detection of VF, most ICDs will begin a shock sequence. As noted earlier, once the device delivers any shock therapy, no further ATP will take place.

An ICD with antibradycardia therapy capability will begin pacing when the R-R interval is too long. In July 1997, the FDA approved devices with sophisticated dual-chamber pacing modes and rate-responsive behavior for ICD patients who need permanent pacing (about 20% of ICD patients). Because of the DAVID study, which suggested that DDD pacing in a patient without a clear need for dual-chamber pacing decreases survival when compared with single-chamber device placement,[101] many electrophysiologists are programming long (>250 msec) AV delays in these patients to limit ventricular pacing. As noted previously, however, long AV delays can lead to R-on-T pacing (see Fig. 43-8A). In addition, many ICD manufacturers have designed algorithms to limit ventricular pacing. Some of these algorithms allow dropped QRS events, which can resemble a second-degree Mobitz II block or malfunction of the pacing system.

ICD Indications

Initially, ICDs were placed for hemodynamically significant VT or VF (Box 43-5). Newer indications associated with sudden death include patients awaiting heart transplantation[102] and those with long QT syndrome,[103] Brugada syndrome (right bundle branch block, ST-segment elevation in leads V_1 to V_3), and arrhythmogenic RV dysplasia.[104,105] Studies suggest that ICDs can be placed prophylactically (i.e., used for primary prevention) to prevent sudden death in young patients with hypertrophic cardiomyopathy,[106] as well as in post–myocardial infarction patients with an ejection fraction less than 30%,[93] but they are of no benefit after coronary artery bypass grafting. Three-chamber ICDs have been approved by the FDA for patients with DCM, and ICDs are in clinical trial for patients with HOCM who have experienced VT or VF.

Box 43-5 Indications for Implantable Cardioverter-Defibrillators

Ventricular tachycardia

Ventricular fibrillation

Brugada syndrome (right bundle branch block, ST-segment elevation in V_1 to V_3)

Arrhythmogenic right ventricular dysplasia

Long Q-T syndrome

Hypertrophic cardiomyopathy

Prophylactic use in a patient who has a cardiomyopathy (CM) without electrophysiologic testing to justify placement: MADIT II (ejection fraction [EF] <30%, ischemic CM),[93] MUSTT (EF <40%, ischemic CM with unsustained ventricular tachycardia),[92] SCD-HeFT (EF <35% and causing CM).[3]

ICD Magnets

Like PMs, magnet behavior in ICDs can be altered by programming. Most devices will suspend tachydysrhythmia detection (and therefore therapy) when a magnet is appropriately placed to activate the magnet switch. Some devices from Angeion, Boston Scientific, CPI, Guidant, Pacesetter, St. Jude Medical, or Ventritex can be programmed to ignore magnet placement, and some Guidant ICDs have had their magnet function permanently disabled because of a magnet switch issue (e.g., see Fig. 43-3).[8]

Depending on programming, antitachycardia therapy in some Boston Scientific/Guidant Medical/CPI devices can be permanently disabled by magnet placement for 30 seconds, and as noted earlier, some patients have been discovered with their ICD antitachycardia therapy unintentionally disabled.[4,5] In Boston Scientific/Guidant Medical/CPI devices, if the magnet mode is enabled and the ICD is enabled for antitachycardia therapy, the ICD will emit beeps synchronized to R waves to signify adequate placement of the magnet and suspension of tachyarrhythmia detection (hence disabling therapy). If the ICD emits a constant tone, antitachycardia therapy has been programmed to "off," regardless of magnet placement. Depending on programming, ICDs from Boston Scientific/Guidant Medical/CPI can toggle between activated and inactivated states with 30 seconds of magnet application. Thus, to re-enable therapy, the magnet must be removed and then replaced until the constant tone reverts to beeps synchronized to R waves. Subsequent removal of the magnet then returns the antitachycardia therapy to the enabled state. Any Boston Scientific/Guidant Medical/CPI device that emits either beeps or constant tones while a magnet is placed will have its antitachycardia therapy disabled during the magnet session.

To ensure correct magnet placement on its devices, Medtronic marketed a device called the "Smart Magnet." Manufacturing ceased around 2005 because not many were sold. This battery-powered instrument contains a magnet and a radiofrequency (RF) receiver. All Medtronic generators broadcast RF destined for the programmer on magnet placement, and the Smart Magnet detects this RF transmission and illuminates the "found" light when an ICD is under the magnet. Medtronic recommends that the Smart Magnet be taped to the patient. Note that during the occurrence of EMI, transmission from the ICD to the Smart Magnet can be interrupted, and the ICD "found" light often turns off. In this setting, though, the ICD remains disabled because it is the physical presence of the magnet rather than the RF communication that disables the antitachycardia therapy.

In general, magnets will not affect ICD antibradycardia pacing mode or rate (except ELA [rate change] and Telectronics

Guardian 4202/4203 [disabled]). Intermedics devices transiently change the pacing rate (VVI mode) to reflect battery voltage. Interrogating the device and calling the manufacturer remain the most reliable method for determining magnet response.

Preanesthetic Evaluation and ICD Reprogramming

In addition to evaluating and optimizing any comorbid disease in ICD patients, I believe that every ICD should undergo preoperative interrogation. These devices store considerable data regarding the occurrence of dysrhythmias. Because ATP is well tolerated, most patients are not aware of this intervention. For any patient scheduled to undergo an elective procedure, the onset of new dysrhythmias probably warrants investigation of the problem before the procedure (Fig. 43-10).

Determination of the need for elective replacement of an ICD because of battery depletion is more complicated than with PMs. Because some ICDs can have multiple battery cells, predicting battery depletion based on battery voltage is difficult. In general, however, the manufacturer should be consulted for any device with a "charging time" in excess of 12 seconds.

Most ICDs should have their antitachycardia therapy disabled before the use of any device that causes EMI. Use of a monopolar ESU can produce inappropriate shocks. Casavant and associates found a stored electrogram sequence in an ICD suggesting that it had misinterpreted use of a monopolar ESU during dermatologic facial surgery as VF,[107] and Figure 43-11 shows VT detection that occurred during surgery. Additionally, there is one report of a central line guidewire interacting with the RV lead that led to a short-circuit shock and subsequent failure of the ICD.[108]

The comments in the pacing section (including Appendix 1 and Box 43-3) apply here for any ICD with antibradycardia pacing. Many ICDs have no noise reversion behavior, so ESU-induced ventricular oversensing might lead to nonpacing in a patient who is dependent on the ICD for pacing.

Intraoperative (or Procedure) Management of ICDs

At this time, no special monitoring (because of the ICD) is required for a patient with an ICD. Electrocardiographic monitoring and the ability to deliver external cardioversion or defibrillation must be present during the time of ICD disablement. Should cardioversion or defibrillation be needed, the defibrillator pads should be placed so that they avoid the pulse generator to the greatest extent possible. Nevertheless, one should remember that the patient, not the ICD, is being treated. The recommendations in the section "Intraoperative (or Procedure) Management of Pacemakers" apply here as well.

No special anesthetic techniques have been championed for patients with an ICD. Most of these patients will have severely depressed systolic function, dilated ventricular cavities, and significant valvular regurgitation. Thus, the choice of anesthetic technique should be dictated by the underlying physiologic derangements that are present. Conflicting data have been published regarding the choice of anesthetic agent or agents and changes in defibrillation threshold (DFT). In 1993, Gill and coworkers examined DFT in dogs and concluded that neither halothane nor isoflurane changed the DFT in open chest defibrillation when compared with pentobarbital infusion.[109] However, Weinbroum and associates evaluated DFTs in humans during ICD implantation and found that halothane, isoflurane, and fen-

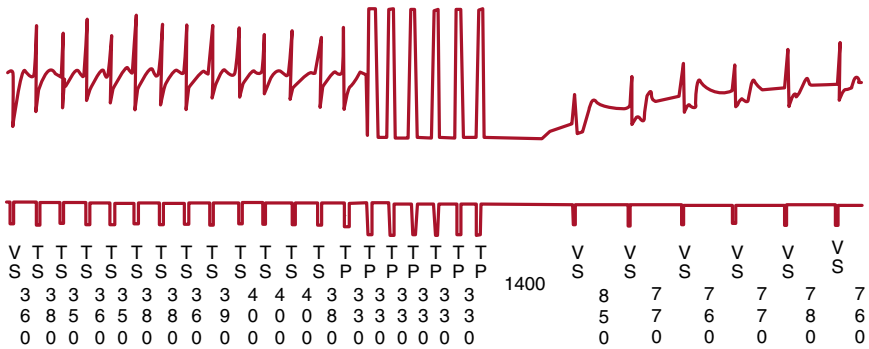

Figure 43-10 Unexpected ventricular tachycardia (VT) with antitachycardia pacing was found in this patient during her preoperative visit. A 65-year-old woman with a history of VT had undergone implantation of a Medtronic single-chamber defibrillator about 8 months previously. She had not had any dizziness or syncopal episodes since placement of an implantable cardioverter-defibrillator (ICD). Interrogation of her device in the preoperative center revealed VVE-VVI programming, along with an episode of tachycardia at 150 to 162 beats/min that was detected by the ICD as VT. The ICD delivered a six-beat burst of antitachycardia pacing at 182 beats/min, which converted the tachycardia back to sinus rhythm. No backup pacing was needed after the VT was terminated. The *upper tracing* is a digitized ventricular electrogram that was stored in the ICD during the tachycardic event. The *lower tracing* is the "marker channel," which reports the interpretation of each event by the ICD. The numbers below the marker channel represent the interval (in milliseconds). The rate is calculated by dividing the interval into 60,000 msec/min. TD marks the final event that starts therapy, TS represents an interval in the VT zone, TP is an antitachycardia pace event, and VS is an intrinsic ventricular depolarization with a rate that is neither too fast (short interval) nor too slow (long interval). This device was set to detect VT as 16 consecutive ventricular events with a rate between 146 and 200 per minute and to deliver antitachycardia pacing at 84% of the last R-R interval (the last interval was 400 msec, so antitachycardia pacing was delivered at a rate of 182/min (330 msec).

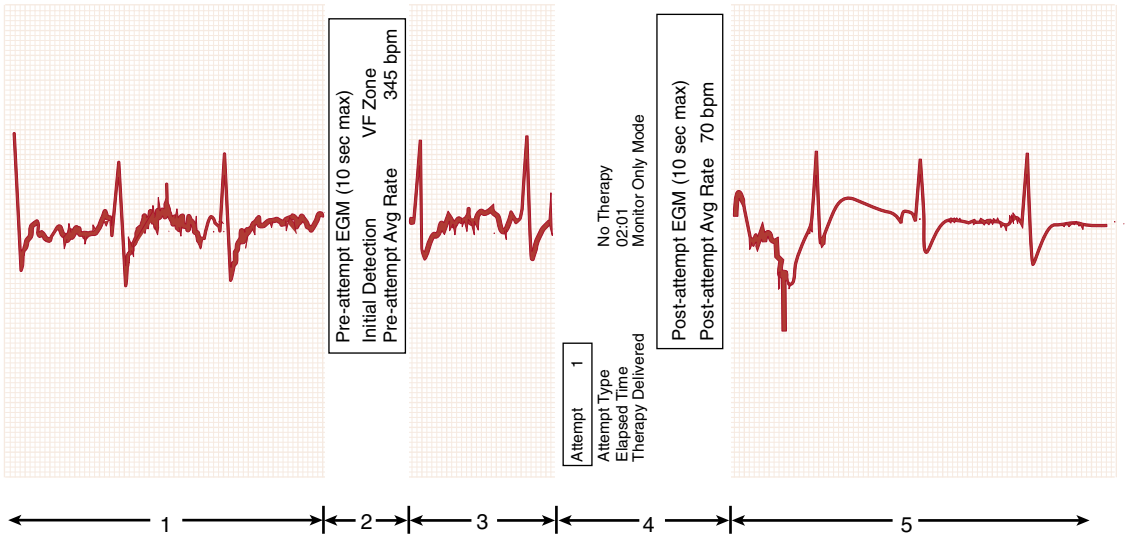

Figure 43-11 Electromagnetic interference (EMI) from the monopolar electrosurgery unit (ESU; "Bovie") caused an implantable cardioverter-defibrillator (ICD) to detect ventricular fibrillation (VF). This stored electrogram (EGM) was one of 73 found at the end of a 4-hour surgical procedure in which considerable monopolar electrosurgery was used. This patient had a Guidant Medical ICD in the VOE-VVI mode. The patient's ICD had been placed in a "monitor only" mode before surgery. As a result, the ICD recorded any instance of ventricular dysrhythmia that would have triggered therapy, but it could not actually deliver therapy. From left to right, (1) the EGM demonstrates a ventricular rate of 70/min, but with considerable noise on the baseline; (2) a VF event was declared for the detected heart rate of 345/min, and the ICD charged its capacitor; (3) the ICD was programmed to "reconfirm before shock," and the ventricular rate remains 70/min with noise on the baseline; (4) again, the noise caused the ICD to believe that the patient remained in VF, and the ICD would have delivered a shock, except that it was programmed to "monitor only"; and (5) because the noise is gone (the ESU had stopped), the ICD declares the event over after "successful" defibrillation.

tanyl increased the DFT.[110] Even with these increases, though, the increased DFTs were still substantially lower than the maximum energy generally available in ICDs, and these increases would not have been noted under the usual testing conditions.

Postanesthesia ICD Evaluation

The ICD must be reinterrogated and re-enabled, and deaths from failure to re-enable an ICD have been reported.[5] All recorded events should be reviewed and counters should be cleared. The pacing parameters must be checked and reprogrammed as necessary.

Summary

Electronic miniaturization has permitted the design and use of sophisticated electronics in patients who have need for artificial pacing or automated cardioversion/defibrillation of their heart. These devices are no longer confined to merely keeping the heart beating between a minimum rate (pacing function) and a maximum rate (ICD functions); they are now being used as therapy to improve a failing heart.

Both aging of the population and our ability to care for a patient with increasingly complex disease suggest that we will be caring for many more patients with these devices, and we must be prepared for this situation. Safe and efficient clinical management of these patients depends on our understanding of implantable systems, indications for their use, and the perioperative needs that they create.

Glossary

Afib Suppression (formerly Dynamic Atrial Overdrive)—A programmable rate enhancement for PMs that increases the pacing rate in response to the presence of intrinsic atrial activity. Afib suppression is designed to pace the atrium at a rate just above the intrinsic rate to prevent atrial fibrillation.[111] It should be disabled before an anesthetic to prevent high pacing rates.

Atrioventricular Delay—The time that a dual-chamber system waits after detecting (or initiating) an atrial event before pacing the ventricle. Some generators shorten this time as the heart rate increases (termed "rate-adaptive AV delay" or "dynamic AV delay"). Some generators can be programmed to extend the AV delay to search for intrinsic conduction ("search AV delay"). Some generators will prolong an AV delay after any atrial event when the last ventricular event was intrinsic ("AV delay hysteresis"). In a patient with a conducting AV node, the sensed AV delay will be slightly longer than the "PR" interval on the surface electrocardiogram (see Fusion Beat and Pseudofusion Beat) because the ventricular sensing element is attached to the apex of the right ventricle and the depolarization takes place only after RV activation (typically >60 msec after activation of the AV node).

Automatic Rate—see Lower Rate Limit.

Bipolar Lead—An electrode with two conductors. Bipolar pacing typically uses less energy than unipolar pacing does, and it will produce smaller artifacts on analog monitors. Bipolar sensing is more resistant to oversensing from muscle artifact or stray electromagnetic fields. Most pacing generators can be programmed to a unipolar mode (separate settings for pacing and sensing), even in the presence of bipolar electrodes.

Electrogram Storage Mode (EGM Mode)—Passive acquisition and internal storage of electrocardiographic data for diagnostic purposes while pacing (or monitoring) with programmed parameters. A PM programmed to enter the EGM mode on application of a magnet will not demonstrate asynchronous pacing behavior.

Fusion Beat (FB)—A PM spike delivered shortly before native depolarization of the ventricle that alters the morphology of the QRS, often misdiagnosed as undersensing. With an FB, the pacing stimulus is delivered after activation of the AV node, but before the sensing element detects the PM-induced depolarization. It is similar to pre-excitation of the ventricle seen in Lown-Ganong-Levine syndrome or Wolff-Parkinson-White syndrome. Confirmation of appropriate sensing behavior can be made by lengthening the sensing interval (i.e., lengthening the AV delay). Fusion beats suggest, but should not be used to confirm ventricular capture. See also Pseudofusion Beat.

Generator—Device with a power source and circuitry to produce an electrical impulse designed to be conducted to the heart. Typically, pacing generators are placed in a pectoral pocket, and leads are inserted into the right atrium, right ventricle, or both. Since 1995, however, ICDs have also been approved for pectoral pocket placement.

Hysteresis—If present, the amount by which the patient's intrinsic rate must fall below the programmed rate before the generator begins pacing. Some pacers periodically decrease the pacing rate to search for resumption of intrinsic activity (called "search hysteresis"). These functions, when present, can mimic PM malfunction.

Implantable Cardioverter-Defibrillator (ICD) Mode—Designation of chambers shocked, chambers paced for antitachycardia pacing, method of tachycardia detection, and chambers paced for antitachycardia therapy. Table 43-3 shows the NASPE/BPEG generic ICD code.

Lower Rate Limit (LRL, also **Automatic Rate** or **Programmed Rate**)—The lowest sustained regular rate at which the generator will pace. Typically, the device begins pacing when the patient's intrinsic rate falls below this value.

Oversensing—Detection of undesired signals that are interpreted as cardiac activity. Oversensing can lead to PM-driven tachycardia (pacing device, DDD mode with atrial oversensing and ventricular tracking), ventricular pause (pacing device with electrosurgically induced ventricular oversensing leading the pacer to "detect" ventricular activity), or inappropriate shock (defibrillator, event oversensing).

Pacing Mode—The designation of chambers paced, chambers sensed, sensing response, rate responsiveness, and antitachyarrhythmia function for a PM system. Table 43-1 shows the NASPE/BPEG generic PM code.

Programmed Rate—see Lower Rate Limit

Pseudofusion Beat (PFB)—A PM spike delivered shortly after native depolarization without alteration of the QRS morphology. PFBs are often misdiagnosed as undersensing, and they result from the position of the sensing electrode relative to the depolarizing wave front (see "Fusion Beat"). Confirmation of appropriate sensing behavior can be achieved by lengthening the sensing interval (i.e., decreasing the program rate [atrial FB] or lengthening the AV delay [ventricular PFB]). PFB cannot be used to confirm electronic capture.

Rate Enhancements—Features such as rate-adaptive AV delay (shortens the AV delay with increasing heart rate), AV search hysteresis (lengthens/shortens the AV delay to produce intrinsic AV conduction), suppression of atrial fibrillation (also called dynamic atrial overdrive—increases the lower rate on appearance of native atrial depolarization so that nearly constant atrial pacing is produced but at a rate only slightly higher than the patient's intrinsic rate), rate smoothing (limits changes in ventricular paced rates caused by changes in atrial rates; rising and falling rate limits can be programmed), sleep rate (see later), ventricular rate regulation (similar to rate smoothing but used to prevent atrial fibrillation), and hysteresis (see earlier). Each of these enhancements can produce pacing/nonpacing that can mimic PM dysfunction, and these enhancements should be programmed "OFF" before delivery of any anesthetic.

Rate Modulation—The ability of the generator to sense the need to increase the heart rate in response to patient activity. Mechanisms include (1) a mechanical sensor in the generator to detect motion or vibration, (2) electronic detection of the QT interval (shortens during exercise), (3) transthoracic impedance to measure changes in respiration, and (4) a sensor or sensors for central venous blood temperature or oxygen saturation (see Box 43-1). Some generators now incorporate multiple sensors. The pacing rate determined by the rate modulation algorithm is called the "Sensor Indicated Rate."

Sensor Indicated Rate—The pacing rate determined by the sensor in a PM programmed to a rate-responsive mode (the fourth character of NBG = "R").

Sleep Rate (also **Circadian Rate**)—The rate (lower than the Programmed Rate) at which the pacing generator will pace during programmed "nighttime" hours.

Undersensing—Failure to detect a desired event.

Unipolar Lead—An electrode with only one conductor. Some devices with bipolar leads are programmed to the unipolar lead mode. Systems with unipolar leads produce larger spikes on the electrocardiogram than bipolar leads do. Systems with unipolar leads use the generator case as the second conductor.

Upper Sensor Rate (**USR**, also **Upper Activity Rate** [**UAR**])—The maximum rate to which a rate-modulated PM can drive the heart. The USR is not affected by the UTR because when the USR becomes active, the PM is pacing the atrium.

Upper Tracking Rate (**UTR**, also called **Upper Rate Limit** [**URL**])—PMs programmed to the VDD or DDD mode cause the ventricles to track atrial activity. Should an atrial tachyarrhythmia develop, such as supraventricular tachycardia, atrial fibrillation, or atrial flutter, the generator acts to limit ventricular pacing. When the atrial rate exceeds the UTR, the generator can change mode (i.e., switch to DDI) or introduce a second-degree AV block. Second-degree blocks can be Mobitz type I (Wenckebach) or Mobitz type II, depending on a variety of programmed settings within the PM.

Appendix 1

Preanesthetic Pulse Generator (Pacemaker, Implantable Cardioverter-Defibrillator) Evaluation

Determining the indication for and date of initial device placement
Identifying the type of device (pacemaker, implantable cardioverter-defibrillator) and manufacturer
Determining the patient's underlying rhythm and rate (if any)
Identifying the number and types of leads
Determining the last generator test date and battery status
Obtaining a history of generator events (if any)
Obtaining the current program information (device interrogation), including mode, rate, and rate enhancements
Ensuring that generator discharges become mechanical systoles with adequate pacing safety margins
Ensuring adequate safety margin for sensing events (if intrinsic events are present)
Ensuring that magnet detection is enabled (magnet behavior and rate should be recorded)
Determining whether the pacemaker should be reprogrammed, depending on pacemaker dependency, surgery type and location, need for increased heart rate, and other factors

The preanesthetic pacemaker evaluation should consist of device interrogation. The above statements can be fashioned into a request to the cardiologist or pacemaker service. Note that for implantable cardioverter-defibrillators, the term "generator events" includes a history of antitachycardia therapy

44 Respiratory Monitoring

Key Points

1. Hypoxemia is caused by reduced P_{IO_2}, hypoventilation, increased ventilation-perfusion ($\dot{V}/\dot{Q}$) heterogeneity, increased shunt, and diffusion nonequilibrium. Hypercapnia is almost always due to hypoventilation.
2. During mechanical ventilation in the operative and intensive care settings, hypoxemia is most often due to increased $\dot{V}/\dot{Q}$ heterogeneity and shunt.
3. A clinically useful approximation to the alveolar gas equation for O_2 is given by $P_{AO_2} = (P_B - 47) \times F_{IO_2} - 1.2 \times P_{CO_2}$. Exchange of O_2 and CO_2 takes place independently in the lung.
4. The alveolar-arterial (A-a) gradient increases with age and supplemental O_2. The P_{aO_2}/F_{IO_2} and A/a ratios typically do not change with increased age or inspired O_2.
5. When derangements in gas tensions are noted on arterial blood gas analysis, it is important to verify that the sample was obtained and analyzed in an appropriate and timely manner.
6. Refinements and further studies on continuous intravascular blood gas monitors may one day lead to widespread routine use of these devices.
7. Pulse oximetry is a rapid, reliable indicator of oxygenation status in surgical and critically ill patients. Newer oximeters feature reduced capability for errors attributable to motion artifact and hypoperfusion.
8. Multiwavelength pulse oximeters are commercially available and allow measurement of carboxyhemoglobin and methemoglobin. Pulse oximetry may one day prove to be a reliable noninvasive monitor of volume status and fluid responsiveness.
9. A sudden decrease in P_{ETCO_2} usually results from a circuit disconnection, airway obstruction, abrupt decrease in cardiac output, or pulmonary embolism. P_{ETCO_2} is not always a reliable approximation of P_{aCO_2}, particularly during general anesthesia or in the critically ill.
10. Mapping of pressure-volume curves in patients with acute respiratory distress syndrome (ARDS) and acute lung injury (ALI) can provide valuable information about lung mechanics and help guide positive end-expiratory pressure (PEEP) and tidal volume settings. Sustained high airway pressure is needed to open collapsed alveoli, and PEEP stabilizes the recruited lung units.
11. Computed tomography has greatly increased our understanding of the complicated interaction between PEEP and lung recruitment in ARDS. Electrical impedance tomography may in the future emerge as a useful bedside monitor of lung recruitment, pulmonary edema, and respiratory mechanics.
12. Recruitment strategies and low–tidal volume ventilation have been shown to improve outcomes in ARDS and ALI. High-frequency ventilators are safe and effective in refractory ARDS and may some day prove to be the ideal mode of lung protective ventilation.

Gas Exchange

The realization that gas exchange takes place in the lung was made by the ancients. However, not until the 18th century, when oxygen was discovered by Joseph Priestley, did Lavoisier ascertain the true purpose of breathing: the biochemical combustion of carbon and oxygen to carbon dioxide, a process known as respiration.[1] More than 200 years later, the exact mechanisms by which the respiratory system takes up oxygen and eliminates carbon dioxide are still being debated.

Alveolar Gases

A practicable method for directly sampling and analyzing alveolar air was first described by Haldane and Priestly in 1905.[2] Because of the inaccuracies and technical difficulty involved in

direct sampling, efforts to develop indirect methods of determining the composition of alveolar air ensued. Subsequently, many equations describing the concentration of alveolar gases have been derived, with a wide range of accuracy and complexity. All are based simply on the law of conservation of mass and derive from the universal alveolar air equation:

$$\text{Alveolar fraction of gas X} = \frac{(\text{Inspired fraction of X} \pm \text{Output or uptake of X})}{\text{Alveolar ventilation}}$$

(i.e., output for CO_2, uptake for O_2) (1)

The equation in this form is only approximate and requires corrections to account for differences in expired and inspired minute volume, discussed later. Moreover, because of the inhomogeneous nature of the lung, the partial pressures calculated should be interpreted as *averages* of various alveolar concentrations present in heterogeneous gas exchange units. Put simply, the gas concentrations in each alveolus are probably different, and values obtained from the equation represent the mean of all alveoli.

In the case of O_2, solving the universal equation for uptake $\left(\dot{V}_{O_2}\right)$ yields a general Fick equation that can be solved for alveolar O_2:

$$\dot{V}_{O_2} = \dot{V}_A\left(F_{IO_2} - F_{AO_2}\right) \quad (2)$$

$$F_{AO_2} = \left(F_{IO_2} - \dot{V}_{O_2}\right)/\dot{V}_A \quad (3)$$

where F_{AO_2} is the alveolar O_2 fraction, F_{IO_2} is the inspired fraction, and $\dot{V}_A$ is alveolar ventilation in volume per minute. In other words, the amount of O_2 in alveoli is equal to the difference between the amount inspired and the amount taken up by pulmonary capillaries (conservation of mass). Multiplying through by dry barometric pressure ($P_{B_{dry}}$) to obtain partial pressures, Equation 3 becomes

$$P_{AO_2} = P_{B_{dry}}\left(F_{IO_2} - \dot{V}_{O_2}/\dot{V}_A\right) \quad (4)$$

where $P_{B_{dry}}$ = barometric pressure − saturated water vapor pressure.

It is most clear in this form of the equation that P_{AO_2} is influenced only by four variables: barometric pressure, fraction of inspired O_2, uptake of O_2, and alveolar ventilation.[3]

The same manipulations of the universal equation yield a formula for determining alveolar CO_2:

$$P_{ACO_2} = P_{B_{dry}}\left(F_{ICO_2} + \dot{V}_{CO_2}/\dot{V}_A\right) \quad (5)$$

Note that CO_2 output must be *added* to the inspired concentration to obtain P_{ACO_2}. However, because F_{ICO_2} is usually zero and $\dot{V}_{CO_2}$ is relatively constant, it is clear that P_{ACO_2} is dependent mainly on one factor, alveolar ventilation, to which it is inversely proportional:

$$P_{ACO_2} = c\left(1/\dot{V}_A\right) \quad (6)$$

where c is a constant. This approximation becomes less accurate in clinical situations in which CO_2 output can be appreciably elevated, as with fever, sepsis, or shivering.[4]

Perhaps the simplest and most widely used approximation of the alveolar gas equation was derived by Riley and colleagues[5] and relates P_{AO_2} and P_{ACO_2} in the following way:

$$P_{AO_2} = P_{IO_2} - P_{ACO_2}/R \quad (7)$$

where R is the respiratory exchange ratio defined as $\dot{V}_{CO_2}/\dot{V}_{O_2}$ and relates CO_2 output to O_2 uptake. Normally, the ratio is relatively constant at 0.8 (i.e., 0.8 mol CO_2 produced for every 1 mol O_2 consumed), and the equation becomes

$$P_{AO_2} = P_{IO_2} - 1.25 \times P_{ACO_2} \quad (8)$$

Note that the term P_{ACO_2}/R in Equation 7 replaces the term $\left(P_{B_{dry}} \cdot \dot{V}_{O_2}\right)/\dot{V}_A$ from Equation 4. Because P_{ACO_2} can be assumed to be equal to P_{aCO_2} based on the Enghoff modification and R relates O_2 uptake to CO_2 output, P_{ACO_2}/R is essentially an indirect measure of O_2 uptake and is much easier to accurately calculate than $\dot{V}_{O_2}/\dot{V}_A$.[6]

A common misconception from the appearance of P_{CO_2} in Equations 7 and 8 is that P_{AO_2} is directly influenced by changes in P_{ACO_2}. Rather, exchange of O_2 and CO_2 takes place independently in the lung, and P_{AO_2} is influenced by only the four aforementioned factors. The apparent influence of P_{ACO_2} on P_{AO_2} is actually reflective of a change in minute ventilation or O_2 consumption, more obvious in Equation 4. For example, as alveolar ventilation decreases, P_{aCO_2} rises and P_{AO_2} will decrease according to Equation 8 as a result of the reduced alveolar ventilation. There is no "displacement" or direct alteration of O_2 by CO_2.[6,7]

Despite being quite adequate for clinical use, the Riley equation does not account for small differences in expired and inspired gas volume because of (1) the respiratory exchange ratio (less CO_2 output than O_2 uptake at a ratio of 4:5) and (2) respired inert gases not being in equilibrium with blood (such as during nitrous oxide induction or washout). An equation proposed by Filley and coworkers[8] corrects for this difference and does not entail calculation of R, which can be higher than the normal 0.8 in certain clinical settings, such as with metabolic acidosis or overfeeding:

$$P_{AO_2} = P_{IO_2} - P_{ACO_2}\left[\left(P_{IO_2} - P_{EO_2}\right)/P_{ECO_2}\right] \quad (9)$$

Though more accurate, it is more cumbersome than the Riley equation in that mixed expired gas concentrations must be measured. This equation should be used, for example, when calculating shunt fraction because precise P_{AO_2} values are imperative.[3]

Arterial Gases

Exchange of gases between alveoli and blood occurs at the pulmonary capillaries. Arterial blood is formed by mixture of this pulmonary capillary blood with the mixed venous shunt fraction. Thus, three major factors influence the efficiency of this exchange and the resultant arterial gas tensions: $\dot{V}/\dot{Q}$ matching, alveolar diffusion capacity, and shunt fraction. Along with hypoventilation and low P_{IO_2}, derangements in any of these factors result in arterial hypoxemia (Box 44-1). Some determination of the cause of the hypoxemia can be made by evaluation of the A-a O_2 gradient; problems with gas exchange increase the gradient, whereas it is normal in hypoxemia because of low P_{IO_2} or hypoventilation. The A-a gradient is usually elevated in a patient breathing supplemental oxygen. Two other indices of oxygenation that remain unchanged with fluctuating F_{IO_2} are the P_{AO_2}/F_{IO_2} and a/A ratios (normally 350 to 500 mm Hg and 0.8 to 0.85, respectively).

Box 44-1 Five Causes of Hypoxemia and the Associated Alveolar-to-Arterial (A-a) O_2 Gradient

Normal A-a O_2 Gradient
- Hypoventilation
- Reduced P_{IO_2}

Increased A-a O_2 Gradient
- Increased $\dot{V}/\dot{Q}$ heterogeneity
- Increased shunt
- Diffusion limitation

The extent to which these factors affect the makeup of arterial blood differs for CO_2 and O_2 because they have different arteriovenous gradients and diffusing capacities. CO_2 is estimated to have a diffusing capacity 20 to 30 times greater than that of O_2,[9] and its exchange is therefore minimally affected by derangements in alveolar membrane diffusion and $\dot{V}/\dot{Q}$ mismatching. The narrower arteriovenous gradient of CO_2 (≈6 mm) versus O_2 (~60 mm) leads to less profound effects of venous shunt on arterial P_{CO_2}. Except in extreme circumstances there is little evidence that impaired diffusion of O_2 or CO_2 across the alveolar membrane occurs to any clinically significant extent, so this is not discussed further in this chapter.

$\dot{V}/\dot{Q}$ Mismatch

In normal subjects, resting minute ventilation is roughly 4 L/m and pulmonary blood flow is 5 L/m, which results in a ventilation-to-perfusion ratio of roughly 0.8 for the entire lung.[10] This would represent the $\dot{V}/\dot{Q}$ ratio of each alveolus if ventilation and perfusion were uniformly distributed in the lung. In reality, distribution is not uniform, and ratios range anywhere from zero (shunt) to infinity (dead space ventilation). For example, alveoli in dependent lung regions are better perfused than those in the apices and therefore have lower $\dot{V}/\dot{Q}$ ratios.[11] Ventilation is usually more evenly distributed throughout the lung than blood flow is, so impaired oxygenation of arterial blood is most often due to derangements in perfusion.

$\dot{V}/\dot{Q}$ mismatching results in hypoxemia for two reasons. First, more blood tends to flow through alveoli with low $\dot{V}/\dot{Q}$, such as dependent lung.[9] Thus, when $\dot{V}/\dot{Q}$ scatter increases, flow through alveoli with low $\dot{V}/\dot{Q}$ (and therefore low P_{O_2}) is greater than flow through areas of high $\dot{V}/\dot{Q}$, which causes a disproportionately large effect from the areas of low $\dot{V}/\dot{Q}$ and hence a reduction in P_{aO_2}. The second reason is due to the nature of oxyhemoglobin (HbO_2) dissociation. Alveoli with high $\dot{V}/\dot{Q}$ are on the plateau portion of the curve, where shifts in P_{AO_2} have little effect on O_2 content. These new areas of high (or higher) $\dot{V}/\dot{Q}$ introduced by scatter are unable to compensate for the new areas of low $\dot{V}/\dot{Q}$, which are on the steep portion of the curve and therefore more profoundly affected by changes in P_{AO_2} (Figs. 44-1 and 44-2).

Shunt

One extreme of $\dot{V}/\dot{Q}$ mismatch is a right-to-left shunt ($\dot{V}/\dot{Q}$ = 0), the other extreme being dead space ventilation ($\dot{V}/\dot{Q}$ = infinity). Normally, a small shunt fraction (<3% of cardiac output) exists because of drainage of bronchial and thebesian venous blood into the left heart.[7] However, as a result of the steep arterio-

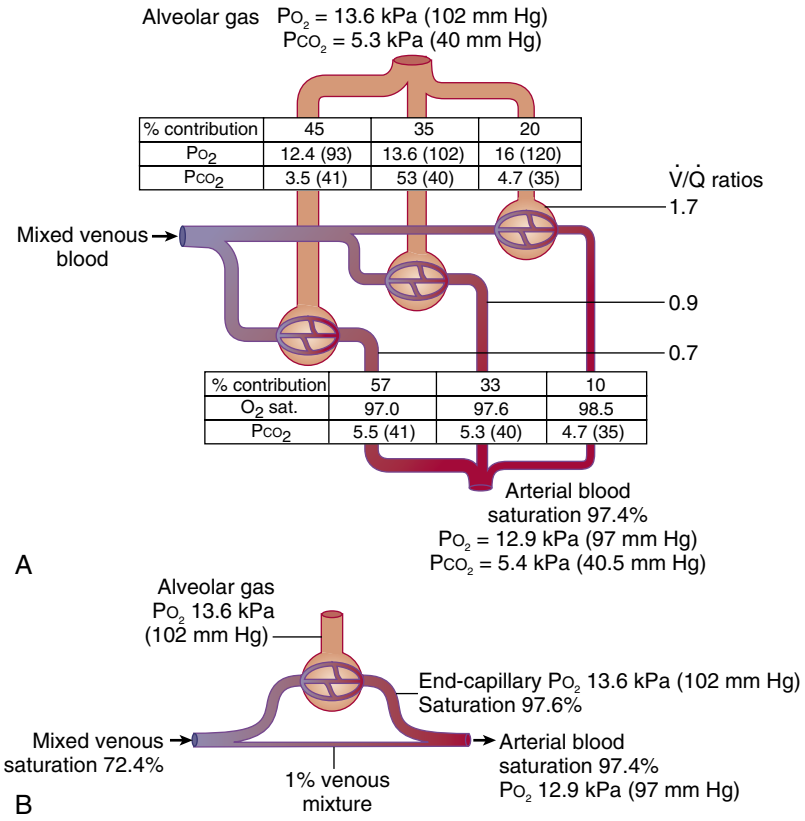

Figure 44-1 Alveolar-to-arterial P_{O_2} difference caused by scatter of $\dot{V}/\dot{Q}$ ratios and its representation by an equivalent degree of venous admixture. **A,** Scatter of $\dot{V}/\dot{Q}$ ratios corresponding roughly to the three zones of the lung in a normal upright subject. Mixed alveolar gas P_{O_2} is calculated with allowance for the contribution of gas volumes from the three zones. Arterial saturation is similarly determined and P_{O_2} derived. There is an alveolar-arterial P_{O_2} difference of 0.7 kPa (5 mm Hg). **B,** Theoretical situation that would account for the same alveolar-to-arterial P_{O_2} difference caused solely by venous admixture. This is a useful method of quantifying the functional effect of scattered $\dot{V}/\dot{Q}$ ratios but should be carefully distinguished from the actual situation. *(From Lumb AB: Nunn's Applied Respiratory Physiology, 6th ed. Philadelphia, Elsevier/Butterworth Heinemann, 2005.)*

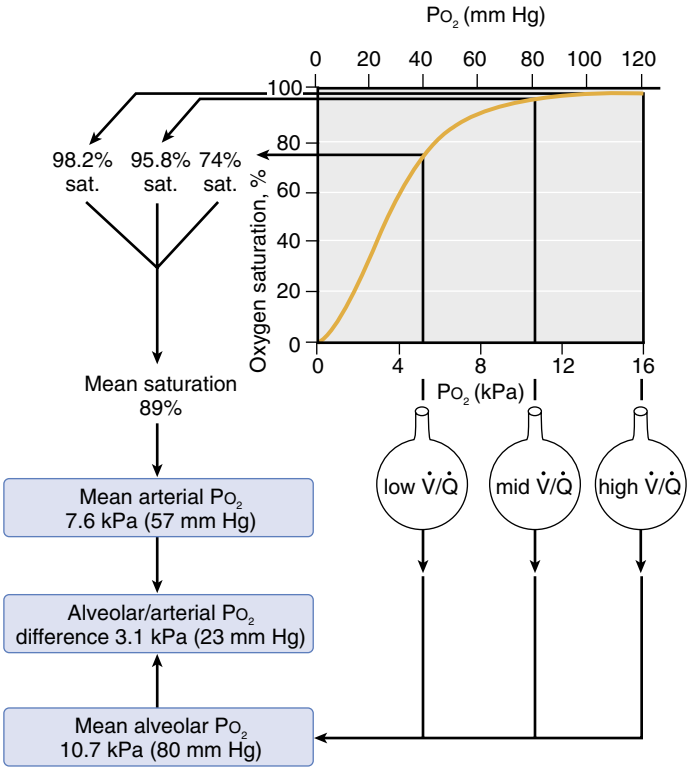

Figure 44-2 Alveolar-arterial P_{O_2} difference caused by scatter of $\dot{V}/\dot{Q}$ ratios resulting in oxygen tensions along the upper inflection of the oxygen dissociation curve. The diagram shows the effect of three groups of alveoli with P_{O_2} values of 5.3, 10.7, and 16.0 kPa (40, 80, and 120 mm Hg). Ignoring the effect of the different volumes of gas and blood contributed by the three groups, mean alveolar P_{O_2} is 10.7 kPa. However, because of the shape of the dissociation curve, the saturation of blood leaving the three groups is not proportional to their P_{O_2}. The mean arterial saturation is in fact 89%, and P_{O_2} is therefore 7.6 kPa. The alveolar-arterial P_{O_2} difference is thus 3.1 kPa. The actual difference would be somewhat greater because gas with a high P_{O_2} would make a relatively greater contribution to alveolar gas and blood with a low P_{O_2} would make a relatively greater contribution to arterial blood. In this example, a calculated venous admixture of 27% would be required to account for the scatter of $\dot{V}/\dot{Q}$ ratios in terms of the measured alveolar-arterial P_{O_2} difference at an alveolar P_{O_2} of 10.7 kPa. *(From Lumb AB: Nunn's Applied Respiratory Physiology, 6th ed. Philadelphia, Elsevier/Butterworth Heinemann, 2005.)*

venous P_{O_2} gradient, this shunt is partly responsible for the normal A-a O_2 gradient of 5 to 10 mm Hg found in children and young adults breathing room air. Shunt introduced by these circulations can increase to 10% of cardiac output in the presence of severe bronchial disease and aortic coarctation.[9] The normal heterogeneity of $\dot{V}/\dot{Q}$ throughout the lung is the other contributor to the baseline A-a gradient. The gradient increases with age, probably secondary to increased closing capacity and $\dot{V}/\dot{Q}$ scatter.[7]

Pathologic right-to-left shunting of blood occurs in areas of atelectasis or airway blockage, as in acute lung injury (ALI) or pneumonia. Alveoli are collapsed or unventilated but continue to be perfused. Venous drainage from lung tumors also constitutes a pathologic shunt. If hypoxic pulmonary vasoconstriction (HPV) fails to adequately limit blood flow to these regions, hypoxemia occurs. Indeed, inhaled anesthetics are known to cause attenuation of HPV, and induction of general anesthesia (GA) causes immediate development of atelectasis (see Chapter 15).[12,13] Both phenomena are probably contributors to the 5% to 10% shunt found in patients undergoing GA with mechanical ventilation.[10]

Calculating Shunt Fraction and Dead Space

A simplified but useful three-compartment lung model aids in approximating what fraction of cardiac output $(\dot{Q}_T)$ constitutes shunt $(\dot{Q}_S)$ and what fraction of tidal volume (V_T) constitutes dead space ventilation $(\dot{V}_{DS})$. Commonly known as the Riley approach, the lung is considered as though it were made up of three compartments at the three extremes of $\dot{V}/\dot{Q}$ matching: (1) a shunt compartment with perfused but unventilated alveoli, (2) a dead space compartment with ventilated but unperfused alveoli, (3) and an ideal compartment with normally distributed ventilation and perfusion (Fig. 44-3).

As discussed earlier, the lung is actually composed of many compartments with a wide distribution of $\dot{V}/\dot{Q}$ ratios, and this as an oversimplified but clinically useful model.

The shunt fraction $(\dot{Q}_S/\dot{Q}_T)$ can be calculated by using the Berggren shunt equation to compare the O_2 content of mixed venous $(C\bar{v}O_2)$, pulmonary capillary $(Cc'O_2)$, and arterial (CaO_2) blood:

$$\dot{Q}_S/\dot{Q}_T = (Cc'O_2 - CaO_2)/(Cc'O_2 - C\bar{v}O_2) \quad (10)$$

In a normal subject with capillary O_2 saturation close to 100%, the following approximation can be made

$$\dot{Q}_S/\dot{Q}_T = (1 - SaO_2)/(1 - S\bar{v}O_2) \quad (11)$$

where $S\bar{v}O_2$ and SaO_2 are mixed venous and arterial O_2 saturation, respectively.

It is important to note that the fraction calculated in Equation 10 is not a *true* shunt (intrapulmonary shunt through alveoli

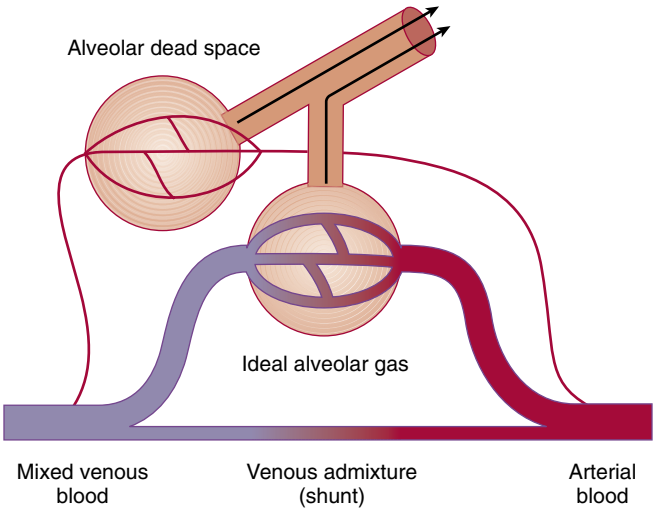

Figure 44-3 Three-compartment (Riley) model of gas exchange. The lung is imagined to consist of three functional units consisting of alveolar dead space, "ideal" alveoli, and venous admixture (shunt). Gas exchange occurs only in the "ideal" alveoli. The measured alveolar dead space consists of true alveolar dead space together with a component caused by $\dot{V}/\dot{Q}$ scatter. The measured venous admixture consists of true venous admixture (shunt) together with a component caused by $\dot{V}/\dot{Q}$ scatter. Note that "ideal" alveolar gas is exhaled contaminated with alveolar dead space gas, so it is not possible to sample "ideal" alveolar gas. *(From Lumb AB: Nunn's Applied Respiratory Physiology, 6th ed. Philadelphia, Elsevier/Butterworth Heinemann, 2005.)*

with zero $\dot{V}/\dot{Q}$) but should be thought of as a *total* shunt because it includes intracardiac and physiologic shunting and the contribution of areas with relatively low (shuntlike) but nonzero $\dot{V}/\dot{Q}$. Thus, the model is unable to predict how much each of these factors contributes to the calculated shunt because they all introduce undersaturated blood into the arterial circulation. It is though that breathing 100% O_2 eliminates the *shuntlike* contribution by fully saturating capillary blood in low-$\dot{V}/\dot{Q}$ alveoli, but it appears instead that these regions may progress via resorption atelectasis into areas of true shunt.[14] Making the distinction between true shunt and shuntlike regions caused by low $\dot{V}/\dot{Q}$ may be clinically important, particularly for anesthesiologists, in that reduced $\dot{V}/\dot{Q}$ has been shown to be more predictive of postoperative hypoxemia than increased shunt is.[10] Techniques allowing more accurate distinction between the components of calculated shunt and dead space have been developed and are described later.

A method has been derived to estimate shunt fraction without sampling arterial or mixed venous blood.[15] Arterial oxygen content is calculated from measured hemoglobin (Hb) and Spo_2, and Po_2 is obtained from the alveolar gas equation by using end-tidal Pco_2 as an estimate of $Paco_2$. Mixed venous O_2 content is estimated by assuming a fixed arterial–to–mixed venous O_2 gradient. Estimates of shunt fraction obtained by this method are expectedly somewhat imprecise (±16%) when compared with invasive measurements but are adequate for clinical use.

The dead space component in the three-compartment gas exchange model can be calculated with the Bohr equation:

$$V_{DS}/V_T = \left(Paco_2 - Peco_2\right)/Pao_2 \qquad (12)$$

where Peo_2 is the mixed expired Pco_2

The fraction calculated includes anatomic, alveolar, and apparatus (i.e., breathing circuit) dead space, which together represent *physiologic* dead space.

As with the shunt calculation described earlier, dead space determined by the equation is not *true* dead space because it includes an indeterminate contribution from relatively underperfused or *dead space–like* alveoli with high $\dot{V}/\dot{Q}$ (see Fig. 44-3). Another limitation of the model is that alterations in cardiac output or Hb concentration can lead to different calculated values of shunt fraction, even when actual $\dot{V}/\dot{Q}$ ratios have not changed. A substantial rise in cardiac output will increase $S\bar{v}o_2$ and cause a subsequent rise in the O_2 content of shunted blood and therefore arterial blood (Fig. 44-4). The calculated shunt fraction would decrease without an actual decrease in percent shunt by volume.

Distinguishing between Shunt and Altered $\dot{V}/\dot{Q}$ as the Cause of Impaired Oxygenation

In 1974, Wagner and coauthors described a technique known as multiple inert gas elimination (MIGET), which allows plotting of pulmonary ventilation and perfusion against the $\dot{V}/\dot{Q}$ ratio for a large number of lung compartments (rather than just three compartments as in the Riley approach), all with different $\dot{V}/\dot{Q}$ ratios.[14] Six inert tracer gases with widely varying blood solubility are infused intravenously and allowed to reach steady state. Arterial and mixed expired gas concentrations are measured, and the mixed venous concentration is calculated via the Fick principle. Retention-solubility and excretion-solubility curves are created and then translated into a continuous plot of perfusion against $\dot{V}/\dot{Q}$ and ventilation against $\dot{V}/\dot{Q}$, respectively, in relation to the heterogeneous spectrum of $\dot{V}/\dot{Q}$ ratios present throughout the lung. A host of other variables can be accurately measured, including intrapulmonary shunt and alveolar dead space. The technique is cumbersome and the numerical analyses rather complicated for routine use, but studies using the technique have been invaluable to our understanding of gas exchange in intensive care unit (ICU)[16] and surgical[17,18] settings. Figure 44-5 shows a typical plot in awake patients, with the development of shunt, increased dead space, and $\dot{V}/\dot{Q}$ scatter on induction of GA. Increasing shunt detected by multiple inert gas elimination (MIGET) has been correlated with increasing atelectasis noted on chest computed tomography (CT).[19] Distinguishing between true shunt and low $\dot{V}/\dot{Q}$ can also be performed noninvasively by simultaneously plotting Sao_2 versus Pio_2 (Fig. 44-6). Increasing shunt shifts the curve downward, whereas reducing $\dot{V}/\dot{Q}$ below the normal 0.8 shifts the curve rightward. The figure schematically shows the long-established observation that hypoxemia caused by true shunt is minimally responsive to increased Pio_2, in contrast to hypoxemia caused by $\dot{V}/\dot{Q}$ mismatch. As mentioned, $\dot{V}/\dot{Q}$ reduction detected by a rightward shift of the curve intraoperatively has been shown to correlate with hypoxemia up to 30 hours postoperatively. The technique may help identify patients at risk for postoperative hypoxemia and in need of supplemental O_2 and closer monitoring. It can also be used in patients with chronic lung disease to determine whether additional O_2 may be needed during air travel or at altitude.[10]

Blood Gas Analysis

Measurement of Blood Gas Tensions

The basic design that modern blood gas analyzers still use today was introduced by Severinghaus and Bradley in 1958.[20] Designed by Leland Clark in 1953,[21] the Po_2 electrode is a platinum probe bathed in an electrolyte solution and separated from the sample (blood) by an O_2 permeable membrane. Oxygen molecules pass from blood through the membrane and are reduced to hydroxyl ions. Po_2 is proportional to the current generated by this reduction reaction. Similarly, the Stow/Severinghaus Pco_2 electrode is a pH-sensitive glass probe bathed in a bicarbonate solution and encased by a CO_2 permeable membrane. Pco_2 is proportional to the H^+ generated as CO_2 reacts with water to form H^+ and HCO_3^-. Severinghaus and Astrup have provided a detailed history of the development of blood gas analysis (BGA).[22,23]

Temperature Correction

Modern blood gas analyzers measure blood gas tensions at 37°C. Because patients rarely have a temperature of exactly 37°C, blood samples must be heated or cooled to 37°C for analysis. Heating a blood sample decreases pH, gas solubility, and Hb affinity for O_2 and CO_2. Thus, as the blood from a hypothermic patient (say 35°C) is heated and analyzed at 37°C, more gas becomes dissolved in solution and the measured Po_2 and Pco_2 will be higher than at 35°C. Raising the temperature also increases the H^+ concentration and would give a falsely low pH in a hypothermic patient. Modern analyzers use one of a number of algorithms to automatically correct pH and blood gas tensions for temperature, and Box 44-2 provides the formulas approved by the National Committee

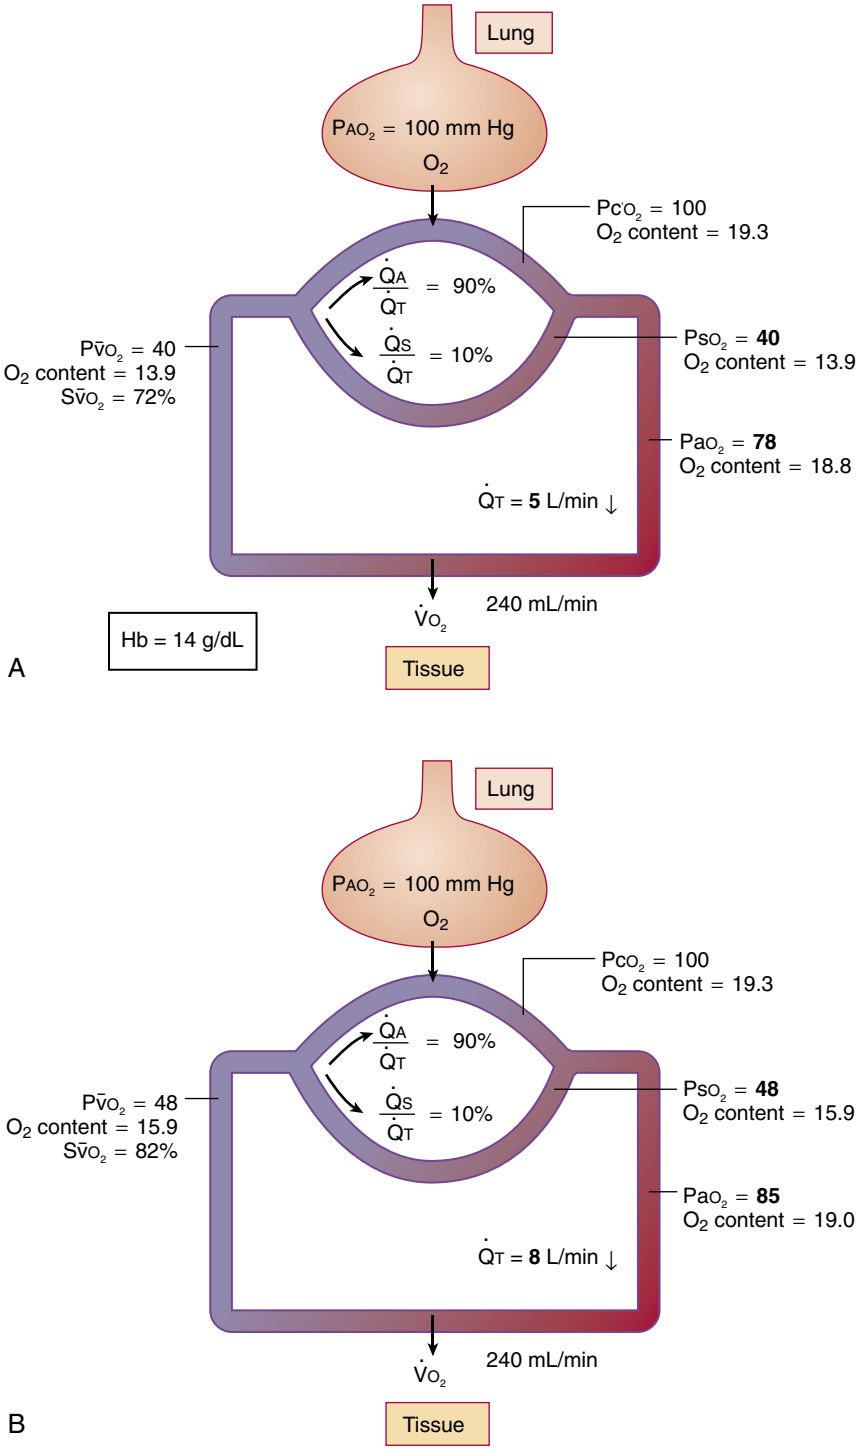

Figure 44-4 Effect of cardiac output on P_{O_2}. **A,** Arterial and mixed venous O_2 tension and content are shown at a cardiac output of 5 L/min. **B,** Assuming constant $\dot{V}_{O_2}$, an increase in cardiac output to 8 L/min increases P_{aO_2} from 78 to 85 mm Hg because $S_{\bar{v}O_2}$ increases at higher cardiac output. The resulting increase in O_2 content of the shunted blood (here assumed to be 10% of cardiac output) then raises the arterial O_2 content and P_{aO_2}. P_{O_2} values are in mm Hg, and O_2 content is in mL/dL.

for Clinical Laboratory Standards (NCCLS). The corrections are all rather slight, and there is little evidence to suggest that temperature-corrected values are clinically more useful than 37°C values. Two approaches, pH-stat and alpha-stat, have been used to manage pH in hypothermic patients undergoing cardiopulmonary bypass. The alpha-stat approach lets pH rise naturally into the alkalotic range as the patient is cooled, and pH-stat maintains normal pH and presumably cerebral perfusion by adding CO_2. Data favoring either approach are very limited.

Artifactual Changes in Arterial Blood Gas Values

Delay in analyzing a blood sample after it is drawn can artifactually change the measured pH and gas tensions. Storing a sample longer than 20 minutes can cause a significant elevation in P_{CO_2} and reduction in P_{O_2} and pH, probably secondary to cellular metabolism. Leukocytosis and thrombocytosis accelerate these

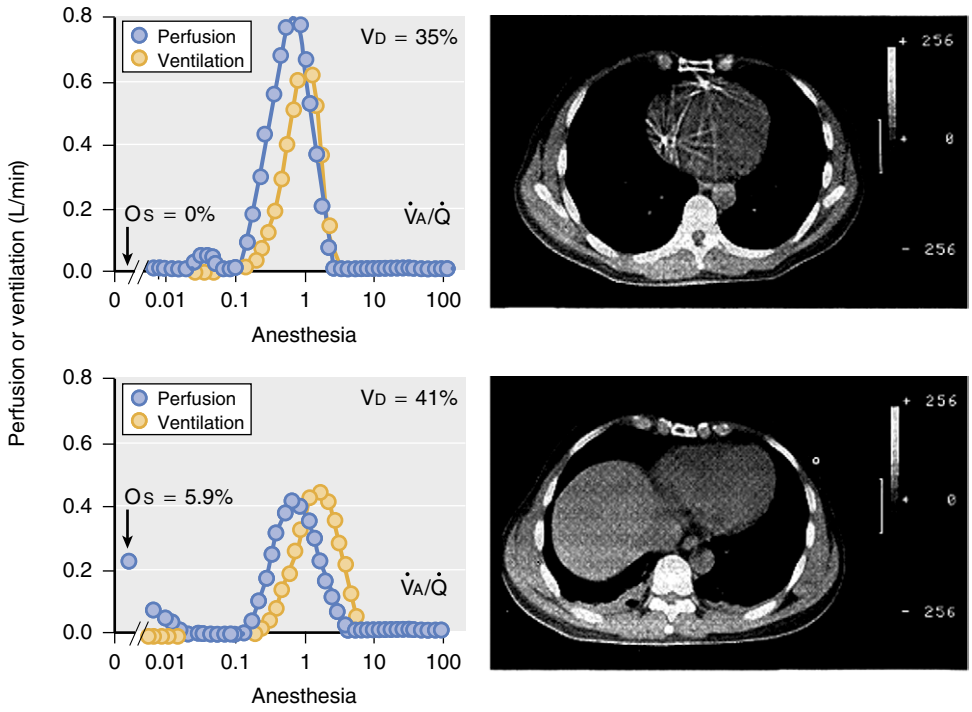

Figure 44-5 Ventilation-perfusion ($\dot{V}_A/\dot{Q}$) distribution and computed tomography in a supine subject. **Left,** $\dot{V}_A/\dot{Q}$ distribution in an awake (*top*) and anesthetized (*bottom*) subject. Note the appearance of a pulmonary shunt and an increase in $\dot{V}_A/\dot{Q}$ mismatch during general anesthesia with mechanical ventilation. **Right,** Computed tomography of the chest just above the top of the right diaphragm. Note the appearance of densities in the dependent lung regions during anesthesia. V_D, volume of distribution. *(Redrawn from Gunnarsson L, Tokics L, Gustavsson H, et al: Influence of age on atelectasis formation and gas exchange impairment during general anesthesia. Figure 44-6 Hemoglobin-oxygen (HbO_2) saturation versus inspired partial pressure of oxygen (P_{O_2}). The curves are plotted by changing inspired P_{O_2} in stepwise fashion. **A,** Series of theoretical curves obtained by calculating the effect of different degrees of right-to-left shunt. Increasing shunt displaces the curves downward. **B,** The curve on the *left* of the graph (0%) is from a normal subject. The *middle* curve (30%) represented a 30% right-to-left shunt from the 30% curve seen in **A**. The curve on the *right* of this graph is from a patient undergoing thoracotomy for esophageal surgery. The points cannot be fitted by any of the shunt curve, but the fit is quite good when the 30% curve is shifted to the right. This implies a combination of shunt and $\dot{V}_A/\dot{Q}$ mismatch. *(Adapted from Jones JG, Jones SE: Discriminating between the effect of shunt and reduced $\dot{V}_A/\dot{Q}$ on arterial oxygen saturation is particularly useful in clinical practice. J Clin Monit Comput 16:337, 2000.)*

changes.[24] Because red cells do not contain mitochondria, this phenomenon is not observed in polycythemia. However, anaerobic glycolysis can generate lactic acid and reduce pH. Placing the sample in ice immediately after it is obtained can maintain its stability, and addition of sodium fluoride or cyanide can inhibit cellular O_2 consumption.[24] The presence of air bubbles in the sample syringe can falsely elevate Po_2 but has little effect on pH and Pco_2. Syringes are usually heparinized to prevent coagulation.

Transcutaneous Blood Gas Monitoring

Although the turnaround time for obtaining Po_2 with traditional blood gas analyzers has drastically decreased since their inception, the ability to assess a patient's oxygenation status even more rapidly and easily has obvious advantages. One alternative is to measure gas tensions at the bedside transcutaneously. This technology relies on the tendency of capillary Po_2 to approximate arterial Po_2 when skin is warmed, which causes blood flow to exceed the amount required for local O_2 consumption. O_2 from capillaries diffuses through the warmed skin, where it is analyzed by a Clark-type electrode adhered to it. Though useful in infants, transcutaneous gas monitoring has many limitations despite good agreement of Po_2 values with traditional BGA.[25] Peripheral vascular disease or vasoconstriction can generate erroneous values. Cutaneous hypoxia caused by reduced cardiac output will give falsely decreased Po_2 readings. These devices must be calibrated frequently, have a relatively slow response time, and can cause skin burns with prolonged application.

In-Line Blood Gas Monitoring

Continuous intra-arterial pH measurement was accomplished as early as 1927 with antimony electrodes. Shortly after Clark developed his Po_2 electrode in 1956, the first continuous intravascular blood gas monitoring (CIBGM) devices were developed. Early devices consisted of electrochemical sensors and were essentially modified Clark electrodes. Problems with these devices included excessive drift, lack of reliability, large size, and interference from anesthetic gases. Later, Lubbers and Opitz, using a technology known as fluorescence quenching, created fiberoptic probes to continuously measure Po_2 and Pco_2, which they named *optodes*.[26] Absorbance-based fiberoptic sensors were also developed. Only two single-parameter devices became commercially available: the Continucath 1000 electrochemical Po_2 sensor for adults and the Neocath (Biomedical Sensors, High Wycomb, UK) O_2 sensor for neonatal umbilical artery placement.

Advances in the design of single-parameter systems inevitably led to the development of multiparameter devices capable of measuring pH, Pco_2, Po_2, and temperature. Most are pure optode systems, with the Paratrend 7 being the only hybrid optode-electrode system. The upgraded Paratrend 7+ replaced the Clark Po_2 electrode with an optode, thus making it a pure optode system (Fig. 44-7).

Agreement between sensor and traditional BGA measurements can be quantified by use of the Bland-Altman calculation

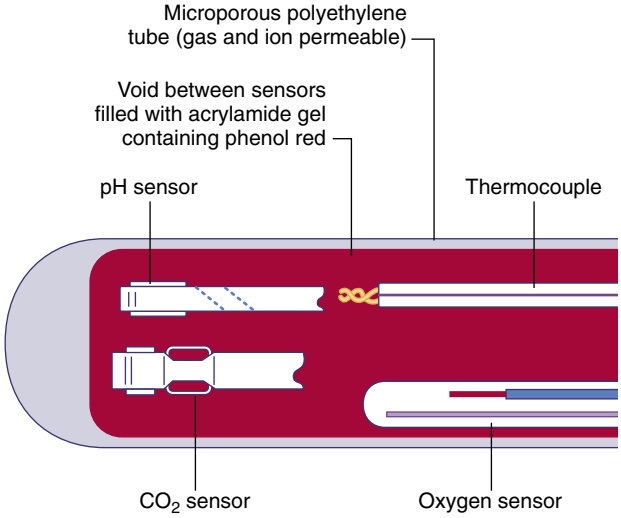

Figure 44-7 Cross section of the Paratrend 7 sensor tip. *(Courtesy of Biomedical Sensors, High Wycombe, UK.)*

of *bias* and *precision*.[27] Bias is the difference between mean values obtained by standard methods (BGA) and those obtained with the new device being tested. Precision is the standard deviation of these differences and measures reproducibility of the results.

Like their predecessors, newer probes remain fragile and continue to exhibit motion artifact, wall effect (decreased Po_2 readings because of contact with the arterial wall), and thrombogenicity. Their accuracy diminishes with insufficient blood flow to the cannulated artery. Moreover, despite encouraging in vitro and animal studies, results from clinical trials have not consistently been as favorable. Data for Pco_2 and pH measurements are impressive, but studies have found poor agreement of sensor Po_2 measurements with those obtained by BGA in elevated Po_2 ranges.[28,29] Weiss and colleagues found accurate results with minimal drift in all parameters up to 10 days after insertion in pediatric patients, but the O_2 sensor required frequent calibration.[30] Several published studies on the clinical performance of various CIABGM devices are summarized in Table 44-1.

Despite its limitations, CIABGM has many theoretical advantages over traditional BGA, although no outcome studies have proved these advantages (Box 44-3). Use of CIABGM in cardiac, thoracic, orthopedic, and transplant surgery may lead to earlier detection of severe blood gas and acid-base derangements.[35,36] Detection of Po_2 changes after cement implantation during hip replacement has been accomplished with this technology.[33] It has been validated for use in anesthesia and intensive care in pediatric patients.[32] Further technologic refinements, outcome studies, and data on cost-effectiveness are necessary for CIABGM to have widespread application in anesthesia and critical care.

Box 44-3 Advantages of a Continuous Intra-arterial Blood Gas Monitoring System over Intermittent Blood Gas Analysis

- Availability of continuous data
- Earlier detection of deleterious events
- Potential for trend analysis
- Decreased blood loss
- Decreased laboratory turnaround time
- Decreased exposure of staff to potentially infected blood

Oxygen Saturation

Although traditional BGA remains the standard modality for determining oxygen content, an alternative is to measure oxygen saturation (So_2). It can provide rapid and clinically useful information about oxygenation status.

Co-oximetry

The co-oximeter is a traditional blood gas analyzer that is also capable of measuring concentrations of HbO_2, reduced hemoglobin (HbR), carboxyhemoglobin (COHb), and methemoglobin (MetHb). Each of these species has unique absorption spectra, and corresponding wavelengths of light are used to analyze a small blood sample. It is currently the gold standard for measuring Sao_2. Results are usually obtained in less than 2 minutes.

Transcutaneous Oximetry

The principle of transcutaneous oximetry is similar to that of transcutaneous gas tension monitoring, but Sao_2 is measured instead of Po_2. Two wavelengths of light are used to measure quantities of oxygenated and deoxygenated blood to give an estimate of Sao_2, provided that the blood being analyzed is mostly arterial and other Hb species are absent. Two-wavelength ear oximeters were developed and used in practice more than 60 years ago.[37] Robert Shaw patented an eight-wavelength ear oximeter in 1972, and a device using this technology was marketed in the late 1970s by Hewlett Packard. Problems with size and reliability of data prevented its widespread use.

Pulse Oximetry

Some of the problems with transcutaneous oximetry were solved with the invention of pulse oximetry. Though first developed in Japan in the early 1970s, it was not until a decade later that its routine use began. Pulse oximetry works by analyzing the pulsatile arterial component of blood flow, thereby ensuring that arterial saturation (Spo_2) rather than venous saturation is being measured (Fig. 44-8). Two wavelengths of light are used, usually

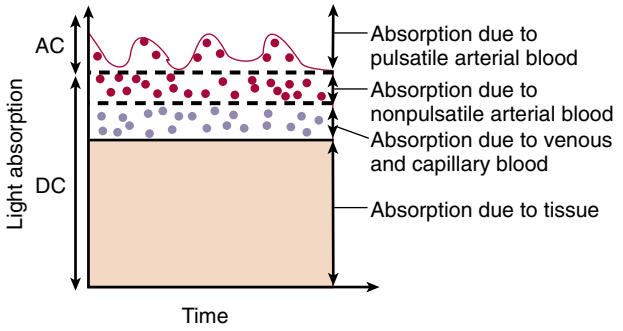

Figure 44-8 Principle of pulse oximetry. Light passing through tissue containing blood is absorbed by tissue and by arterial, capillary, and venous blood. Usually, only the arterial blood is pulsatile. Light absorption may therefore be split into a pulsatile component (AC) and a constant or nonpulsatile component (DC). Hemoglobin O_2 saturation may be obtained by application of Equation 19. *(Data from Tremper KK, Barker SJ: Pulse oximetry. Anesthesiology 70:98, 1989.)*

660 nm (red) and 940 nm (infrared), because oxygenated and deoxygenated blood each absorb light quite differently at these wavelengths. At 660 nm, HbO_2 absorbs less light than HbR does, whereas the opposite is observed with infrared light. Two diodes emitting light of each wavelength are placed on one side of the probe and a photo diode that senses the transmitted light on the opposite side. The amount of light absorbed at each wavelength by the pulsatile arterial component (AC) of blood flow can be distinguished from baseline absorbance of the nonpulsatile component and surrounding tissue (DC). The ratio R is calculated by the oximeter as follows and is empirically related to O_2 saturation:

$$R = \left(AC_{660}/DC_{660}\right)\Big/\left(AC_{660}/DC_{660}\right) \qquad (13)$$

A calibration curve (Fig. 44-9) is derived from R and laboratory measurements of arterial oxygen saturation in healthy volunteers and the algorithm stored in the oximeter. Modern devices

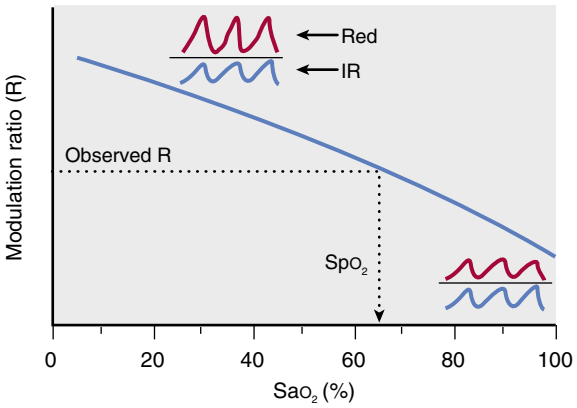

Figure 44-9 Red/infrared modulation ratio (R) versus oxygen saturation (Sao_2). At high Sao_2 (*right* side of the graph), the pulse amplitude (or modulation) of the red signal is less than that of the infrared signal, whereas the reverse is true at low Sao_2. Pulse oximeters measure R, the ratio of red to infrared pulse amplitudes (see Equation 13), and estimate Sao_2 by applying the calibration curve (*solid line*) as depicted by the *dashed line* and *arrow*. *(From Mannheimer PD: The light-tissue interaction of pulse oximetry. Anesth Analg 105(6 Suppl):S10-S17, 2007.)*

are calibrated against laboratory Sao_2 down to 70% saturation, and lower saturations are determined by extrapolation of the curve. Thus, pulse oximeters cannot be calibrated by the user, and their reliability is dependent on the quality of signal processing and the stored calibration curve.

Accuracy of Pulse Oximetry

Because of its impressive accuracy, reliability, and convenience, pulse oximetry has become one of the most important technologic developments in clinical monitoring. Several studies comparing co-oximetry and pulse oximetry report substantial agreement between Spo_2 and Sao_2 over a wide range of Sao_2 values.[38,39]

Errors in Pulse Oximetry

Because Spo_2 measurements are averaged over a few seconds to provide readings, there is some degree of delay in response time. Hypothermia, low CO, and vasoconstriction secondary to drugs or peripheral hypoxia all increase bias, imprecision, and response time for hypoxic episodes (Table 44-2).[40] This appears to be more common with finger probes than with ear or forehead monitoring (Fig. 44-10).[41] Motion artifact and hypoperfusion are the most common causes of Spo_2 inaccuracy,[42,43] both of which are less problematic with newer oximeters. Caution is advised in using pulse oximetry to not make inferences about gas exchange. Spo_2 should not be used to assess the adequacy of ventilation because Sao_2 is only minimally affected by changes in Pco_2 (via the Bohr effect). In addition, when Po_2 is high, large decreases in oxygen tension produce only small changes (if any) in Sao_2 and may not be detected with pulse oximetry (see Fig. 44-2).

Anemia, with an Hb concentration as low as 2.3 g/dL, has little or no effect on Spo_2 readings when Sao_2 is normal,[44] but underestimation of Sao_2 has been observed during hypoxemia.[45] Because MetHb substantially absorbs both red and infrared light, falsely low Spo_2 readings are generated when actual Sao_2 is above 85%, and readings are falsely high when actual Sao_2 is below 85%. Spo_2 invariably reads 85% when very large amounts of MetHb are present.[46] Conversely, COHb absorbs very little infrared light, but it is very similar to HbO_2 in its red light absorbance. Oximeters using only two wavelengths therefore cannot distinguish between HbCO and HbO_2, and the presence of HbCO produces falsely elevated Spo_2 readings. Erroneous Spo_2 readings can be caused by structural hemoglobinopathies,[47,48] as well as by a host of other factors, many of which are summarized in Table 44-2.

Recent Advances in Pulse Oximetry

Error Correction. Motion sensitivity and signal loss secondary to hypoperfusion are two of the more common errors that occur with pulse oximetry. These inaccuracies have been reduced with the recent advances in signal analysis that have been incorporated into units from a number of manufacturers.[49] Several studies suggest that newer units can detect hypoxemic episodes more reliably than their predecessors can under these conditions.[50,51] Indeed, one study reported that during hypoperfusion or excessive motion, oximeters using this technology give accurate Sao_2 readings in 92% of cases in which older monitors failed.[52]

Multiwavelength Pulse Oximeters. Because only two wavelengths of light are used in traditional pulse oximeters, the presence of additional Hb species cannot be detected, which may result in erroneous readings. Using principles from both pulse

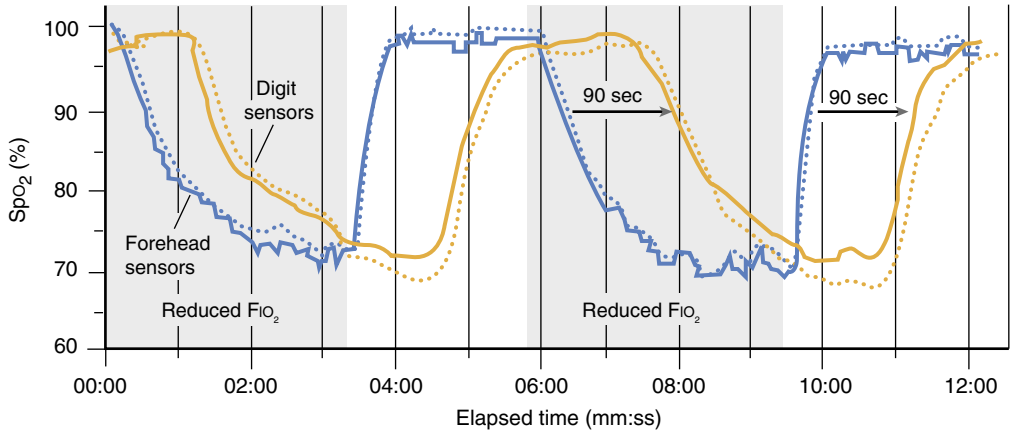

Figure 44-10 Effect of pulse oximeter probe replacement on delay from onset of hypoxemia to a drop in measured Spo_2. During cold-induced peripheral vasoconstriction in normal volunteers, the onset of hypoxemia was detected more quickly with an oximeter probe on the forehead than on the finger. Other studies have shown a similar advantage for pulse oximeter probes placed on the ear. *(From Bebout DE, Mannheimer PD, Wun C-C: Site-dependent differences in the time to detect changes in saturation during low perfusion. Crit Care Med 29:A115, 2002.)*

oximetry and co-oximetry, the first eight-wavelength pulse oximeter capable of measuring several species of Hb has become commercially available and may prove to be a major advance in oxygen monitoring. The Massimo Rad-57 (Massimo Corp, Irvine, CA) gained Food and Drug Administration (FDA) clearance in 2006 and boasts the ability to accurately measure MetHb and COHb, in addition to all the features of conventional pulse oximetry. Two large studies comparing measurements from the unit with conventional co-oximetry in emergency department patients have produced equivocal results, with one reporting a significant number of false-positive readings.[53,54] One smaller study in healthy volunteers reported good agreement between oximeter and laboratory measurements,[55] and other investigations to determine accuracy of the device are ongoing.

Reflectance Pulse Oximetry. The technology was developed to combat problems with signal transmission during hypoperfusion and for use when a transmission path is unavailable. Probes are commonly placed on the forehead, where motion artifact and hypoperfusion tend to be less of a problem than with other sites.[56] Forehead probes are commercially available and appear to detect hypoxemia more quickly than ear or finger probes do.[41] The light-emitting and light-sensing diodes are on the same side of the probe instead of opposite sides as in traditional pulse oximetry, and the reflected light from the tissue bed is analyzed. Indeed, reflectance oximetry has been used to monitor fetal oxygen saturation with scalp probes and been shown to decrease surgical intervention in the face of non-reassuring fetal status.[57] Esophageal probes have been designed and have shown success in measuring Spo_2 during cardiothoracic surgery when finger probes have failed.[58] The investigators reported minimal bias and narrow limits of agreement when compared with finger probes used in the study. Monitoring of gastric Spo_2 as an indicator of splanchnic perfusion has also shown promise.[59] Excessive edema, poor skin contact, and motion artifact are the most common sources of error in reflectance oximetry. Artifacts have also been shown to occur with probe placement directly over a pulsating superficial artery.[60]

Clinical Applications of Pulse Oximetry

Pulse oximetry is arguably most useful as an early warning sign of hypoxemia. Because this is of paramount importance in the surgical setting, pulse oximetry became a standard of care in anesthesia practice in 1986. In a large study comparing intraoperative pulse oximeter use with standard care, 80% of anesthesiologists felt more comfortable when using pulse oximetry.[61] It is interesting to note that despite its widely accepted value, there is little evidence that pulse oximetry affects outcomes in anesthesia,[62] and a study evaluating postsurgical patients did not demonstrate that routine Sao_2 monitoring reduces mortality, cost of hospitalization, or ICU transfer.[63]

Perioperative. In a randomized, controlled study of 200 surgical patients, Moller and colleagues found a reduced incidence of hypoxemia intraoperatively and in the postanesthesia care unit (PACU) when pulse oximetry was used. In the recovery room, patients in the oximeter group on average received higher FIO_2 and more naloxone, had a longer stay, and were discharged with supplemental O_2 more frequently.[64] The same group later conducted a study looking at postoperative complications with and without intraoperative pulse oximetry in 20,802 patients. No overall difference was found in complication rate, outcome, mean hospital stay, or in-hospital death between the groups, even though hypoxemia and hypoventilation were detected more frequently when pulse oximetry was used.[64] However, post hoc analysis of this trial suggests that pulse oximetry may have decreased the incidence of myocardial ischemia.[62] A number of studies report detection of hypoxemia several days postoperatively with pulse oximetry.[65,66] Intrapartum fetal pulse oximetry in the presence of a non-reassuring fetal heart rate is associated with a reduction in operative interventions.[57] The peak effects of analgesia may correlate with hypoxemia, so monitoring of patients receiving narcotics may be important to prevent adverse cardiac events.[67]

Critically Ill. The complicated pathophysiologic milieu of critical illness is such that many monitoring devices can produce inaccurate data in this patient population. Pulse oximetry, on the other hand, appears to maintain its reliability. Jubran and Tobin found that pulse oximeters accurately estimate Sao_2 in critically ill patients when Sao_2 is greater than 90% (bias, 1.7%; precision, ±1.2%) but are less accurate when Sao_2 falls below 90%.[68] An Spo_2 of 92% was indicative of adequate oxygenation when titrating O_2 in white patients. In black patients, however, significant hypoxemia was commonly present with an Spo_2 of

Table 44-2 Artifacts in Pulse Oximetry

Factor	Effect
Toxic Alterations in Hemoglobin	
Carboxyhemoglobin (COHb)	Slight reduction of the assessment of oxygen saturation (Sao_2) by pulse oximetry (Spo_2) (i.e., overestimates the fraction of hemoglobin available for O_2 transport)
Cyanmethemoglobin	Not reported
Methemoglobin (MetHb)	At high levels of MetHb, Spo_2 approaches 85%, independent of actual Sao_2
Sulfhemoglobin	Not reported (affects CO oximetry by producing a falsely high reading of MetHb)
Structural Hemoglobinopathies	
Hemoglobin F	No significant effect
Hemoglobin H	No significant effect (i.e., overestimates the fraction of hemoglobin available for O_2 transport)
Hemoglobin Köln	Artifactual reduction in Spo_2 of 8% to 10%
Hemoglobin S	No significant effect
Hemoglobin Replacement Solutions	
Diaspirin cross-linked hemoglobin	No significant effect
Bovine polymerized hemoglobin (oxygen carrier-201)	No significant effect
Dyes	
Fluorescein	No significant effect
Indigo carmine	Transient decrease
Indocyanine green	Transient decrease
Isosulfan blue (patent blue V)	No significant effect at low dose; prolonged reduction in Spo_2 at high dose
Methylene blue	Transient, marked decrease in Spo_2 lasting up to several minutes; possible secondary effects as a result of effects on hemodynamics
Hemoglobin Concentration	
Anemia	If Sao_2 is normal, no effect; during hypoxemia with Hb values less than 14.5 g/dL, progressive underestimation of actual Sao_2
Polycythemia	No significant effect
Other Factors	
Acrylic fingernails	No significant effect
Ambient light interference	Bright light, particularly if flicker frequency is close to a harmonic of the light-emitting diode switching frequency, can falsely elevate the Spo_2 reading
Arterial O_2 saturation	Depends on manufacturer; during hypoxemia, Spo_2 tends to be artifactually low
Blood flow	Reduced amplitude of pulsations can hinder obtaining a reading or cause a falsely low reading
Henna	Red henna, no effect; black henna, may block light sufficiently to preclude measurement
Jaundice	No effect; multiwavelength laboratory oximeters may register a falsely low Sao_2 and falsely high COHb and MetHb
Motion	Movement, especially shivering, may depress the Spo_2 reading
Nail polish	Slight decrease in Spo_2 reading, with greatest effect using blue nail polish, or no change
Sensor contact	"Optical shunting" of light from source to detector directly or by reflection from skin results in falsely low Spo_2 reading
Skin pigmentation	Small errors or no significant effect reported; deep pigmentation can result in reduced signal
Tape	Transparent tape between sensor and skin has little effect; falsely low Spo_2 has been reported when smeared adhesive is in the optical path
Vasodilatation	Slight decrease
Venous pulsation (e.g., tricuspid insufficiency)	Artifactual decrease in Spo_2

92%, and an Spo_2 of 95% was needed to ensure adequate oxygenation. After cardiac surgery, use of pulse oximetry has been shown to increase detection of hypoxemic episodes and decrease the number of arterial BGAs performed in the ICU.[69]

New and Future Applications

Analysis of the plethysmographic waveform generated by pulse oximeters has been advocated as a means of assessing volume status, fluid responsiveness, and a number of other clinical variables.[70,71] Respiratory variations in systolic pressure (dPs) and arterial pulse pressure (dPp) have been shown to be accurate indicators of volume status and fluid responsiveness in mechanically ventilated patients (Fig. 44-11).[72] Pulse pressure variation may predict fluid responsiveness more reliably than the use of dPs can. Such analyses require placement of an arterial catheter and are not always practical. Recently, variation in the pulse oximeter plethysmograph (dPOP) amplitude was shown to be a reliable noninvasive surrogate for dPp because both parameters are dependent on

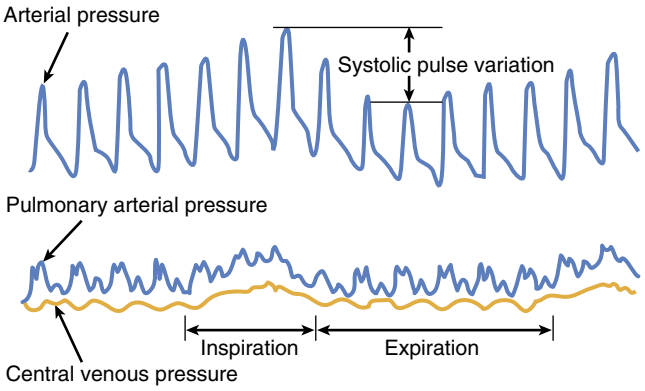

Figure 44-11 Cyclic variation of vascular pressures during positive-pressure ventilation. Inspiratory reduction in preload leads to reduced left ventricular volume after a lag phase of a few heartbeats because of pulmonary vascular transit time. The inspiratory decrease in left ventricular volume results in decreased stroke volume and systolic blood pressure during expiration. Similar variations in amplitude can be noted in pulse oximeter waveforms. *(From Nanchal R, Taylor RW. Hemodynamic monitoring.* In *Papadakos PJ, Lachmann B [eds]: Mechanical Ventilation: Clinical Applications and Pathophysiology. Philadelphia, Elsevier, 2008.)*

stroke volume.[73] In a study of patients under GA, Cannesson and colleagues found that baseline dPOP was correlated with percent change in cardiac index induced by volume expansion.[74] Similar results were obtained in a separate study on critically ill septic patients.[75] The authors of these trials concluded that dPOP can predict response to fluid administration and quantifies the effect of volume expansion on a number of hemodynamic parameters. To elucidate where the oximeter probe should be placed to best detect these variations, Shelley and colleagues analyzed plethysmographic waveforms from finger, ear, and forehead probes in patients undergoing positive-pressure ventilation during surgery, as well as in spontaneously breathing patients.[76] Their results suggest that the ear and forehead may be better monitoring sites than the finger for detection of variation in respiratory waveform. Because error and artifact correction in most commercial pulse oximeters can obscure the often subtle respiratory variations, unaltered plethysmographic waveforms are needed for such analyses.

Many other novel applications of pulse oximetry in anesthetic practice have been studied. Mowafi found that dPOP may be a better indicator of intravascular test dose injection during epidural placement than traditional hemodynamic markers are (i.e., heart rate and blood pressure).[77] A 10% decrease in POP indicated intravascular injection with 100% sensitivity, specificity, positive predictive value, and negative predictive value. Sensitivities using heart rate and blood pressure change as criteria were 85% to 95%. Changes in perfusion index (defined as AC_{940}/DC_{940}) have been used as confirmation of epidural placement and as an indicator of painful stimulus under anesthesia.[78,79] Many modern oximeters are programmed to measure perfusion index.

Mixed Venous Monitoring

Shock represents an imbalance between oxygen demand, delivery, and utilization at the tissue level. Monitoring of mixed venous oxygen saturation ($S\bar{v}O_2$) can give insight into the adequacy of this balance. It can be calculated by rearranging the Fick equation for O_2:

$$S\bar{v}O_2 = SaO_2 - \dot{V}O_2/(Hb \times 1.39 \times CO) \quad (14)$$

From this equation, it is clear that decreased $S\bar{v}O_2$ can be caused by low SaO_2, low Hb, or low cardiac output, all of which decrease oxygen delivery (DO_2), or by increased O_2 consumption ($\dot{V}O_2$). These variables are related in the following way:

$$\dot{V}O_2 = DO_2 \cdot ERO_2 \quad (15)$$

where ERO_2 is the extraction ratio (%) of O_2.

If oxygen delivery to tissue falls and consumption is to remain constant, oxygen extraction by tissues must increase. Blood returning to the right heart will therefore have a reduced O_2 content and $S\bar{v}O_2$. Thus, a reduced $S\bar{v}O_2$ is suggestive of global tissue hypoxia, which often precedes multiorgan failure and death.[80] Increased anaerobic metabolism as evidenced by increased lactate levels ensues and is associated with increased mortality.[81] These processes are usually under way as $S\bar{v}O_2$ approaches 40%. A pulmonary artery catheter is required to measure mixed venous saturation, and continuous monitoring can be performed with a catheter that incorporates a fiberoptic bundle. A superior vena cava sample obtained from a central venous catheter is often used as a surrogate for mixed venous saturation when a pulmonary artery catheter is impractical or unavailable.[82]

Shock of any etiology can cause the aforementioned turn of events, and a low $S\bar{v}O_2$ sheds no light on the cause of the global hypoxia. As mentioned, low $S\bar{v}O_2$ may not always be secondary to impaired delivery but may be due to increased oxygen consumption in the face of fever, thyrotoxicosis, and other conditions (Fig. 44-12). Moreover, a normal $S\bar{v}O_2$ is not necessarily indicative of adequate tissue oxygenation. Although cardiogenic and hypovolemic shock is very often associated with low $S\bar{v}O_2$, it can be normal or elevated in shock secondary to severe sepsis or hepatic failure because these conditions are frequently associated with microvascular dysfunction and impaired oxygen extraction by tissues. DO_2 is often elevated in these states.

In a novel application of continuous $S\bar{v}O_2$ measurement, pulse oximetry combined with $S\bar{v}O_2$ monitoring has been used in patients with acute respiratory failure to continuously monitor shunt fraction and adjust ventilator settings accordingly.[82] The authors of this study adjusted continuous positive airway pressure (CPAP) levels to obtain the lowest shunt fraction and showed that use of this method results in CPAP settings similar to those obtained by conventional means. Though somewhat invasive, the technique was found to be cost-effective and accurate in titrating CPAP in this subset of patients.

Tissue Oxygenation

The goal of optimizing pulmonary gas exchange is to ultimately optimize oxygenation at the cellular level. Analysis of alveolar, arterial, and venous gases is used in conjunction with clinical indices of tissue function (i.e., urine output, mental status) to make inferences about the state of affairs in cells. Oxygen is transported from alveoli with a PO_2 of around 100 mm Hg down a steep gradient, known as the oxygen cascade, to its final site of utilization, the mitochondrion, where PO_2 is estimated to be less

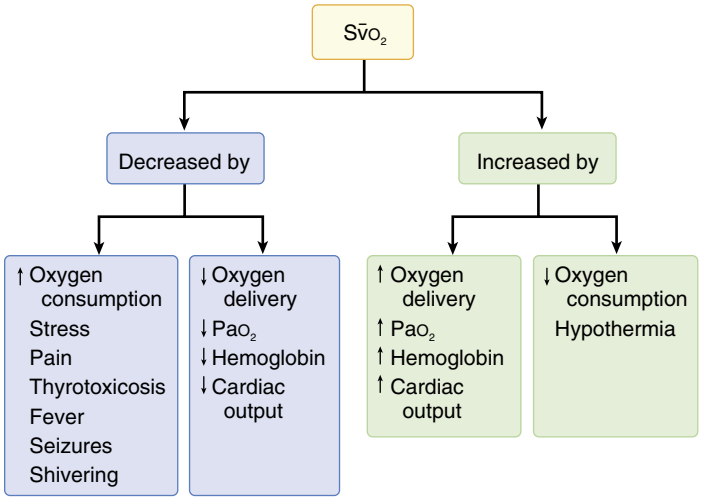

Figure 44-12 Causes of changes in mixed venous oxygen saturation. *(From Nanchal R, Taylor RW. Hemodynamic monitoring.* In *Papadakos PJ, Lachmann B [eds]: Mechanical Ventilation: Clinical Applications and Pathophysiology. Philadelphia, Elsevier, 2008.)*

than 1 mm Hg. Mitochondria from skeletal muscle appear to maintain their function with a Po_2 as low as 0.1 mm Hg.[83]

Unlike arterial Po_2 measurements, which should be nearly equal regardless of the artery sampled, Po_2 varies considerably within a particular organ or tissue bed because blood flow and O_2 consumption are not uniform but vary from point to point within the tissue. Because O_2 diffuses down a gradient from arterioles to mitochondria, measurements may also vary depending on where along this pathway a reading is obtained. Thus, it is generally thought that a distribution of Po_2 measurements across the tissue must be obtained to best describe its oxygenation status. Because of variable O_2 supply and demand, normal Po_2 levels and distributions differ from organ to organ.

A variety of methods have been devised to directly measure oxygen tensions and concentrations within tissues, and it has been an area of intense research for several decades. Most of the technologic advances have been made in the laboratory and have yet to be proved practical in the clinical setting.

Polarography is the current standard modality for measuring tissue oxygenation. It has the best resolution of all the available technology. Similar in principle to laboratory BGA, a Clark or needle-type electrode is inserted into tissue (rather than a blood sample), and Po_2 is proportional to the current generated as oxygen is reduced. Oxygen tension as low as 0.1 mm Hg can be resolved quite accurately. Though too invasive for routine clinical use, the technology is commercially available and has found application in neurosurgery and oncology.[84,85]

Near-infrared spectroscopy is a noninvasive system capable of measuring the oxygenation state of hemoglobin, myoglobin, and mitochondrial cytochromes.[86] The ability to monitor the oxygenation status of cytochromes along the electron transport chain will probably prove to be the best estimate of cellular oxygenation. Up to four wavelengths of light are applied to tissue, and the scattered light is returned via fiberoptic cables to the monitor for analysis. The technology has been incorporated into devices capable of measuring blood O_2 saturation in the brain, which have been commercially available for some 20 years.[87] Resolution is inferior to that of polarography, and problems with calibration and interference have limited its widespread use. Images can be obtained depicting changes in Hb concentration, but the resolution is poor.

A number of new systems for measuring tissue oxygenation are under laboratory investigation and have yet to reach commercial availability. Such systems include phosphorescence, fluorescence, electron paramagnetic resonance oximetry, and nuclear magnetic resonance spectroscopy. A number of reviews detailing all of these techniques have been compiled.[87]

Expired Gas Analysis

The ability to rapidly measure concentrations of inspired and expired gas is of paramount importance in anesthetic practice. Most anesthesia machines are equipped with oxygen sensors on the inspiratory limb of the circuit to help ensure that an adequate supply of oxygen is delivered to the patient at all times. Expired gas analysis is used to make inferences about blood concentrations and depth of anesthesia. Several systems are available for the measurement of gas tensions in exhaled air.

Mass Spectrometry

Mass spectrometry is a technique by which concentrations of gas particles in a sample can be determined according to their mass-charge ratio. A gas sample is passed through an ionizer and molecules become positively charged ions. Because all of the ions generated carry the same positive charge, this allows separation of particles based solely on mass. A detector then counts the number of ions of each mass, and the results are translated into concentrations. Measurements are quite reliable and can be obtained in fractions of a second.

Clinical use of mass spectrometry for expired gas analysis began in respiratory care units in the mid-1970s. They were introduced into operating rooms and anesthesia practice shortly thereafter. Because of their size and complexity, hospitals often connected many operating rooms to a single spectrometer and had the results relayed back to the anesthesiologist. The convenience plus low cost of infrared analyzers has largely phased mass spectrometry out of clinical use.

Infrared Absorption

Presently, most expired gas analyzers used in anesthesia involve infrared absorption. A gas sample is collected in a chamber through which infrared light is passed, and gas tensions are derived based on the intensity of the transmitted light. Today's infrared gas analyzers are capable of measuring all anesthetic agents currently in use, as well as CO_2 and N_2O. Oxygen does not absorb infrared light and therefore must be measured by other means, such as electrochemical or paramagnetic analysis.

Electrochemical Analysis

The same principles allowing electrochemical determination of oxygen in blood or tissue can be used to measure Po_2 in a mixture of gas. Polarographic (Clark type) electrodes, which require an applied voltage, or galvanic cells (most common) can be used for this purpose. In either arrangement, the amount of current generated as oxygen is reduced is proportional to the amount of oxygen present in the gas mixture, thus providing reliable estimates of Po_2 electrochemically. These sensor types are often used to measure inspired oxygen concentrations in anesthesia machines and conventional ventilators. Response time is somewhat slow and the method is rarely used for expired gas analysis.

Paramagnetic Analysis

Because the oxygen molecule has magnetic properties, its behavior in a magnetic field can be used to determine the concentration of oxygen in a gaseous mixture. Some newer anesthesia machines (e.g., Datex Ohmeda S/5) have incorporated paramagnetic oxygen analyzers capable of measuring oxygen in both the inspired and expired limbs of the circuit. Paramagnetic devices boast a longer life span and faster response time than electrochemical cells do.

Measurement of Nitric Oxide

Nitric oxide (NO) is a potent pulmonary vasodilator and has been used for a number of years to improve oxygenation in the face of acute respiratory distress syndrome (ARDS) and severe pulmonary hypertension (see also Chapter 31). It is produced endogenously and has multiple physiologic functions, including neurotransmission, regulation of vascular tone, and mediation of inflammation. Studies have identified NO as a marker of airway eosinophil activation, and exhaled levels are elevated in a number of inflammatory airway diseases such as asthma and chronic obstructive pulmonary disease (COPD).[88] Elevation of exhaled NO is greater than 90% specific for the diagnosis of asthma in both children and adults.[89,90] NO_2, the toxic oxidation product of NO, can accumulate with prolonged treatment or if stored NO is exposed to oxygen. Although accumulation of harmful levels is rare, NO_2 is known to cause pulmonary toxicity even at relatively low concentrations. Thus, an ideal NO analyzer would also have the ability to accurately measure NO_2 levels to avoid delivery or accumulation of toxic levels of this by-product. As the diagnostic and therapeutic use of NO has increased, methods to accurately quantify inhaled and exhaled concentrations of both NO and NO_2 have been sought.

Continuous measurement of inhaled NO has traditionally been accomplished with the use of electrochemical sensors. NO is oxidized to nitric acid, and its concentration is proportional to the current generated by the reaction. A number of electrochemical NO sensors have been independently evaluated and are reported to be quite accurate in measuring inhaled NO and NO_2.[91,92] The electrodes are sensitive to water vapor, and prolonged exposure can shorten the life span of the sensor and promote inaccurate readings. Accuracy also begins to wane at concentrations below 1 part per million (ppm), thus making them inappropriate for measurement of exhaled concentrations, which are typically in the parts-per-billion (ppb) range. Moreover, the slow response time of electrochemical sensors prevents their use for single-breath and exhaled NO analysis.

Because it is normally exhaled in very low concentrations, NO in expired air can be measured only with mass spectrometry or a process known as chemiluminescence. These analyzers, currently the most commonly used, have a shorter response time and can detect less than 1 ppb NO and NO_2. Wide variations in exhaled NO readings have been reported with chemiluminescence analyzers, and NO_2 levels may be underestimated in the presence of high oxygen concentrations.[93,94] Unstable instrument temperature, varying expiratory flow rate, and interference are some of the factors that may explain these variations.[95] Another study comparing four analyzers found that only the most rapid device provided accurate analysis in a continuous flow system and that the other three overestimated low levels and underestimated high levels.[96] A mid-infrared laser spectroscopy system has been developed that may eliminate some of the problems encountered with chemiluminescence analyzers by simultaneously measuring CO_2. It has shown promise in a small study comparing its results with typical exhaled NO levels.[95]

Waveform Analysis of Expired Respiratory Gases

Capnographs

Changes in the shape of the expired CO_2 waveform in an intubated patient can provide very useful monitoring information. Capnometry is the measurement of expired CO_2 and has become increasingly popular as a diagnostic tool in a number of settings. It is now the confirmation method of choice in anesthesia for proper placement of an endotracheal tube. CO_2 concentration is usually measured by infrared absorption with either a mainstream or sidestream capnometer. Measurements can then be plotted against time or exhaled volume to generate a *capnograph*. Capnography has found many useful clinical applications, and in 1998 it was adopted by the American Society of Anesthesiologists as standard care for all general anesthetics administered.

Mainstream versus Sidestream

The major difference between sidestream and mainstream capnometry is location of the sensor. However, this seemingly minor

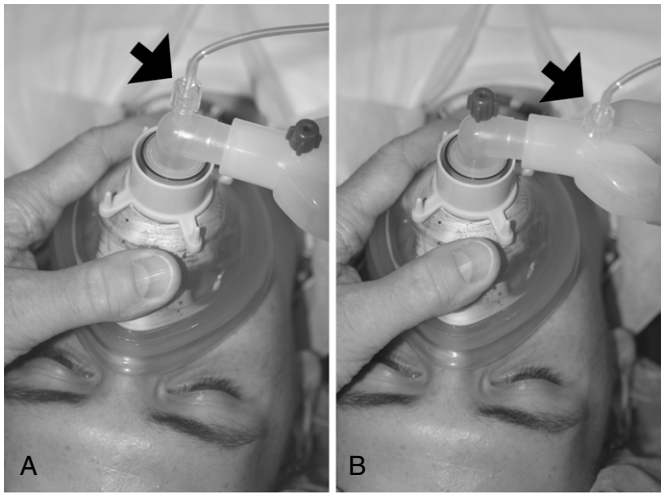

Figure 44-13 Sidestream sampling port placement. **A,** To minimize the effects of breathing circuit dead space, attachment of the sampling port should be as close to the patient as possible (*arrow*). **B,** Placement of the port as shown (*arrow*) can cause artifactual lowering of the end-tidal measurement.

difference plays a major role in the complexity, accuracy, and response time of each system.

SIDESTREAM. In sidestream capnometry, a fixed volume of gas is continuously sampled from the circuit. The sampled gas is aspirated through nylon or Teflon tubing into the measuring cell and then released into the atmosphere or returned to the circuit through a second tube (Fig. 44-13). Sampling should take place as close to the patient as possible to minimize the effects of circuit dead space, and the rate is usually adjusted to between 50 and 500 mL/min. It is imperative that the sampling rate be adjusted properly. Erroneous measurements will be obtained if the sampling rate exceeds the expiratory flow rate and causes inspired gas to be sampled. Hypoventilation may occur if the sampling flow exceeds fresh gas flow. Particular attention should be paid to this factor in the pediatric setting, in which expired and fresh gas flow can be quite low. Oxygen masks or nasal cannulas can be adapted to allow CO_2 monitoring (Fig. 44-14). The respiratory rate can be monitored adequately, but P_{ETCO_2} measurements may be falsely low unless the sample tubing is placed close to the nostril. Cannulas specifically designed to allow P_{ETCO_2} monitoring while administering O_2 have been developed and are commercially available.

There are several sources of potential error in sidestream capnometry. Water vapor condenses in the sample tubing and often accumulates in the measuring chamber. Liquids and particulate matter can also enter the measuring cell and produce erroneous readings. Most systems incorporate filters and water traps to help minimize these factors. Response time is delayed because gas samples must travel to the measuring cell through the sample tubing. Such delay can be minimized by using short tubing with a small lumen and high sample flow rates. The somewhat complicated sampling system and tubing connections provide multiple sites for damage or gas leakage. CO_2 can diffuse out of sample tubing and cause falsely low readings. Longer tubing and slower sampling rates increase this error, and nylon appears to be less permeable to CO_2 than other commonly used materials are.

MAINSTREAM. Mainstream capnometers incorporate the infrared sensor into the circuit very close to the endotracheal tube. Consequently, many of the problems with sidestream capnometry have been eliminated. CO_2 is measured directly in the circuit and no gas is subtracted, thus obviating the need for a complicated sampling system. The effects of breathing circuit and sample tubing dead space are minimized and the response time is therefore faster with mainstream systems. They are often used in the pediatric population, where circuit dead space can be more significant and response time is more critical. The measuring chamber must be warmed to about 40°C to prevent condensation of water vapor on the sensor window. Care must be taken to avoid skin contact with the chamber. It is somewhat heavy, and the

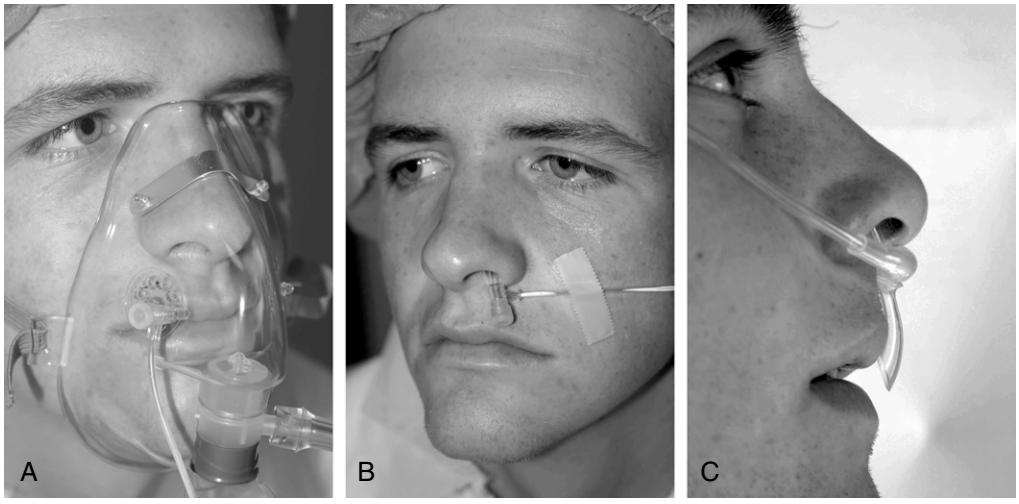

Figure 44-14 Monitoring a spontaneously breathing patient with a sidestream capnometer. **A,** Attachment of the sampling line to a non-rebreathing mask usually provides waveforms adequate for monitoring the respiratory rate, but end-tidal CO_2 tension (P_{ETCO_2}) is low because of mixing within the mask. **B,** Placement of a sample probe close to a nostril increases the accuracy of P_{ETCO_2} measurement. **C,** A specially designed probe (Oridion, Needham, MA) samples exhaled gas from the nose and mouth for assessing exhaled gas from mouth breathers. A second port in the same device can be used to administer supplemental oxygen.

circuit should be inspected frequently to avoid kinking of the endotracheal tube. Mainstream capnometers require frequent calibration, usually daily, and are prone to soiling with saliva or mucus because of their close proximity to the patient.

Time versus Volume Capnographs

TIME. The most commonly used type of capnograph plots P_{CO_2} versus time. The tracing is traditionally divided into an inspiratory phase and three (sometimes four) expiratory phases (Fig. 44-15):

Phase 0: inspiratory phase
Phase I: dead space and little or no CO_2
Phase II: mixture of alveolar and dead space gas
Phase III: alveolar plateau, with the peak representing end-expiratory (end-tidal) CO_2 (P_{ETCO_2}).

In patients with normal lung function, P_{ETCO_2} generally underestimates P_{aCO_2} by 1 to 5 mm Hg because of the presence of a small amount of alveolar dead space.[7] Factors that increase alveolar dead space will widen this gradient and increase the slope of phase III. During anesthesia there is often increased alveolar dead space caused by reduced cardiac output and decreased perfusion of the lung apices.[97] It is therefore not surprising that studies under anesthesia have found the P_{ETCO_2}-P_{aCO_2} gradient to be slightly elevated at 5 to 10 mm Hg.[98] An extreme example of acutely increased alveolar dead space is pulmonary embolism. Thus, an abruptly decreased P_{ETCO_2} with ventilation held constant is often indicative of a sudden decrease in cardiac output or pulmonary embolism. Other common causes of a widened gradient include obstructive lung disease, smoking, and advanced age. Examples of commonly encountered capnographic waveforms are shown in Figure 44-16.

The slope of the alveolar plateau (phase III) can also be increased in obstructive airway disease or during prolonged expiration. Two explanations for this phenomenon have generally been forwarded. First, obstructed (slow) lung units with low $\dot{V}/\dot{Q}$ and high P_{CO_2} empty slower and later than "fast" alveoli with normal $\dot{V}/\dot{Q}$ and low P_{CO_2}. This is manifested as a linear upsloping of phase III instead of the typical "plateau." Second, as lung volume decreases during exhalation and CO_2 excretion from capillaries remains constant, P_{CO_2} slowly rises throughout expiration and causes an upsloping plateau (Fig. 44-17).[99] Accordingly, even a person with completely normal lungs can have an upsloping plateau during prolonged expiration. End-tidal CO_2 therefore approximates *peak* alveolar CO_2, whereas P_{aCO_2} can be thought of as average alveolar P_{CO_2}.

At the terminal end of the phase III plateau, a sharp rise in P_{CO_2} is sometimes observed and is referred to as phase IV. Although its exact cause is unknown, this rise is thought to occur when closing capacity is reached and small airways close, usually

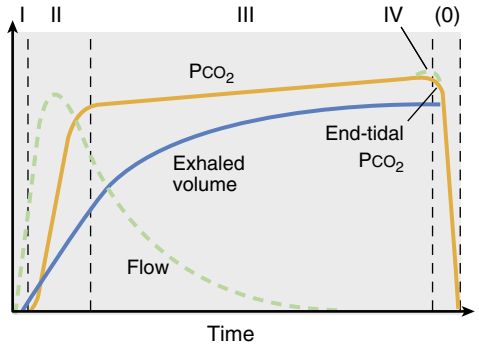

Figure 44-15 Time and volume capnographs. **A,** Expired P_{CO_2} versus time (i.e., standard time capnogram). The waveform is conventionally subdivided into phases. During phase I, exhaled gas from the large airways has a P_{CO_2} of 0. Phase II is the transition between airway and alveolar gas. Phase III (i.e., alveolar plateau) is normally flat, but in the presence of $\dot{V}_A/\dot{Q}$ mismatching, it has a positive slope. The downslope of the capnogram at the onset of inspiration is usually referred to as phase 0, but sometimes there is a terminal increase in the slope associated with the onset of airway closure (*dashed line* labeled IV). The P_{CO_2} value at the end of exhalation is referred to as the end-tidal P_{CO_2} (P_{ETCO_2}). Also shown are the exhaled gas flow rate and volume.

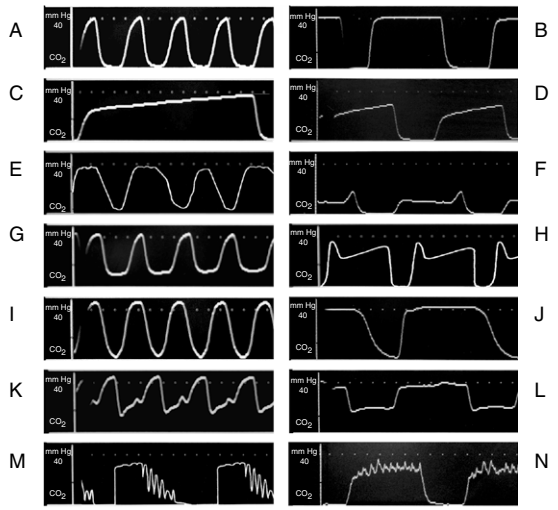

Figure 44-16 Examples of capnograph waves. **A,** Normal spontaneous breathing. **B,** Normal mechanical ventilation. **C,** Prolonged exhalation during spontaneous breathing. As CO_2 diffuses from mixed venous blood into alveoli, its concentration progressively rises (see Fig. 44-17). **D,** Increased slope of phase III in a mechanically ventilated patient with emphysema. **E,** Added dead space during spontaneous ventilation. **F,** Dual plateau (i.e., tails-up pattern) caused by a leak in the sample line. The alveolar plateau is artifactually low because of dilution of exhaled gas with air leaking inward. During each mechanical breath the leak is reduced because of higher pressure within the airway and tubing, thus explaining the rise in CO_2 concentration at the end of the alveolar plateau. This pattern is not seen during spontaneous ventilation because the required increase in airway pressure is absent. **G,** Exhausted CO_2 absorbent producing an inhaled CO_2 concentration greater than zero. **H,** Double peak in a patient with a single lung transplant. The first peak represents CO_2 from the transplanted (normal) lung. Exhalation of CO_2 from the remaining (obstructed) lung is delayed, thereby producing the second peak. **I,** Inspiratory valve stuck open during spontaneous breathing. Some backflow into the inspired limb of the circuit causes a rise in the level of inspired CO_2. **J,** Inspiratory valve stuck open during mechanical ventilation. The "slurred" downslope during inspiration represents a small amount of inspired CO_2 in the inspired limb of the circuit. **K** and **L,** Expiratory valve stuck open during spontaneous breathing and mechanical ventilation, respectively. Inhalation of exhaled gas causes an increase in inspired CO_2. **M,** Cardiogenic oscillations, when seen, usually occur on sidestream capnographs of spontaneously breathing patients at the end of each exhalation. Cardiac action causes to-and-fro movement of the interface between exhaled and fresh gas. The CO_2 concentration in gas entering the sampling line therefore alternates between high and low values. **N,** Electrical noise resulting from a malfunctioning component. The seemingly random nature of the signal perturbations (about three per second) implies a nonbiologic cause.

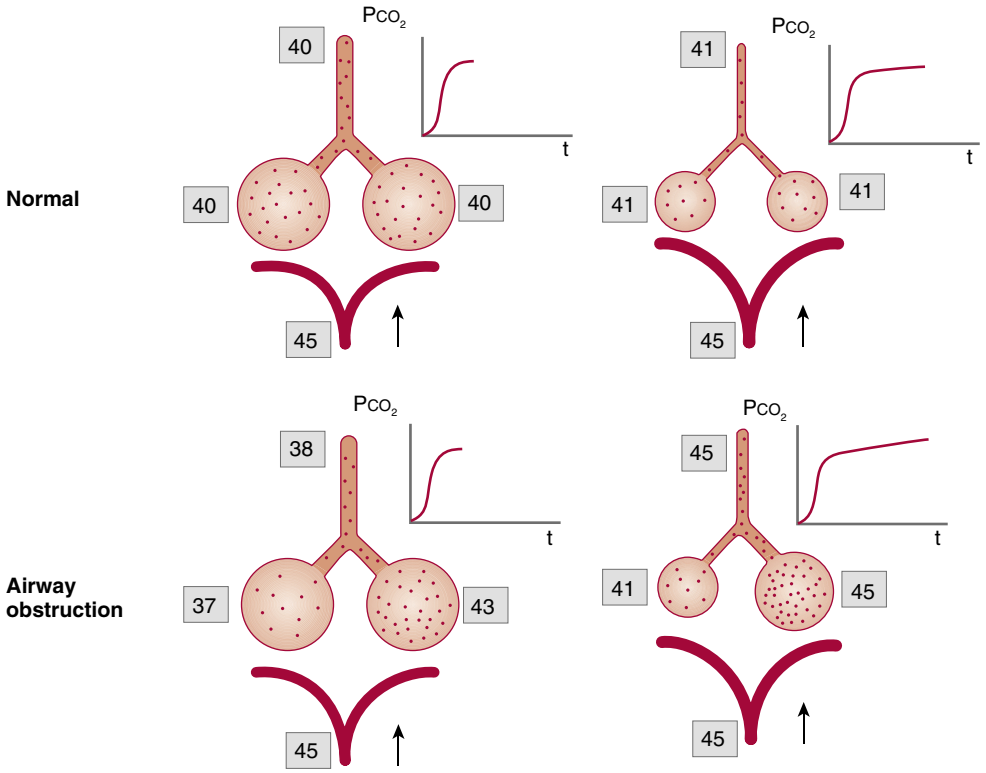

Figure 44-17 Mechanisms of airway obstruction producing an upsloping phase III capnogram. In a normal, healthy person (*upper panel*), there is a narrow range of $\dot{V}_A/\dot{Q}$ ratios with values close to 1. Gas exchange units therefore have similar P_{CO_2} and tend to empty synchronously, and the expired P_{CO_2} remains relatively constant. During the course of exhalation, alveolar P_{CO_2} slowly rises as CO_2 continuously diffuses from blood. This causes a slight increase in P_{CO_2} toward the end of expiration, and this increase can be pronounced if the exhalation is prolonged (see Fig. 44-16C). In a patient with diffuse airway obstruction (*lower panel*), the airway pathology is heterogeneous, with gas exchange units having a wide range of $\dot{V}_A/\dot{Q}$ ratios. Well-ventilated gas exchange units, with gas containing lower P_{CO_2}, empty first; poorly ventilated units, with higher P_{CO_2}, empty last. In addition to the continuous rise in P_{CO_2} mentioned previously, there is a progressive increase caused by asynchronous exhalation.

after prolonged expiration. These small airways may supply lung units with little CO_2 for various reasons, and their closure would therefore allow CO_2-rich gas from other lung units to abruptly reach the upper airway. Bhavani-Shankar and colleagues favor a different explanation and state that well-ventilated, open lung units have an upsloping increase in P_{CO_2} whereas P_{CO_2} in poorly ventilated, closure-prone units increases linearly. When poorly ventilated airways close, the pattern from well-ventilated units predominates and the slope of the plateau rises suddenly.[99] This concept is nicely cartooned at capnography.com in the phase IV section.

To summarize, any condition that increases alveolar dead space or $\dot{V}/\dot{Q}$ heterogeneity will increase the slope of phase III. This includes acute and chronic airway obstruction, and prolonged expiration in a normal subject can also generate this pattern. Sometimes this slope is so significant that the reported P_{ETCO_2} actually exceeds Pa_{CO_2}. This has been observed during anesthesia in obese patients and in 50% of both normal infants and pregnant women.[100] It is probably secondary to reduced thoracic compliance and functional residual capacity (FRC), increased cardiac output, and increased CO_2 production.[101] High mixed venous CO_2 tension and malignant hyperthermia have also been reported to cause a negative Pa_{CO_2}-P_{ETCO_2} gradient.[102] In such cases, P_{ETCO_2} is clearly not an accurate estimate of Pa_{CO_2}, and the average alveolar P_{CO_2} obtained from a volume capnograph may be more indicative of Pa_{CO_2}.[103]

Volume. A volume capnograph is obtained by plotting expired P_{CO_2} versus exhaled gas volume, usually obtained with a spirometer or pneumotachometer. There is no inspiratory phase in a volume capnograph, and the curve is divided into three expiratory phases. Several measurements that are not possible with time capnography can be made, such as partitioning of dead space components. The area under the P_{CO_2} curve is the total volume of CO_2 (V_{CO_2}) exhaled for that single breath. Dividing this value by the total exhaled tidal volume (V_T) gives the fraction of expired CO_2 (F_{ECO_2}), and the product of this fraction and barometric pressure yields a value for mixed expired P_{CO_2} (P_{ECO_2}). The Enghoff-modified Bohr equation can then be used to determine total (physiologic) dead space ($V_{DS_{phys}}$ or $V_{DS_{tot}}$) (Figs. 44-18 and 44-19):

$$V_{DS_{tot}} = V_T\left[\left(Pa_{CO_2} - P_{ECO_2}\right)/Pa_{CO_2}\right] \quad (16)$$

Once $V_{DS_{tot}}$ has been determined, subtracting the anatomic dead space ($V_{DS_{anat}}$) derived from the capnograph (see Fig. 44-18) yields the alveolar dead space component ($V_{DS_{alv}}$):

$$V_{DS_{alv}} = V_{D_{tot}} - V_{DS_{anat}} \quad (17)$$

Alternatively, alveolar dead space can be calculated by replacing P_{ECO_2} in the Bohr equation with *average* alveolar P_{CO_2} ($P_{A'CO_2}$), which can be derived from the volume capnograph[104]:

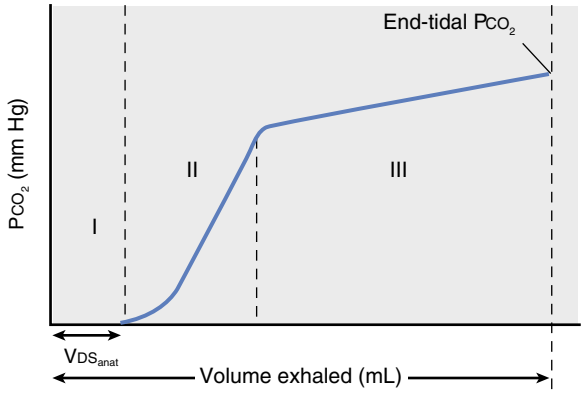

Figure 44-18 Volume capnograph: single-breath CO_2 ($SBCO_2$) curve. The horizontal axis of the graph represents expiratory/inspiratory tidal volume and is generally divided into three areas: I, the anatomic dead space volume ($V_{DS_{anat}}$); II, the transitional phase II volume; and III, the phase III alveolar volume. The sum of these values is the tidal volume. The vertical axis represents the concentration of CO_2. P_{CO_2}, partial pressure of carbon dioxide. *(From Pilbeam SP, Cairo JM: Mechanical Ventilation: Physiological and Clinical Applications, 4th ed. St. Louis, Elsevier, 2006.)*

$$V_{DS_{alv}} = (V_T - V_{DS_{anat}}) / \left[\left(Pa_{CO_2} - P_{A'CO_2} \right) / Pa_{CO_2} \right] \quad (18)$$

Capnography has been used to titrate positive end-expiratory pressure (PEEP) settings inasmuch as narrowing of the Pa_{CO_2}-P_{ETCO_2} gradient suggests reduced alveolar dead space and shunt fraction as a result of alveolar recruitment and improved $\dot{V}/\dot{Q}$ matching. These changes are often subtle or absent on a time capnograph and may be detectable only with volume capnography.[100] It has been suggested that an incompetent inspiratory valve and rebreathing during mechanical ventilation may require volume capnography to be detected reliably.[105] The technique may also be better than time capnography for the diagnosis of pulmonary embolism.[106]

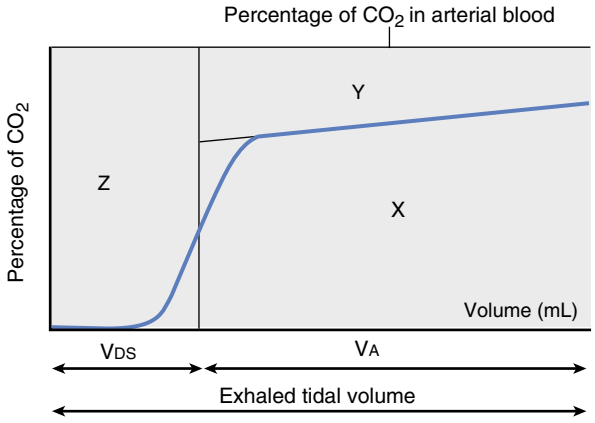

Figure 44-19 Volume capnograph: graph of the percentage of carbon dioxide (%CO_2) (*y* axis) and volume (*x* axis). A *horizontal line* drawn at the top of the curve represents %CO_2 in arterial blood. Three distinct regions are established. Area X represents the actual CO_2 exhaled in one breath (assuming that no CO_2 is rebreathed), area Y is the amount of CO_2 that is not eliminated because of alveolar dead space, and area Z is the amount of CO_2 not eliminated because of anatomic dead space. The ratios of these areas are the same as in the relationship seen in the Bohr equation: $(Pa_{CO_2} - P_{ECO_2})/Pa_{CO_2} = (Y + Z)/(X + Y + Z)$. P_{ECO_2}, mixed expired P_{CO_2}; V_A, alveolar volume; V_{DS}, dead space volume.

Additional Clinical Applications of Capnography

In addition to those outlined in the preceding sections, capnography has a host of clinical applications. Monitoring of P_{ETCO_2} can be invaluable during mechanical ventilation in the operating room and ICU to make inferences about cardiovascular status, Pa_{CO_2} trends, and adequacy of ventilation. Disappearance of the capnograph waveform may warn of cardiovascular collapse or massive airway obstruction, but it is most often due to disconnection or a large leak in the circuit. Capnography has been used to assess the efficacy of chest compressions during cardiopulmonary resuscitation and even to verify proper placement of enteric feeding tubes.[107]

Errors

Various disease states discussed previously may cause overestimation or underestimation of Pa_{CO_2} with use of P_{ETCO_2}. Condensation of water vapor in the sample tubing and measuring cell can elevate the reported P_{CO_2} slightly. Warming these pieces of equipment plus avoiding the use of drying agents in the sample line reduces this error. Capnometers may underreport true P_{ETCO_2} at higher respiratory rates. Exhausted CO_2 absorbent increases inspired CO_2, and failure to recognize such depletion may lead to suspicion of rebreathing from other causes.

Pulmonary and Chest Wall Monitoring

Pressure-Volume Curve Analysis

Lung mechanics can be severely impaired in a number of respiratory disorders. Monitoring changes in mechanical function of the lung is vital in developing a safe and effective support strategy in the face of respiratory failure. In a mechanically ventilated patient, construction of pressure-volume (PV) curves can provide important information about mechanics and help guide ventilator management. A *dynamic* PV curve is one that is constructed during gas flow, whereas *static* curves are derived when flow is absent. Techniques for constructing static curves were introduced in the mid-1970s and soon thereafter were shown to be useful in determining the cause of acute respiratory distress (Fig. 44-20). In recent years, the PV relationship has been studied extensively as a means of determining optimal PEEP and tidal volume in ARDS and ALI.

Static Curve

A static curve is constructed by using the ventilator or a large syringe to deliver known tidal volumes, and patients must be sedated and paralyzed for an optimal study. The resultant plateau (P_{plat}) and peak inspiratory pressures (P_{pk}) are recorded after each breath to allow determination of both static (C_{stat}) and dynamic (C_{dyn}) compliance. Because C_{stat} is calculated by using plateau

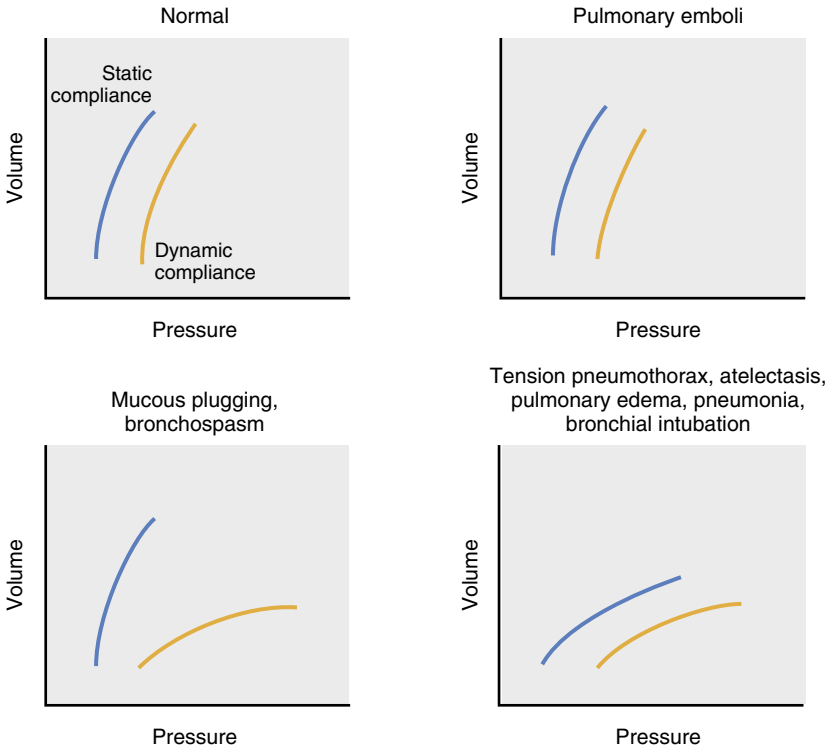

Figure 44-20 Pressure-volume curves reflecting changes in static and dynamic compliance (C_{stat} and C_{dyn}) during mechanical ventilation. Under normal conditions, the C_{stat} and C_{dyn} curves are similar. Because pulmonary emboli do not affect resistance or compliance, neither curve changes with this condition. With mucous plugging or bronchospasm, airway resistance (Raw) increases, the C_{dyn} curve shifts to the right and flattens (more pressure is required), and the C_{stat} curve remains unchanged. With conditions that reduce lung compliance (C_L), both curves shift to the right and flatten. *(From Bone RC: Monitoring ventilatory mechanics in acute respiratory failure. Respir Care 28:597-604, 1983.)*

pressure, it is mainly influenced by chest wall and alveolar elastic recoil:

$$C_{stat} = V_T / (P_{plat} - PEEP) \quad (19)$$

C_{dyn} is derived by using P_{pk} and therefore takes airway and circuit resistance into account as well:

$$C_{dyn} = V_T / (P_{pk} - PEEP) \quad (20)$$

In patients with normal lung function, the static PV curve is usually linear, and C_{stat} ranges from 50 to 100 mL/cm H_2O (Fig. 44-21). In disorders such as ARDS and ALI, where compliance can be substantially decreased, the curve becomes sigmoidal or S shaped.[108,109] Upper (UIP) and lower (LIP) inflection points can often be identified. The LIP, sometimes called P_{flex}, signifies an abrupt increase in compliance and is thought to result from the sudden recruitment of a large number of alveoli. The plateau pressure at which the LIP occurs is often referred to as the *opening pressure* of the lung. Overdistention of alveoli begins to occur once a critical volume (or pressure) is reached, marked by the UIP. Maintaining airway pressures between the LIP and UIP is therefore believed by many to prevent derecruitment and overdistention of alveoli, both of which contribute to ventilator-induced lung injury.[108,109] Using this reasoning, PEEP would be set slightly above the LIP to keep recruited alveoli open.[110] Indeed, this approach has been shown to result in earlier weaning from the ventilator, less release of inflammatory cytokines, and a trend toward reduced mortality in ARDS patients.[108,111]

Despite positive results using the LIP and UIP to guide PEEP and V_T settings, recent evidence suggests that the LIP does not correlate with the pressure at which recruited alveoli will begin to close, known as the *critical closing pressure*.[112,113] A probable explanation is that contrary to previous thought, recruitment has been shown to occur along the entire PV curve, independent of the LIP and UIP. Thus, setting PEEP above the LIP is not always beneficial and may instead increase the risk for overdistention and barotrauma.[114] Direct measures of appropriate response may be more suitable in determining the best PEEP level (see "Analysis of the Level of PEEP").

Once the lung has been fully recruited, a deflation curve can be drawn by stepwise deflation of the lung, similar to mapping of the inspiratory limb. As lung volume decreases, critical closing

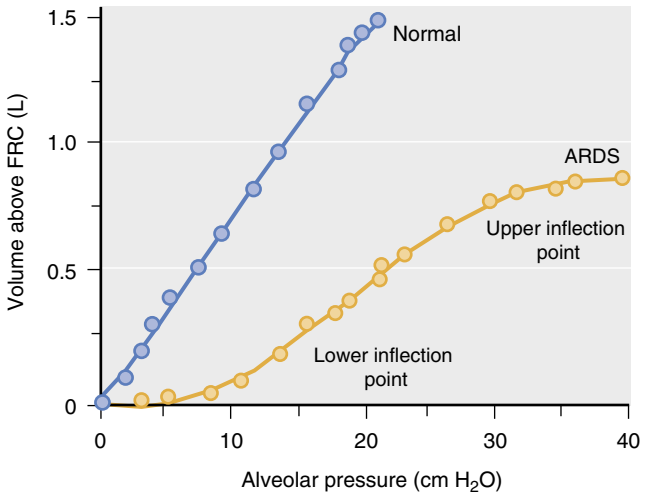

Figure 44-21 Example of a static, inspiratory pressure-volume curve of the respiratory system in a patient with acute respiratory distress syndrome (ARDS) versus a healthy subject. Upper (about 30 cm H_2O) and lower (about 10 cm H_2O) inflection points are present in the patient with ARDS. FRC, functional residual capacity. *(From Hess DR, Kacmarek RM: Essentials of Mechanical Ventilation, 2nd ed. New York, McGraw-Hill, 2002.)*

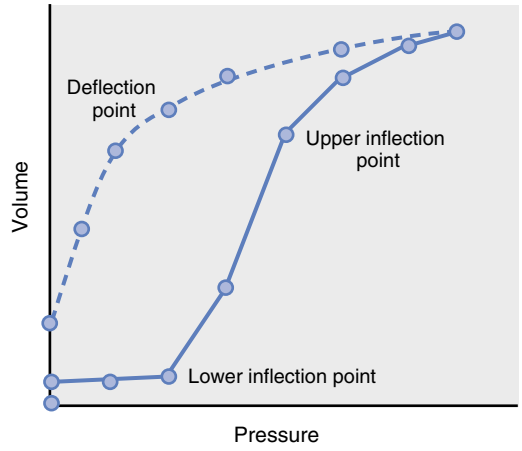

Figure 44-22 Pressure-volume relationship of the lung showing the inflation (*solid line*) and the deflation limb (*dashed line*). Note the clear difference in lung volume between both limbs at identical pressure (hysteresis). *(From van Kaam AHLC: Neonatal mechanical ventilation.* In *Papadakos PJ, Lachmann B [eds]: Mechanical Ventilation: Clinical Applications and Pathophysiology. Philadelphia, Elsevier, 2008.)*

pressure is reached, and a *deflection* point appears on the curve corresponding to a rapid decrease in compliance and closure of a large number of lung units (Fig. 44-22). Because compliance improves during inflation as lung units are recruited, higher volumes are observed at the same pressure during deflation than during inflation, a phenomenon referred to as *hysteresis*. Accordingly, critical closing pressure will be lower than opening pressure, and setting PEEP slightly above the deflection point rather than the LIP may provide superior alveolar stabilization with less risk of overdistention and ventilator-induced lung injury.[115,116] A number of recent studies suggest that the LIP does not reliably indicate the pressure at which maximal alveolar derecruitment occurs.[112,117] In addition, there is mounting evidence that using the deflation limb rather than the inflation limb of PV curves to guide ventilation may improve gas exchange and mechanics, often at lower mPaw and PEEP levels.[118,119] Therefore, although the presence of an LIP on the PV curve indicates a *need* for lung recruitment, the deflection point may be more valuable in determining the amount of PEEP required to prevent alveolar collapse. Evaluating deflation C_{stat} in this manner to determine closing pressure is at least as effective as monitoring Pao_2 for selection of the optimum PEEP level.[115,116] Moreover, recruitment maneuvers have been shown to be quite safe and are less injurious than allowing shear stress damage associated with derecruitment to proceed unchecked.[120,121]

Static PV curves can also be obtained from a single breath delivered slowly (2 to 3 L/m) until a predetermined pressure is reached and are referred to as slow-flow or quasi-static PV loops. The curves derived are comparable to those obtained with typical static techniques, but the deflation limb is often difficult to acquire.[122,123] Several modern ventilators have incorporated this capability. The Hamilton Galileo ventilator allows selection of the desired flow rate for the PV study, and an interactive curve is then displayed on the monitor, usually within 30 seconds.

Dynamic Curve

A number of ventilators are capable of mapping dynamic PV curves during tidal breaths delivered with normal gas flow. Newer ventilators automatically display the curve with each tidal volume. Though useful in following general trends in compliance, identification of inflection points is more difficult on dynamic PV curves. Several factors can alter the loop from breath to breath, and using dynamic curves for determination of optimal V_T and PEEP is not generally recommended.[122]

Analysis of the Level of PEEP

Application of PEEP has long been known to improve lung mechanics and gas exchange in many forms of acute respiratory failure. Appropriate PEEP increases FRC, decreases pulmonary edema, and maintains the patency of airways and recruited alveoli. It is important to note that PEEP does not recruit the lung; rather, it is sustained high pressure that reopens closed alveoli and airways, and PEEP stabilizes these recruited lung units. A host of tools and parameters described in this chapter have been used by clinicians to evaluate PEEP settings, including capnography, titration to the best Pao_2/Sao_2 ratio, continuous $S\bar{v}o_2$ and shunt monitoring, PV curve analysis, and others. None have unequivocally been shown to result in superior outcome. Consequently, there is no consensus on a single method of titrating and evaluating clinical response to PEEP. More than 30 years ago it was noted that the PEEP level resulting in maximum O_2 delivery also produced optimal compliance while minimizing dead space and shunt fraction.[124] The authors coined the phrase "optimum" PEEP to refer to that producing the maximum improvement in pulmonary function with minimal hemodynamic compromise. Recent trials have shown that during a derecruitment study, measuring C_{stat} may be as useful and more cost-effective than measuring Pao_2 in determining closing pressure and guiding PEEP selection.[115,116] Nowadays most clinicians use one of these two parameters to set PEEP after the recruitment maneuver. Inflection points on PV curves are not always easy to identify, and a decrease in Pao_2 rather than C_{stat} should be used to identify closing pressure in such cases.

Patients under GA are prone to compression atelectasis in dependent lung regions (see Fig. 44-5).[125] Thus, it is tempting to apply PEEP to all patients undergoing surgery with mechanical ventilation to prevent this atelectasis. It has been shown that application of PEEP during GA can attenuate and reverse dependent atelectasis but does not improve gas exchange.[126] A study comparing normal and obese subjects also found that application of PEEP during GA did not alter gas exchange in normal patients, but some improvement was noted in the obese population.[127] Thus, there is no evidence to support routine use of PEEP during GA. However, these studies did not use recruitment maneuvers, and a trial by Tusman and colleagues showed that alveolar recruitment can improve oxygenation during GA (see also Chapter 15).[128] In addition, PEEP combined with recruitment maneuvers has been shown to provide a sustained increase in Pao_2 and lung volume in mechanically ventilated postsurgical patients.[128,129]

Analysis of Lung Recruitment

The importance of early lung recruitment in respiratory failure and ARDS has been well documented.[130] Lung-protective ventilation in ARDS via frequent recruitment maneuvers results in improved 28-day survival, earlier weaning from mechanical ven-

tilation, and less barotrauma than with conventional ventilation strategies.[111] Effective recruitment is performed by applying sustained high airway pressure, usually for 30 to 90 seconds. Many successful techniques, all using essentially these same principles, have been described.[131,132] Recruitment maneuvers are typically well tolerated, with no significant hemodynamic deterioration or inflammatory response.[133,134] Although improvements in pulmonary compliance and oxygenation are indicative of successful recruitment, direct methods of quantifying and monitoring lung recruitment are emerging.

Computed Tomography

Technologic advances in CT have made it a valuable tool for studying ARDS and lung recruitment. It has been used in numerous studies to evaluate the effects of a wide range of variables on alveolar recruitment and stabilization.[135] Recently, Gattinoni and colleagues performed a trial to examine whether measuring the amount of recruitable lung by CT could help predict how the lung would respond to PEEP after recruitment. They concluded that a higher amount of recruitable lung was correlated with a positive response to PEEP whereas PEEP was of little benefit and perhaps detrimental in patients with less recruitable lung measured by CT.[136] This conclusion was in line with previous studies showing that PEEP results in hyperinflation and increased stress in normal lung regions when the amount of recruitable lung is low.[137] Quantitative CT analysis of potentially recruitable lung may therefore be useful in determining the best PEEP level, but further studies are needed on the practicality of routine use. CT was instrumental in the discovery that lung recruitment occurs throughout inspiration and not solely around the LIP of the PV curve.[138]

Electrical Impedance Tomography

A new and exciting form of monitoring of pulmonary function may be electrical impedance tomography (EIT).[139,149] It is a noninvasive and radiation-free technique based on the measurement of electric potentials at the chest wall surface. Within a particular cross-sectional plane, harmless electrical currents are driven across the thorax in a rotating pattern to generate a potential gradient at the surface, which is then transformed into a two-dimensional image of the distribution of electrical impedance within the thorax. The dynamic behavior and the qualitative information extracted from EIT images look similar to that reported in dynamic studies (Fig. 44-23).[141,142]

This technology may be an excellent assessment tool for easy bedside use to evaluate alveolar lung recruitment, pulmonary embolism, lung water, and other lung pathology. The importance of lung recruitment in both the operating room and the ICU has clearly changed the practice of mechanical ventilation.

Amato's group in Brazil recently completed a validation study of EIT.[142] It is an easy bedside tool to evaluate mechanical ventilation with immediate feedback. EIT devices may, in the future, easily detect selective intubation, pneumothorax, and alveolar atelectasis. Titration of PEEP may someday be evaluated in real time, with EIT used instead of waiting for BGA, radiologic studies, and CT scans. This technology may one day be integrated into the bedside monitor or into closed-loop mechanical ventilators.

Inspiratory Pressure Monitoring

Impaired respiratory muscle function from fatigue or neuromuscular disorders can contribute to respiratory failure and difficulty weaning from mechanical ventilation. Measurement of maximum inspiratory pressure (MIP), also called negative inspiratory force, gives a useful bedside appraisal of respiratory muscle strength. It can be performed on intubated and nonintubated patients by attaching a pressure manometer to the endotracheal tube or a noninvasive mouthpiece. Alternatively, use of a one-way valve that allows exhalation only has been described, although it is quite uncomfortable for the patient.[143] Normal MIP is about −90 cm H_2O but can range between −50 and −120 cm H_2O. To obtain accurate measurements, MIP should be measured after maximal expiration because the diaphragm can generate the greatest pressure at residual volume. Studies have demonstrated that inability to generate MIP more negative than −20 cm results in tidal volumes that are insufficient for generating a strong cough. Moreover, this cutoff has been shown to result in weaning failure with

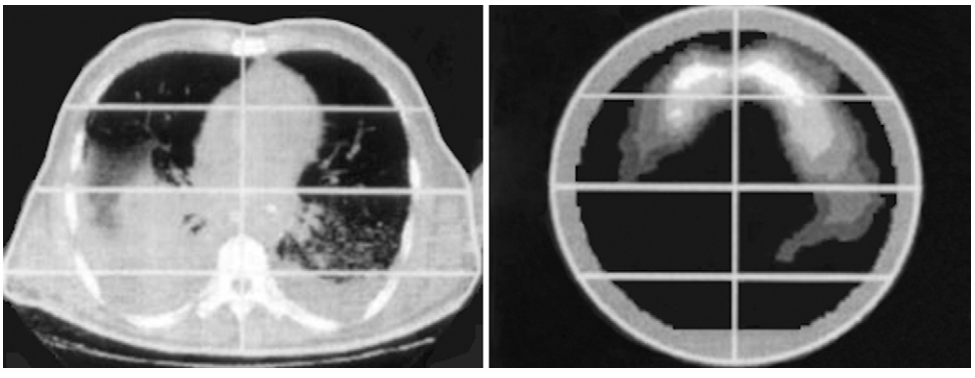

Figure 44-23 Comparison of a computed tomographic (CT) scan and an electrical impedance tomographic (EIT) image during mechanical ventilation of a patient with acute lung injury. The *gray* and *white* areas in the EIT image reflect areas with change in impedance (volume changes) and correlate with well-inflated areas on the CT scan. There is no impedance change on the EIT scan in the dorsal area, where atelectasis is present on the CT scan. *(From Wolf GK, Arnold JH: High-frequency oscillatory ventilation for adult acute respiratory distress syndrome: A decade of progress. Crit Care Med 33(Suppl):S163-S169, 2005.)*

a negative predictive value of 1.[144] Though not yet a firmly established predictor of weaning outcome, MIP is useful in determining whether patient weakness or neuromuscular dysfunction is playing a role in unsuccessful weaning trials.

Esophageal Monitoring

Transpulmonary pressure, rather than peak or plateau pressure, is the most important determinant of alveolar distention and is defined as alveolar pressure (PA) minus pleural pressure (Ppl).[145] Thus, true distending pressure of the lung cannot be measured without determination of Ppl. Direct measurement of Ppl is clinically impractical, but it can be estimated quite reliably in upright patients by measuring pressure in the distal third of the esophagus. The esophagus is a fairly passive structure and the third part is very close to the pleural space, thus allowing transmission of pleural pressure to an intraesophageal pressure monitor.[146] A balloon-tipped catheter is typically used, and this technique is considered the standard modality for evaluating inspiratory effort and work of breathing (WOB). In the supine position, this relationship is less predictable because gravitational forces cause compression of the esophagus and dependent lung, thereby skewing the measurements.

Placement of a second balloon catheter into the stomach allows simultaneous measurement of gastric pressure and provides a means of obtaining a host of useful information about respiratory mechanics. For example, transdiaphragmatic pressure monitoring can be performed to assess diaphragmatic contraction. As the diaphragm contracts and the domes descend, negative Ppl (or Pes) should coincide with positive abdominal pressure (or Pg) generating transdiaphragmatic pressure. Inability of the diaphragm to contract properly results in loss of transdiaphragmatic pressure and has been observed after uncomplicated upper abdominal surgery (Fig. 44-24). Diaphragmatic fatigue and phrenic nerve palsy elicit a similar pattern.[147] This can also be observed clinically inasmuch as impaired diaphragmatic activity is associated with paradoxical inward movement of the abdomen during inspiration.

Work of Breathing

The work involved in normal respiration, often referred to as *work of breathing (WOB)*, usually requires minimal energy expenditure. Work is defined as the force needed to move a mass times the distance moved: $W = F \times d$. In the respiratory system, it represents the pressure (or force) needed to inspire a certain volume of gas: $WOB = P \times V$. With respiratory compromise, WOB can be quite high, as much as 40% of total oxygen consumption (normally <5%). WOB can be estimated by measuring pressure and volume changes from a PV curve. Total work is the area enclosed by the curve (integral of pressure and volume). Thus, the larger the loop, the greater the WOB (Fig. 44-25). However, studies indicate that mechanical work calculated in this manner may underestimate true WOB and is weakly correlated with the $\dot{V}O_2$ of respiratory muscles. Alternatively, many clinicians believe that the *pressure-time product* (PTP) is the most accurate measure of work performed by the diaphragm during inspiration and better correlates with $\dot{V}O_2$[148] because the PTP takes isometric contraction of the diaphragm into account, which consumes additional O_2. Increases in PTP indicate stronger diaphragmatic contraction and vice versa. Calculation of PTP requires measurement of transdiaphragmatic pressure as outlined earlier and is not routinely performed. Occlusion pressures (P_{100}) measured with a dedicated valve system or conventional ventilator have also been shown to correlate with WOB.[148,149]

Closed-Loop Analysis

Closed-loop ventilation involves computer-based real-time interpretation of respiratory mechanics with continuous adjustment of the level of support delivered to the patient.[150] Any change in mechanics or patient effort is detected and a new breathing pattern is initiated by the ventilator. Ventilator dyssynchrony and WOB are minimized. Moreover, erroneous or unsafe settings could potentially be minimized with a system that continuously regulates ventilator support based on real-time assessment of the

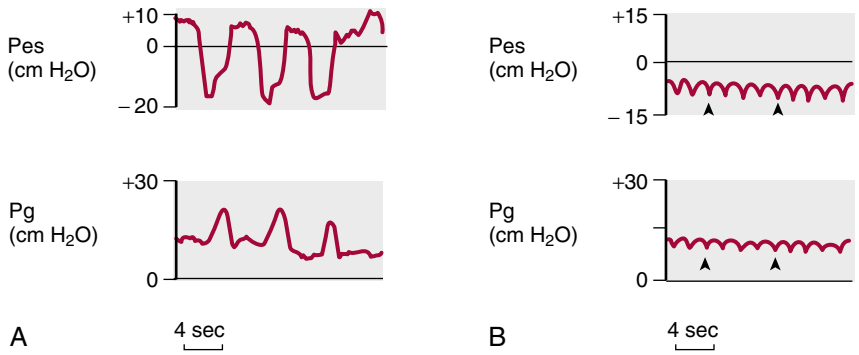

Figure 44-24 Examples of transdiaphragmatic pressure monitoring. **A,** Simultaneous esophageal (Pes) and gastric (Pg) pressure waveforms during tidal breathing in a normal individual. Negative esophageal (and therefore pleural) pressure swings are accompanied by positive gastric pressure waves indicative of the development of transdiaphragmatic pressure during inspiration. **B,** The same waveforms in a patient with phrenic nerve palsy (and therefore absent diaphragmatic contraction). Negative intrathoracic pressure swings (*arrowheads*) are accompanied by gastric pressure swings in the same direction. Intrathoracic pressure changes are directly transmitted through a passive diaphragm. These changes can also be observed in the early postoperative period in patients who have undergone upper abdominal surgery. *(From Brown KA, Hoffstein V, Byrick RJ: Bedside diagnosis of bilateral diaphragmatic paralysis in a ventilator-dependent patient after open-heart surgery. Anesth Analg 64:1208, 1985.)*

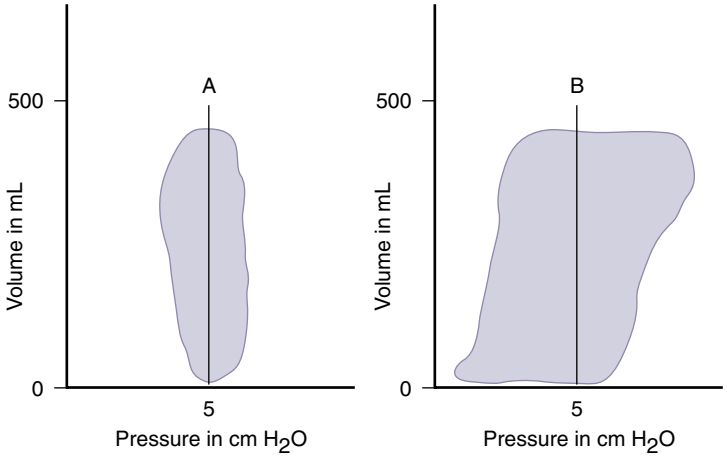

Figure 44-25 Work of breathing (WOB) during continuous positive airway pressure (CPAP). WOB in this figure is the integral of airway pressure and tidal volume. Loop A is an example of a freestanding CPAP system. Spontaneous breaths occur clockwise, inspiration to expiration. Loop B is CPAP through a ventilator demand valve system. Breathing occurs clockwise. *(Redrawn from Hirsch C, Kacmarek RM, Stanek K: Work of breathing during CPAP and PSV imposed by the new generation mechanical ventilators: A lung model study. Respir Care 36:815–828, 1991; and Kirby RR, Banner MJ, Downs JB: Clinical Applications of Ventilatory Support. New York, Churchill Livingstone, 1990.)*

patient. Table 44-3 summarizes the four commercially available closed-loop systems. A study was performed to compare ARDS and COPD patients ventilated with a closed-loop mode termed *adaptive support ventilation* (ASV) available on the Hamilton Galileo ventilator. The authors found that on average, ARDS patients received lower tidal volumes with a higher respiratory rate than COPD patients did.[151] This would be expected and desired based on current knowledge of mechanics and the importance of low–tidal volume ventilation in ARDS. Moreover, the results support the possibility that closed-loop ventilation with ASV can appropriately tailor ventilation based on respiratory mechanics. It is highly conceivable that closed-loop ventilator modes may one day prove to be safer and more convenient than traditional mechanical ventilation.

Apnea Monitoring

The postoperative period is often characterized by episodes of apnea and hypoxemia. Paradoxical breathing and other ventilatory disturbances can also occur frequently. Though more common with narcotic administration, residual effects of other anesthetic agents can play a role in the cause of these disturbances. They are often subtle and are more likely to be noticed with continuous respiratory monitoring as opposed to intermittent observation.[152] A wide variety of continuous apnea monitoring systems have been developed. Most methods detect changes in chest wall movement, gas exchange, or gas flow to make inferences about changes in respiratory pattern.

Movement of the chest wall is most commonly detected by transthoracic impedance. The technology is usually incorporated into the electrocardiographic (ECG) monitoring system. A small current is passed between two ECG leads, and chest wall movement is detected by a change in impedance to the current induced by the motion. Respiratory inductive plethysmography (RIP) is another method of apnea detection that monitors chest movement. The chest and abdomen are encircled by one or more coils that measure changes in their cross-sectional area occurring with respiration. Inductance of the bands depends on the area that they enclose and thereby allows detection of respiratory movements. A technique called photoplethysmography (PPG) also relies on detection of anatomic changes induced by breathing. Infrared PPG sensors placed near upper extremity veins can detect cyclic changes in venous blood flow occurring with respiration.[153] Respiratory muscle electromyography has also been used as a means of monitoring respiration. A limitation common to all these techniques is that respiratory efforts during episodes of obstructive apnea may be interpreted as normal respirations despite absent gas flow.[154] Monitoring of gas flow and exchange may therefore be a more reliable indicator of adequate respiration.

Table 44-3 Main Characteristics of Proportional Assist Ventilation (PAV), Neurally Adjusted Ventilatory Assist (NAVA), Knowledge-Based System (KBS), and Adaptive Support Ventilation (ASV)

	PAV	NAVA	KBS	ASV
Principle	P_{insp} proportional to $flow_{insp}$	P_{insp} proportional to EMG_{dia}	P_{insp} to maintain RR in comfort zone	P_{insp} and RR to minimize WOB
Breath type	Spontaneous	Spontaneous	PSV	PSV, PCV, P-SIMV
Sedated patients	No	No	No	Yes
Active patients	Yes	Yes	Yes	Yes
Automatic weaning	No	No	Yes	Yes

EMG_{dia}, diaphragmatic electromyographic activity; $Flow_{insp}$, inspiratory flow; PCV, pressure-controlled ventilation; P-SIMV, pressure-controlled intermittent mandatory ventilation; PSV, pressure-support ventilation; RR, respiratory rate; WOB, work of breathing.

Apnea monitoring systems that rely on airflow detection may be a more sensitive alternative to monitors of patient movement. In a study comparing transthoracic impedance and a nasal-oral airflow system in the PACU, Wiklund and colleagues found that impedance monitoring failed to detect apneic episodes more frequently than flow detection did.[154] False alarm rates were similar between the two groups. Hök and associates studied an acoustic airflow monitoring system and reported that it was more sensitive in detecting episodes of apnea and hypoventilation than pulse oximetry was.[155] Another acoustic airflow sensor was compared with a thoracic impedance system by Werthammer and colleagues.[155a] Of 26 apneic episodes observed by direct observation, the airflow sensor detected all 26, whereas only 7 episodes were detected by the impedance monitor. Other airflow monitors detect respiration by measuring changes in humidity. Tatara and Tsuzaki studied a device called a rapid-response hygrometer that monitors changes in humidity at the nostril and can measure respiratory rates of up to 60 breaths per minute.[156] Respiratory phases could be identified almost 2 seconds faster than with capnography. The development of fiberoptic humidity-based systems has also been described.[157,158]

Because end-tidal CO_2 monitoring and pulse oximetry can rapidly detect derangements in gas exchange, they may prove to be the most dependable options for apnea monitoring. In a study of more than 4000 apneic episodes from overnight polysomnograms, detection of apnea by pulse oximetry was compared with manual detection, such as airflow or respiratory movement.[158a] Only 1.32% of apneic episodes were reportedly missed by pulse oximetry, whereas manual devices missed 7.9% of apnea events. Although end-tidal CO_2 monitoring can be performed easily and accurately on intubated patients, measurements from a mask or nasal cannula are often unreliable. However, the respiratory rate is usually reported accurately, and trends in P_{ETCO_2} can be monitored with these devices. As pulse oximetry and capnography systems become more portable and inexpensive, their use for apnea monitoring will probably continue to grow. Large outcome studies may be needed to demonstrate the possible superiority of one system over another.

Lung Water Analysis

Many disease states can cause abnormal accumulation of extravascular lung water (EVLW), commonly known as pulmonary edema. Clinicians have long been aware of the severe cardiac and respiratory insufficiency that pulmonary edema can cause, yet it remains unclear whether accurately quantifying it can guide management in a way that ultimately improves outcome. Nonetheless, investigators continue to seek simple and reliable methods for detecting and quantifying EVLW, and many advances have been made in recent years. Research in this field is complicated by the fact that gravimetry, which requires analysis of postmortem lung weight, remains the standard for EVLW measurement.[159,160] As a result, much of the data evaluating new techniques come from animal studies.

Radiographic Methods

The chest radiograph is the most widely used test to screen for pulmonary edema. Under ideal conditions, obtaining a chest film allows semiquantitative measures of EVLW, as well as determination of its distribution and possible etiology. Even under such conditions, sensitivity is rather poor; a 30% to 35% increase in EVLW is needed before radiographic changes consistent with pulmonary edema can be detected on the chest film.[161] In typical critical care settings, where image quality and acquisition technique can vary greatly, it is estimated that a 100% increase in EVLW may be needed to produce observable radiographic changes. Moreover, weak correlation of EVLW measurements between chest radiography and other established methods has been observed in the ICU environment.[159]

CT has been increasingly studied in recent years as a means of quantification of EVLW. In animal experiments, CT densitometry could detect an increase in EVLW by as little as 50%.[162] Using thin-section CT, Scillia and colleagues found that significant hypoxemia secondary to pulmonary edema may not develop until the increase in EVLW approaches the 200% to 300% range.[163] Lack of portability and high radiation exposure limit the use of CT for serial EVLW measurement. Research continues on a number of other imaging modalities, including ultrasonography,[164] positron emission tomography,[165] nuclear magnetic resonance,[166] and EIT,[167] but none have been incorporated into routine clinical use.

Indicator Dilution Methods

Quantification of EVLW via double indicator dilution curves was first described more than 50 years ago. More recently, a transpulmonary thermodilution technique that uses cold saline as a single indicator has been described. Although controversy exists over the accuracy of dilution techniques, many studies report excellent reproducibility and correlation with gravimetric methods.[159] One study using transpulmonary thermodilution reported that changes in EVLW of as little as 10% to 20% can be detected with high sensitivity.[168] Both techniques are somewhat invasive and require placement of arterial and central venous catheters. Although early devices were quite cumbersome, currently available systems are relatively safe and easy to implement and allow bedside measurements to be obtained.

Despite recent improvements in a number of the aforementioned modalities, chest radiography remains the only tool widely integrated into clinical practice. A probable explanation is that studies have suggested potential clinical utility in precise EVLW analysis, but none have shown that obtaining such measurements facilitates decision-making or improves patient outcome.

Monitoring High-Frequency Ventilation

Recent data on the benefits of low–tidal volume, high-PEEP ventilation in ARDS have prompted a search for the optimal lung protective mode of ventilation. First introduced in the late 1950s, high-frequency ventilation (HFV) offers an alternative to conventional ventilation in patients with ARDS and ALI. HFV is characterized by rapid delivery of small tidal volumes and maintenance of high mean airway pressure.[169] Whereas routine use in adults is a fairly recent trend, trials in preterm infants with neonatal res-

piratory distress syndrome began almost 20 years ago.[170] Clear evidence of outcome benefit with HFV versus conventional ventilation is lacking, but numerous studies have implied that HFV may reduce the risk for ventilator-induced lung injury,[171] improve oxygenation,[172] and be as safe as conventional ventilation in ARDS.[173] The FDA has defined HFV as any form of ventilation that delivers a respiratory rate greater than 150 breaths/min. Although several forms of HFV have evolved since its development, the most widely used method in both adults and pediatric patients is high-frequency oscillatory ventilation (HFOV). Other modes include high-frequency jet ventilation (HFJV), high-frequency flow interruption (HFFI), and high-frequency percussive ventilation (HFPV). Before the widespread availability of HFV modes, a conventional ventilator was used to deliver low tidal volumes with high frequency, a technique that became known as high-frequency positive-pressure ventilation (HFPPV).

Because mechanisms of gas exchange during HFV differ from those regulating conventional ventilation, standard monitoring equipment may not provide accurate data. Fortunately, the reliability of pulse oximetry in assessing oxygenation status with other modes of ventilation seems to extend to HFV. Early studies showed a correlation between airway pressure and gas exchange efficiency during HFJV, with higher peak and driving pressures resulting in lower $Paco_2$ and higher Pao_2. Monitoring $Petco_2$ conventionally during HFV produces unreliable measurements for a number of reasons, but mainly because of difficulty obtaining undiluted, CO_2-rich gas samples.[174,175] Though useful in monitoring conventional ventilation, the concept of "end-tidal" CO_2 is altogether misguided in HFV because no inspiratory or expiratory phases are identifiable on capnographic waveforms.[176] Moreover, the likelihood that expired CO_2 tensions accurately reflect $Paco_2$ is low in patients requiring HFV inasmuch as alveolar dead space and intrapulmonary shunting can be extensive.[174]

Despite its limitations, studies have demonstrated the ability of capnometry to provide accurate $Paco_2$ estimates during HFV. A common technique is to interrupt or slow the ventilator down to deliver a normal breath. CO_2 tensions measured with intermittent capnography have been shown to agree well with simultaneously obtained $Paco_2$ values.[177] The accuracy of capnometric Pco_2 readings may also depend on where the sample is obtained. Gas sampled from the distal tip of the endotracheal tube seems to provide more valid approximations of $Paco_2$ than sampling proximally does.[176] However, these measurements must also be obtained intermittently. In an effort to eliminate this problem and others associated with expired gas analysis during HFV, Berkenbosch and Tobias studied the accuracy of continuous transcutaneous CO_2 monitoring in this setting. When compared with $Paco_2$ values from BGA obtained simultaneously, bias and precision were only 2.1 and 2.7 mm Hg, respectively.[174] Studies by these authors and other investigators have also demonstrated that transcutaneous CO_2 monitoring may approximate $Paco_2$ better than $Petco_2$ in both adults and children undergoing mechanical ventilation.[178,179] Although the technique has gained a footing in pediatric critical care, transcutaneous O_2 and CO_2 monitoring in adults will probably increase in popularity as refinements to this technology continue to be made.

As the potential benefits of HFV continue to be elucidated, investigators have sought practical techniques for bedside monitoring of lung mechanics, recruitment, and regional aeration. Portable chest radiography has been shown to be a poor tool for assessing lung morphology in ARDS.[179,180] CT has proved useful for such analyses but continues to be limited by portability issues. Recently, some investigators have focused on EIT and RIP as modalities that may be able to provide accurate lung volume measurements at the bedside during HFV.[181,182] RIP has been used experimentally to construct PV curves during HFV and thereby determine optimal lung volume and pressure settings.[183,184] In the first infant study of this kind, Tingay and colleagues used the open-lung concept to recruit lung and then map the deflation limb of the PV curve.[185,186] The authors concluded that RIP could be used during HFOV to construct satisfactory deflation curves. Ventilation along the deflation limb resulted in greater lung volume and oxygenation, often with lower distending pressure requirements, than did ventilation on the inflation limb (Fig. 44-26). This was in line with previous animal studies demonstrating improved mechanics and oxygenation with deflation limb ventilation after recruitment.[117] An earlier infant trial using single-occlusion compliance measurements failed to demonstrate the utility of PV curves in optimizing lung volume during HFV, but neither recruitment maneuvers nor deflation limb ventilation had been used.[187] EIT has the advantage of providing information about global and regional changes in lung volume, as well as continuous imaging of changes in impedance (and probably volume) occurring throughout the respiratory cycle. Bedside availability would potentially allow clinicians to detect aeration changes in real time and reverse them by adjusting ventilation parameters.[182]

Estimation of pulmonary mechanics during HFV has most often been accomplished by the conventional passive techniques described earlier. This practice has raised concern among some authors, who argue that technical aspects of these strategies may exacerbate derecruitment and provide inadequate information about lung parenchyma.[187] In the study by Tingay and colleagues, passive deflation was not used for PV analysis, and derecruitment was further prevented by avoiding full deflation of the lung below closing pressure. Others suggest that the high frequencies and flow rates associated with HFV currently limit the feasibility of obtaining accurate dynamic measurements. Thus, efforts have been undertaken to identify safe alternatives for reliably assessing lung compliance and determining optimal airway pressure during

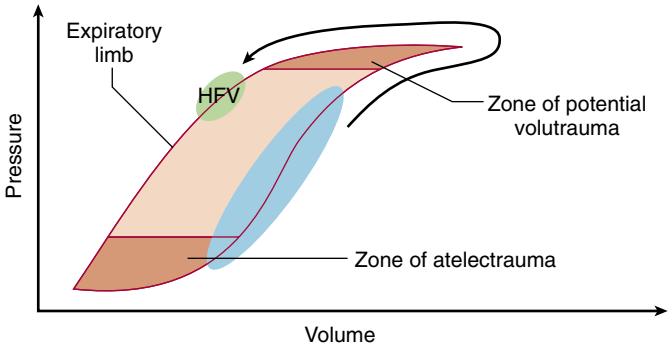

Figure 44-26 Pressure-volume curve depicting the "open lung" concept using high-frequency ventilation (HFV). Potential lung injury is reduced when ventilation of the lung is shifted onto the expiratory portion of the curve by aggressive lung recruitment. Lung volume is then maintained with high mean airway pressure and small tidal volumes. *(From Singh JM, Stewart TE: High-frequency ventilation.* In *Fink MP, Abraham E, Vincent JL, et al [eds]: Textbook of Critical Care, 5th ed. Philadelphia, Elsevier, 2005.)*

HFV. The oscillatory pressure ratio (OPR), defined as the ratio of pressure swings at the distal and proximal ends of the endotracheal tube, was shown to be inversely related to lung compliance in an animal model of ALI.[188] The mPaw setting resulting in the lowest OPR also generated the best lung compliance and oxygenation. Titrating mPaw to a minimal OPR may therefore prove to be a reliable, noninvasive means of optimizing lung mechanics and oxygenation during HFV. The low-frequency forced oscillation technique is another experimental monitor that allows partitioning of lung mechanics into airway and parenchymal components, as well as determination of chest wall impedance.[189] Monitoring chest vibration can provide a crude indicator of changes in compliance during HFOV. Oscillator power is often titrated to generate vibrations from the clavicle down to the midportion of the thigh, and a change in pattern may signal the development of an obstruction, pneumothorax, or worsening mechanics of any etiology.

Monitoring the Respiratory System in Transport

Intrahospital transport of critically ill and mechanically ventilated patients becomes necessary in a number of situations (see Chapter 79). The need for diagnostic or surgical procedures is among the most frequent reasons for patient transport. A number of studies have reported on the high number of transports that critically ill patients require.[190] Children and trauma victims seem to require more frequent transportation for diagnostic purposes than other critically ill patients do. Not surprisingly, intrahospital transport of this tenuous patient population can be fraught with problems ranging from simple equipment malfunction to major disasters such as anoxic brain injury and even death. Studies report a widely varying incidence of adverse events during transportation of critically ill patients. Complex and numerous pieces of equipment are often necessary to safely perform the transfer. One study looking at 125 transports from the ICU found a 34% incidence of equipment-related adverse events, the most common being ECG lead disconnection and monitor power failure.[190]

Lack of agreed-upon monitoring techniques and definitions of "adverse events" partly explains the wide discrepancy in reported incidence. Moreover, few outcome studies comparing monitoring strategies during transport have been performed. It has long been observed, however, that transport of critically ill patients may put them at increased risk for cardiovascular and respiratory compromise, both during and after transport.[191] A higher incidence of gas exchange deterioration and even pneumonia has been reported after intrahospital transport.[192,193] Arrhythmias, hypotensive episodes, and blood gas derangements are not uncommon. Studies in trauma patients have revealed widely variable heart rate and blood pressure during transportation for diagnostic procedures.[194] Thus, a continually displayed electrocardiogram and blood pressure must be available during transport of all critically ill patients. In addition, pulse oximetry should be used in light of its high reliability in forewarning of hypoxemia and deterioration in gas exchange. A good rule of thumb is to monitor critically ill patients at least as closely during transport as deemed necessary within the ICU before transport. Complications are reduced when personnel trained to deal with the intricacies of intrahospital transport are available.[195] Emergency cardiovascular drugs should be available for postoperative transport of all hemodynamically unstable and critically ill subjects. Preparation of equipment and medication checklists before transport can help ensure readiness for any untoward events. The receiving location should confirm before transport that it has the equipment and necessary staff in place to receive the patient.

Transport of a mechanically ventilated patient presents the inherent risks of airway loss and further derangements in gas exchange. Equipment and medications needed to establish and maintain a secure airway must accompany such patients during any transfer. The presence of adequate oxygen supply with properly functioning low-pressure alarms should be verified during pretransport preparation. Many authors advocate the use of a mechanical ventilator rather than manual ventilation devices for intrahospital transport because more variability in pH and CO_2 tension has been observed with the use of manual devices.[196] A higher incidence of significant Pa_{O_2}/F_{IO_2} deterioration may also be associated with manual versus mechanical ventilation ($P = .056$).[196] In a blinded study using capnography, Tobias and associates noted a high incidence of unintentional hyperventilation when using manual devices during the intrahospital transfer of intubated pediatric patients.[197] Similar findings have been noted in adults, and tighter control of Pa_{CO_2} can be achieved if P_{ETCO_2}[198] or V_T is monitored during manual ventilation. These findings have led many experts to recommend P_{ETCO_2} monitoring in addition to standard monitoring for high-risk patients requiring a more optimal level of ventilation.

Obvious contraindications to the transport of critically ill patients include an inability to provide adequate oxygenation and ventilation during transport or at the receiving location. Unstable hemodynamics or an inability to adequately monitor cardiovascular status throughout the trip should prompt postponement or cancellation. The risk-benefit ratio should be considered before all transports to help determine whether a trip is truly warranted; performing such analyses may be the most effective way of avoiding adverse events during transportation. Indeck and coworkers found that 68% of patients transferred from a trauma unit for diagnostic testing experienced serious physiologic changes whereas only 24% of the transfers resulted in significant modification of patient management.[199] The development of increasingly sophisticated portable devices has provided a bedside alternative for many diagnostic and therapeutic procedures.

45 Renal Function Monitoring

Key Points

1. Perioperative acute renal failure (ARF), although uncommon, is associated with extremely high morbidity and mortality rates.
2. The mechanism for perioperative ARF is complex and most commonly involves multiple factors such as ischemia/reperfusion, inflammation, and toxins.
3. Repeated direct perioperative assessment of renal hemodynamics, tubular function, or pathogenesis of perioperative renal dysfunction is impractical; therefore, indirect assessments, such as serum creatinine trends, are the best practical currently available perioperative tool to assess renal function.
4. Intraoperative urine formation depends on a number of factors and is an insensitive and unreliable method for assessing postoperative risk of renal dysfunction.
5. Serum chemistries and urine indices such as blood urea nitrogen, creatinine, fractional excretion of sodium, and free water clearance are generally late indicators of renal function deterioration and do not enable the clinician to clearly delineate the cause of renal failure.
6. Creatinine clearance is the most sensitive and specific clinical method for determining renal function, but it is limited by time and measurement restrictions.
7. Early biochemical markers for renal function hold promise and are a current focus for research that may soon lead to new tests able to provide prompt clinical information.

Acute kidney injury (AKI) characterized by rapid decline in glomerular filtration and accumulation of nitrogenous waste products (blood urea nitrogen [BUN] and creatinine) is a common medical problem occurring in 5% and 30% of all hospital and intensive care unit (ICU) patients, respectively.[1] AKI is also a serious perioperative complication for patients undergoing major surgery (Fig. 45-1).[2-10] Disentangling the clinical effects of AKI from those of other conditions (e.g., sepsis) is difficult because renal impairment rarely presents in isolation in critically ill patients. However, a prevailing observation is that AKI itself portends poor prognosis, not only owing to the loss of renal function and potential for excessive volume and solutes but also from the ineffective clearance of "uremic toxins," such as inflammatory mediators,[11-13] and the numerous potentially life-threatening complications related to impaired renal function, including sepsis, respiratory failure, gastrointestinal hemorrhage, and central nervous system dysfunction. Acute renal failure (ARF) requiring dialysis develops in 1% to 7% of patients after cardiac or major vascular surgery (Fig. 45-2) and is strongly associated with morbidity and mortality (Fig. 45-3) (see Chapters 60 and 62).[14-17] The mortality rate of ARF was 91% during World War II, 68% in the Korean War, and 67% in the Vietnam War. Today, depending on associated comorbidities, postoperative renal failure is responsible for up to 60% mortality in the postoperative period.[3,4,7,8] ARF in the presence of no other comorbidities has a 10% to 40% mortality rate, whereas ARF in the ICU setting carries a 50% to 80% mortality rate (see Chapter 91).[18] Perioperative renal failure accounts for one half of all patients requiring acute dialysis.[18]

The overall reported frequency of ARF among all patients admitted to the hospital is 1%[19] and may increase to 2% to 5%[3,20] during hospitalization. The incidence of perioperative ARF requiring dialysis has remained largely unchanged since it was first described over 40 years ago[21,22]; however, recognition of this disorder is increasing[9] and reinvigorated efforts to reduce its occurrence are underway as medical populations shift toward older and more critically ill patients undergoing increasingly higher-risk procedures (see Chapter 71). An emerging strategy to reduce the incidence of perioperative renal failure involves improvement of renal function monitoring to allow prompt recognition of the onset of ARF in the operative and critical care setting.

Perioperative renal failure, for example, has long been defined as the need for postoperative dialysis; however, this is by no means the only tool that has been used as a marker to describe acute changes in kidney well-being. In one review of 28 studies,[23] no two definitions for perioperative ARF were the same. Because the implications of needing postoperative dialysis are quite

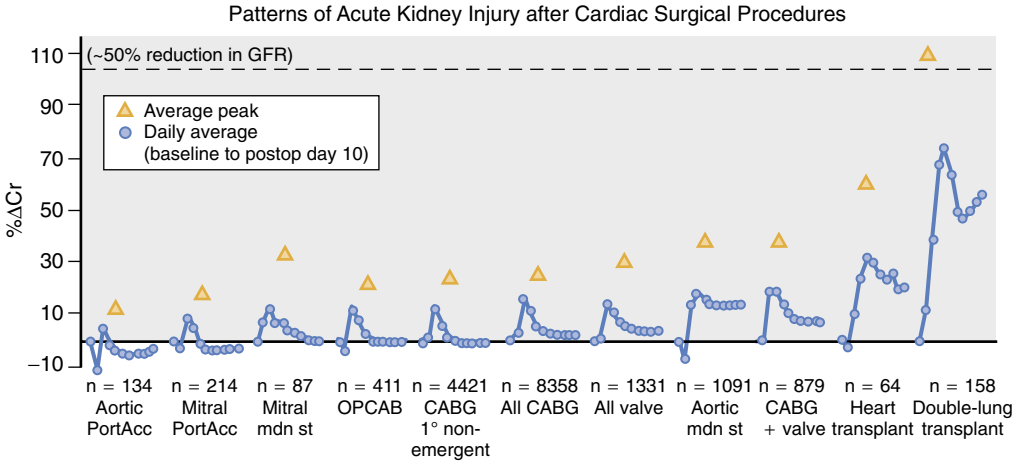

Figure 45-1 Average daily (*circles*) and unadjusted average peak (*triangles*) serum creatinine values for the first 10 days after several different cardiac surgery procedures, represented as change relative to preoperative serum creatinine.[118,334-340] The average peak value considerably exceeds the highest average daily value for each procedure because creatinine peaks on different days for different patients. % ΔCr, peak fractional serum creatinine rise; Aortic PortAcc, minimally invasive parasternotomy aortic valve replacement; Mitral PortAcc, port access mitral valve surgery; Mitral mdn st, median sternotomy mitral valve surgery; OPCAB, off-pump coronary artery bypass surgery; CABG, coronary artery bypass surgery 1° nonemergent; Aortic mdn st, median sternotomy aortic valve replacement. (*Used with permission from Stafford-Smith M, Patel U, Phillips-Bute B, et al: Acute kidney injury and chronic kidney disease after cardiac surgery. Adv Chronic Kidney Dis 15:157-177, 2008.*)

different for a patient starting with normal baseline function than one starting near the brink of filtration failure, even the usefulness of dialysis as a marker of outcome has been questioned.[24] Recent research efforts have been directed toward developing a universally accepted standard for describing AKI or renal failure.[25-32]

Although ischemic causes have long been believed to be primarily responsible for perioperative ARF,[33,34] lack of success with this paradigm in developing renoprotective strategies,[35] combined with accumulating evidence that postoperative renal dysfunction possesses characteristics of multiple types of AKI,[36,37] has resulted in a reevaluation of the pathophysiology of this disorder. Much can be learned from the many settings beyond ischemia-reperfusion where specific types of AKI occur; examples include contrast-associated nephropathy, pigment nephropathy (e.g., hemoglobin, myoglobin), cholesterol embolism (atheroembolism) nephropathy, aminoglycoside nephropathy, norepinephrine-induced nephropathy, and as part of the sepsis/systemic inflammatory response syndrome. In these examples, the disorder describes the renal pathophysiology and strategies to prevent or attenuate each condition are interventions directed specifically toward the cause. Animal studies of such "pure" nephropathies treated with logical renoprotective interventions often demonstrate success; unfortunately, this has rarely extended to equivalent renoprotection in human perioperative studies. However, it makes sense that a specific treatment for a "pure" nephropathy applied nonselectively to a mixture of nephropathies, variably expressed in different patients, would be unsuccessful. Protection from one perioperative nephropathy may even add

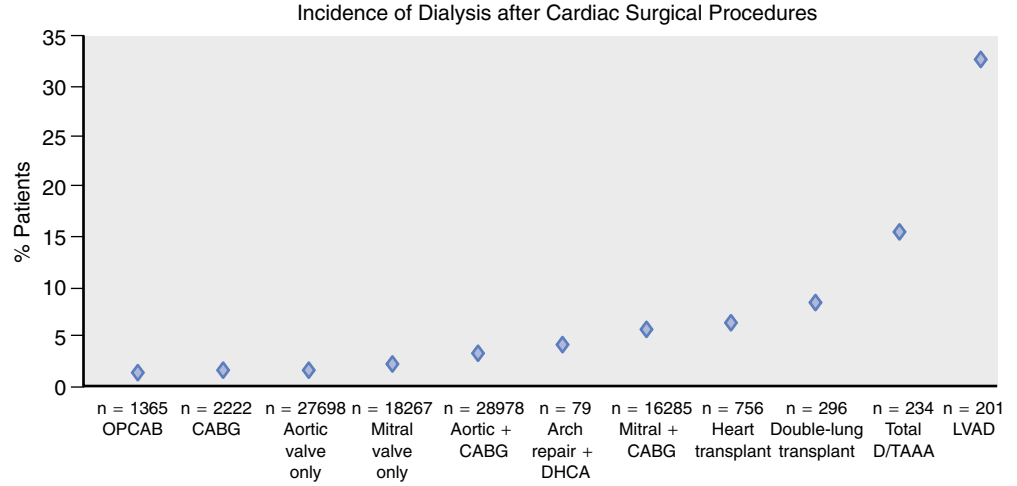

Figure 45-2 Rate of new-onset dialysis differs significantly for various surgical procedures.[4,341-348] OPCAB, off-pump coronary artery bypass surgery; CABG, coronary artery bypass surgery; DHCA, deep hypothermic circulatory arrest; D/TAAA, descending/thoracoabdominal aortic aneurysm; LVAD, left ventricular assist device. (*Used with permission from Stafford-Smith M, Patel U, Phillips-Bute B, et al: Acute kidney injury and chronic kidney disease after cardiac surgery. Adv Chronic Kidney Dis 15:157-177, 2008.*)

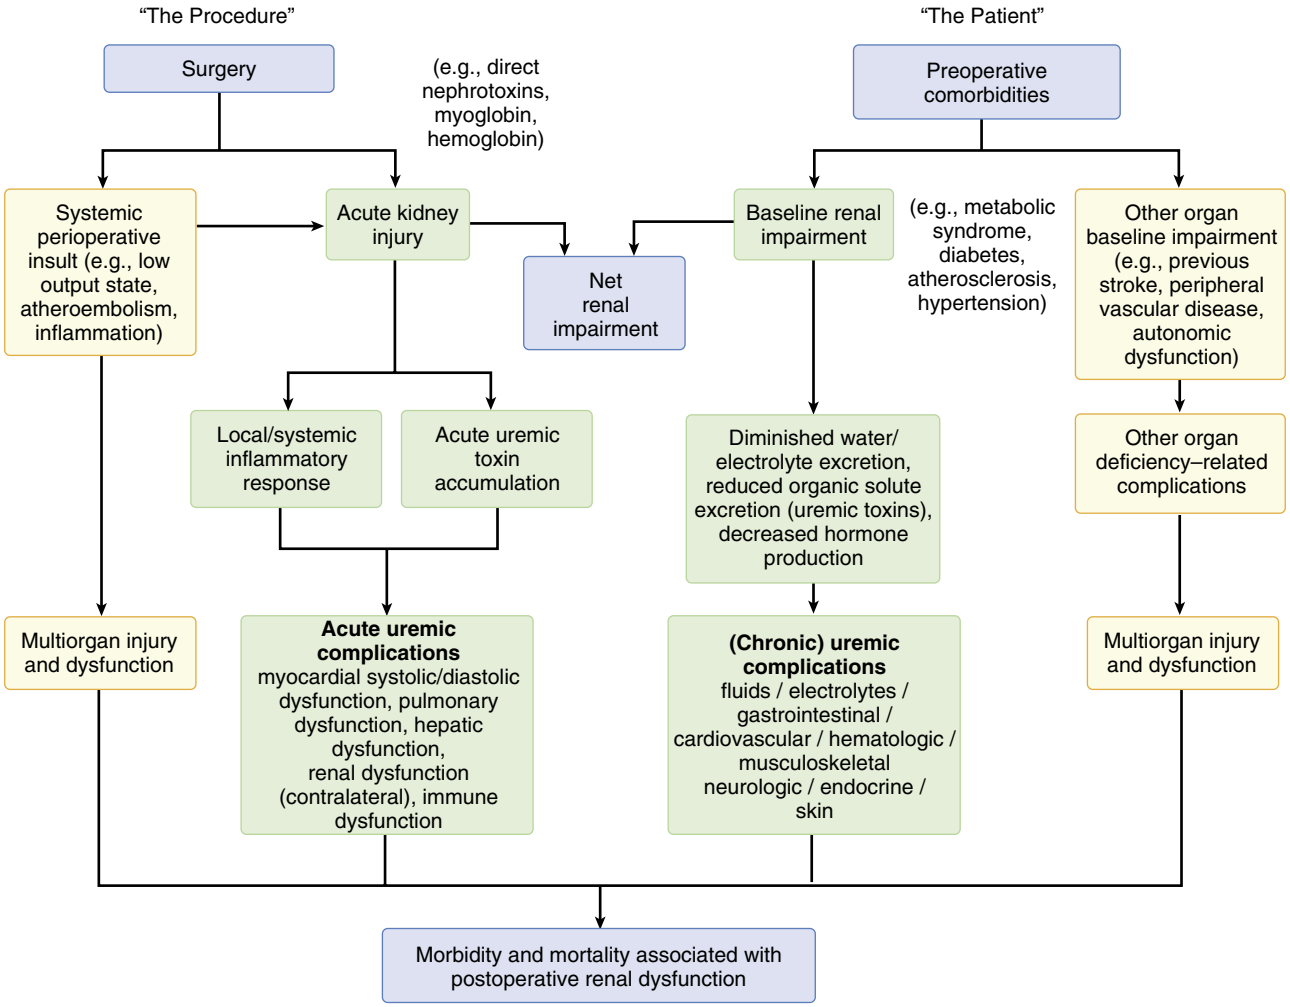

Figure 45-3 Procedural and patient factors related to surgery contributing to risk of perioperative acute kidney injury (AKI) and postoperative morbidity and mortality. Of note, although AKI contributes to this risk, a significant part of this association must also be attributed to other very serious conditions that can cause injury, such as sepsis, that themselves are major sources of adverse outcome. (*Modified with permission from Stafford-Smith M, Patel U, Phillips-Bute B, Shaw A, Swaminathan M: Acute kidney injury and chronic kidney disease after cardiac surgery. Adv Chr Kid Dis 15:157-177, 2008.*)

risk for another type; for example, augmenting renal blood flow (RBF) may attenuate ischemia-reperfusion injury while delivering more atheroemboli and inflammatory mediators. Evidence continues to grow supporting the idea that postoperative AKI is a mosaic of several "pure" nephropathies, each of varying importance for a particular patient and procedure, suggesting that only individualized renoprotection strategies, guided by timely point-of-care renal function monitoring, will be helpful in developing effective renoprotection strategies. Hence, advances in renal function monitoring are currently a major focus in the search for improved renal protection and risk stratification strategies for AKI (see Chapter 18).

Renal Physiology

The kidneys are mesoderm-derived, bean-shaped retroperitoneal organs and weigh approximately 150 g each. They are the most highly perfused major organs in the body, representing only 0.4% of body weight but receiving an impressive 25% of cardiac output; as a comparison, "at rest" blood flow to the kidneys is eightfold greater per gram of tissue than blood flow to muscle during heavy exercise. Notably, renal artery blood flow is not primarily linked to metabolic demand; it is this "excess" blood flow that allows filtration of plasma at rates as rapid as 125 to 140 mL/min in adults. However, autoregulatory reflexes do exist that regulate renal perfusion; these are myogenic and tubular-glomerular reflexes that exist to "protect" the glomeruli from damage due to pressure overload by restricting RBF at higher pressures (e.g., >80 mm Hg).[38,39] However, the kidneys may not receive a luxury supply of nutrients and oxygen, because marked regional differences in blood flow within the kidney paradoxically make some areas (i.e., the medulla) very vulnerable to ischemic injury. Cortical blood flow exceeds outer and inner medullary perfusion by 3- and 20-fold per gram of tissue, respectively.[40] Although there is strong evidence that paracrine regulation of oxygen delivery is important in the medulla, little is known about the specifics of this process.[41]

Gross Anatomy and Internal Architecture

A detailed description of the anatomy of the kidney can be obtained elsewhere.[42] In simple terms, the internal morphology of the kidney parenchyma is highly organized, including a deep medullary region and superficial cortical layer. The medulla is further subdivided into inner and outer regions. Tightly packed nephrons are tubular structures that contain specialized segments including the glomerulus, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting duct (Fig. 45-4). The collecting ducts feed urine to the renal pelvis, which empties into the ureter and goes on to the bladder. Each kidney contains approximately 1 million nephrons. The loops of Henle and collecting ducts are found in the deeper parts of the kidney (medulla). Two types of nephrons are differentiated by glomerular location into cortical (85%) and juxtamedullary (15%) types; only the latter have loops of Henle that course deep into the medulla and participate in *countercurrent exchange,* a mechanism that makes possible the formation of highly concentrated urine.

Vascular Anatomy

A single *renal artery* enters at the kidney hilum and then divides many times, ultimately producing *arcuate arteries* that pass along the boundary between cortex and outer medulla (see Fig. 45-4).[41] Arcuate arteries give rise to *interlobular arteries* that branch toward the outer kidney surface, passing through the cortex as they produce numerous *afferent arterioles,* which in turn supply a *capillary tuft* to each glomerulus. The glomerular capillary tuft is the barrier where plasma elements are filtered and pass from the vascular to tubular space. Specialized negatively charged fenestrated capillary endothelial cells and tubular epithelial cells (podocytes) separated by a basement membrane allow approximately 25% of plasma volume to pass into the glomerulus (Bowman's capsule); normally, only elements smaller than 60 to 70 kDa are small enough to be filtered. Many disease conditions cause abnormalities of this interface and allow much larger proteins and even red blood cells to pass through; this manifests as either nephrotic syndrome (proteinuria > 3.5 g/24 hr) or glomerulonephritis (proteinuria and hematuria). As the vascular tuft exits the glomerulus, capillaries merge and become the *efferent arteriole.* Subsequent branches of the afferent arterioles become *peritubular capillaries* to nourish the tubules. Peritubular capillaries receive reabsorbed fluids and solutes from tubular cells before rejoining to form *venules.* Peritubular vessels of juxtamedullary glomeruli are known as *vasa recta* and accompany the loops of Henle deep into the medulla. The venous system of the kidney runs parallel and close to the arterial vasculature, finally returning blood to the inferior vena cava through the *renal vein.* Vascular supply to the kidney is strictly segmental, and embolic arterial or venous obstruction affects renal tissue in a "pizza wedge" parenchymal distribution involving all cortical and medullary tubular elements of affected nephrons.

Medullary hypoxia is a key concept that refers to the low oxygen levels that exist in the renal medulla, even during normal resting conditions. Sodium and water reabsorption depend on the hypertonicity of the medullary interstitium. The countercurrent multiplier system in the loop of Henle is a critical component of the kidney's ability to excrete or conserve salt and water.

The apparent overabundance of blood flow to the cortex is designed to maximize flow-dependent functions, such as glomerular filtration and tubular reabsorption. In the medulla, blood flow and oxygen reserve are restricted by a tubulovascular anatomy specifically designed for urinary concentration. The tubules carrying blood to the medulla are arranged in a hairpin-loop pattern to allow a countercurrent exchange of solute between the ascending and the descending limbs of the hairpin loop.[43] The osmotic gradient in the deeper portions of the medulla requires active transport of sodium in the thick ascending loop of Henle and limited blood flow through the medullary vessels to prevent washout of the solutes in those deeper tubules. To maintain this concentration gradient in the thick ascending limb, high energy demand (i.e., active sodium transport) must be coupled with low oxygen delivery.

Factors necessary to allow countercurrent exchange and create a urea gradient conspire to make normal medullary Po_2 very low (e.g., 10 to 20 mm Hg); these include high oxygen demand from active solute transport and sluggish blood supply (5% to 10% of RBF). Average blood flow is 5.0 mL/g/min and 0.03 mL/g/min for the cortex and medulla, respectively, and the oxygen extraction ratio (i.e., oxygen consumption over oxygen delivery) is 0.18 and 0.79 for the cortex and medulla, respectively. The descending vasa recta are vasoactive arteriolar microvessels that are anatomically positioned to regulate total and regional blood flow to the outer and inner medulla.[43] Normally, the partial pressure of oxygen is about 50 mm Hg in the cortex and 8 to 15 mm Hg in the medulla, making the thick ascending loop of Henle most vulnerable to tissue hypoxia. Medullary oxygen delivery is made more inefficient by the unique hairpin loop anatomy of the loops of Henle and vasa recta that allows "oxygen escape" from entering to exiting capillaries (see Fig. 45-4).[44,45] This precarious arrangement underpins some of the specialized homeostatic abilities of the kidney, particularly the formation of concentrated urine, but also underlies the extreme vulnerability of the renal medulla to ischemic injury.[46]

The high metabolic requirement of the thick ascending loop of Henle in a hypoxic environment makes it especially vulnerable to injury associated with an imbalance in oxygen supply and demand.[47,48] Hypoxic perfusion of an isolated kidney preparation has demonstrated that the cells of the thick ascending limb of the loop of Henle in the medulla are extremely vulnerable to hypoxic damage.[48] Most recent available evidence suggests specific roles for prostaglandins (mediated by cyclooxygenase-2 receptors), angiotensin II, bradykinin, adenosine, nitric oxide (generated by nitric oxide synthase type 3), norepinephrine, and vasopressin in the paracrine autoregulation of medullary blood flow.[41] An adenosine receptor–mediated renal *ischemic preconditioning reflex* has been characterized, but the relevance of this to humans is unknown.[49-51]

Normal Function

The "resting" kidney continuously regulates body composition by processing plasma filtrate to keep fluid volume, osmolarity, acidity, and numerous electrolytes within narrow limits. Every 3 minutes a plasma volume equivalent to a 12-oz soft drink is filtered, and all but 1% (4 mL) is returned to circulation; the remnant is urine. Tightly regulated through tubular processing are extracellular solutes, including sodium, potassium, hydrogen ion, bicarbonate,

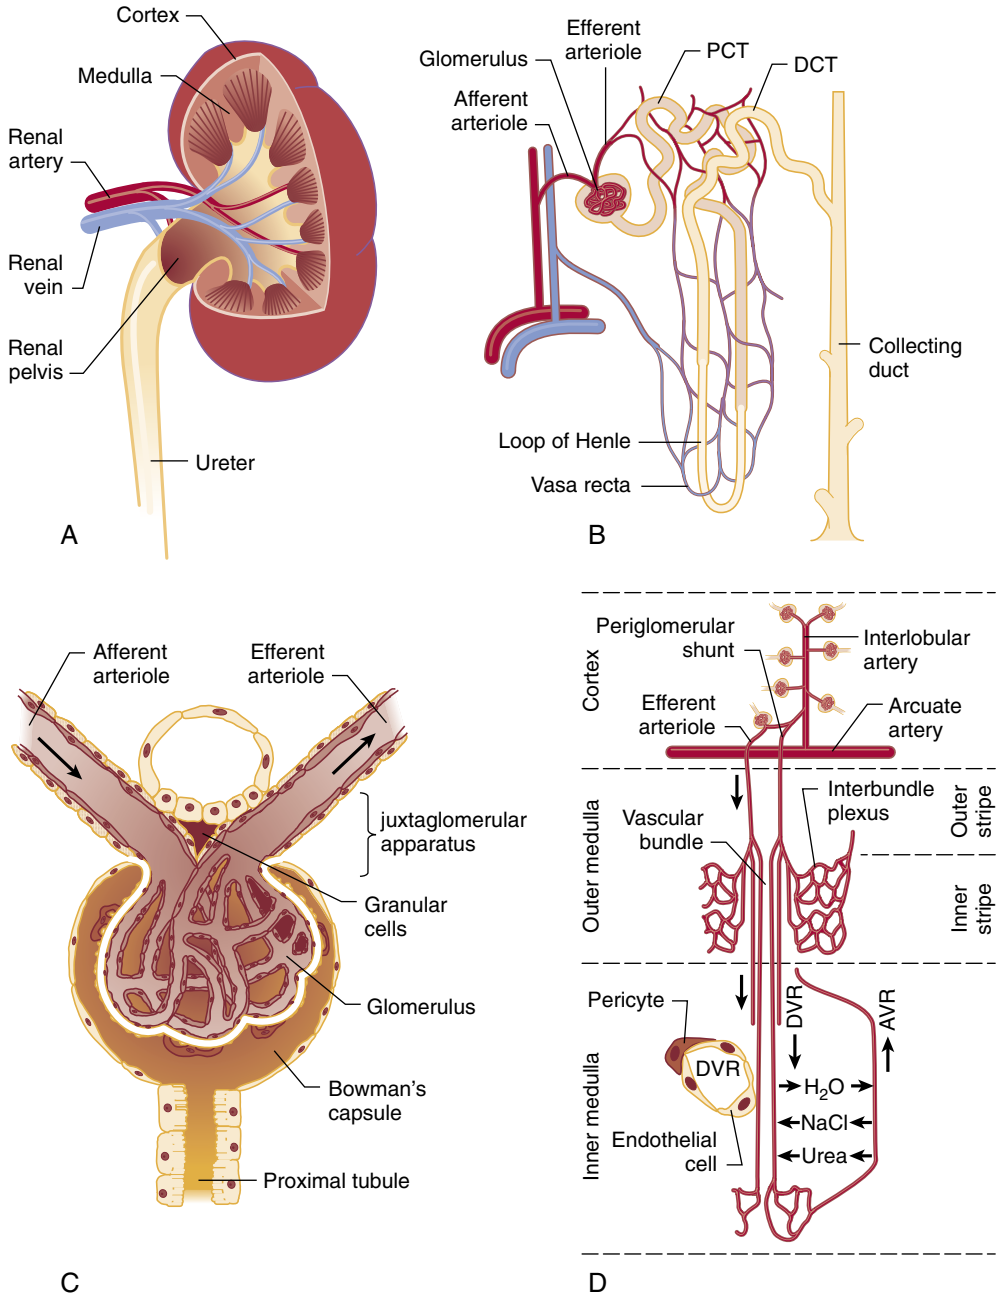

Figure 45-4 A, The internal structure of the kidney includes the vasculature, cortex and medulla regions, and urinary tract structures. **B,** The functional unit of the kidney is the nephron. **C,** The glomerulus is the site where plasma filtration occurs; approximately 20% of plasma entering the glomerulus will pass through the specialized capillary wall into Bowman's capsule and enter the tubule to be processed and generate urine. **D,** The vascular anatomy of the kidney is highly organized, and the medullary microcirculation is part of the mechanism that permits countercurrent exchange.[41] AVR, ascending vasa recta, DVR, descending vasa recta. and glucose. The kidney also generates ammonia and eliminates metabolic and nitrogenous wastes, including creatinine, urea, and bilirubin, as well as toxins and many classes of drugs. Finally, the kidneys generate glucose and secrete circulating hormones that influence erythrocyte generation, systemic blood pressure, and calcium homeostasis.

High concentrations of aldosterone stimulate reabsorption of sodium and water, primarily in the distal tubule and the collecting ducts. Aldosterone is produced by the adrenal cortex in response to the feedback from the renin-angiotensin-aldosterone system, simplified as follows. Reduced delivery of sodium to the macula densa causes release of renin from the granular cells of

the juxtaglomerular apparatus. Renin catalyzes the release of angiotensin I from angiotensinogen. Angiotensin I is then transformed to angiotensin II in the lungs, catalyzed by angiotensin-converting enzyme. Angiotensin II stimulates the production of aldosterone.

Antidiuretic hormone (ADH, vasopressin) acts primarily on the collecting ducts to increase water reabsorption. ADH is released from the posterior pituitary gland in response to increased blood osmolarity, which stimulates osmoreceptors in the hypothalamus. ADH release is also influenced by stress and increased partial pressure of arterial carbon dioxide.[52] A high level of ADH results in the excretion of small volumes of concentrated urine. ADH is inhibited by stimulation of atrial baroreceptors or increased atrial volume.[53]

Atrial natriuretic peptide causes systemic vasodilation and promotes renal excretion of sodium and water by increasing glomerular filtration.[54] Atrial natriuretic peptide is secreted by the cardiac atria and other organs in response to increased intravascular volume. It decreases systemic blood pressure by relaxing vascular smooth muscle, reducing sympathetic stimulation, and inhibiting the renin-angiotensin-aldosterone system. The kidney also synthesizes prostaglandins, which regulate the influence of other hormones. During hemodynamic instability and increased adrenergic stimulation, for example, prostaglandin E_2 decreases the vasoconstrictive effect of angiotensin II on the afferent arterioles and preserves RBF. Inhibition of prostaglandin synthesis during normal states of hydration, renal perfusion, and sodium balance does not affect renal function. When the kidney is confronted with a vasoconstricted state, such as hypotension and hypovolemia, however, the presence of renal prostaglandins is essential for preserving adequate RBF. Patients taking nonsteroidal anti-inflammatory drugs are at risk during conditions of impaired circulatory status because these agents inhibit cyclooxygenase activity, an important enzyme in the prostaglandin synthesis pathway, thereby rendering the kidney (afferent arteriole) susceptible to the systemic vasoconstrictive effect of angiotensin II and other catecholamines normally secreted to preserve intravascular volume and perfusion pressure.

Interaction between the urinary bladder, the kidney, and the ureters influences urine production.[55] General anesthesia decreases the rate of ureteral contractility.[56] The autonomic nervous system also plays an important role in ureteral function and consequently in urine formation.[55] Cholinergic agonists generally increase the frequency and the force of ureteral contraction. Drugs that act primarily on adrenergic receptors tend to stimulate ureteral activity, whereas agents that primarily activate adrenergic receptors tend to inhibit ureteral activity. Histamine stimulates ureteral activity. In a variety of preparations, morphine increases ureteral tone. In humans, irregular peristaltic contractions occur with retroperitoneal inflammation resulting from appendicitis, regional enteritis, ulcerative colitis, and peritonitis.[57]

A gross summary of plasma processing by the kidney involves glomerular filtration (~120 mL/min); subsequently, up to two thirds of the water and electrolytes is quickly returned to the circulation through active transport processes by the proximal convoluted tubule. Two thirds of remaining tubular contents is more sluggishly reabsorbed in the loop of Henle and distal convoluted tubule. Finally, more water is reabsorbed from the remaining effluent in the collecting ducts (5-10 mL/hr) as it passes to larger urine collecting structures (1-2 mL/min).

The Pathophysiology of Ischemic Acute Kidney Injury

The sources of perioperative insults to the kidney are extensively reviewed elsewhere.[37] Two primary contributing mechanisms are ischemia-reperfusion and nephrotoxic effects, with three notable sources of insult common to many surgical procedures where postoperative AKI is prevalent: hypoperfusion, inflammation, and atheroembolism. Several other less common sources of renal insult may contribute in selected patients (e.g., rhabdomyolysis, drug-related).

Ischemic renal failure related to shock or severe dehydration is always preceded by an early compensatory phase of normal renal adaptation (e.g., pre-prerenal failure) followed by a condition termed *prerenal azotemia* in which the kidney maximizes activities at the expense of retention of nitrogenous end products to preserve the internal environment through extreme retention of solutes and water (Fig. 45-5). Prerenal azotemia precedes 70% of general community-acquired ARF.[19,20] Although prerenal azotemia is ominous and typically accompanied by oliguria (<0.5 mL/kg/hr), it is reversible and sometimes jokingly referred to as "acute renal success" (i.e., the kidney is succeeding in maintaining homeostasis). At a critical tilting point, as conditions go beyond the compensatory mechanisms that maintain renal perfusion, ischemia leads to irreversible renal cell necrosis.[58,59] This event is called *acute tubular necrosis* and represents the "pure" form of ischemic nephropathy. The terms *acute tubular necrosis, vasomotor nephropathy,* and *ischemic tubular injury* are often used interchangeably in the literature. Notably, several other "pure" nephropathies exist that can themselves cause ARF; these include pathophysiologies related to inflammation, pigments (hemoglobin, myoglobin), and contrast dye. Other types of "pure" nephropathy do not involve the typical pattern of prerenal azotemia and oliguria. Importantly, most cases of perioperative ARF are the result of numerous renal insults, rather than being due to one "pure" source (Fig. 45-6).

Interruption of blood flow to kidneys for more than 30 to 60 minutes results in ARF and irreversible cell damage. The kidneys receive 1000 to 1250 mL/min of blood, or 3 to 5 mL/min/g of tissue for the average adult, and this amount far exceeds that needed to provide the kidney's intrinsic oxygen requirement. Intracortical blood flow may not be evenly distributed (see Fig. 45-4).[60] Because the renal cortex contains most of the glomeruli and depends on oxidative metabolism for energy, ischemic hypoxia injures the renal cortical structures, particularly the pars recta of the proximal tubules. As ischemia persists, the supply of glucose and substrates continues to decrease; glycogen is consumed, and the medulla, which depends to a greater extent on glycolysis for its energy sources, becomes more adversely affected. Early cell changes are reversible, such as the swelling of cell organelles, especially the mitochondria. As ischemia progresses, lack of adenosine triphosphate interferes with the sodium pump mechanism, water and sodium accumulate in the endoplasmic reticulum of tubular cells, and the cells begin to swell. In irreversible ARF, several pathologic changes occur. Swelling of tubular epithelial cells leads to formation of bullae, which protrude into the tubular lumen distal to the cell; necrosis of tubular cells results in abnormal membrane permeability; structural changes in the glomerular epithelium may decrease glomerular filtration; and

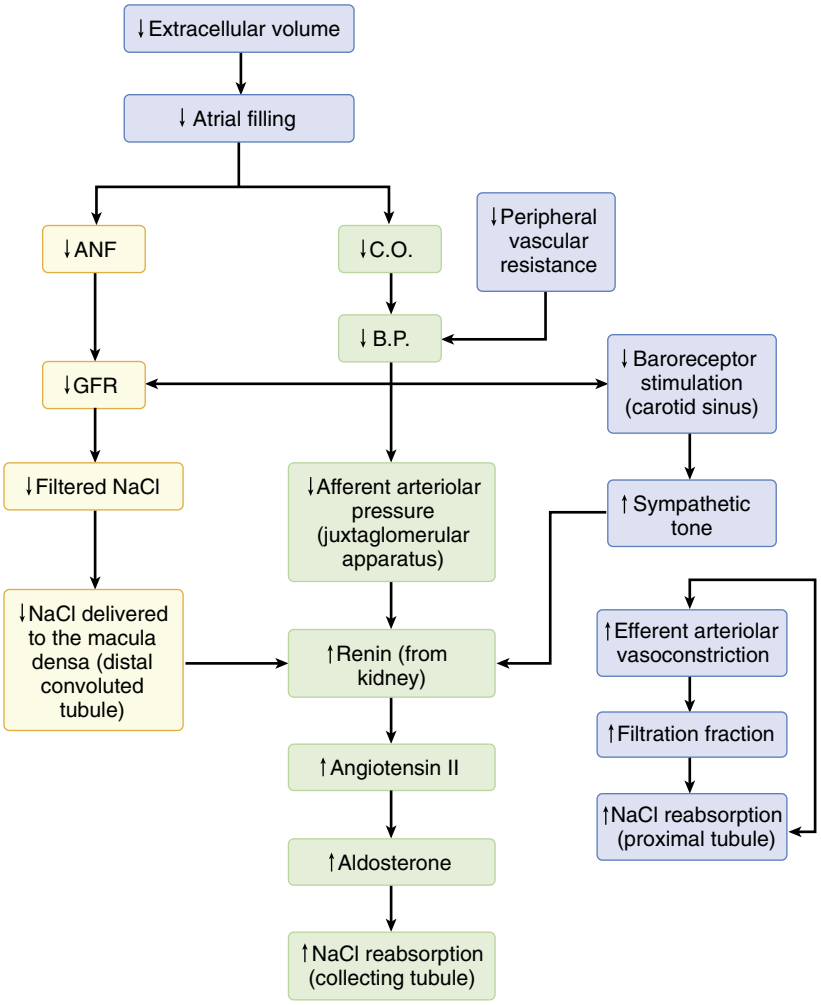

Figure 45-5 Mechanism for renal sodium and volume regulation in response to decreased extracellular volume (e.g., hypovolemia, hemorrhage). ANF, atrial natriuretic factor; B.P., blood pressure; C.O., cardiac output; GFR, glomerular filtration rate; NaCl, sodium chloride.

constriction of intrarenal arteries and arterioles may further reduce glomerular blood flow.

Onset of tubular damage usually occurs within 25 minutes of ischemia as the microvilli of the proximal tubular cell brush borders begin to change. Within an hour, they slough off into the tubular lumen and membrane bullae protrude into the straight portion of the proximal tubule. After a few hours, intratubular pressure rises, and tubular fluid backflows passively. Within 24 hours, obstructing casts appear in the distal tubular lumen. Even when RBF is completely restored after 60 to 120 minutes of ischemia, long-lasting vasoconstriction means that glomerular filtration rate (GFR) will not improve to baseline levels for an extended period.[61]

Lesions created during ischemia-induced ARF are unevenly distributed among nephrons. In contrast, lesions from nephrotoxin-induced failure are more evenly distributed among all nephrons. Proximal tubular obstruction of the tubular lumen with necrotic cell casts is characteristic.[62] After restoration of blood flow, intrarenal vascular resistance is high because of cell swelling and ischemic damage, and flow is as much as 50% below control values.[61] As blood flow becomes inadequate to support glomerular filtration, urine flow ceases and toxic substances accumulate in the urine and renal parenchyma. Other factors contributing to the increased risk of renal failure include the interference of certain drugs (e.g., nonsteroidal anti-inflammatory drugs) with autoregulation and preservation of blood flow to strategic regions of the kidney, drug-induced membrane damage, or mitochondrial uncoupling, causing an inefficient use of oxygen. Toxic substances (e.g., aminoglycosides) and oxygen deprivation cause depletion of adenosine triphosphate due to low blood flow.

Anesthesia, Surgery, and Normal Renal Function

Notably, the importance of oliguria (<0.5 mL/kg/hr) as a predictor of AKI is very limited in the perioperative setting (Fig. 45-7).[63] Anesthesia and surgery influence normal renal function primarily through changes in GFR.[64] Fluctuations in blood pressure have a major effect on RBF and glomerular filtration.[65,66] Anesthetic interventions, whether involving volatile agents, intravenous drugs, or regional blocks, generally reduce blood pressure and cardiac output, thereby diminishing RBF, leading to decreased glomerular filtration and urine formation.[67] Commonly used premedications can similarly influence urine output.[68] Narcotics and barbiturates, for example, cause a small decrease in GFR and urine volume.

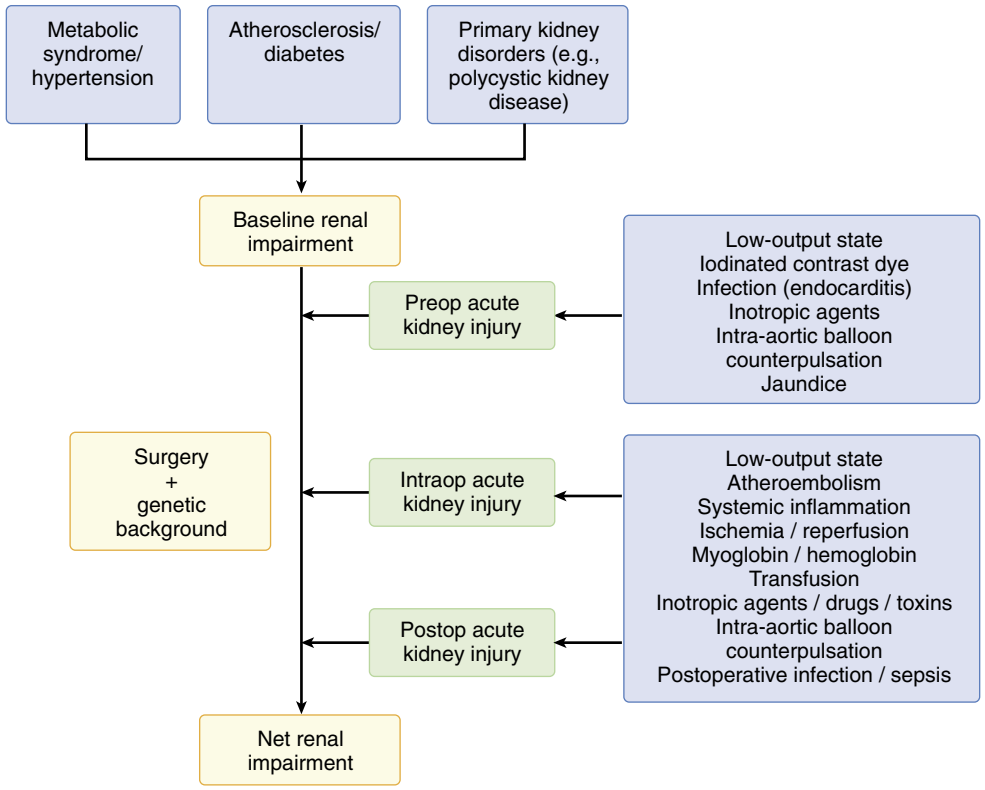

Figure 45-6 Perioperative clinical risk factors that predict risk of postoperative kidney injury and chronic kidney disease.

Surgical and anesthetic interventions may have autonomic consequences, such as increasing circulating catecholamines, that also reduce glomerular filtration by altering renal vascular resistance and decreasing RBF. The normal physiology of the kidney includes a role of adrenergic receptors in modulating vasoconstrictor (alpha 1) and vasodilating (alpha 2) effects, respectively. In animal models, infusion of norepinephrine is a well-described source of renal vasoconstriction and reduction in glomerular filtration[69,70]; this effect also appears to be relevant to human physiology.[71] The perioperative stress response to major surgery, particularly related to neurosurgical procedures, can further reduce urine output by increasing circulating ADH levels.[72,73]

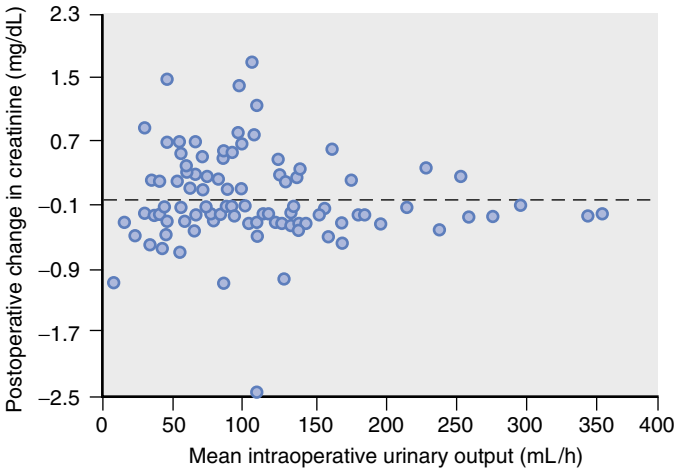

Figure 45-7 Low hourly urine flow (<0.5 mL/kg/hr) is a marker in some widely used criteria to diagnose AKI but is not a meaningful assessment to make this diagnosis in the immediate perioperative period. The lack of association of urine output with postoperative renal complications is exemplified by data in the figure comparing postoperative urine output and postoperative change in serum creatinine after aortic surgery. (*Used with permission from Alpert RA, Roizen MF, Hamilton WK, et al: Intraoperative urinary output does not predict postoperative renal function in patients undergoing abdominal aortic revascularization. Surgery 95:707-711, 1984.*)

Effects of Regional Anesthesia

Regional anesthetics and the kidneys interact in a complex manner that varies according to the underlying cardiovascular, renal, fluid, and electrolyte status of the patient (see Chapters 51 and 52).[74] Epidural and spinal anesthesia reduce systemic and renal vascular sympathetic tone.[75] Spinal cord segments T4 through L1 contribute to the sympathetic innervation of the renal vasculature, which is mediated by sympathetic fibers from the celiac and renal plexus.[76,77] Autonomic blockade above the fourth thoracic level also blocks cardioaccelerator sympathetic innervation to the heart. If neuraxial blockade reduces blood pressure and cardiac output, it will reduce RBF, with matching reductions in glomerular filtration and urine output. Suleiman and colleagues[78] demonstrated in healthy volunteers that RBF is unchanged during epidural anesthesia with a T6 sensory block. In their study, mean arterial pressure remained above 70 mm Hg and RBF never decreased below 6% of the baseline level.

The effect of neuraxial blockade varies not only on the level of sympathetic block but also the presence of underlying disease. In all perioperative settings, renal filtration and urine formation

depend on the net sum of numerous endogenous effects, including circulating catecholamines, autonomic blockade, ADH, angiotensin, dopamine, vasopressin, prostaglandin, atrial natriuretic peptide, endothelin, and nitric oxide. Superimposed on endogenous factors are surgical and anesthetic interventions, such as aortic cross-clamping, cardiopulmonary bypass (CPB), diuretics, and vasoactive infusions (e.g., vasopressin, dopaminergic and adrenergic agonists).

Urine volume and free water clearance may decrease during spinal anesthesia as a result of increased ADH secretion. Increased renal sympathomimetic activity decreases RBF through α-adrenergic mediation and increases renin release through β-adrenergic innervation directly or by interaction with the renal tubular macula densa and the baroreceptor reflex mechanism.[79-82] Of note, thoracic epidural anesthesia has been shown to increase RBF and urine output in animal models of endotoxic shock.[83]

Two recent large reviews on epidural anesthesia have findings that relate to perioperative renal outcomes. Moraca and colleagues[81,82] conducted a meta-analysis and reported on the association of thoracic epidural anesthesia with improved surgical outcomes in part attributable to reduction of perioperative morbidity, including blunting of stress response, attenuating infections, reduced ileus, reduced blood loss, and reduction in ARF. Liu and Wu[80] reviewed 18 meta-analyses, 10 reviews, eight randomized controlled trials, and two observational studies on epidural analgesia and found that the data support the ability of epidural analgesia to reduce cardiovascular and pulmonary complications, including renal morbidity after major vascular surgery on high-risk patients.

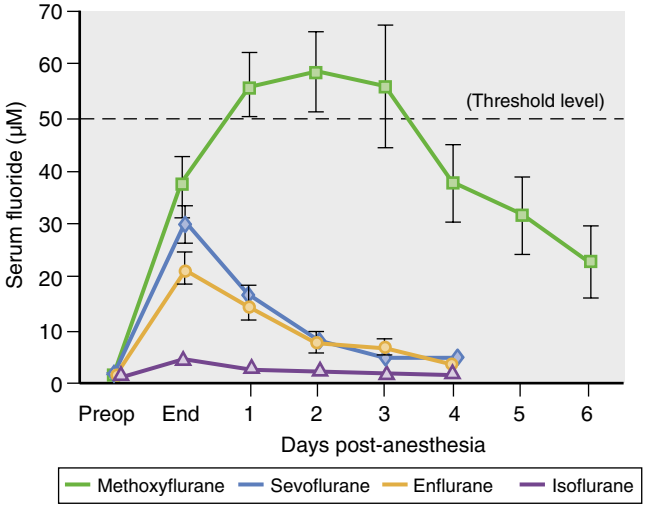

Figure 45-8 The nephrotoxic effect of the older volatile inhaled anesthetics are attributed to the liberation of inorganic fluoride when they are metabolized. Methoxyflurane-related AKI was related to threshold circulating fluoride levels greater than 50 μM/L. Levels of inorganic fluoride do not correlate as closely with the risk of AKI for modern volatile anesthetics such as sevoflurane. (*Used with permission from Mazze RI: Methoxyflurane revisited: tale of an anesthetic from cradle to grave. Anesthesiology 105:843-846, 2006.*)

Effects of Inhaled Anesthetics

There is a well-recognized nephrotoxic effect of the older volatile inhaled anesthetics that has been attributed to the liberation of inorganic fluoride when they are metabolized (see Chapter 24).[84] Methoxyflurane (no longer used clinically) and enflurane, when employed for prolonged periods (9.6 minimum alveolar concentration [MAC] hours), lead to significant generation of inorganic fluoride.[84-87] Increased serum levels of inorganic fluoride caused polyuric renal insufficiency.[84,85] Approximately 100 published cases of renal failure and 20 renal-related deaths attest to the significance of methoxyflurane-related nephrotoxicity.[84]

Because sevoflurane metabolism is similar to enflurane in regard to liberation of free fluoride ions,[84,88-91] (Fig. 45-8) concerns were raised during development that this agent may also impair the ability of the kidneys to concentrate urine.[89,92] Methoxyflurane studies indicated that AKI was likely to occur with circulating fluoride levels greater than 50 μM/L.[84,86] This presumed toxic threshold was extrapolated to the study of other halogenated anesthetic agents, including enflurane and sevoflurane (see Fig. 45-8). Notably, mean plasma fluoride levels in volunteers are approximately twice as high with sevoflurane as enflurane and 43% of volunteers receiving sevoflurane have plasma fluoride levels that exceed 50 μM/L. Healthy patients receiving 9 MAC hours of sevoflurane anesthesia have serum fluoride levels averaging 36.6 ± 4.3 μM/L.[88,93] However, relative to methoxyflurane, high fluoride levels with sevoflurane are short-lived, peaking 2 hours after the end of anesthesia and dropping by 50% within 8 hours. Despite high fluoride levels with sevoflurane, volunteers have no impairment in their ability to concentrate urine in response to desmopressin, whereas 20% of volunteers receiving enflurane have transient concentrating deficits on day 1 but not day 5 post exposure.[93] To interpret these findings, investigators postulate that intrarenal production of fluoride ion may be more important for nephrotoxicity than circulating plasma fluoride levels.[91] The intrarenal metabolism of methoxyflurane is fourfold greater than the intrarenal metabolism of sevoflurane.

Other explanations for differences in the renal effects of volatile agents were sought, including evaluation of variation in nephrotoxic compounds generated when an inhaled anesthetic agent interacts with carbon dioxide absorbents. In breathing circuit systems at high temperature and low flow rates, carbon dioxide absorbents degrade sevoflurane, creating fluoromethyl-2,2-difluoro-1-(trifluoroethyl) vinyl ether, also known as compound A. Metabolism of compound A includes conjugation in the liver with glutathione and then modification in the kidney by an enzyme (cysteineconjugate β-lyase). Some compound A metabolites can cause renal injury, characterized by diuresis, glycosuria, proteinuria, and elevated serum BUN and creatinine levels. AKI by this mechanism in experimental models is a function of the degree and duration of exposure to compound A,[94] with well-defined exposure thresholds in rats for injury (50-114 ppm for 3 hours) and death (331 for 3 hours, 203 for 6 hours, or 127 ppm for 12 hours).[95] However, a disparity exists between the results in rats and humans that may be due to differences in compound A processing; of the four recognized pathways for metabolism, three do not involve renal β-lyase nor result in kidney toxicity. Humans have 10- to 30-fold less renal β-lyase enzyme activity compared with rats, which may account for the absence of kidney injury from sevoflurane in humans. One study[96] compared the safety of low-flow sevoflurane and isoflurane anesthesia in patients having prolonged surgeries (>6 hr). The average MAC hours in both groups was similar, and the

average compound A concentration in the sevoflurane group was 20 ± 7 ppm. Markers of renal injury, including BUN, creatinine, *N*-acetyl-β-D-glucosaminidase (NAG), and alanine aminopeptidase, were increased similarly in all groups during the prolonged exposure to the volatile anesthetics.

The concentrations of compound A possible with sevoflurane during anesthesia has been evaluated in human volunteers.[97] Fresh carbon dioxide absorbent was used, and 1.25 MAC sevoflurane was given (without nitrous oxide) for 8 hours. Compound A levels approached 50 ppm, and 24-hour urine collections were analyzed for 3 consecutive days after exposure. Urinary glutathione S-transferase (GST) and other highly sensitive markers of tubular damage after nephrotoxic and ischemic insults were measured.[98] The investigators reported transient elevations of urinary protein, albumin, glucose, α-GST, and π-GST in patients receiving sevoflurane. Interestingly, no such increases were observed after similar exposure to desflurane. A multicenter study[99] involving 73 elective surgical procedures lasting 2 to 8 hours compared the safety and efficacy of low flow (less than 2 L/min) sevoflurane to isoflurane. Fresh carbon dioxide absorbent was used for all cases, and nitrous oxide was not permitted. Sevoflurane use averaged 3.6 MAC hour, and compound A levels were as high as 223 ppm (mean 79 ± 54 ppm). No differences were found in urine albumin, glucose, protein, or osmolality between treatment groups. Moreover, within the sevoflurane group, there were no significant correlations between compound A levels and BUN, creatinine, or urinary excretion of protein, glucose, NAG, α-GST, or π-GST.[99]

Despite the fact that 7% to 15% of patients receiving sevoflurane may have (short-lived) circulating levels of fluoride in excess of 50 μM/L and/or significant exposure to compound A, adverse renal effects do not seem to occur.[84] While explanation for the apparent safety of sevoflurane in the presence of nephrotoxins is not completely understood, some have proposed that the source of methoxyflurane-related renal injury may even be some other metabolic "villain" than fluoride or compound A that is unique to methoxyflurane metabolism, such as dichloroacetic acid.[100] Potential benefits of sevoflurane to the kidney have been described. In patients undergoing cardiac surgery, preconditioning with sevoflurane has been reported to decrease biochemical markers for renal (as well as myocardial) dysfunction.[101] Seventy-two patients scheduled for coronary artery bypass graft surgery (CABG) were randomly assigned to preconditioning conditions (oxygen-air versus sevoflurane 4%) during the first 10 minutes of CPB. Sevoflurane preconditioning significantly decreased postoperative release of brain natriuretic peptide and plasma cystatin C concentrations compared with oxygen-air.

Perioperative Hemodynamic Instability and Renal Function

An early compensated phase of renal adaptation in response to decreased glomerular blood flow with oliguria is sometimes referred to as "pre-prerenal failure" or "acute renal success."[58] When compensatory mechanisms are overwhelmed, accumulation of nitrogenous waste ensues (e.g., blood urea nitrogen) and prerenal failure. Renal clearance is determined by the delivery of waste products to the kidney (i.e., RBF) and by the kidney's ability to extract them (i.e., glomerular filtration).

In animal models, RBF is interrupted mechanically or pharmacologically; flow reduction by more than 50% is followed by a timed episode of complete renal ischemia (e.g., 40 to 60 minutes); and the consequent functional and histologic lesion, laboratory, and pathologic features resemble significant AKI without the need for dialysis. A number of theories have been proposed to explain the pathogenesis of hemodynamically mediated AKI. Although an extreme reduction in RBF is clearly necessary,[34,102] the unpredictable degree of AKI after hypotension suggests that it is not always sufficient. Even with decreased glomerular perfusion, a series of compensatory mechanisms can still preserve renal filtration.[58] Salt and water retention can restore intravascular volume and fractional tubular reabsorption. At a given level of cardiac output, intrarenal factors affect the ratio of renal-to-systemic vascular resistance, thereby influencing the fraction of cardiac output received by the kidneys. At the glomerular capillary, plasma is separated into a protein-free ultrafiltrate and a nonfiltered portion. Normally, the filtration fraction (i.e., relationship of glomerular filtration to renal plasma flow) is about 0.2. Initially, the filtration fraction is maintained by efferent arteriolar constriction. Unabated, the mechanisms that influence efferent arteriolar vasoconstriction ultimately may influence afferent arteriolar vasoconstriction. The resulting decrease in filtration fraction is the hallmark of postischemic AKI.[58] Ischemic tubular damage may be exacerbated further by an imbalance between oxygen supply and demand. Most vulnerable to the imbalance are the thick ascending tubular cells of the loop of Henle in the medulla.[48,102-105]

Microsphere, xenon washout, and angiographic techniques have shown that outer cortical blood flow decreases in ischemic models of AKI.[106-108] Because 85% to 90% of RBF is normally distributed to cortical glomeruli, the finding of cortical pallor and RBF redistribution away from cortex suggests that redistribution may contribute to the functional lesions of AKI. In some cases, the return of perfusion to the cortex has correlated with a return of renal function.[107] The theory that intrarenal distribution of blood flow away from the outer cortex to the inner medulla decreases oxygen supply while increased tubular reabsorption of solute increases oxygen demand is further supported by studies of renal energetics during AKI.[109-111] A decrease in the glomerular filtration, and consequently in the energy requirement for tubular reabsorption, may be a mechanism by which the kidney reduces energy demands before energy supply is critically limited.

Other Perioperative Perturbations and Renal Function

Whereas aortic cross-clamping above the renal arteries has obvious influence on glomerular filtration, infrarenal aortic cross-clamping and declamping also has significant indirect effects on glomerular filtration and urine formation through changes in myocardial function, sympathetic activity, neuronal and hormonal activity (e.g., renin and angiotensin production), intravascular volume, and systemic vascular resistance.[112] During standard CPB, cardiorenal relationships are approximately as expected;

RBF falls to 12% to 13% of total pump flow and is predicted by flow rate and perfusion pressure; however, only mean pressure correlates with urine output.[65,66] The intactness of myogenic and tubular-glomerular autoregulatory feedback has not been evaluated during CPB.[38,39]

ARF after aortocoronary bypass surgery continues to be a devastating complication that is associated with multiorgan dysfunction, increased resource utilization, high cost, and increased mortality (see Chapters 60 and 62).[2-10] Annually, 1 million patients worldwide have coronary revascularization with use of CPB with approximately 77,000 patients a year developing postoperative AKI, among which approximately 14,000 require dialysis for the first time.[4] The mechanism of perioperative AKI during cardiac surgery appears to be multifactorial, involving preoperative and intraoperative risk factors, including preexisting renal dysfunction, diabetes, ventricular dysfunction, older age, hypertension, microembolic and macroembolic processes, inflammatory mediators, prolonged CPB time, sensitivity to sympathetic stimulation, perturbation in renovascular resistance and flow,[3,8,113] and hypertension subtype (namely, pulse pressure hypertension).[2]

The importance of CPB has been evaluated in numerous studies of postoperative AKI between patients undergoing off-pump and on-pump coronary revascularization surgeries[114-124] with no conclusive evidence that CPB directly contributes to postoperative AKI. In a recent multicenter study of patients undergoing cardiac surgery, independent and significant risk factors for AKI were age older than 75 years, preoperative congestive heart failure, prior history of myocardial infarction, preexisting renal disease, intraoperative use of multiple inotropes, intraoperative insertion of intra-aortic balloon pump, and extended duration of CPB (>2 hr). In addition, preoperative pulse pressure (systolic minus diastolic) greater than 40 mm Hg had an incremental and progressive relationship with renal risk, such that for every additional 20-mm Hg increment in pulse pressure there was an additive odds ratio of 1.49 (CI, 1.17 to 1.89; $P = .001$). In this large study, with a high incidence of AKI (4.8%) in both the derivation (n = 2381) and validation (n = 2402) cohorts, AKI was nearly two times and renal-related death three times more common in patients with a pulse pressure greater than 80 mm Hg.

Genetic variants are an established predictor of chronic kidney disease (e.g., renal transplant nephropathy) and explain twofold to threefold more variation in postoperative AKI than standard clinical risk factors alone.[125,126] A handful of candidate polymorphisms known to affect inflammation and vasoconstriction have been studied, and several demonstrate strong associations with postcardiac surgery AKI.[126,127] The most clinically relevant genetic findings to date identify co-possession of the IL-6 572C and angiotensinogen (AGT) 842C polymorphisms in whites (9% of patients) as a predictor of an approximately fourfold greater than average peak creatinine rise after coronary revascularization (121%) (Fig. 45-9) and may have potential as a preoperative screening tool if validated in other populations. In African Americans, a similar, but statistically less robust finding, co-possession of the endothelial nitric oxide synthase (eNOS) 894T and angiotensin-converting enzyme deletion polymorphisms, also predicts a large creatinine rise (162.5%) (see Fig. 45-9). This compelling evidence of a genetic basis for postoperative AKI has come from analysis of a relatively small number of candidate genetic variants.

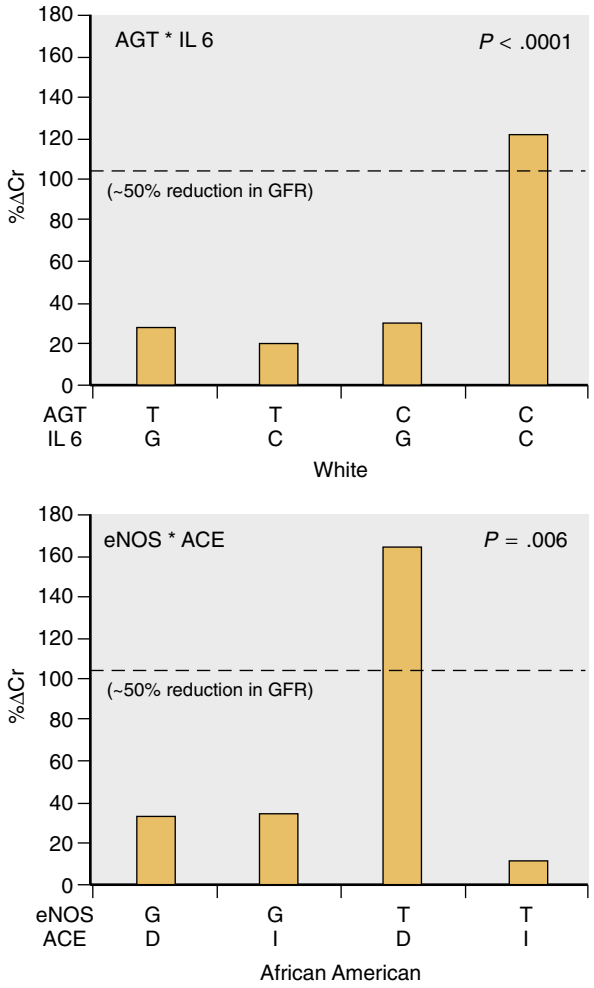

Figure 45-9 AKI after cardiac surgery is better predicted by knowledge of genetic variants than by standard clinical risk factors alone. Common gene polymorphism combinations predict increased risk; angiotensinogen (AGT) 842T→C and interleukin (IL) -6 572G→C in whites; endothelial nitric oxide synthase (eNOS) 894G→T and angiotensin-converting enzyme (ACE) insertion/deletion (I/D) in African Americans. % ΔCr, peak fractional serum creatinine rise; GFR, glomerular filtration rate. (*Used with permission from Stafford-Smith M, Podgoreanu M, Swaminathan M, et al: Association of genetic polymorphisms with risk of renal injury after coronary artery bypass graft surgery. Am J Kidney Dis 45:519-530, 2005.*)

Monitors of Renal Function

In patients with perioperative AKI, one of the major challenges to optimal perioperative management and early intervention has been the absence of tools for early recognition of subtle AKI. Traditional renal failure monitoring tools typically are insensitive until less than 40% of normal functioning nephrons remain (Fig. 45-10); this leaves only a small margin of renal function before uremic symptoms are apparent, when less than 5% of normal functioning nephrons remain.[58]

The highest standard for evidence of perioperative renal preservation is the avoidance of renal replacement therapy and reduced mortality. For example, optimal postoperative management of hyperglycemia in critically ill patients reduces the incidence of dialysis and improves survival.[128] Unfortunately, most

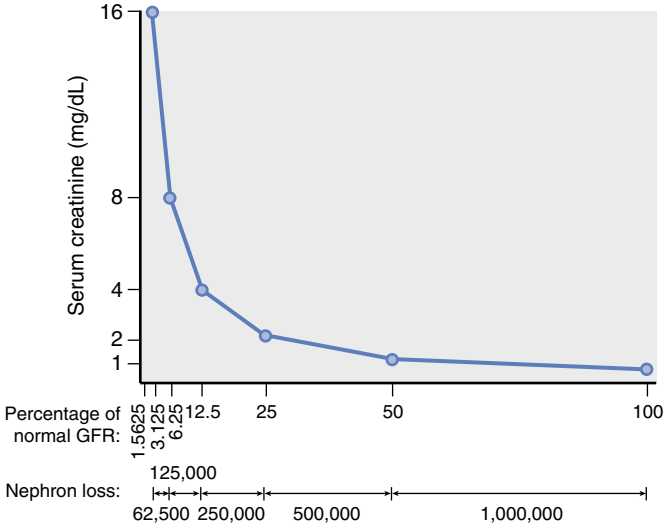

Figure 45-10 The inverse logarithmic relationship between serum creatinine concentration (*y* axis) and relative reductions in glomerular filtration rate (GFR) and approximate nephron loss (*x* axis). The nonlinear relationship means that serum creatinine level is not markedly increased until there is a 75% reduction in GFR (e.g., 120 to 30 mL/min). (*Modified from Faber MD, Kupin WL, Krishna G, Nairns RG: The differential diagnosis of ARF. In Lazarus JM, Brenner BM [eds]: ARF, 3rd ed. New York, Churchill Livingstone, 1993, p 133.*)

studies do not have sufficient sample size to show differences in mortality or dialysis rates and instead employ surrogates.

Most commonly, renal preservation is measured using secondary surrogate end points as markers for dialysis and death. Secondary measures most commonly reflect changes in glomerular filtration after surgery rather than renal failure requiring dialysis; peak filtration impairment is compared with a critical threshold or to renal function at baseline. Although most markers of renal filtration impairment based on serum creatinine have been validated through their association with postoperative mortality, there is little consensus on a standard assessment modality[129]; one review of 28 controlled perioperative studies found no two reports with the same AKI or ARF criteria.[23] Many studies present a variety of markers of AKI to describe an effect.[130]

Renal function is monitored indirectly. Among obstructive causes that may initiate ARF, an occluded or kinked urinary catheter must be eliminated as a source of oliguria. Toxic causes of ARF include antibiotics (e.g., aminoglycosides, amphotericin B) or radiocontrast agents. For example, with aminoglycosides, nephrotoxicity is poorly correlated with kidney tissue or plasma levels of the drug but is markedly augmented by concomitant volume depletion or liver cirrhosis.[20] In contrast, the likelihood of AKI correlates with baseline renal impairment and the amount of radiocontrast material injected, particularly when the contrast volume to creatinine clearance ratio is greater than 6.0.[131] The vigilance of the anesthesiologist is the first monitor required for preserving renal function.

The monitoring of renal function possible during the perioperative period is highly related to perioperative timing, postoperative disposition, and operative procedure. Unlike the postoperative/critical care setting where renal monitoring can involve periodic evaluation of kidney function under relatively stable conditions, intraoperative renal monitoring involves a briefer more unstable period, often involving significant blood loss, major fluid shifts, wide hemodynamic fluctuations, and even direct compromise to renal artery blood flow; all of these factors undermine the steady state so essential to most standard tests of renal function, such as creatinine clearance. The anesthesiologist often relies on indirect variables, such as urine volume, to assess renal perfusion. Unfortunately, urine output does not reliably reflect glomerular filtration and renal function under intraoperative conditions. Even knowledge of renal artery blood flow is not particularly informative, because increased flow mandates increased filtration and active transport demands, as well as increased oxygen delivery. As previously discussed, a monitor of balanced supply/demand of regional renal perfusion, particularly in the renal medulla, would be an ideal, although currently unavailable, direct monitoring tool. The best tools currently available intraoperatively are indirect hemodynamic monitors that can assist in optimizing conditions consistent with kidney well-being, such as ensuring adequate intravascular volume (i.e., preload), cardiac performance, and systemic perfusion. Serum chemistries and urinary indices may enable the assessment of adequate distribution of cardiac output to the kidneys themselves.

Indirect Markers of Optimal Renal Perfusion and Function

Nonoperative epidemiologic studies show a pattern for the development of renal failure that commonly involves the combination of severe dehydration with chronic renal conditions. For example, the combination of diabetes mellitus and volume depletion increases the chance of developing ARF by 100-fold.[20] The most practical preoperative methods to assess volume status are by standard preoperative history and physical examination and by evaluating changes in blood pressure in response to changing conditions. An awake patient normally does not have significant orthostatic changes in blood pressure unless he or she is dehydrated, whereas a similarly dehydrated anesthetized patient may demonstrate paradoxical arterial pulse changes with positive-pressure inspiration.[132]

Oxygen Delivery: Blood Gas, Acid-Base Balance, and Hematocrit

Severe arterial hypoxemia to a partial pressure of arterial oxygen (Pao_2) value of less than 40 mm Hg is associated with decreased RBF and renal vasoconstriction.[133,134] It appears that systemic hypoxia can produce antidiuresis and antinatriuresis independent of renal nerve innervation.[135] Capnometry may be a useful monitor because hypercarbia has been associated with decreased RBF in patients requiring mechanical ventilation.[136] Animal studies indicate that oxygen supply demand inequalities are exaggerated and medullary hypoxia is extreme during CPB, effects that last well beyond separation from circulatory support.[137]

The effects of anemia on the kidney have been most studied in the context of CPB management. When crystalloid/colloid solutions are used to prime an extracorporeal circuit, initiation of CPB obligates an acute drop of approximately 30% in oxygen-carrying capacity. Animal studies endorse moderate hemodilution (hematocrit 20%-30%) as renoprotective during CPB through

reduction of blood viscosity and improved regional blood flow.[138,139] However, although hematocrits less than 20% during CPB are commonly accepted clinically (extreme hemodilution), recent studies have linked very low hematocrit values with adverse outcome.[140-142] Several large retrospective studies identify lowest hematocrit during CPB as a predictor of postoperative AKI and renal failure.[130,143-145] Ironically, one alternative to tolerating extreme CPB hemodilution, transfusion, has also been considered risky for the kidney.[143,145]

Swaminathan and colleagues found an independent association of lowest CPB hematocrit (range, 22% to 24%) with postoperative AKI in a retrospective study of 1404 CABG surgery patients, a risk that was increased for obese patients.[143] These authors also observed a relationship between transfusion with renal impairment. In a similar study of AKI, Habib and colleagues[130] identified a near sigmoid-shaped detrimental CPB hematocrit "elbow" effect below 24%, even after adjustment for transfusion and extended CPB duration. Finally, Karkouti and colleagues evaluated the incidence of dialysis relative to lowest CPB hematocrit in 9080 cardiac surgery patients, noting a hematocrit less than 21% to be detrimental, compared with 21% to 25%, with a 2.3-fold increased risk of dialysis.[144] Interestingly, high hematocrits (>25%) were also associated with an increased risk for dialysis in this study. Although these studies endorse efforts to prevent extreme hemodilution during CPB, and guidelines for transfusion have been described,[146] support for transfusion as a treatment for all but the most extreme anemia (<15%)[147,148] is more controversial.[149]

Systemic Perfusion: Systolic Arterial and Pulse Pressure

Large multicenter epidemiologic studies have identified a relationship between markers of abnormal central aortic compliance, such as preoperative isolated systolic hypertension (>160 mm Hg) and wide pulse pressure hypertension (>40 mm Hg),[2,8,150] and postoperative AKI and dialysis. Preexisting systolic hypertension predicts a 40% greater risk, and wide pulse pressure also predicts postoperative AKI such that in cardiac surgery patients for every additional 20–mm Hg increment in pulse pressure greater than 40 mm Hg there is an OR of 1.49 (CI, 1.17 to 1.89; $P = .001$).

The systolic component of blood pressure is determined by stroke volume and the rate of ventricular ejection, whereas the pulsatile component of blood pressure is governed by the relationships among stroke volume, ventricular ejection, viscoelastic properties of large arteries, and peripheral vascular resistance. Pulse pressure is an index of the effects of large artery stiffness and the rate of pressure on propagation and reflection within the arterial tree. Early return of reflected arterial waves during late systolic rather than early diastolic pressure (from increased propagation velocity in stiff vessels) increases systolic blood pressure (i.e., afterload) and decreases diastolic blood pressure (i.e., perfusion pressure). It is likely that perfusion pressure and risk of perioperative renal dysfunction are linked by the preexisting capacity of the vasculature to compensate for low pressure as it determines flow. Those with a predisposition to low flow due to abnormal central aortic compliance may represent patients who require higher pressure to maintain adequate flow and minimize renal risk compared with normotensive patients.

RBF during CPB is not autoregulated and varies with pump flow rates and blood pressure.[65] However, CPB hypotension is not equivalent to hypotension with hemorrhagic shock or low cardiac output states, because low pressure during CPB is rarely associated with low flow. Fischer and colleagues retrospectively compared CPB flow rates and perfusion pressures in a case-control analysis of three groups of patients with normal baseline renal function who postoperatively either required dialysis (n = 44), sustained a renal injury without requiring dialysis (n = 51) or had no renal impairment (n = 48).[151] These authors noted that, on average, greater renal injury was associated with longer bypass durations, lower flows, and longer periods with CPB pressure less than 60 mm Hg. A serious limitation of this study is the potential for confounding CPB variables and known renal risk factors. In contrast, several large retrospective studies that accounted for known risk factors in evaluating perfusion management did not link low CPB blood pressure (with maintained flow) with postoperative AKI.[152-155]

RBF is affected by renal artery stenosis. In a retrospective study of 798 aortocoronary bypass patients whose cardiac catheterization procedures routinely included renal angiogram, Conlon and colleagues found that 18.7% of patients had at least 50% stenosis of one renal artery (9 patients had > 95% renal artery stenosis bilaterally).[156] However, in a multivariable logistic regression analysis there was no association of the presence or severity of renal artery stenosis with postoperative AKI.

Intravascular Volume Status: Central Venous Pressure, Pulmonary Capillary Wedge Pressure, Left Atrial Pressure, and Left Ventricular End-Diastolic Area

The decision to use any monitor should depend on the patient's functional cardiac reserve status and the extent of the proposed surgical insult. Although maintaining adequate cardiac output is necessary for maintaining adequate RBF, it may not guarantee adequate flow. Intravascular volume monitoring techniques must include caution to identify physiologic conditions that influence their validity as a reflection of preload in a particular patient (see Chapters 16, 18, 40, and 88). Monitoring central venous pressure to assess preload involves assumptions about normal left and right ventricular function, pulmonary vascular resistance, and mitral, pulmonary, and tricuspid valve function. Similarly, monitoring pulmonary artery pressure or pulmonary capillary wedge pressure assumes normal left ventricular compliance, mitral valve function, and normal airway pressure.

Direct measurements of left atrial pressure may offer insight into the kidney pressure-flow relationship because left atrial hypotension is a powerful stimulus for renal vasoconstriction.[85] Despite equivalent reductions in cardiac output and arterial blood pressure, RBF decreases much more when left atrial pressure is decreased (e.g., hemorrhagic shock) compared with when left atrial pressure is increased (e.g., cardiogenic shock).[157] Left atrial pressure receptors modulate renal vasoconstriction through release of atrial natriuretic peptide, a hormone secreted by the cardiac atria in response to intravascular volume expansion.[158] Atrial natriuretic hormone acts on the arterial and venous systems, the adrenals, and the kidneys to reduce intravascular volume and decrease blood pressure.[54] Within the kidney, the hormone

increases hydraulic pressure in the glomerular capillaries through afferent arteriolar dilation and efferent arteriolar vasoconstriction. Atrial natriuretic peptide reduces blood pressure by relaxing smooth muscle and reducing sympathetic vascular stimulation and also inhibits renin and aldosterone secretion, causing renal vasodilation, natriuresis, and diuresis.[54]

Intraoperatively, one of the most direct ways to monitor intravascular volume may be by direct assessment of the left ventricular end-diastolic area with transesophageal echocardiography.[159,160] In addition, assessment of adequate cardiac function through pulse oximetry, acid-base assessment, cardiac output monitoring, and left ventricular fractional area of change as a surrogate for ejection fraction contribute to evidence of normovolemia and renal perfusion (see Chapters 16, 18, 40, and 88).[161] However, monitoring with invasive devices, such as pulmonary artery catheters, arterial cannulas, and transesophageal echocardiography, has never been demonstrated to reduce the incidence of ARF.

Blood Flow: Cardiac Output and Esophageal Doppler Ultrasonography–Guided "Fluid Optimization"

The electrocardiogram is essential to detect the depolarization-repolarization changes consistent with the electrolyte abnormalities of renal dysfunction and to monitor for normal rate and rhythm. The synchronized atrial kick preceding ventricular contraction may contribute significantly to cardiac output in the patient with a noncompliant left ventricle. Transesophageal echocardiography 2D and renal arterial Doppler waveform images, primarily of the left kidney, can be used to assess changes in pulsatility and resistive indices and qualitatively describe RBF changes over time.[162,163]

Many believe that dehydration, hypovolemia, and blood loss are major contributors to perioperative renal dysfunction.[164] An update to enhance traditional, somewhat unreliable guides to fluid administration (e.g., central venous pressure) is the concept of "guided fluid optimization." The principle behind fluid optimization is to maximize tissue-oxygen delivery by achieving a maximum stroke volume, typically achieved by esophageal Doppler ultrasonography–monitored fluid boluses.[165] Some randomized studies have evaluated fluid optimization, a strategy that leads to increased perioperative volume administration for almost all patients, and reported improved outcomes such as shorter hospital stays.[166] In contrast, other studies have studied restrictive fluid regimens and also reported improved outcomes without evidence of increased ARF, despite decreases in perioperative urine output.[167,168] A systematic review of over 80 perioperative fluid management randomized trials concluded that current evidence does not allow evidence-based recommendations of one type of fluid over another or on the optimal amount of fluid to be administered for fluid replacement in elective surgical procedures but recommended strict avoidance of fluid overload.[169] Others have described the disastrous and unpredictable occurrence of acute pulmonary edema related to postoperative fluid retention.[170] There is insufficient evidence on which to base judgments on the importance of fluid selection and management strategies on perioperative renal function.[165,169]

Autoregulation and Distribution of Cardiac Output to the Kidneys

Standard cardiorenal relationships identify cardiac output and perfusion pressure as major predictors of RBF, whereas pressure alone correlates with urine output.[65,66] As previously mentioned, renal artery autoregulatory reflexes are *not* influenced by metabolic need and serve to "protect" the glomeruli from overload by restricting blood flow at higher pressures (e.g., >80 mm Hg).[38,39] Renal reflexes guided by different stimuli are the afferent and efferent arteriolar myogenic and tubular-glomerular feedback reflexes and the paracrine reflexes of the medullary microcirculation.

The fraction of cardiac output perfusing the kidneys depends on the ratio of renal vascular resistance to systemic vascular resistance.[58] In general, the response to renal hypoperfusion involves three major regulatory mechanisms that support renal function: (1) afferent arteriolar dilation increases the proportion of cardiac output that perfuses the kidney; (2) efferent arteriolar resistance increases the filtration fraction; and (3) hormonal and neural responses improve renal perfusion by increasing intravascular volume, thereby indirectly increasing cardiac output. The afferent arterioles react to reductions in perfusion pressure by relaxing their smooth muscle elements to decrease renal vascular resistance. Decreased solute delivery to the macula densa in the cortical portion of the thick ascending loop of Henle results in relaxation of the juxtaposed afferent arteriolar smooth muscle cells, improving glomerular perfusion and filtration.

The kidney produces vasodilator prostaglandins to counteract the effects of systemic vasoconstrictor hormones such as angiotensin II.[171] In a state of low cardiac output when systemic blood pressure is preserved by the action of systemic vasopressors, RBF is not depressed because the effect of the vasopressors is blunted within the kidney.

A selective increase in efferent arteriolar resistance decreases glomerular plasma flow, thereby preserving GFR. Glomerular filtration is augmented because capillary pressure upstream from the site of vasoconstriction tends to rise. This mechanism enables the kidney to offer high organ vascular resistance to contribute to the maintenance of systemic blood pressure without compromising its function of filtration. Studies using specific inhibitors of angiotensin II have shown that efferent arteriolar resistance largely results from the action of angiotensin II.[172] At low concentrations, norepinephrine has a vasoconstricting effect on efferent arterioles, indicating that the adrenergic system may also be important for maintaining the renal compensatory response.[173]

Evidence supports the notion that reductions in cardiac output are accompanied by the release of vasopressin and by increased activity of the sympathetic nervous system and the renin-angiotensin-aldosterone system. These regulatory mechanisms to preserve RBF conserve salt and water. The control of blood delivery to the kidney, the fraction of plasma filtered, and the amount of volume returned to the systemic circulation are determined by regulatory mechanisms within the kidney that attempt to preserve filtration function during compromised circulation.

One study reported the normal response to hemorrhage in otherwise healthy patients, describing a 30% reduction in RBF

with a decrease in mean perfusion pressure from 80 to 60 mm Hg.[174] Changes known to occur at the initiation of CPB include greater reduction in renal than systemic perfusion, loss of RBF autoregulation, and stress hormone and inflammatory responses known to be harmful to the kidney.[65,175,176] These effects may explain why the duration of CPB independently predicts post–cardiac surgery renal impairment.[3,4,177,178] Notably, during experimental CPB, medullary Po_2 drops from typically low levels to unmeasurable levels.[137]

Laboratory Tests of Serum and Urine as Markers of Renal Function

An ideal glomerular filtration monitor for perioperative AKI recognition would be accurate, point-of-care, simple, brief, and inexpensive and, in addition, should have confirmed links with AKI-related outcomes (e.g., mortality). Although no such test exists, trends in repeated serum creatinine determinations (relative or absolute changes), alone or integrated into estimates of GFR, are currently the most used clinical tool for this purpose.[179-181]

Although traditional tests are useful in identifying kidney failure, an inherent limitation of almost all currently available tools is the obligate delay between the *onset* of AKI and the *diagnosis* of AKI. One striking difference between management of AKI and acute myocardial infarction (AMI) is the lack of *early biomarkers* for AKI to guide prompt recognition and intervention when tissue is threatened (i.e., AMI—troponin, creatinine kinase-MB). Thus, one of the primary priorities of the largest current collaborative initiative, the AKI network (AKIN),[30] is to explore the existence and value of early AKI biomarkers. Therefore, the following discussion will be categorized into traditional diagnostic tools that provide only delayed recognition of AKI and the currently expanding field of early biomarkers for AKI.

Traditional (Delayed) Biomarkers of Acute Kidney Injury

Biomarkers for renal failure and acute tubular necrosis, which are reviewed next, include urine volume, urine specific gravity, urine osmolality, serum creatinine level, serum blood urea nitrogen level, urine-to-plasma creatinine ratio, urine-to-plasma urea ratio, urine sodium level, fractional excretion of sodium (FE_{Na}), free water clearance, creatinine clearance, inulin clearance, and RBF (Table 45-1).

Table 45-1 Biomarkers of Kidney Function*

- Serum creatinine

    - Baseline to peak postoperative fractional change
    - Peak in-hospital postoperative
    - Maximum change baseline-to-peak
    - ARF definitions
    - STS definition
    - AKIN criteria[30]
    - RIFLE criteria[31]
    - Modified contrast nephropathy
- Creatinine clearance
  - Estimates
    - Cockroft-Gault equation[180]
    - MDRD equation[181]
  - Direct measures
    - 24-hr urine collection
    - 2-hr urine collection
  - Analysis tools
    - Nadir postoperative
    - Baseline-to-nadir postoperative
    - Baseline-to-nadir postoperative fractional change
- Glomerular filtration rate
- Inulin clearance
- Iohexol clearance
  - Analysis tools
    - Nadir postoperative
    - Baseline-to-nadir postoperative
    - Baseline-to-nadir postoperative fractional change
- Urine volume
  - Analysis tools
    - AKIN criteria[30]
    - RIFLE criteria[31]
- Blood urea nitrogen
- Urine specific gravity
- Urine osmolality
- Urine-to-plasma creatinine ratio
- Urine-to-plasma urea ratio
- Urinary sodium
- Fractional excretion of sodium
- Free water clearance
- Renal blood flow

*Traditional biomarkers of kidney function primarily focus on measurements or estimates of function for comparison to expected normal values. With regard to diagnosis of prerenal azotemia and acute kidney injury, these tools typically provide information to confirm a diagnosis as long as 48 hours after the event.
STS, Society of Thoracic Surgeons; AKIN, AKI Network; MDRD, Modification of Diet in Renal Disease (study).

Urine Volume

Although recorded religiously, intraoperative urine output remains a controversial perioperative marker of renal function. Whereas the presence of urine (regardless of amount) confirms blood flow to the kidney, urine flow rate is an indirect parameter of renal function, and many nonrenal factors directly and profoundly influence urine production. Multiple studies have shown no correlation between urine volume and histologic evidence of acute tubular necrosis, GFR, creatinine clearance, or changes from preoperative to postoperative levels of BUN and creatinine levels in patients with burn injury,[182] trauma,[183,184] or shock status or in those undergoing cardiovascular surgery.[63,185,186] Alpert and colleagues observed oliguric aortic surgery patients (urine flow < 0.125 mL/kg/hr) given either additional crystalloid solution, intravenous mannitol, furosemide, or no intervention[63] and found no correlation between intraoperative mean or lowest hourly urine output and subsequent AKI (see Fig. 45-7).

In contrast to the intraoperative setting, significant prolonged preoperative or postoperative oliguria (<0.5 mL/kg/hr for > 6 hr) is more predictive and even diagnostic of AKI; for example, oliguria has been incorporated into the AKIN and RIFLE AKI criteria.[30,31] The kidney concentrates the ultrafiltrate so that at maximal concentration, a minimum of 400 to 500 mL of urine is

required to clear the daily obligatory nitrogenous wastes.[187] Among the factors that influence tubular excretion of solute and water are local and systemic levels of renin, aldosterone, and ADH. In the operating room, patients are often hemodynamically unstable; decreased blood volume or cardiac output, fluctuating hormone levels (e.g., aldosterone, renin, ADH), nervous system reflexes, and increased catecholamine concentrations, added to the effects of general anesthesia, can alter GFR. The data do not support oliguria as a reliable intraoperative sign of pending renal dysfunction.[63,182-187] Notably, the lack of correlation of immediate perioperative oliguria with AKI requires further incorporation into recent consensus statements developed primarily by nephrologists and critical care physicians as one of the criteria to diagnose AKI, such as the RIFLE and AKIN criteria.[30,31]

Urine Specific Gravity

Urine specific gravity reflects the mass of 1 mL of urine compared with 1 mL of distilled water. Normal values range between 1.001 and 1.035. In settings of poor perfusion or prerenal azotemia, urine specific gravity is high (e.g., 1.030), reflecting the kidney's ability to conserve sodium and water. With loss of concentrating ability due to acute tubular necrosis, urine specific gravity resembles plasma osmolarity (i.e., 1.010). Specific gravity is a surrogate for osmolarity (normal range, 50 to 1000 mOsm/kg). Unfortunately, when substances that raise specific gravity without significantly changing osmolarity are present in large amounts (e.g., glucose, protein, contrast dye) (Table 45-2), high urine specific gravity can provide misleading reassurance that renal concentrating ability is preserved.[188,189] The ability of the kidneys to concentrate urine after water deprivation is impaired in elderly patients, also making urine specific gravity an unreliable test.

Urine Osmolality

Osmolality is a measure of the number of osmotically active particles in solution in the solvent phase. It is one of the major forces that move fluid throughout the body, especially in the kidney. Theoretically, urine osmolality is physiologically superior to urine specific gravity as a test of renal function; however, the same substances and conditions that render urine specific gravity a nonspecific test can also affect the reliability of urine osmolality (see Table 45-2). A defective urinary concentrating mechanism tends to be one of the most consistent and lasting tubular defects of ARF.

Table 45-2 Substances and Conditions Affecting Urine Specific Gravity and Urine Osmolality

Proteins
Glucose
Mannitol
Dextran
Diuretics
Advanced age
Extremes of age
Radiographic contrast media
Antibiotics (e.g., carbenicillin)
Hydrometer calibration
Detergents
Temperature
Hormonal imbalances

The sensitivity and specificity of urine osmolality as a test for predicting or distinguishing acute tubular necrosis from prerenal azotemia are clinically inadequate.[186,190-195] With values greater than 500 mOsm, the positive predictive value for diagnosing prerenal azotemia ranges from 60% to 100%. With a value less than 350 mOsm, the positive predictive value for diagnosing acute tubular necrosis ranges from 69% to 95%.

Serum Creatinine Concentration

In spite of all its limitations, the serum creatinine concentration remains the most used clinical tool to assess renal function. However, due to its nonlinear relationship with changes in renal function (see Fig. 45-10), variability among individuals, and susceptibility to changes unrelated to changes in GFR (e.g., cimetidine, trimethoprim, acetylcysteine),[196,197] elevation of serum creatinine concentration is only somewhat reliable as a sign of renal dysfunction, and GFR may be reduced by as much as 75% before elevations reach abnormal levels.[198]

Creatinine, a cyclic anhydride of creatine, is a small molecule (113 daltons) that is continuously released during skeletal muscle protein catabolism. Muscle mass, which is smaller in women and declines with age, directly predicts creatinine release. Curiously, age- and gender-related differences in GFR are well matched with differences in creatinine release such that normal serum creatinine levels vary little with age or between genders (Fig. 45-11). Creatinine levels in body fluids (e.g., plasma, serum, urine) are also easy and inexpensive to measure. These properties have made serum creatinine a mainstay as a marker of steady-state changes in renal filtration.

Developing a consensus definition of AKI has been a recent focus. A consensus opinion from the Acute Kidney Injury Network asserts that the term *AKI* be used to represent the entire spectrum of ARF.[30] The AKIN definition, a 1.5-fold or 0.3 mg/dL (≥ 26.4 μmol/L) creatinine rise within a 48-hour period or more than 6 hours of oliguria (<0.5 mL/kg/hr), is a modification of its predecessor, the Acute Dialysis Quality Initiative (ADQI) Group so-called RIFLE criteria.[31] Specific to cardiac surgery is the Society of Thoracic Surgeons' definition of ARF as at least a twofold creatinine rise to a value exceeding 2.0 mg/dL or new dialysis or both.[25] Another commonly used AKI definition requires creatinine rise to exceed 25% or 0.5 mg/dL (44 μmol/L).[26,37]

Whereas creatinine has many advantages as a marker of changes in filtration function, its many drawbacks continue to fuel the search for a more ideal marker of renal filtration. In conditions such as the perioperative period where steady state is difficult to ascertain, serum creatinine may fail to accurately reflect the magnitude of nephron loss, and relative changes in serum creatinine may be more important than whether a value lies within or outside the normal range. Because creatinine production is proportional to muscle mass, many chronically ill, malnourished, elderly patients have serum creatinine values in the normal range, despite reduced renal concentrating ability and GFR. Conversely, many critically ill patients at risk for developing ARF may have high metabolic rates because of hyperalimentation, sepsis, or post-traumatic states. Higher metabolic rates mean higher nitrogenous waste production requiring greater than average RBF and urine flow rates to maintain normal serum creatinine concentration. Because creatinine is excreted by glomerular filtration and tubular secretion, as the GFR decreases the tubular secretion becomes a progressively more important fraction of creatinine excretion, such that creatinine clearance

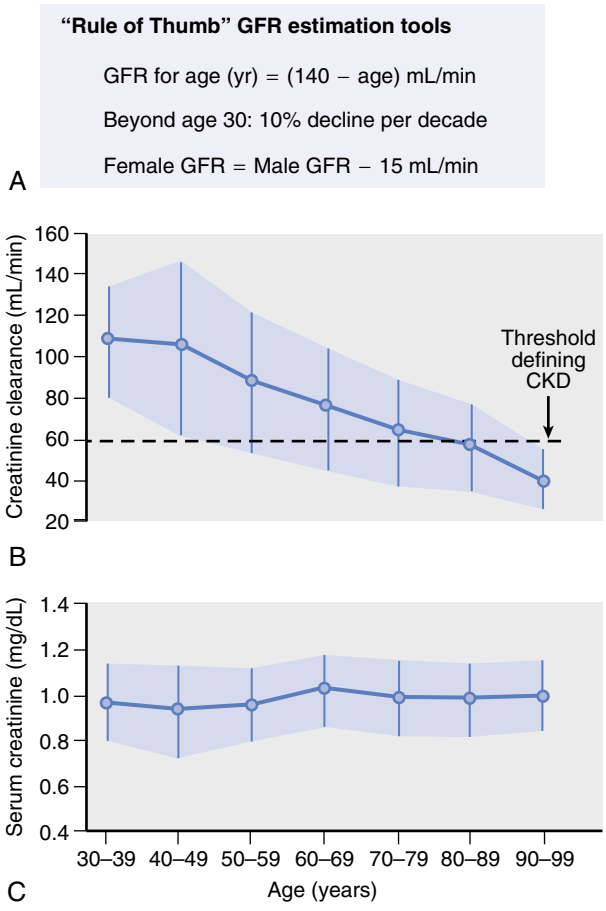

Figure 45-11 Several "rule of thumb" tools exist to estimate normal glomerular filtration rate (GFR) values based on age and gender (**A**). Creatinine clearance approximates but overestimates GFR due to creatinine secretion from the proximal renal tubule. Notably, owing to the similarity in rate of decline of GFR and creatinine release related to age (**B**), and based on gender, normal serum creatinine values remain remarkably similar throughout life (**C**). Notably, by the fifth decade some individuals, and by the ninth decade most individuals, with serum creatinine values in the normal range have GFR values reflecting chronic renal dysfunction (<60 mL/min). CKD, chronic kidney disease. (*Modified with permission from Davies DF, Shock NW: Age changes in glomerular filtration rate, effective renal plasma flow, and tubular excretory capacity in adult males. J Clin Invest 29:496-507, 1950.*)

overestimates the GFR by 50% to 100% if the true GFR is less than 15 mL/min.[198,199] Postoperative rise of serial serum creatinine measurements do not definitively identify AKI sometimes for several days after cardiac or noncardiac surgery.[32,200] Nonetheless, the serum creatinine concentration remains a useful, inexpensive, and, so far, unsurpassed clinical tool particularly to reflect *trends* of change in renal filtration function and predict outcome, even during the perioperative period.[179,201,202]

Blood Urea Nitrogen

BUN remains widely used to assess renal function but possesses few of the characteristics of an "ideal" substance. A product of protein metabolism, BUN level is increased by high protein intake, blood in the gastrointestinal tract, and accelerated catabolism (e.g., in traumatized or septic patients). The normal range is 8 to 20 mg/dL. Because urea is synthesized in the liver, hepatic dysfunction decreases urea production and, therefore, BUN concentration. BUN concentration fails in a key criterion as a reliable estimate of the GFR. Although urea is freely filtered at the glomerulus, it is reabsorbed to a large and variable extent. The reabsorption of urea is greater, approximately 60% of the filtered load, when urinary flow is low; only about 40% is reabsorbed when flow is high. In addition, perioperative hemodilution (e.g., CPB) may affect circulating BUN levels.

It was believed that combining BUN and serum creatinine levels would provide more reliable information than using either alone. If ratios of BUN to serum creatinine exceeded 20:1, for example, dehydration was suspected.

Urine-to-Plasma Creatinine Ratio

The urine-to-plasma creatinine index was first introduced in 1950 by Bull and colleagues[203] as a method of evaluating patients with acute tubular necrosis. It was determined retrospectively that patients whose urine-to-plasma creatinine levels rose above 10 after having been below 10 were no longer at serious risk for "uncontrolled mineral and water loss." This index was introduced primarily as a prognostic aid and not as a diagnostic test.

The sensitivity and specificity of the urine-to-plasma creatinine index are unfortunately clinically unreliable for diagnosing acute tubular necrosis and prerenal azotemia.[204] Miller and coworkers[191] concluded that the index was not useful, except in extreme situations, because of significant overlap between groups. Espinel and Gregory[192] prospectively studied 87 patients (61 with acute tubular necrosis or prerenal azotemia) and concluded that the urine-to-plasma creatinine ratio might be a useful indicator of acute tubular necrosis if the ratio was less than 10 and that it might be an indicator of prerenal azotemia if the ratio was less than 40. However, a significant overlap in values was found for 33% of patients.

Urine-to-Plasma Urea Ratio

In 1959, Perlmutter and colleagues[205] proposed that the ratio between urine and serum urea nitrogen levels could differentiate prerenal azotemia from acute tubular necrosis. These investigators thought that a ratio of greater than 14 was associated with transient oliguria and that a ratio of less than 10 was associated with acute tubular necrosis. In 1965, Eliahou and Bata[190] reported that the urine-to-blood urea ratio might not be useful for diagnosis in all cases. Subsequently, Chisholm and associates[206] confirmed that the urine-to-plasma urea ratio was often misleading in the diagnosis of uremia.

Urea production is not constant and is affected by many nonrenal variables.[207] Variables include sudden increases or decreases in protein intake, states of increased protein catabolism (i.e., trauma, infections, hyperthermia, or corticosteroid therapy), gastrointestinal bleeding, and liver dysfunction. Because urea levels can vary tremendously independent of renal function, it is not surprising that knowing the urine-to-plasma urea ratio does not make it possible to differentiate between prerenal azotemia and acute tubular necrosis.

Urinary Sodium Concentration

With decreasing perfusion, the normally functioning kidney conserves sodium and water. The factors affecting this phenomenon are numerous and include heterogenicity of nephrons, secretion of aldosterone, secretion of ADH, diuretic therapy, saline content

of intravenous infusion solutions, sympathetic neural tone, and sodium-avid states (e.g., congestive heart failure, cirrhosis). It is traditionally accepted that a urinary sodium level of less than 20 mEq suggests prerenal azotemia and that a level of greater than 40 mEq indicates acute tubular necrosis.

The reported sensitivity and specificity of urinary sodium levels for diagnosis of acute tubular necrosis and prerenal azotemia suggest that the levels can be used for diagnosis of approximately one half of the patients with acute tubular necrosis.[186,191-193,203,208,209] Considering the complex physiology of sodium homeostasis, it is not surprising that levels of urinary sodium are unreliable indicators of prerenal azotemia or acute tubular necrosis. The test is nonspecific because a significant overlap exists between the diagnostic categories and because urinary sodium measurement tends to correlate more with volume and type of resuscitation fluid than with renal function.[184]

Fractional Excretion of Sodium

Failure of avid sodium reuptake by the kidney in the setting of dehydration manifests by increased urine sodium and is the principle underpinning the utility of FE_{Na} as a diagnostic tool. A sodium excretion value of less than 1% compared with greater than 1% often enables differentiation between prerenal azotemia and acute tubular necrosis, particularly in the presence of oliguria.[210] The FE_{Na} was first described by Espinel[208]; it represents the fraction of sodium excreted versus that filtered by the kidneys. Handa and Morrin[204] had previously described the "renal failure ratio," which is a derivative of the excreted fraction of filtered sodium. The only difference between the two is that in determining renal failure ratio the plasma sodium level is assumed to be constant. FE_{Na} is calculated as follows:

$$FE_{Na} = \frac{\text{Excreted Na}}{\text{Filtered Na} \cdot 100} = \frac{U_{Na}P_{Cr}}{\left(U_{Cr}P_{Na} \cdot 100\right)}$$

where P_{Cr} is the plasma creatinine level, P_{Na} is the plasma sodium level, U_{Cr} is the urinary creatinine level, and U_{Na} is the urinary sodium level.

At first, investigators reported that FE_{Na} permitted clear differentiation between prerenal azotemia and acute tubular necrosis.[191-193,208] However, subsequent case reports cast doubt on the sensitivity and specificity of FE_{Na} as a useful discriminator between these conditions.[208,209,211-213] Brown[211] suggested that the FE_{Na} was diagnostic of acute tubular necrosis but was of little or no value for the early prediction of renal failure. Brosius and Lau[212] showed that early determinations of the FE_{Na} were more likely to be misleading than later determinations, indicating that the measurement was unlikely to be helpful in the early diagnosis of acute tubular necrosis. Shin and colleagues[210] concluded that knowing the FE_{Na} was useful only when oliguria was already present. However, because this indicator is usually observed later in the course of renal disease than the changes in creatinine or free water clearance, the FE_{Na} is not a highly valuable tool for predicting imminent renal failure and is rarely used now for this purpose.[214,215]

Free Water Clearance

Water that contains no solutes is considered "free water." Thus, compared with normal isosmotic plasma, hyperosmotic urine can be considered to represent the clearance of a negative amount of free water (i.e., avid water retention). Normal free water clearance (C_{H2O}) in the setting of dehydration can be as high as −25 to −20 mL/hr, whereas free water clearance of −15 to +15 mL/hr reflects incipient renal dysfunction. Free water clearance is a measure of the kidney's ability to dilute or concentrate urine as necessary to maintain homeostasis and is determined using the following equation:

$$C_{H2O} = UV - \left(U_{Osm} \times UV / P_{Osm}\right)$$

where UV is urine volume, U_{Osm} is urinary osmolality, and P_{Osm} is plasma osmolality.

Jones and Weil[216] assessed the sensitivity of free water clearance and concluded that serial measurements predicted the patients who would experience progressive renal dysfunction.[186] However, Rosenberg and coworkers[184] found no correlation between renal function and free water clearance in a prospective study of 69 trauma and sepsis patients. After studying 38 ICU patients, Baek and associates[217] concluded that ARF was diagnosed 1 to 3 days sooner with free water clearance than by other clinical and laboratory diagnostic criteria (creatinine clearance was not measured). These investigators recommended sequential measurements of free water clearance as an early indicator of ARF.

In a retrospective study of 675 trauma victims, Shin and colleagues[183] found free water clearance alone was not sufficient for the early detection of renal dysfunction. However, these authors found free water clearance greater than 20 mL/hr combined with a creatinine clearance less than 25 mL/min identified a high-risk group. However, in a prospective study of postoperative patients,[210] these same authors concluded that free water clearance was not as sensitive as creatinine clearance for predicting ARF in trauma patients. The same substances and conditions that decrease the usefulness of urine osmolality for indicating renal failure can similarly decrease the usefulness of free water clearance (see Table 45-2).[218]

Creatinine Clearance

Substances used to assess GFR through their clearance from the circulation are presumed to have certain "ideal" properties, including a steady supply to the circulation, free glomerular filtration, and neither reabsorption or excretion by the tubules. As previously mentioned, creatinine partially fails these criteria, owing to its minimal secretion from the proximal tubule; however, because "gold standard" methodologies such as inulin, ^{51}Cr-EDTA, or ^{99m}Tc-DTPA clearance are expensive and cumbersome, creatinine clearance continues to be the most commonly used direct measurement of renal filtration function. Creatinine clearance is the volume of plasma that the kidneys can completely clear of creatinine per minute and is measured by calculating the amount of creatinine reaching the urine during a period of time (urine volume and urine creatinine concentration) and comparing it with the concentration of creatinine in the blood. Measurements of creatinine clearance are most useful to quantify renal reserve.

Precise measurements of creatinine clearance require collection of timed urine samples using the following formula:

$$GFR = UV/P$$

where U is the urinary concentration of creatinine (mg/dL), V is the volume of urine (mL/min), and P is the plasma concentration (mg/dL). The major limitation in the determination of creatinine clearance is the necessity of collecting urine accurately. Although

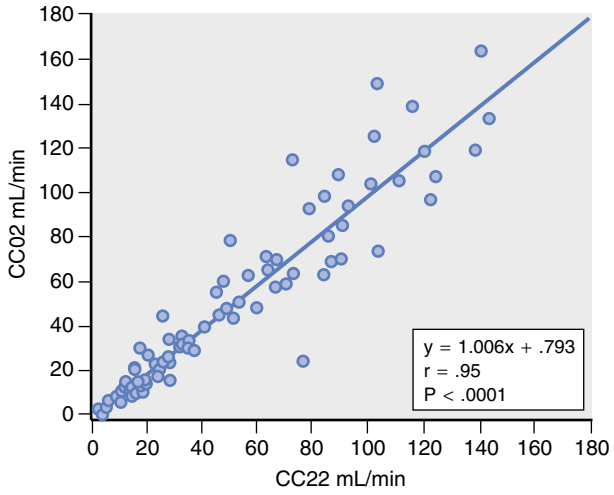

Figure 45-12 Correlation between the 2-hour creatinine clearance (CC02) and the 22-hour creatinine clearance (CC22). (*Adapted from Sladen RN, Endo E, Harrison T: Two-hour versus 22-hour creatinine clearance in critically ill patients. Anesthesiology 67:1013-1016, 1987.*)

reasonable correlation between 2-hour and 24-hour creatinine clearance (R = 0.85) has been reported for patients in ICUs (Fig. 45-12),[219,220] it remains true that the longer the urine collection period, the more accurate is the calculation of creatinine clearance. Changing hydration of the patient invalidates short-term determinations of the GFR, as does failure to record urine volume accurately. The error in calculation of creatinine clearance can vary from 10% to 27%, depending on the accuracy of urine collection,[221] body weight, surface area, and normal day-to-day variations. Another significant drawback is that for the patient with ARF a test that requires 24-hour urine collection is often impractical.

Perioperatively, creatinine clearance can be estimated by integrating serum creatinine values with other patient characteristics.[180] However, the dynamic changes in renal function and rapid fluid shifts typical of the surgical period often compromise precise measurement of renal glomerular filtration rate at this time. Until more precise validated perioperative markers are available, many believe that serum creatinine–derived markers are at least as accurate (and less expensive) than other more invasive tests.[179,201,202] A variety of algorithms have been developed to estimate creatinine clearance from a single steady-state serum creatinine value during conditions; these formulas are usually developed through modeling using data from large nonsurgical populations and require knowledge of factors that influence creatinine generation (gender, age, body weight). Of the many predictive tools that exist, the Cockcroft-Gault equation has been the most validated and durable.[180] The Cockcroft-Gault equation calculates estimated GFR (eGFR) based on patient gender, age (years), weight (kg), and serum creatinine (Cr) (mg/dL):

$$\text{Cockcroft-Gault eGFR}\left(\text{mL/min}\right) = \left(140-\text{age}\right)\times\text{weight}\left(\text{kg}\right)/\left(\text{Cr}\times 72\right)$$
$$\left(\times 0.85 \text{ for females}\right)$$

More recently, an estimating method from the Modification of Diet in Renal Disease (MDRD) study that adds knowledge of ethnicity (black versus nonblack) to standard components of the Cockcroft-Gault equation may improve accuracy.[181]

An abbreviated MDRD formula is available that can estimate GFR measured in mL/min/1.73 m^2

$$\text{GFR} = 186\times\left(\text{serum creatinine}\left[\text{mg/dL}\right]\right)^{-1.154}\times\left(\text{age}\right)^{-0.203}$$
$$\left(\times 0.742 \text{ for females}\right)$$
$$\left(\times 1.210 \text{ for blacks}\right)$$

However, even the most detailed MDRD eGFR equation under ideal conditions correlates poorly with GFR determined using "gold standard" tools, with a 30% or greater error in 10% patients and more than a 50% deviation in 2%.[181]

When Shin and associates[183] retrospectively reviewed the records of 26 patients who had acute tubular necrosis, they concluded that the diagnosis was likely to be made in patients who had a creatinine clearance of less than 25 mL/min and a free water clearance of greater than 15 mL/hr. In a follow-up study of 40 trauma patients who underwent surgery, these researchers[210] concluded that creatinine clearance of less than 25 mL/min alone permitted the early detection of renal dysfunction in patients with the potential for development of renal failure and that free water clearance was not as sensitive.

So-called Starling forces are important in understanding the factors that affect glomerular filtration. Glomerular filtration is governed by the following equation:

$$\text{GFR} = K_f\times\left(P_{GC}-P_{BC}-P_{PO}\right)$$

where GFR is the glomerular filtration rate or the rate at which fluid is filtered through the glomerular capillaries into the Bowman capsule, K_f is the glomerular filtration coefficient or the factor that considers the permeability and surface area of the glomerular basement membrane, P_{GC} is the glomerular capillary pressure, P_{BC} is the pressure in the Bowman capsule, and P_{PO} is the plasma oncotic pressure.

Acute changes in GFR, and consequently in urine formation, are commonly caused by changes in glomerular capillary pressure. For example, events that reduce plasma flow rates reduce the hydraulic pressure of glomerular capillaries and favor decreased ultrafiltration whereas events that increase plasma flow rate have the opposite effect. Theoretically, varying concentrations of plasma proteins may influence urine formation and the GFR. As the concentration of proteins in plasma decreases, the oncotic pressure and the oncotic force opposing ultrafiltration also decrease. Conversely, an increase in oncotic pressure reduces the GFR. This effect is most likely offset by the oncotic force of plasma proteins (e.g., albumin), which enables adequate intravascular volume to be maintained. However, in one series,[222] patients resuscitated with albumin after massive transfusion had more renal dysfunction than those resuscitated with saline.

Intravenous fluid choices are associated with increased renal risk in some studies of postoperative AKI. When the impact of normal saline-based intravenous fluid replacement was evaluated and compared with lactated Ringer's solution (i.e., albumin 5% in normal saline, hetastarch in normal saline, or lactated Ringer's solution), renal function indices (i.e., creatinine clearance, serum creatinine, and urine output) were all inferior in the normal saline-based vehicle groups.[223] The patients receiving lactated Ringer's solution were more likely to exhibit a hypercoagulable

state.[223] Outcome data, however, did not enable a distinction between albumin and normal saline as a fluid replacement option. Volume expansion using hydroxyethyl starch (HES) preparations is associated with AKI in critically ill and surgical patients in several retrospective reports.[224-227] In a randomized study of 129 patients with septic shock or severe sepsis that received either 3% gelatin or 6% HES, peak serum creatinine and the frequency of ARF and oliguria was higher in the HES group.[228] In the same study, a multivariable analysis also identified the use of HES as an independent predictor of ARF. In contrast, Boldt and colleagues found no evidence of increased renal risk in two small perioperative randomized studies of surgical patients receiving either gelatin or 6% HES.[229,230] Recent studies have focused on the contents of the solutions supporting the HES preparations and their potential to influence the development of metabolic hyperchloremic acidosis and variations in renal outcome.

Use of saline or saline-based colloid solutions in perioperative patients is commonly associated with the acid-base abnormality metabolic hyperchloremic acidosis. In a randomized, blinded trial, 47 elderly patients undergoing major surgery received 6% HES suspended in either 0.9% sodium chloride (HESPAN, B. Braun Medical, Inc., Irvine, CA) or a balanced salt solution (Hextend, BioTime, Inc., Berkeley, CA) (see Chapters 71 and 88). None of the patients receiving the balanced salt-based solution but two thirds of those receiving sodium chloride developed hyperchloremic metabolic acidosis ($P < .0001$).[231] In addition, in the saline group, gastric tonometry identified a larger increase in the CO_2 gap ($P = .04$), suggesting poorer splanchnic perfusion. Some have speculated that this metabolic abnormality may be a relevant modifier of perioperative renal vulnerability.[232] Increased chloride levels and acidosis can reduce RBF and GFR, increase afferent arteriolar tone, and alter renin release.[233,234] The avoidance of saline and the development of metabolic hyperchloremic acidosis may prove to be an important modifier of renal risk.

In general, the GFR is determined by the rate of glomerular plasma flow (as it influences ultrafiltration pressure), systemic oncotic pressure, glomerular hydraulic pressure differences, and an ultrafiltration coefficient. The ultrafiltration coefficient is the product of glomerular capillary hydraulic permeability and total surface area available for filtration. The filtration rate across a capillary bed is, therefore, the product of surface area, pressure gradients, and permeability. Hydrostatic pressures are normally maintained higher in glomerular capillaries than in other capillary beds by a delicate balance of preglomerular and postglomerular vascular tone in arterioles. The permeability of the glomerular capillary wall is equal for substances with molecular masses up to 5000 to 6000 daltons and decreases to almost zero at 60,000 to 70,000 daltons.[235] Metabolic wastes and essential nutrients are filtered freely, and larger proteins, such as albumin and immunoglobulin G, are filtered in trace amounts or not at all. The glomerulopathic process in diabetes,[236] for example, results from all of the factors that cause sustained increase in glomerular pressure and flow. Hyperglycemia induces a state of extracellular fluid volume expansion, structural hypertrophy of the kidney, and altered glucoregulatory and vasoregulatory hormone action. These hemodynamic consequences of hyperglycemia lead to renal vasodilation and increased plasma flow rate. The increase of plasma flow causes increased glomerular transcapillary flux of plasma proteins. The elevation in glomerular flow (i.e., pressure) also alters the permeability and selectivity of the glomerular basement membrane, resulting in increased protein filtration. The increased transglomerular flux of plasma proteins leads to their accumulation in the mesangium, which further propagates glomerulosclerosis.

Inulin Clearance

Glomerular filtration is an important index of renal function. Because the tubule reabsorbs most of the water filtered through the glomerulus, urine volume cannot be used to measure GFR. For measurement, a substance is required that is filtered through the glomerulus at the same rate as water and is excreted in the urine (i.e., neither reabsorbed nor secreted). The amount of such a substance filtered is then equal to the amount eliminated in the urine and can be determined from the product of the substances' concentration in plasma and the amount of plasma water filtered.

Inulin, a polymer of fructose with a molecular mass of 5200 daltons that is found in Jerusalem artichokes, dahlias, and chicory, has been used to measure GFR because it is filtered freely in the glomerulus, not reabsorbed or secreted, and is excreted in the urine. Purified inulin is expensive and difficult to measure. However, since its introduction in 1934, inulin clearance has been considered the standard for measurement of GFR.[237] To assess inulin clearance, the clinician administers a priming dose of inulin intravenously, followed by a continuous infusion calculated to maintain constant blood concentrations. After an equilibration period (usually 1 hour), clearance measurements are obtained. Urine is collected (typically with a Foley catheter), and venous blood samples are obtained at the midpoint of each clearance period. The longer the clearance period, the less likely is the introduction of error from incomplete voiding. The standard formula for calculation of clearance is as follows:

$$C_I = (U_I V)/P_I$$

where U_I and P_I are the urine and plasma concentrations of inulin, C_I is the rate of inulin clearance, and V is the urine flow rate.

Whereas inulin clearance is considered a "gold standard" tool to measure GFR in clinical practice, the endogenous substance creatinine is used to measure clearance. Creatinine is a smaller substance than inulin and is not an ideal substance for measuring clearance because a small amount is secreted under normal conditions. Although creatinine clearance may exceed inulin clearance, the clearance of endogenous creatinine approximates that of inulin and has proved to be a reasonable measure of GFR.[238] The creatinine-to-inulin clearance ratio is almost identical in healthy infants, children, and adults. In subjects with moderate to severe renal insufficiency, however, the creatinine-to-inulin clearance ratio is increased.[239] Increased secretion and clearance of creatinine in patients with renal insufficiency may, therefore, result in overestimates of true GFR.

Urea (molecular mass of 60 daltons) cannot be used to estimate GFR because, under normal conditions, it is filtered and reabsorbed. More importantly, urea clearance changes with the state of hydration; for example, under conditions of dehydration, urea clearance is significantly less than inulin clearance.

Renal Blood Flow

Although it is certainly true that an extended period of renal artery clamping (e.g., 30-40 min) sufficient to cause blood flow to cease is also sufficient to cause ischemic AKI, it is simplistic to assume that moderate increases and decreases in renal artery

blood flow are good and bad for the kidney, respectively. Regional variations in perfusion result in a precarious balance between oxygen supply and demand in some renal tissues, particularly in the inner renal medulla. Notably, high levels of RBF also oblige high levels of oxygen demand to facilitate active transport of sodium and other solutes back into the circulation. Unfortunately, RBF is a very poor indicator of the adequacy of regional medullary perfusion and oxygen delivery. Despite an overwhelming number of clinical trials failing to demonstrate the value of the dopaminergic agonist effects of low dose intravenous dopamine (3-5 μg/kg/min) that include increased renal artery blood flow as renoprotective[240,241] and many editorials discouraging its use,[242,243] this strategy continues to be popular with some clinicians.[244,245]

Interest in RBF as a predictor of renal function was first stimulated in 1947 when Trueta and associates[246] introduced the concept of cortical ischemia and attributed the pathogenesis of ARF to increased blood flow through the medulla. Supporting evidence for this view has since been offered by many investigators who measured RBF distribution with various methods.[247-250] Perhaps nephrons in the outer cortex are "salt losers" and those in the inner cortex are "salt retainers." If this is true, salt-retaining states should occur with the selective reduction of RBF to the superficial cortex, and these states may or may not be accompanied by a rise in RBF to the deep cortex.[222,250]

It is essential to understand how hypovolemia affects distribution of RBF. Activation of the sympathetic nervous system and possibly the renin-angiotensin system reduces RBF and GFR. Despite well-maintained arterial blood pressure, blood flow may decrease to one third of its normal level but still significantly exceed the intrinsic oxygen needs of the kidney. Constriction of afferent arterioles becomes sufficient to reduce the hydrostatic pressure in glomerular capillaries to levels inadequate for maintenance of normal filtration. Only when hypovolemia or hemorrhage is extreme does this extend to adverse effects on the metabolic function of the kidney itself. As RBF decreases further, arteriolar vasoconstriction leads to ischemia and morphologic damage.

Renal arteriographic and xenon washout studies in patients with ARF have shown selected, profound reduction in RBF.[249] Arteriography reveals severe attenuation of the intrarenal arterial tree, inability to visualize cortical vessels, absence of a normal cortical nephrogram, and striking reduction in the velocity of contrast dye as it passed through the kidney. These same patients have no bleeding from the cortex during open renal biopsy. The xenon washout studies also show that the usual transit of xenon through the cortex (indicating cortical perfusion) that is usual in the normal kidney is absent in acute oliguria. Renal cortical perfusion at one third of its normal level, involving constriction of the afferent arterioles, appears sufficient to impair renal function.

The understanding that distribution of RBF is nonhomogeneous, the recognition of nephron structure and functional heterogenicity, and the suggestion that changes in the zonal distribution of RBF affect renal salt and water homeostasis have focused investigators on developing improved techniques to measure intrarenal blood flow.[250] Methods to measure distribution of RBF in humans include the clearance of para-aminohippurate, indicator dilution, renocortical tissue Po_2, radiolabeled tracers, Doppler ultrasonography, and external gas-washout techniques. Owing to the risks and limitations associated with these techniques their clinical use has been limited.

Any nontoxic substance cleared by the kidney and not metabolized may be used to measure RBF by application of the Fick principle, whereby renal plasma flow (RPF) is calculated as follows:

$$RPF = UV/(A - RV)$$

where U is urinary concentration, V is urine flow rate, A is arterial plasma concentration, and RV is renal venous plasma concentration. RBF is then calculated from the following formula:

$$RBF = RPF/(1 - Hematocrit)$$

The volume of plasma from which the kidney can extract and excrete a specific substance in a given time is the renal clearance of the substance. An ideal substance for measuring renal plasma flow would be completely eliminated from the plasma in one pass through the renal circulation due to filtration at the glomerulus without any further tubular metabolism. Para-aminohippurate is a substance that almost meets these criteria. The practical advantage of measuring the extraction of para-aminohippurate is that its renal extraction is approximately 90% in humans after one passage. Measurement of RBF is based on the assumption that cortical extraction is 100% and that extraction in the medulla is 0%; therefore, it has been assumed that the nonextracted fraction (10%) should reflect the fraction of blood flowing through the medulla. However, experimental evidence shows that cortical extraction is not 100%,[251] casting doubt on the accuracy of intrarenal blood flow assessment with extraction techniques. Other limitations of the extraction technique include the requirement for a high rate of urine flow, a steady state for 15 to 30 minutes, and the sampling of systemic arterial and renal venous blood.

Indocyanine green, which is bound to albumin in plasma, has been used in the indicator dilution method with densitometry. The indicator dilution method necessitates catheterization of a renal artery and vein. Although attempts have been made to measure renocortical (fast) and medullar (slow) blood flows separately from dye dilution curves, no convincing results have been produced.[252] Measurement of RBF by a continuous thermodilution technique, which requires renal venous cannulation and continuous injection of normal saline, has been proposed.[253] Measurements have correlated with calculated RBFs derived from clearance techniques in patients after cardiac catheterization; however, only total RBF is measured with the thermodilution technique.

Tissue oxygen pressure is measured with a multiwire surface Po_2 electrode and temperature probe. This polarographic Clark-type electrode has multiple platinum microelectrodes arranged in an array in the center of the tissue contact area, with a polarographic silver anode positioned at its circumference. The probe is placed directly on the renal cortex and measures changes in local tissue Po_2, which is an indirect indicator of renal surface perfusion.[254-256] However, this device measures only outer cortical RBF changes. Because ischemic insults to the kidney are associated with a marked decrease in blood flow to the outer cortex, a redistribution of blood flow to the juxtamedullary glomeruli in the inner cortex and medulla is presumed.

Monitoring of urinary oxygen tension, as an indicator of medullary oxygen tension, has been examined as a method for assessing renal function.[257-260] Drops in urine Po_2 after CPB predict creatinine rise after cardiac surgery,[261] a finding possibly

related to the strong correlation between medullary and urine oxygen levels observed in animal models.[137] Although urine Po_2 measured in the ureter provides a good "online" estimate of medullary Po_2 in a pig model of CPB, this technology has not been evaluated in humans.[137] Urine samples exposed to the atmosphere during collection from bladder catheters provide artificially high urine Po_2 values because samples are easily contaminated with oxygen from room air. Another problem with measuring urinary oxygen tension or saturation is that bladder wall oxygen tension differs considerably from urine measurements.

External krypton-85 and xenon-133 clearance are techniques that can estimate RBF per gram of tissue from gas clearance.[262] The gas-washout technique requires selective catheterization of the renal artery and is usually performed in conjunction with arteriography. Alternatively, the renal artery can be punctured intraoperatively for injection. After injection, the gas diffuses rapidly into the renal tissue, theoretically equilibrating in tissue and blood. The renal washout curve is then assessed by external counting. The reliability of washout methods in some circumstances has been questioned.[263]

Qualitative and semi-quantitative evaluation of renal perfusion can be obtained with a gamma camera recording of the transit of a radiopharmaceutical tracer through the kidney. Qualitative evaluation of renal perfusion consists of the visual assessment of the serial images and comparative assessment of the first transit of tracer from the aorta (or iliac-renal artery) to the kidney. Among the limitations associated with the renogram is movement of the radiopharmaceutical (injected intravenously as a bolus) before it reaches the kidney, necessitating that the pharmacokinetic model contain all the possible exchange compartments between the kidney and the plasma for accurate analysis of the tissue radioactivity curve. The presence of low urine flow rates, dilated pelvic caliceal cavities, or severely reduced renal function may also cause difficulties for test interpretation. In general, the information that can be derived from the renogram includes renal clearance (as a fraction of the radioisotope to blood volume) and blood flow of the two kidneys relative to each other.[264] Because the results obtained are comparative, lesions are revealed only when they have asymmetric distribution.

Intraoperative transesophageal echocardiography 2D and renal arterial Doppler waveform images, primarily of the left kidney, can be used to assess changes in pulsatility and resistive indices and qualitatively describe RBF changes over time.[162] Typically, an interlobar artery is selected for evaluation. The anatomic course and relationships of the vessel allow easy recognition on subsequent serial scans in the same patient; the vessel is large enough to assume laminar flow throughout its length; and the angle of the ultrasound beam can generally be minimized to assume maximum Doppler frequency shift. Renal vascular resistance can be assessed by the pulsatility index.[265] The lower the pulsatile index, the less resistance there is to flow. The value is derived by dividing the difference between systolic maximum height and diastolic minimum height of the waveform by its mean height. Change in flow velocity can be assessed from a change in the mean frequency shift. The frequency shift is proportional to the mean velocity of blood flow within the vessel multiplied by the cosine of the angle between the ultrasound beam and the direction of flow. The angle is assumed to be close to zero. With this method, only blood flow velocity in large interlobar arteries and resistance can be assessed. The duplex Doppler ultrasound technique may provide a unique opportunity to demonstrate the effects of drugs on the renal vasculature and to predict the onset of pending renal failure or transplanted kidney rejection. Overall, this technique should provide an opportunity for measuring relative changes in large vessel flow velocity but not in absolute RBF.

Contrast ultrasonography has been used to image RBF.[266-269] The microbubbles produced by ultrasonic cavitation (i.e., sonication) are smaller than red blood cells and, in passing with them through the microcapillary vascular bed, reflect an echo beam to permit direct ultrasonic imaging of tissue volume and flow. Sonicated microbubbles have been shown to exhibit intracavitary velocities comparable to those of red blood cells, as observed by Doppler ultrasound techniques. Modest correlations have been found between calculated RBF assessed by contrast ultrasonography and direct flow assessment.[269]

Although not evaluated in surgical patients, a novel approach to the recognition of AKI is scintigraphic functional magnetic resonance imaging that can characterize abnormal kidney physiology, including glomerular filtration rate, tubular concentration, transit, blood volume, perfusion, inflammation, and even hypoxia.[163]

Novel (Early) Biomarkers of Acute Kidney Injury

Disappointing progress in care for AKI has prompted a strategic reevaluation of research in this area and fueled a rebirth of interest in old early indicators and a search for new "early biomarkers."[270,271] While early biomarkers are as yet some of the least validated tools in clinical AKI management, a very large research initiative is underway.[270-280] A unifying theme is the goal of providing information to facilitate prompt intervention strategies to improve care of AKI. While a few of the new tools represent attempts to find a substitute "ideal" creatinine-like substance to use in estimates of renal filtration (e.g., cystatin C), most markers take advantage of one of the three early consequences of AKI: tubular cell damage, tubular cell dysfunction, and the adaptive stress response of the kidney. The hope is that prompt biomarker information will allow timely AKI risk identification, surveillance (i.e., recognition of "pre-AKI" states such as pre-renal azotemia), diagnosis, and prognosis. Strategic approaches to improve the usefulness of early biomarkers have included combining tests to create focused panels for specific AKI concerns. Test panels could address issues such as the timing of onset, grade of a problem, and even the type of AKI (e.g., ischemic versus inflammatory). For example, in children developing AKI after cardiac surgery, one early biomarker (neutrophil gelatinase-associated lipocalin) increases 25-fold within 2 hours of surgery, facilitating diagnosis of AKI 2 days sooner than by serum creatinine values,[281] whereas another biomarker (urinary IL-18) rises 4 to 6 hours postoperatively and persists for more than 48 hours (Fig. 45-13).[282] In septic AKI, elevated levels of urinary IL-18 and two other markers (platelet-activating factor and urinary sodium hydrogen exchanger isoform-3) precede overt kidney failure by as much as 48 hours.[271] Urinary IL-18 levels in this study also differentiated septic from nonseptic AKI. A collection of the most promising biomarkers are presented here, including classes reflecting impaired renal filtration, tubular cell damage (tubular enzymuria), tubular cell

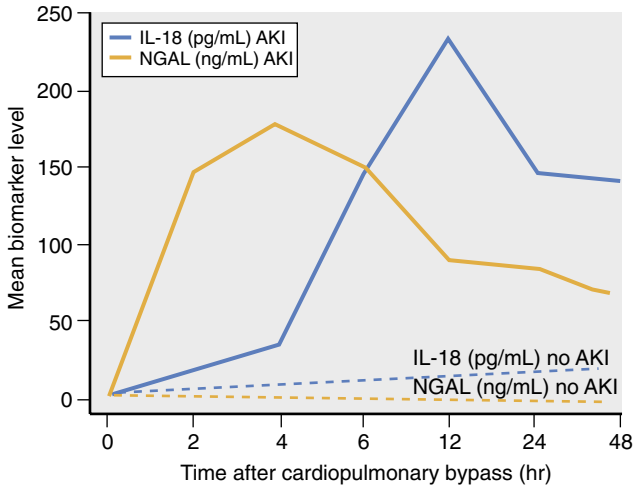

Figure 45-13 Pattern of early biomarkers urinary IL-18 and NGAL after CPB in 55 cardiac surgery patients with and without criteria for AKI diagnosed 48 to 72 hours postoperatively (defined as a peak rise in serum creatinine concentration greater than 50% of baseline). IL, interleukin; NGAL, neutrophil gelatinase-associated lipocalin. (*Used with permission from Parikh CR, Mishra J, Thiessen-Philbrook H, et al: Urinary IL-18 is an early predictive biomarker of acute kidney injury after cardiac surgery. Kidney Int 70:199-203, 2006.*)

dysfunction (tubular proteinuria), and adaptive responses of the kidney to stress (Table 45-3).

New Filtration-Based Markers of Renal Dysfunction

Examples of the search for a replacement for creatinine include cystatin C, proatrial natriuretic peptide(1-98) (proANP[1-98]), and tryptophan glycoconjugate. Cystatin C is a member of the cystatin "superfamily" of cysteine proteinase inhibitors and is produced by all nucleated cells at a constant rate. Cystatin C has been available clinically for more than 15 years and can be determined rapidly. Much like creatinine, cystatin C accumulates in the circulation with renal impairment and can be used as a marker of glomerular filtration. But cystatin C has theoretical advantages over creatinine, particularly as an indicator of mild chronic renal failure.[270,283,284] Equivalent to creatinine clearance, cystatin C clearance can be calculated using the Larsson equation.[285] Cystatin C outperformed creatinine in detecting AKI after cardiac and renal transplantation surgery in a small number of studies, although these studies have received valid criticism.[270,286] In one cardiac surgery study, serum creatinine peaked on day 3 while cystatin C peaked on day 2,[286] although another cardiac surgery study did not see such a clear-cut difference in timing.[287] Studies have linked rises in cystatin C with mortality in congestive heart failure and acute coronary syndrome patients,[288,289] validating cystatin C as a marker of important change in renal function, something notably lacking for many of the new early AKI biomarkers. However, there are concerns with the usefulness of cystatin C compared with creatinine.[290] Interindividual variability in steady-state cystatin C levels is much greater compared with creatinine (75% versus 7%). In addition, conditions such as malignancy, human immunodeficiency virus infection, corticosteroid, or thyroid hormone therapy are associated with increased serum levels without changes in renal function.[270] Finally, three studies in critically ill patients have questioned the prognostic ability of cystatin C in this setting.[270]

ProANP(1-98) is the remnant of the prohormone that remains when α–atrial natriuretic peptide is generated.[270] ProANP(1-98) disappears from the blood largely due to renal clearance and is, therefore, suitable to assess glomerular filtration. Although numerous studies of this substance have been performed in patients with chronic renal disease, understanding of this substance in AKI is limited to a single study.[291] In this investigation of 29 septic patients, proANP(1-98) was a better predictor for the occurrence of ARF than cystatin C. In addition, proANP(1-98) levels were four times higher in nonsurvivors.

Tryptophan glycoconjugate 2-(α-mannopyranosyl)-L-tryptophan is a novel circulating marker of glomerular filtration that is excreted independent of muscle mass and tubular secretion.[292] The behavior of this substance is very similar to that of inulin, making it an "ideal" substance to assess glomerular filtration; however, unfortunately measurement is currently prohibitively labor intensive and expensive.

Table 45-3 Early Biomarkers* of Acute Kidney Injury

Filtration-Based Markers of Renal Dysfunction
Cystatin C
Proatrial natriuretic peptide (1-98)
Tryptophan glycoconjugate
Biomarkers Reflecting Renal Tubular Cell Damage (Tubular Enzymuria)
α-Glutathione S-transferase
π-Glutathione S-transferase
β-*N*-Acetyl-β-D-glucosaminidase
γ-Glutamyl transpeptidase
Alkaline phosphatase
Lactate dehydrogenase
Ala-(Leu-Gly)-aminopeptidase
Proximal renal tubular epithelial antigen
Urinary sodium hydrogen exchanger isoform 3
Biomarkers Reflecting Renal Tubular Cell Dysfunction (Tubular Proteinuria)
α_1-Microglobulin
β_2-Microglobulin
Albumin
Adenosine deaminase binding protein
Renal tubular epithelial antigen-1
Retinol binding protein
Lysozyme
Ribonuclease
IgG
Transferrin
Ceruloplasmin
Lambda and kappa light chains
Urinary total protein
Biomarkers Reflecting the Renal Stress Response
Neutrophil gelatinase-associated lipocalin
Urinary interleukin-18
Platelet-activating factor
Kidney injury molecule-1
Cysteine-rich protein 61

*New early biomarkers are being developed to promptly provide information to improve risk stratification, surveillance, diagnosis, and prognostic information about acute kidney injury.

Biomarkers Reflecting Renal Tubular Cell Damage (Tubular Enzymuria)

Renal tubular cells contain enzyme proteins that are highly specific to their location within the kidney and even tubule region, making detected enzyme leakage from damaged tubular cells into urine an appealing target for early biomarker discovery. Many tubular enzyme tests have been available for years, but only recently has their clinical use been seriously considered. Segmental involvement and ultrastructural origin of AKI is known, for example, with α and π isomers of glutathione *S*-transferase (GST), which are cytosolic enzymes from proximal and distal tubular cells, respectively. *N*-acetyl-β-D-glucosaminidase (NAG) is a proximal tubular lysosomal enzyme. General brush border injury is reflected by other markers including γ-glutamyl transpeptidase (γ-GT), alkaline phosphatase, and Ala-(Leu-Gly)-aminopeptidase. The concentration of many of these substances measured soon after a renal stress, normalized relative to urine creatinine, appears able to differentiate AKI from other conditions. In a study of 26 critically ill patients, Westhuyzen and colleagues found that by testing for several tubular enzymes twice daily, detection of AKI was accelerated by 12 hours to 4 days compared with serum creatinine. [293] These authors speculated that low expense and easy automated assays for γ-GT and alkaline phosphatase made these enzyme tests appealing for identifying AKI in random urine samples. In a study of proximal renal tubular epithelial antigen (HRTE-1) urine levels from 36 normal subjects and 51 patients with renal conditions (acute tubular necrosis [ATN]), chronic nephropathies, prerenal azotemia), 79% of ATN patients had abnormal concentrations, whereas all other subjects had normal levels.[193] As a diagnostic test, HRTE-1 had 90% and 81% discrimination in differentiating ATN versus chronic nephropathies and ATN versus prerenal azotemia, respectively.

NAG is the most commonly used investigational urinary enzyme assay for assessment of renal disease and the detection of nephrotoxicity. Unlike a number of unstable enzymes excreted into the urine, NAG remains suitable for clinical diagnosis of renal disease. Increased NAG activity detected in urine is a sensitive test for renal tubular damage[294]; its molecular mass precludes filtration by the glomerulus, and it is neither absorbed nor secreted by the tubules. Any increase in urinary concentration of NAG may be considered a marker for tubular damage. The value of NAG as a diagnostic test is further enhanced by its presence in a number of isoenzyme forms. The relative amount of each isoenzyme varies at different stages of renal disease.

A number of analytical methods are available for the determination of urinary NAG, including fluorometric, colorimetric, spectrophotometric, and dipstick tests. Each of these methods is tedious, and this limits its clinical application. Low levels of NAG are excreted by normal individuals, and assay procedures must be sensitive enough to overcome the endogenous inhibitor urea.[295] Another factor to overcome is variation from urine collection that occurs over time. Factoring the enzyme activity with creatinine concentration over the same urine flow collection period is a reasonable approach for this problem.[296] In general, the sensitivity and reproducibility of the fluorometric method, when it is performed correctly, is excellent, but the equipment necessary is not commonly available in laboratories.

The colorimetric technique overcomes the limitations of the fluorometric technique by the incorporation of a calibrant for easy interlaboratory comparison and access in most clinical chemistry laboratories, with modification for use with spectrophotometric analysis.[297] A dipstick method exists for detection of NAG in the urine.[298] The NAG strip incorporates a biochemical derivative that releases a blue-violet color on hydrolysis but requires up to 30 minutes from the addition of reagents. Unfortunately, if the sample is contaminated with blood or bilirubin, results from this test can be misleading. Besides pigmented material in urine, a concentrated urine specimen that is high in urea also renders the test inaccurate.

Perhaps the most interesting discovery regarding urinary NAG for detection of renal disease is that there appears to be isoenzyme specificity for various types of pathology.[299] NAG is the most active lysosomal hydrolase and is normally found in tissues as two major forms: A and B. These major forms differ in their subunit composition. Traditionally, the main clinical interest in these isoenzymes had been their use in the detection of two autosomal recessive disorders: Tay-Sachs disease and Sandhoff disease. In 1970, Price and colleagues[300] reported that the B form increased in a urinary pattern of NAG after surgical trauma. Since that time it has been appreciated that the relative amount of the B form increased (i.e., the ratio of A to B forms decreased) compared with urine in the normal population. Automated methods for separation of NAG isoenzymes allow the pattern of excretion to be compared in various disease states. Of interest to the anesthesiologist is that evidence suggests that after major surgery the percentage of an intermediate isoenzyme (I) increases in the urine.[301] Smaller increases in the I form were also observed in rejection of renal transplants. Rejection was more strongly associated with a decrease in the A/B ratio in a cohort of renal transplant patients. No change in the isoenzyme profile was found in stable transplant patients, whereas reversible rejection was characterized by an increase in the I form and a decrease in the relative amount of the A form present. When a patient did not respond to treatment, the I and the B forms were elevated but levels of the A form decreased.[302]

Different nephrotoxic drugs or conditions appear to produce characteristic urinary NAG isoenzyme profiles. For example, the B and I forms are elevated after administration of aminoglycosides. Total urinary and serum NAG activity also has been reported to increase in diabetic patients. Overall, NAG activity in the urine reflects the activity of the disease or severity of the damage. Serial monitoring is, therefore, most useful because relative change over time is the most useful way to interpret the results. The NAG-to-creatinine ratio is a more sensitive and specific marker for renal tubular dysfunction. It is useful to express NAG as a ratio of urinary creatinine to minimize dilutional or concentration effects. The lack of sensitive, simple, inexpensive, and efficient methods is the limiting factor for widespread clinical use of NAG monitoring. Another urinary enzyme, clusterin, may prove to be more specific than NAG[303] for evaluating nephrotoxicity caused by aminoglycoside use while remaining equally sensitive.

Other urinary constituents can detect cytotoxic and abnormal processes in specific regions of the nephron. α-GST is found principally in the proximal convoluted tubules, and π-GST is found principally in the distal convoluted tubule. Ala-(Leu-Gly)-aminopeptidase and γ-GT excretion are specific markers for proximal tubular brush border injury. Of note, although enhanced urinary excretion of tubular enzymes can signal damaged tubular cells, it can also reflect an increased turnover of tubular cells or some other metabolic disturbance; thus, the signals of early, irreversible disease may not always be distinguished from the noise

of biologic variability and use of these markers should be applied with appropriate caution. In addition, their validation compared to clinically important outcomes, such as dialysis or mortality, has received little attention.

Urinary sodium hydrogen exchanger isoform-3 (NHE-3) is the isoform of the Na^+/H^+ exchanger present in the apical membrane of proximal tubular cells and responsible for the majority of Na^+ uptake and H^+ excretion by the kidney.[304] NHE-3 is found in the urine with tubular injury, and levels can be estimated from semiquantitative immunoblots of the urine membrane fraction. In a study of 54 critically ill patients and 14 controls, NHE-3 was only seen with tubular injury and, when normalized to urinary creatinine, was six times higher with ATN than prerenal azotemia, without overlap.[305] In addition, urinary NHE-3 was not present with intrinsic ARF other than ATN, and the normalized level correlated with serum creatinine rise in patients with tubular injury.

Biomarkers Reflecting Renal Tubular Cell Dysfunction (Tubular Proteinuria)

When small proteins are filtered by the glomerulus, binding and endocytic reuptake in the proximal tubule normally returns these substances to the body through a megalin-mediated transport system. So-called tubular proteinuria results from functional impairment of this process and the escape of small proteins into the urine. Endogenous low-molecular-weight (LMW) proteins that are normally taken up in this way include β_2- and α_1-microglobulin, albumin, adenosine deaminase binding protein, renal tubular epithelial antigen-1, retinol binding protein, lysozyme, ribonuclease, IgG, transferrin, ceruloplasmin, lambda and kappa light chains, and urinary total protein. Appearance of any of these substances in the urine heralds abnormal proximal nephron function consistent with AKI. However, enthusiasm for LMW protein markers as perioperative tools to diagnose AKI has been reduced, particularly with cardiac surgery, by the confusion that can occur when an antifibrinolytic agent is used.[306] Lysine and its analog (e.g., ε-aminocaproic acid, tranexamic acid) specifically block renal binding sites, causing a profound but reversible inhibition of LMW protein reuptake (Fig. 45-14) [307]; the effect is transient and apparently benign but so potent that urine LMW protein measurement after a small dose of intravenous lysine has been proposed as a tool for estimating GFR.[307] The serine protease inhibitor antifibrinolytic drug aprotinin is a small protein and does not inhibit tubular reuptake but is itself metabolized by the same renal transport system as LMW proteins.[308] Although the influence of aprotinin on renal processing of LMW proteins has not been examined, α_1-microglobulinuria without change in serum creatinine has been reported in cardiac surgical patients after use of this agent.[309]

β_2-Microglobulin is a subunit of the class I antigen of the major histocompatibility complex and is structurally homologous to immunoglobulins.[310] Its mass is 11,600 daltons, it is freely filtered from plasma by the renal glomerulus, and more than 99.9% reabsorbed in the proximal tubule. β_2-Microglobulin is measured by radioimmunoassay and immunodiffusion techniques.[311] Specific limitations to its use include its unstable nature in urine of pH 5.5 or below, thereby precluding its use for patients with concomitant urinary tract infection or pyuria. Its degradation by proteolysis is affected by temperature, and its measurement requires a sophisticated laboratory that precludes widespread clinical use. α_1-Microglobulin is filtered at the glomerulus and is

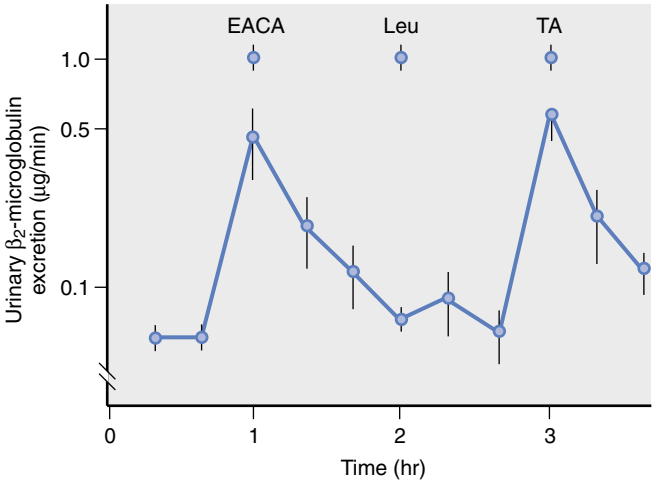

Figure 45-14 Spillage of low-molecular-weight proteins, such as β_2-microglobulin, into the urine, also known as tubular proteinuria, is a poor early biomarker of AKI when lysine analog antifibrinolytic agents are being used.[306] In volunteers, significant but transient increases in urinary β_2-microglobulin levels occur after injection with ε-aminocaproic acid (EACA) and tranexamic acid (TA), but not injection of an unrelated amino acid, leucine (Leu).[307] This potent but transient effect reflects inhibition of normal small protein reuptake by the proximal tubule transport system. (*Modified with permission from Mogensen CE, Solling K: Studies on renal tubular protein reabsorption: Partial and near complete inhibition by certain amino acids. Scand J Clin Lab Invest 37:477-486, 1977.*)

95% reabsorbed at the proximal tubule, thereby indicating proximal tubular dysfunction when present in the urine.[1,312,313]

Lysozymuria, an increase of the enzymatic protein lysozyme in urine, occurs if the serum level is elevated above the normal renal threshold (45 mg/mL) or when renal tubular function is impaired.[314] The normal urinary lysozyme level is less than 1.9 mg/mL, and a level greater than 5 mg/mL is regarded as evidence for significant renal tubular damage. Elevated serum levels of lysozyme may be a consequence of renal failure as well as a marker for it. Because white blood cells have a high concentration of lysozyme, urinary tract infections may also lead to elevated serum levels.

Biomarkers Reflecting the Renal Tubular Cell Response to Stress

Examples of markers that assess the response of the kidney to stress include neutrophil gelatinase–associated lipocalin (NGAL), urinary interleukin-18, platelet-activating factor, kidney injury molecule-1, and cysteine rich protein-61. NGAL is a small protease-resistant polypeptide. Although its role remains largely obscure, NGAL infusion in mice attenuates AKI after renal ischemia.[315] A transcriptome-wide interrogation for genes induced very early after renal ischemia identified NGAL as a protein generated by ischemic renal tubular cells.[316] NGAL appears in kidney parenchyma within 1 hour and in urine of cardiac surgery patients within 2 hours after injury (see Fig. 45-13), earlier than traditional markers,[282,317] and elevated levels are highly predictive of postoperative AKI.[281] Although NGAL demonstrates great promise as an early AKI biomarker, a notable limitation is the high variability among patients in baseline values. Like many early biomarkers, NGAL requires validation as a useful clinical tool in a wide variety of clinical settings and correlation with important outcomes.

Inflammation is a central aspect of the pathophysiology of AKI. Cytokines and adhesion molecules mediate injury in the

kidney, and levels of urinary cytokines such as interleukin-18 (IL-18) and platelet-activating factor have been assessed as early biomarkers of AKI. IL-18 is an inflammatory mediator of ischemic acute tubular necrosis in animals.[318] In human studies, a cross-sectional study comparing a variety of renal conditions with AKI found increased urinary IL-18 level to be a good discriminator between AKI patients and those with prerenal azotemia, urinary tract infections, chronic renal insufficiency, and nephrotic syndrome.[319] This study found that a cut-off urinary IL-18-to-serum creatinine ratio of 500 pg/mg creatinine had sensitivity and specificity of 85% and 88% for the diagnosis of ATN, respectively. Another study in critically ill patients with adult respiratory distress syndrome found that urinary IL-18 levels predicted AKI and mortality risk.[318] Interestingly, in this report, urinary IL-18 levels were significantly higher in septic than nonseptic AKI patients, despite similar serum creatinine concentrations. In one study of cardiac surgery patients, increased urinary IL-18 levels within 6 hours postoperatively predicted subsequent diagnosis of AKI by traditional criteria (see Fig. 45-13).[282] Other plasma and urinary cytokines, such as IL-8, IL-10, IL-1 receptor antagonist, and tissue necrosis factor soluble receptor-2, are less studied but have been shown to correlate with proximal tubular dysfunction.[1]

Platelet-activating factor is a phospholipid mediator of inflammation also known to participate in the pathophysiology of AKI.[271] In a study of 12 critically ill patients with septic shock and AKI, blood and urinary concentrations of platelet-activating factor correlated with several standard clinical and laboratory parameters related to ARF.[320]

Kidney injury molecule-1 (KIM-1) is a transmembrane protein expressed at low levels in normal kidney that is markedly upregulated in proximal renal tubular cells in response to ischemic or nephrotoxic AKI.[271] Increases in rat urine KIM-1 levels correlate with increases in serum creatinine values.[321,322] In a study of humans with ARF, KIM-1 expression is markedly increased in renal biopsy samples with ATN and accompanied by elevated urine KIM-1 levels.[323] In this study, urine KIM-1 was also a better predictive tool than γ-GT and AP.[323] KIM-1 appears in urine within 12 hours of AKI and remains elevated; however, to date there are no published data to correlate the extent of damage with KIM-1 levels. KIM-1 also appears in the urine before a rise in serum creatinine level with cisplatin or high-dose folic acid nephrotoxicity.[270] Measurement of KIM-1 in urine requires Western blot analysis and quantification by enzyme-linked immunosorbent assay.

Cysteine-rich protein-61 (CYR61) is a heparin-binding protein that is secreted by injured tissues, including the kidney, and is involved in tissue growth and repair.[316] In an animal model, CYR61 was expressed in renal tissue within 1 hour and detected in urine 3 to 6 hours after ischemia, peaking in urine 6 to 9 hours after injury. The CYR61 gene is upregulated more than 10-fold after renal ischemic injury.[324] Notably, CYR61 does not appear in animals with prerenal azotemia.

Preoperative Evaluation of Renal Function

The greater the magnitude and duration of the surgical insult and the number of acute and chronic risk factors, the greater is the likelihood of perioperative renal compromise and the need for preoperative identification of renal function (see Chapters 34 and 35). In patients with inadequate blood flow, injury is commonly caused by the added risk of drugs, by abnormal hemodynamics, or by preexisting disease.[325] Studies have shown that 12% to 14% of patients who develop acute renal insufficiency during hospitalization do so after radiographic procedures requiring use of a contrast agent. If preexisting renal insufficiency exists, progressive deterioration in renal function occurs in 42% of cases, with a poor prognosis if dialysis is required.[326] Risk factors, such as volume depletion, aminoglycoside use, radiocontrast dye exposure, use of nonsteroidal anti-inflammatory drugs, septic shock, and pigmenturia all contribute to the development of ARF. It appears that the combined interaction of these multiple acute risk factors is central in the pathogenesis of ARF (see Fig. 45-6).[20] Patients with preexisting renal insufficiency, for example, are especially prone to develop ARF that requires dialysis as a result of cardiovascular surgery. Similarly, diabetic patients with renal insufficiency are especially vulnerable to radiocontrast agents. Of course, part of this association is due to the insensitivity of standard tools such as serum creatinine to loss of renal function (see Fig. 45-10), leaving limited reserve and only a small further loss in renal function required to push an individual to the brink of dialysis. Some key determinants of postoperative renal function are preoperative renal function, maintenance of appropriate intravascular volume, and normal myocardial function.[23]

The potential value of understanding the genetic makeup of patients has yet to be fully explored and is likely to be important (see earlier discussion). Genetic variants are an established predictor of chronic kidney disease (e.g., renal transplant nephropathy), and early perioperative studies in cardiac surgery patients have already identified genetic factors that explain twofold to threefold more variation in postoperative AKI compared with standard clinical risk factors alone.[125,126]

In addition to intrinsic renal disease, several extrinsic variables influence the outcome of renal function tests: intracellular and extracellular volume, cardiovascular function, and neuroendocrine factors.[327,328] Advanced age also markedly decreases renal function reserve. GFR, normally about 125 mL/min in a young adult, decreases to about 80 mL/min at 60 years of age and to 60 mL/min at 80 years (see Fig. 45-11). Although not necessarily the primary cause for end-stage renal disease, hypertension in up to 85% of patients with renal failure is a major risk factor for the high cardiovascular morbidity that occurs.[329] The role of metabolic syndrome in contributing to end-stage renal disease is also becoming more apparent.[330]

In addition to its contribution to renal failure in hypertensive nephrosclerosis resulting from essential hypertension and hyperfiltration in diabetic nephropathy, hypertension also contributes to the loss of renal function associated with aging. Preoperative isolated systolic blood pressure hypertension and wide pulse pressure (i.e., the difference between systolic and diastolic blood pressure) are strong independent predictors of postoperative renal dysfunction.[150,331] It appears that an increase in conduit vessel stiffness with inadequate flow during low-pressure states contributes to increased preoperative renal dysfunction and hemodialysis-dependent renal failure.

Urinalysis provides qualitative information that must be interpreted cautiously. Hematuria (i.e., more than one or two red blood cells per high-power field in a concentrated sediment)

suggests glomerular disease or, in a trauma patient, injury to the kidneys or the lower urinary tract. A urine test result that is positive for blood in the absence of red blood cells suggests the presence of free hemoglobin or myoglobin in the urine. Pyuria (i.e., more than four white blood cells per high-power field) suggests urinary tract infection. Although urine may normally contain hyaline and granular casts, cellular casts represent a pathologic condition. Red blood cell casts suggest interstitial nephritis, including pyelonephritis. Urinary pH, although difficult to interpret on a spot urine sample, may assist in the diagnosis of some acid-base disturbances. The pH of urine tends to be more acidic when factors that initiate failure are prerenal rather than postrenal. The presence of proteinuria on a routine dipstick examination may be normal, or it may suggest severe renal disease. In a concentrated urine sample, trace or 1+ proteinuria is a nonspecific finding, whereas 3+ or 4+ proteinuria suggests glomerular disease. The existence of glucosuria without hyperglycemia indicates proximal tubular damage.

Serum creatinine levels offer rapid but inexact estimates of creatinine clearance. Acute elevations of serum creatinine levels occur in approximately 5% of all hospitalized patients and in up to 20% of patients in intensive care units.[32] The incidence increases directly with the severity of trauma and the degree of injury or disease. The incidence and severity of ARF usually are greater when the preoperative serum creatinine level is greater than 2 mg/dL[332]; however, an isolated serum creatinine measurement is an unreliable indicator of GFR when renal function is changing. There is an inverse logarithmic relationship between GFR and serum creatinine concentration (see Fig. 45-10). Decreasing the rate by one half results in twice the serum creatinine level. For example, a patient with a baseline serum creatinine level of 0.6 mg/dL who develops contrast nephropathy sufficient to reduce the number of glomeruli and filtration rate by one half would have a serum creatinine level of 1.2 mg/dL, still in the normal range. Thus, a trend in serum creatinine values is always more useful than a single serum creatinine measurement to evaluate renal function reserve, particularly when changes are anticipated. The measurement of creatinine clearance may constitute the best overall indicator of GFR, although this index also has limitations. In one study, more than one half of 131 critically ill patients had normal values for urine output, BUN, and serum creatinine but had reduced creatinine clearance. Creatinine clearance was the best predictor of mortality among these patients compared with the other measures of renal function.[333] Although serum creatinine level may be a more reliable measure of glomerular function than the BUN level, the simultaneous determination of BUN and serum creatinine levels offers a more complete evaluation of renal function than either determination alone. Ordinarily, the BUN-to-creatinine ratio is approximately 10, and if the BUN level is approximately 10 times as great as the serum creatinine level, the clinician may conclude that the measurements are probably correct. Conversely, if the ratio deviates significantly from 10, the clinician should consider the nonrenal factors influencing the BUN level or serum creatinine level or both. All three measurements (i.e., BUN, serum creatinine level, and creatinine clearance) require careful interpretation.

Summary

In patients with, or at risk for developing, AKI the perioperative management continues to be challenging. Numerous factors contribute to the heterogeneous condition referred to as perioperative AKI, but insults collectively combine through ischemic and toxic mechanisms. The recent revision of mission in the research community in regard to the investigation of AKI will likely lead to rapid developments in the field of renal function monitoring, including "early biomarker" tests or panels of tests that aid in risk prediction, identification of patients with conditions that precede AKI, such as prerenal azotemia, and the diagnosis and prognosis of AKI. The major hope is that improvements in monitoring will translate into better prevention, treatment, and outcome from AKI, something that has been disappointingly absent over the past half century since the problem of perioperative ARF was first described. As understanding of renal function and AKI evolves, traditional tests, such as serum creatinine, are being questioned as to allow sufficiently early intervention to improve the care of patients with AKI. The introduction of new "early biomarker" tests and even preoperative genetic testing may contribute significant advances to renal function monitoring. That this information will improve the prognosis of AKI is hoped for but not known. Meanwhile, serum creatinine continues to be the mainstay of most renal function monitoring strategies.

46 Neurologic Monitoring

Key Points

1. There are four key principles of intraoperative neurologic monitoring.
2. The pathway at risk during the surgical procedure must be amenable to monitoring.
3. If evidence of injury to the pathway is detected, there must be some intervention possible.
4. If changes in the neurologic monitor are detected, and no intervention is possible, although the monitor may be of prognostic value, it does not have the potential to provide direct benefit to the patient from early detection of impending neurologic injury.
5. The monitor must provide reliable and reproducible data.
6. There are few randomized prospective studies evaluating the efficacy of neurologic monitoring modalities.
7. Based on clinical experience and nonrandomized studies, practice patterns for use of neurologic monitoring have emerged.
8. There are procedures for which monitoring is recommended and used by most centers
9. There are procedures for which monitoring is used frequently in some centers, but not in others.
10. There are procedures for which there is no clear clinical experience or evidence indicating that monitoring is useful at all (experimental use).
11. There are procedures in which monitoring is used selectively for patients believed to be at higher-than-usual risk for intraoperative neurologic injury.

Neurologic monitoring in the context of anesthesia care for a patient spans a wide spectrum of techniques, diverse procedures, and various intraoperative or even postoperative settings. Techniques for monitoring fall into two broad categories: techniques to assess metabolic integrity of the nervous system, which typically entail either global or regional determinations of blood flow or oxygenation, or techniques to assess functional integrity, which likewise may be global or focused on specific anatomic components of the nervous system.

The procedures and settings in which neurologic monitoring is typically applied all share the characteristic that changes in the monitored parameters can be corrected or minimized by either modifying the surgical approach or manipulating parameters under the control of the anesthesiologist. Monitored procedures range from procedures where monitoring dictates the surgical approach, such as localization of the motor strip during tumor surgery or the neurologic examination during an "awake" craniotomy, to procedures that by their nature put parts of the nervous system at increased risk.

In many procedures that require neurologic monitoring, the surgical target overlaps with the site of action of drugs a patient receives. The anesthesiologist and the surgeon need to be aware not only of limitations inherent in individual monitoring techniques, but also of nonsurgical factors that influence the monitoring results. The monitoring approach ideally should anticipate nonsurgical factors by providing a degree of redundancy that helps distinguish a localized surgical trespass from a systemic event.

For some procedures, neurologic monitoring is a marker of the quality of care and is routinely employed because outcome data support its use. Examples include correction of scoliosis and resection of vestibular schwannomas. More frequently, the approach to monitoring is based on local conventions and surgical expectations. In this latter case, monitoring utility depends even more on a good understanding of the technique's capabilities and limitations by anesthesiologists and surgeons and on their mutual collaboration to allow corrective action in the face of changing signals or to prevent false alarms that disrupt surgery.

This chapter first discusses individual monitoring modalities in isolation so that the clinician can appreciate the inherent strengths and weaknesses of each. Subsequent sections apply this information by describing suitable approaches to various clinical settings that combine and integrate individual techniques to optimize neurologic outcome for patients. The chapter ends with a brief discussion of how neurologic monitoring is believed to be useful today, and where more work is needed to determine whether monitoring has a role in surgical patients in the future.

Monitoring Modalities

Monitors of Adequacy of Nervous System Blood Flow

Adequacy of cerebral blood flow (CBF) can be monitored by two principal methods. The first method assesses blood flow itself with the implicit assumption that "normal" flow provides adequately for the metabolic needs of the brain. The second approach assesses oxygen delivery either locally or globally with the implicit assumption that "normal" values at the site of measurement are reflective of adequate blood supply throughout the central nervous system (CNS). To illustrate the limitations imposed by such implicit assumptions, let us examine global or hemispheric CBF in the context of a patient's disease process.

In normal brain, values of hemispheric CBF of approximately 50 mL/100 g/min reflect adequate oxygen delivery for maintaining structural integrity and function. Values of less than 20 to 25 mL/100 g/min are associated first with failure of function and on further decrease with structural damage.[1] In neurosurgical patients, structural integrity and function may be altered by disease processes and anesthetics, which have an impact on the interpretation of measured CBF. A CBF of 40 mL/100 g/min in a patient in barbiturate coma after resection of an arteriovenous malformation may represent hyperemia (because metabolic demand is very low), whereas the same CBF in a patient with a mass lesion may reflect a modest decrease in cerebral perfusion pressure secondary to increasing intracranial pressure.

Global Blood Flow Monitoring Techniques (Noninvasive)

Intravascular Tracer Compounds. Direct measurement of CBF is possible by determining kinetics of washin or washout, or both, of an inert tracer compound, a method originally described by Kety and Schmidt.[2] The most widely used measurement technique involves administration of a radioactive isotope of xenon (^{133}Xe), followed by measurement of the radioactivity washout with gamma detectors placed over specific areas of the brain. Depending on the number of detectors, this method can provide a spatial resolution of 4 cm. In normal brain, flow at different depths may be inferred from the early washout, which should reflect high-perfusion cortical gray matter, and late washout from low-perfusion deeper white matter.

Drawbacks of the method are the patient's exposure to radioactive compounds and the need for externally placed and potentially cumbersome detector equipment, which may interfere with surgery itself in the case of intracranial surgery. Focal areas of hypoperfusion may be missed because of underlying or overlying adequate flow, a phenomenon described as "look-through."[3] Despite these shortcomings, ^{133}Xe washout has been used at a few major centers for intraoperative monitoring during operations such as carotid endarterectomy.[4-8] Modern variations of the same concept are mean transit time determinations of intravascular contrast agents during neuroimaging for determining locoregional blood flow[7,8] or a double-indicator technique for determining global CBF.[9] All these techniques share the limitation of providing a snapshot of CBF in time instead of continuous monitoring.

Transcranial Doppler Ultrasound. Transcranial Doppler (TCD) ultrasound is a technique that infers CBF from measurements of the blood flow velocity in the large conducting arteries of the brain. The TCD probe transmits pulses of sound waves through the thin temporal bone in a variation of the pulsed wave Doppler technique with which anesthesiologists may be familiar from echocardiography. When these sound waves are reflected off the red blood cells back toward the TCD probe, the velocity of the reflected sound waves is changed because the blood cells themselves are in motion toward or away from the probe. This phenomenon is known as the "Doppler shift," and is directly related to flow velocity and flow direction of the blood cells. Blood flow is faster during systole and in the center of a vessel and slower in diastole and near the vessel wall. TCD records a spectrum of flow velocities, whose outline resembles an arterial waveform tracing. These concepts are illustrated in Figure 46-1.

Intraoperatively, TCD measurements are most commonly and easily made by continuous monitoring of the middle cerebral artery for the purpose of detecting either significant changes in flow velocity or the presence of particulate emboli. As a diagnostic study, in addition to the middle cerebral artery, the anterior cerebral, anterior communicating, posterior cerebral, and posterior communicating arteries can be examined through the temporal bone window. The basilar, ophthalmic, and internal carotid arteries also can be insonated through the foramen magnum (TCD probe at the back of the flexed neck) (basilar artery), the closed eyelid (with reduced sound energy) (ophthalmic artery), and near the angle of the jaw (internal carotid artery). An important limitation of TCD results from the fact that most of the examination is done through the temporal bone, which may be thick enough to preclude an adequate examination in 10% to 20% of patients.[10,11]

Two assumptions that are intuitive and plausible, but ultimately unproven, must be made for TCD-measured blood flow velocity to have a direct relationship to CBF. First, blood flow velocity is directly related to blood flow only if the diameter of the artery where the flow velocity is measured and the measurement angle of the Doppler probe remain constant. In practical terms, the difficulty with this assumption lies in finding a means to affix the TCD probe in a way that prevents dislodgment or movement during monitoring. The second assumption requires that CBF in the basal arteries of the brain is directly related to cortical CBF. Because TCD monitoring is typically done mainly using the middle cerebral artery, this assumption may be invalid if collateral blood flow by leptomeningeal collaterals from anterior and posterior cerebral artery territories is adequate. Although these two assumptions constrain the utility of TCD as a standalone monitor of CBF, the changes in flow velocity seen in typical applications (discussed subsequently) are large enough to provide useful clinical information.

More importantly, TCD is the only continuous neurologic monitoring technique that provides early warning for hyperperfusion and for the number of emboli delivered to the brain during various phases of an operation. Because of their high echogenicity, emboli show up in the TCD spectrum as high-intensity transient signals (HITSs) (see Fig. 46-1) and are easily identified as brief beeps or chirps within the background of the Doppler sounds.

Jugular Bulb Venous Oxygen Saturation. The degree of oxygen extraction by an organ can be monitored by following the

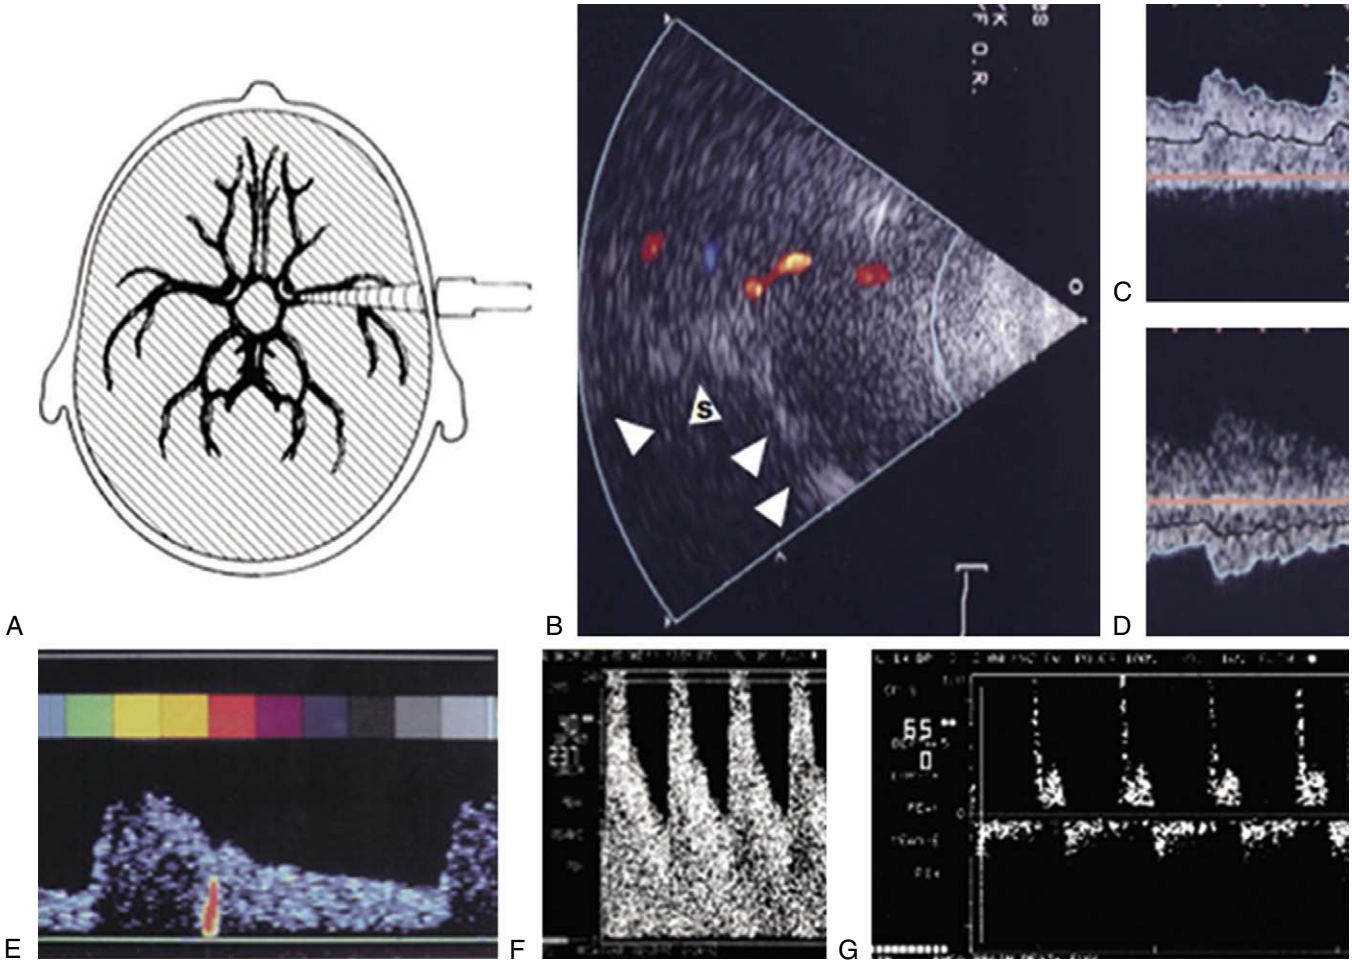

Figure 46-1 **A,** Transcranial Doppler monitoring is done by insonating the arteries at the base of the brain through a thin part of the temporal bone. **B,** If this is done with an imaging probe, some intracranial structures, such as the cerebral peduncles (*white triangles*) or the sella complex (*white triangle labeled "S"*), can be visualized. The Doppler signals originate from the right middle, right anterior, and left anterior cerebral arteries. **C,** Normal Doppler spectrum obtained from the middle cerebral artery. **D,** Doppler profile of the bifurcation of the terminal internal carotid artery as it branches into the middle cerebral artery (flowing toward the transducer) and the anterior cerebral artery (flowing away). This flow signal can be obtained if the transducer is focused as shown in **A**. **E-G,** Examples of three clinical applications of transcranial Doppler. **E,** Emboli are highly echogenic and show up as high-energy transient signals (HITS). On the audible output, these emboli are easily noticed as brief beeps or chirps. **F,** Doppler profile of a middle cerebral artery in a patient with severe vasospasm after an aneurysmal subarachnoid hemorrhage (compare with **C**). **G,** Transcranial Doppler examination consistent with intracranial circulatory arrest. There is a brief systolic inflow followed by retrograde flow during diastole.

oxygen saturation of the mixed venous blood that drains that organ. In the case of the brain, jugular bulb venous oxygen saturation ($Sjvo_2$) is believed to measure the degree of oxygen extraction and to represent the balance between cerebral oxygen supply and demand. To monitor $Sjvo_2$, a fiberoptic catheter is placed in a retrograde fashion into the jugular bulb through the internal jugular vein under fluoroscopic guidance. The fiberoptic bundle emits near-infrared light and records light reflected back to the catheter, a technique known as "reflectance oximetry." Because near-infrared light can travel several centimeters in tissue and is mostly absorbed by hemoglobin, it is possible to determine the oxygen saturation of the surrounding tissue (i.e., the jugular venous blood). Correct tip placement is crucial to minimize admixture of extracranial venous blood. To decrease the risk of complications, usually only one side is monitored.

Several theoretical limitations of the technique must be borne in mind to interpret $Sjvo_2$ values and trends properly. Although nearly all blood from the brain drains via the jugular veins, intracranial mixing of venous blood is incomplete and may result in differences between right-sided and left-sided measurements. The dominant jugular vein (i.e., the right for most patients) drains predominantly cortical venous blood, whereas the contralateral jugular vein drains more of the subcortical regions.[12] Despite such regional differences, $Sjvo_2$ must be considered a monitor of global cerebral oxygenation because inadequate perfusion to a focal brain region may not decrease $Sjvo_2$ values below the normal range of 55% to 75%. Because $Sjvo_2$ represents the balance between supply and demand, interpretation of the absolute value of $Sjvo_2$ must take the clinical circumstances into account.

Cerebral Oximetry. Cerebral oximetry is a noninvasive technique that, similar to $Sjvo_2$ monitoring, uses reflectance oximetry to measure the oxygen saturation of the tissues underneath the sensor. Typically, two sensors are applied to both sides of the forehead. The light passes not only through parts of the frontal

brain, but also through the overlying skull and scalp. Contamination of the oximetry signal by extracranial blood sources is a serious concern, although the use of two sensing diodes with different distances from the light source within one sensor patch and adjustments of the algorithm of the oximeter may minimize this problem.[13,14]

Because two thirds to four fifths of the cerebral blood volume is venous blood, cerebral oximetry determines predominantly "local venous oxygen saturation."[15] It can be expected that in the face of cerebral ischemia, oximetry values decrease as a result of increased oxygen extraction, well before function fails, or permanent neuronal damage ensues. The simplicity of its use and the familiarity with the principles of treating decreases in systemic mixed venous oxygen saturation have made cerebral oximetry a popular trend monitor in operations that potentially cause decreases in blood flow to the vessels of the head. There are some significant limitations, however, of the use of cerebral oximetry during such procedures. First, adequacy of global cerebral perfusion is inferred from measurements over the frontopolar brain. Second, normative data on normal values or expected changes for cerebral oximetry are largely absent, but preoperative application of the sensors allows the start of a trend in conjunction with a neurologic baseline examination.

An example of how these limitations play out is provided by a study of the use of cerebral oximetry during 100 carotid endarterectomies in awake patients.[16] Cerebral oximetry was able to identify 97.4% of patients with adequate CBF as indicated by the absence of clinical symptoms. The monitor frequently indicated inadequate CBF, defined as a 20% decrease in cerebral oxygen saturation from the preclamp baseline, although the patient had no clinical symptoms of inadequate CBF. The false-positive rate of 66.7% may simply illustrate the fact that oxygen extraction increases before function fails. The real problem is that the lower limit for acceptable regional oxygen saturation is unknown in a large population of patients.[17] The value may be different from patient to patient, and addition of anesthetic drugs that influence cerebral metabolism may confuse the picture further.

Tissue-Level Blood Flow Monitoring Techniques (Invasive)

Tissue-level monitoring for the brain is by definition invasive. All monitors in current clinical or research use are implanted through a burr hole, extend either into the white matter or ventricular system, and typically use a bolt for stabilization. They all share a 1% to 2% risk of bleeding, infection, or ischemia owing to the implantation procedure.[18] A second shared feature is their limited spatial resolution (i.e., each monitoring probe monitors only a limited area of brain surrounding the probe). When these monitors were first developed, there was considerable debate regarding the optimal placement of the device given such limited spatial resolution. Based on today's appreciation for the impact of secondary neurologic insults on the ultimate outcome, there is growing agreement that tissue-level monitoring is best performed in morphologically and functionally normal tissue that is part of the penumbra or vulnerable zone of interest.[19-21] Placing a blood flow monitor into the brain tissue supplied by an aneurysm-carrying artery in the setting of a subarachnoid hemorrhage maximizes, but does not ensure, the chances of early detection of vasospasm.

Of the tissue-level monitors, two have undergone sufficient refinement to be in wider clinical use. They represent the two principal modes of assessing adequate blood flow—assessing CBF through thermal diffusion monitoring or assessing oxygen delivery through tissue partial pressure of oxygen (Po_2) monitoring.

Thermal Diffusion Cerebral Blood Flow Monitoring. Thermal diffusion CBF monitoring is based on the idea that the rate at which heat dissipates in a tissue depends on the tissue's thermal conductive properties and the blood flow in that area. Because thermal conduction properties remain constant, changes in heat dissipation reflect changes in blood flow and can be expressed quantitatively in the conventional units of CBF as mL/100 g/min. In practice, the probe consists of a thin catheter with two thermistors placed 5 mm apart (Fig. 46-2). When inserted, both thermistors are located in subcortical white matter. The proximal or passive thermistor measures brain temperature, whereas the distal or active thermistor is heated to 2°C above the temperature measured by the passive thermistor. The power required to sustain the 2°C temperature difference is directly proportional to CBF. The initial rate of propagation of the thermal field is used to establish the fixed conductive component of heat transfer.

The acute performance of this technology has been validated against stable xenon computed tomography (CT) in patients with head injury and performed well across a wide range of CBF

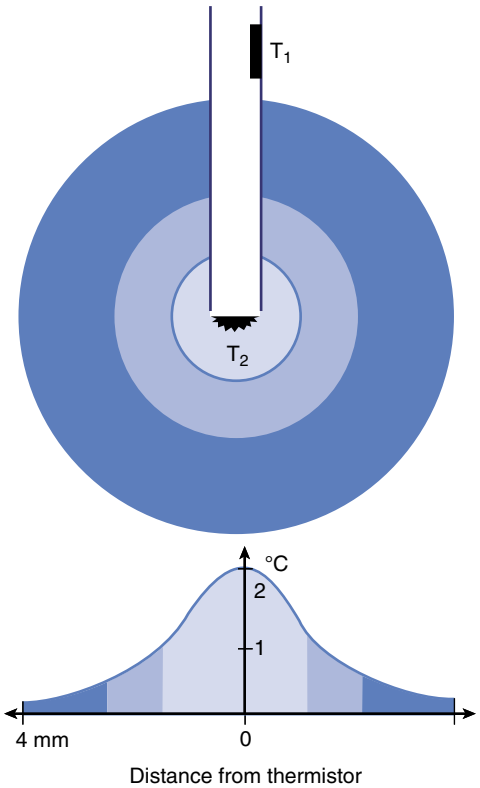

Figure 46-2 Thermal diffusion measurement of cerebral blood flow. The probe is placed in the subcortical white matter. It contains a passive thermistor (T_1) that measures brain temperature and is located outside of the area influenced by the active thermistor. The active thermistor (T_2) is heated to 2°C above brain temperature. The energy required to maintain that increase in temperature is proportional to cerebral blood flow.

values in a sheep model of hypercarbia, hyperventilation, and cardiac arrest.[22] In continuous clinical use, the probe shows some drift and recalibrates at regular intervals.[23] To avoid thermal tissue injury, measurement is automatically suspended if the passive thermistor measures a brain temperature of 39.1°C. Because fever is a frequent complication, particularly in patients with severe brain disease, the inability to monitor during a febrile episode may constitute a true limitation of the technique.

Tissue Partial Pressure of Oxygen Monitoring. Localized monitoring of tissue Po_2 is based on an oxygen-sensitive electrode originally described by Clark.[24] The diffusion of oxygen molecules through an oxygen-permeable membrane into an electrolyte solution causes an electric current that is proportional to Po_2. Currently available catheter-based electrodes provide stable recording conditions over long periods. Similar to regional CBF probes, they are placed into the subcortical white matter.

Most of the data on brain tissue oxygen levels ($P_{Br}O_2$) comes from studies in patients with head trauma. Comparison with stable xenon CT for assessment of CBF shows good correlation between $P_{Br}O_2$ and CBF.[25,26] Similarly, the time course of changes in $P_{Br}O_2$ after traumatic brain injury resembles that of CBF.[27,28] Critics of the technique argue that $P_{Br}O_2$ values are highly influenced by the partial pressure of arterial oxygen (Pao_2) and are merely an elaborate indicator of the quality of patient ventilation. This view is supported by the observation that increasing the fraction of inspired oxygen (Fio_2) increases $P_{Br}O_2$, but likely represents an oversimplification.[29] Concurrent microdialysis studies have shown that increasing Fio_2 not only increases $P_{Br}O_2$, but also decreases tissue lactate levels, suggesting a true improvement in the metabolic milieu of the brain tissue itself.[30,31]

Monitors of Nervous System Function

The most commonly used monitors of function are the electroencephalogram (EEG), sensory evoked responses (SERs), motor evoked responses, and the electromyogram (EMG). The EEG is a surface recording of the summation of excitatory and inhibitory postsynaptic potentials spontaneously generated by the pyramidal cells in the cerebral cortex. The signals are very small, and each recording electrode records only information generated directly beneath the electrode. Monitoring the EEG is usually directed toward one or more of four perioperative uses. First, the EEG is used to help identify inadequate blood flow to the cerebral cortex caused by either a surgically induced or anesthetic-induced reduction in blood flow or retraction on cerebral tissue. Second, the EEG may be used to guide an anesthetic-induced reduction of cerebral metabolism either in anticipation of a loss of CBF or in the treatment of high intracranial pressure, when a reduction in CBF and blood volume is desired. Third, the EEG may be used to predict neurologic outcome after a brain insult. Finally, the EEG may be used to gauge the depth of the hypnotic state of the patient under general anesthesia (see Chapter 39).

More than 50 years of experience monitoring the EEG has led to many known correlations of EEG patterns with clinical states of the normal and pathologic cerebral cortex. The electroencephalographer can accurately identify consciousness, unconsciousness, seizure activity, stages of sleep, and coma. In the absence of significant changes in anesthetic technique, the electroencephalographer also can accurately identify inadequate oxygen delivery to the brain (from either hypoxemia or ischemia). By using high-speed computerized EEG analysis and statistical methods, EEG patterns in the continuum from awake to deeply anesthetized are becoming, with few exceptions, much better understood. In addition, computer advances have made possible high-speed mathematic manipulation of the EEG signal to present the data in a manner more suitable to continuous trends for use during surgical or anesthetic monitoring.

Evoked potentials are electric activity generated in response to either a sensory or a motor stimulus. Measurements of evoked responses may be made at multiple points along an involved nervous system pathway. The evoked responses are generally smaller than other electric activity generated in nearby tissue (muscle or brain) and are readily obscured by these other biologic signals. In the case of SERs, repeated sampling and sophisticated electronic summation and averaging techniques are needed to extract the desired evoked potential signal from background biologic signals. Motor evoked responses are generally larger and commonly do not require averaging.

SERs are the most common type of evoked potentials monitored intraoperatively. During the last 2 decades, much research has been done on the use of intraoperative motor evoked potentials (MEPs). Although routine use of MEP monitoring is still not widespread, it is becoming more so. There are three basic types of sensory evoked responses: somatosensory evoked potentials (SSEPs), brainstem auditory evoked potentials (BAEPs), and visual evoked potentials (VEPs).

The SSEP is produced by electrically stimulating a peripheral (or rarely cranial) nerve. Responses may be recorded proximally over the stimulated nerve, the spinal cord, and the cerebral cortex. The recorded responses assess the function of the peripheral nerve, the posterior and lateral aspects of the spinal cord, a small portion of the brainstem, the ventral posterolateral nucleus of the thalamus, the thalamocortical radiation, and a portion of the sensory cortex. The BAEP is usually produced by a series of rapid, loud clicks applied directly to the external auditory canal. Responses are most commonly recorded from electrodes applied to the scalp, although more invasive direct recordings from auditory structures and nerves may also be made. BAEPs assess function of the auditory apparatus itself; cranial nerve VIII; the cochlear nucleus; and a small area of the rostral brainstem, the inferior colliculus, and the auditory cortex. The VEP is produced by flash stimulation of the retina. Recordings are made from cortically placed electrodes and assess visual pathways from the optic nerve to the occipital cortex.

MEP responses are generated most commonly by the application of a transcranial train of electric stimuli, and responses are recorded at various points along the spinal column, peripheral nerve, and innervated muscle. Electric stimuli to activate motor tracts also may be applied at the level of the spinal cord, but this method of stimulation is controversial (see later), with research suggesting that the response, as it is currently recorded, is at best a mixed response and at worst primarily a sensory response. Magnetic stimuli also may be applied transcranially or at the level of the spinal cord, but use of magnetic stimulation is much less common than electric stimulation, primarily for technical reasons involving fixation of the magnet to the patient to avoid shifts in magnetic field application, which would significantly alter responses. MEPs assess the integrity of the descending motor

pathway through the internal capsule, the brainstem, the spinal cord, the peripheral nerve, and finally the muscle itself. The ability to record MEPs from some patients with cerebral palsy indicates that normal functional organization of the motor cortex cannot be inferred from MEPs.

Electroencephalogram

Basic Unprocessed Electroencephalogram Concepts. The EEG is produced by a summation of excitatory and inhibitory postsynaptic potentials produced in cortical gray matter. Because the EEG signal is generated only by postsynaptic potentials and is much smaller than action potentials recorded over nerves or from the heart, extreme care must be taken when placing electrodes to ensure proper placement and excellent contact with the skin to avoid significant signal loss. Alternatively, subdermal needle electrodes may be used, particularly when sterile application of an electrode close to a surgical field is necessary. When electrodes are applied directly to the surface of the brain, impedance is minimized by close electrode contact and saturation of the area with an electrolyte solution.

EEG electrodes generally are placed according to a mapping system that relates surface head anatomy to underlying brain cortical regions. The placement pattern of recording electrodes is called a montage. Use of a standard recording montage permits anatomic localization of signals produced by the brain and allows development of normative EEG patterns and comparison of EEG recordings made at different times. The standard EEG "map" is called the 10-20 system for EEG electrode placement (Fig. 46-3). This system is a symmetric array of scalp electrodes placed systematically based on the distance from the nasion to the inion and from the pretragal bony indentations associated with both temporomandibular joints. Based on 10% or 20% of these distances, recording electrodes are placed systematically over the frontal (F), parietal (P), temporal (T), and occipital (O) regions at increasing distances from the midline. Left-sided electrodes are given odd number subscripts, and right-sided electrodes are given even number subscripts. Increasing numbers indicate an increasing distance from the midline. Midline electrodes are designated with a "z" subscript. The standard diagnostic EEG uses at least 16 channels of information,[32] but intraoperative recordings have been reported using 1 to 32 discreet channels.

The intraoperative EEG is most commonly recorded from electrodes placed on the scalp. Recordings also may be made from electrodes placed on the surface of the brain (electrocorticography), or from microelectrodes placed transcortically to record from individual neurons (e.g., during surgery for Parkinson's disease).[33,34] The EEG signal is described using three basic parameters: amplitude, frequency, and time. Amplitude is the size, or voltage, of the recorded signal and ranges commonly from 5 to 500 μV (versus 1 to 2 mV for the electrocardiogram signal). Because neurons are irreversibly lost during the normal aging process, EEG amplitude decreases with age. Frequency can be thought of simply as the number of times per second the signal oscillates or crosses the zero voltage line. Time is the duration of the sampling of the signal; this is continuous and real time in the standard paper or digital EEG, but is a sampling epoch in the processed EEG (see later).

Normal Electroencephalogram. Normal patterns seen on the EEG vary among normal individuals, but are consistent enough to allow for accurate recognition of normal and pathologic patterns. The usual base frequency in an awake patient is the beta range (>13 Hz). This high-frequency and usually low-amplitude signal is common from an alert attentive brain and may be recorded from all regions. With eye closure, higher amplitude signals in the alpha frequency range (8 to 13 Hz) seen best in the occipital region appear (Fig. 46-4). This "eyes closed" resting pattern is the baseline awake pattern used when anesthetic effects on the EEG are described. When events that lead the brain to produce higher frequencies and larger amplitudes occur, the EEG is described as "activated," and when slower frequencies are produced (theta = 4 to 7 Hz, and delta = <4 Hz), the EEG is said to be "depressed." The EEG in a sleeping patient may contain all of these frequencies at various times. The slower frequencies occur during deep natural sleep with "sleep spindles" (Fig. 46-5), but during light sleep or rapid eye movement (REM) sleep, the EEG becomes activated, and the eye muscle EMG appears on the EEG.

In the normal EEG in awake and asleep patients, patterns recorded from corresponding electrodes on each hemisphere are symmetric in terms of frequency and amplitude, the patterns are predictable if clinical states are known, and spike (epileptic) waveforms are absent. In most cases, normal EEG patterns are associated with normal underlying brain function in awake and anesthetized patients.

Abnormal Electroencephalogram. General characteristics of the "abnormal" EEG include asymmetry with respect to frequency, amplitude, or both, recorded from corresponding electrodes on each hemisphere, and patterns of amplitude and

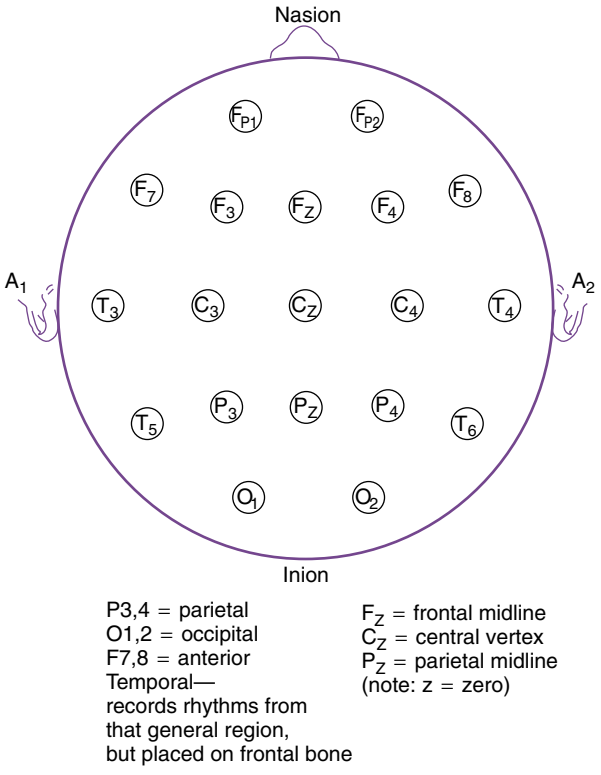

Figure 46-3 International 10-20 system of electrode placement for recording electroencephalogram and sensory evoked responses. *(From Hughes JR: EEG in Clinical Practice, 2nd ed. Newton, MA, Butterworth-Heinemann, 1994.)*

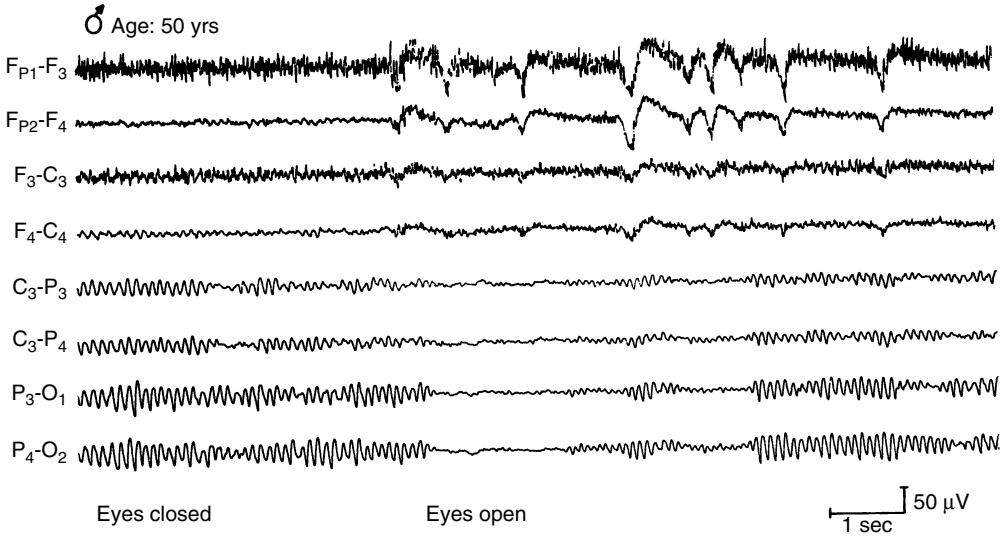

Figure 46-4 The loss and return of α activity as the eyes open and close can be seen. The large spikes are muscle artifact.

frequency that are unpredictable or unexpected in the normal recording. These abnormal patterns reflect either anatomic or metabolic alterations in the underlying brain. Regional asymmetry can be seen with tumors, epilepsy, and cerebral ischemia or infarction. Epilepsy may be recognized by high-voltage spike and slow waves, whereas cerebral ischemia manifests first with EEG slowing with preservation of voltage. Further slowing and loss of voltage occurs as ischemia becomes more severe. Factors affecting the entire brain may produce symmetric abnormalities of the signal. Identifying pathologic abnormal patterns in the global EEG signal is very important, although sometimes quite difficult, in the clinical situation. Many of the normal global pattern changes produced by anesthetic drugs are similar to pathologic patterns produced by ischemia or hypoxemia. Control of anesthetic technique is very important when the EEG is being used for clinical monitoring of the nervous system.

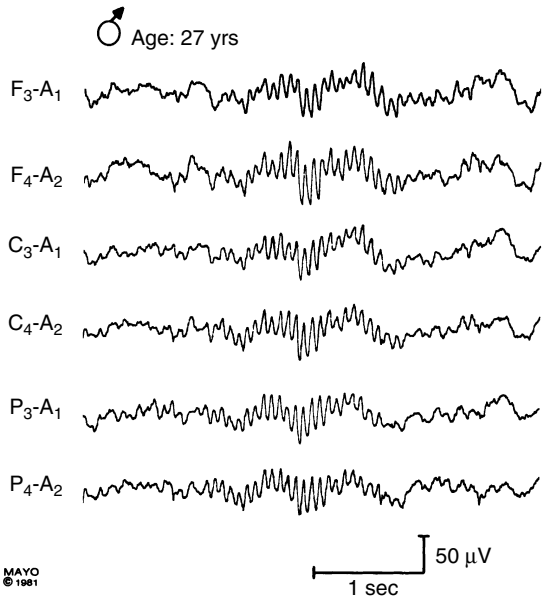

Figure 46-5 Characteristic sleep spindles in normal sleep are shown in the center.

Processed Electroencephalogram Concepts. Interpretation of the standard paper EEG tracing is a science and an art. Until the last quarter of the 20th century, the paper EEG was used during intraoperative monitoring with the technologist relying on memory of the baseline and on experience to determine when significant EEG changes occurred. This qualitative approach was used simply because the waveforms could not be described mathematically in a time frame that would make such information of any practical use. Computer hardware has dramatically improved in speed and size, and real-time signal processing is now possible and commonly used.

Numerous limitations are introduced when moving from the raw EEG domain to the processed EEG domain. First, artifact is processed in many cases along with desired signal leading to a perfectly believable processed EEG display that is materially incorrect. Second, the standard 16-channel EEG montage provides more information than can be practically analyzed or displayed by most processed EEG monitors and perhaps more than is needed for routine intraoperative use. Most available processed EEG devices used by anesthesiology personnel use four or fewer channels of information—translating to at most two channels per hemisphere. Processed EEG devices generally monitor less cerebral territory than a standard 16-channel EEG. Third, some intraoperative changes are unilateral (e.g., regional ischemia owing to carotid clamping), and some are bilateral (e.g., EEG depression by bolus administration of an anesthetic). Display of the activity of both hemispheres is necessary to delineate unilateral from bilateral changes. An appropriate number of leads over both hemispheres is needed. Most early studies validating intraoperative EEG monitoring used continuous visual inspection of a 16- to 32-channel analog EEG by an experienced electroencephalographer—such monitoring was considered the gold standard.[35,36] Adequate studies comparing the processed EEG with fewer channels with this gold standard across multiple uses and operations have not been done, although limited data using processed EEG

monitoring during carotid surgery suggest that two- or four-channel instruments would detect most significant changes,[37,38] provided that the electrodes are appropriately placed over watershed areas of blood supply.

Devices. Two basic forms of EEG processing are used currently: power analysis and bispectral analysis. Power analysis uses Fourier transformation to convert the digitized raw EEG signal into component sine waves of identifiable frequency and amplitude. The raw EEG data, which is a plot of voltage versus time, is converted to a plot of frequency and amplitude versus time. Many commercially available processed EEG machines display power (voltage or amplitude squared) as a function of frequency and time. These monitors display the data in two general forms, either compressed spectral array or density spectral array. In compressed spectral array, frequency is displayed along the *x* axis, and power is displayed along the *y* axis with height of the waveform equal to the power at that frequency. Time is displayed along the *z* axis. Tracings overlap each other, with the most recent information in front (Fig. 46-6). Density spectral array also displays frequency along the *x* axis; time is displayed along the *y* axis, and power is reflected by the density of the dots at each frequency. Each display format provides the same data, and choice depends on the preference of the user.

Many changes that occur during anesthesia and surgery are reflected as changes in amplitude, frequency, or both. These changes can be clearly seen in these displays if adequate and appropriate channels are monitored. Power analysis has been used clinically for many years as a diagnostic tool during procedures with risk for intraoperative cerebral ischemia, such as carotid endarterectomy and cardiopulmonary bypass (CPB). Power analysis has proven to be a sensitive and reliable monitor in the hands of experienced operators using an adequate number of channels. In addition, parameters obtained from power analysis have been investigated as monitors for depth of anesthesia.[39-42] Although earlier attempts to use parameters derived from power analysis for assessment of anesthetic depth were largely unsuccessful, these same parameters are now used to varying degrees with much more success as a part of different algorithms (including BIS [Bispectral Index Score] and PSI [Patient State Index]) to measure hypnotic states.

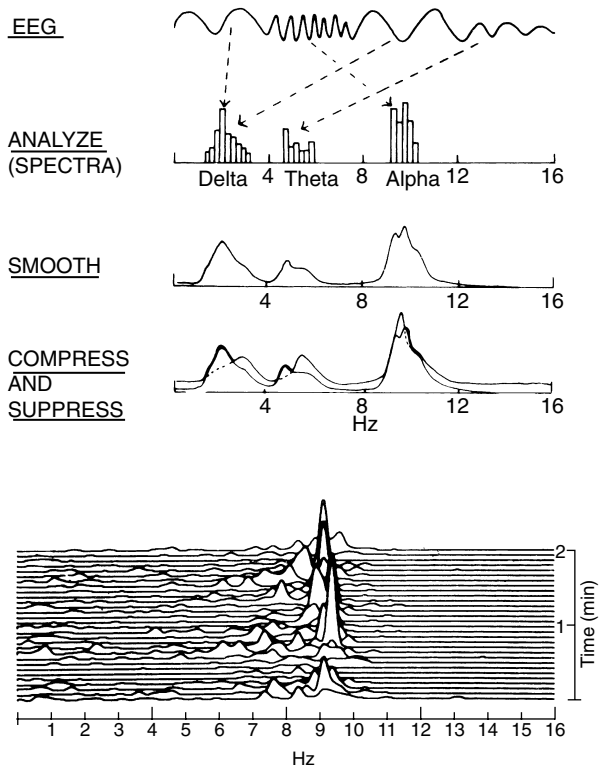

Figure 46-6 Diagram of technique used to generate compressed spectral array. Example at the bottom of the figure shows compressed spectra of the α rhythm from a normal subject. *(From Stockard JJ, Bickford RG: The neurophysiology of anaesthesia. In Gordon E [ed]: A Basis and Practice of Neuroanesthesia. New York, Elsevier, 1981, p 3.)*

Data Acquisition Period. An important consideration in the processed EEG is time. The standard paper or digital EEG is continuous in real time. The processed EEG samples data over a given time period (epoch), processes the data, and then displays information in various formats. There is a relationship between epoch length and spectral resolution. If a long epoch length is chosen, the waveform can be described precisely, but the time required for data processing is long and not real time. If a short length of data is sampled, analysis may be done in near real time, but the epoch chosen for analysis may not be representative of the overall waveform (i.e., the condition of the patient). There also may be insufficient data points for meaningful Fourier transformation. This issue, as related to the use of intraoperative EEG for analysis of anesthetic depth, has been studied by Levy.[43] A longer epoch may produce less epoch-to-epoch variability and allow more precise description of frequency and power; however, the longer epoch increases the delay before new information is processed and displayed, reducing the amount and timeliness of information available for clinical decision making. In studying EEG epochs of 2 to 32 seconds, Levy[43] concluded that 2-second epochs are appropriate during general anesthesia. Many commercially available devices have used 2-second epoch lengths, updated at varying user-selected intervals. With better and faster computers, continuous monitoring of 2-second epochs and now even longer epochs is possible.

Evoked Potentials

Basic Concepts Common to All Modalities. EEG signals provide information about cortical function, but little to no information about subcortical neural pathways crucial to normal neurologic function. Intraoperative monitoring of SERs has gained increasing popularity over the last 25 years because it provides the ability to monitor the functional integrity of sensory pathways in an anesthetized patient undergoing surgical procedures placing these pathways at risk. Because motor pathways are often adjacent anatomically to these sensory pathways or supplied by the same blood vessels, or both, function of motor pathways may be inferred, albeit imperfectly, from the function of these sensory pathways. Today, MEPs are ideally monitored together with SERs to provide direct information about function of motor pathways.

Sensory Evoked Responses. SERs are electric CNS responses to electric, auditory, or visual stimuli. SERs are produced by stimulating a sensory system and recording the resulting electric responses at various sites along the sensory pathway

up to and including the cerebral cortex. Because of the very low amplitude of SERs (0.1 to 10 μV), it is often impossible to distinguish SERs from other background biologic signals, such as the EEG or EMG, which may be considered in this case undesirable "noise." To extract the SER from the background noise, the recorded signal is digitized, and signal averaging is applied. With this technique, signal recording is time-locked to the application of the sensory stimulus. During intraoperative median nerve SER monitoring, after nerve stimulation at the wrist, only signal information occurring less than 50 msec after the stimulus is recorded. The SER occurs at a constant time after the stimulus application; other electric activity, such as spontaneous EEG, occurs at random intervals after the sensory stimulus. The averaging technique improves the SER signal-to-noise ratio by eliminating random elements and enhancing the SER. This enhancing effect increases directly with the square root of the number of responses added into the averaged response.

SER recordings are of two general types determined by the distance of the recording electrode from the neural generator of the evoked response. SERs recorded from electrodes close to the neural generators (within approximately 3 to 4 cm in the average adult) are termed "near-field potentials."[44] Near-field potentials are recorded from electrodes placed very close to the actual signal generator site,[45] and the morphology is directly affected by electrode location.[44] Far-field potentials are recorded from electrodes located a greater distance from the neural generator and are conducted to the recording electrode through a volume conductor (brain, cerebrospinal fluid, and membranes). As a result, it is more difficult to locate the source of the recorded signal (the current spreads diffusely throughout the conducting medium), and the electrode position has little effect on the morphology of the recorded evoked potential.[44,45] As the distance between the recording electrode and the neural generator increases, the recorded SER becomes smaller. More responses have to be averaged to record far-field potentials (several thousand) than near-field potentials (50 to 100).[44,45]

SERs also may be described as cortical or subcortical in origin. Cortical SERs are generated by the arrival at the cortex of the volley of action potentials generated by stimulating the sensory system. Because they are recorded as a near-field potential, they are typically easy to identify by elapsed time, waveform morphology, and amplitude. Subcortical responses may arise from many different structures depending on the type of response, including peripheral nerves, spinal cord, brainstem, thalamus, cranial nerves, and others. Cortical SERs are usually recorded from scalp electrodes placed according to the standard 10-20 system for EEG recordings (see Fig. 46-3). Subcortical evoked responses also may be recorded as far-field potentials from scalp electrodes or, as appropriate, from electrodes placed over the spinal column or peripheral nerve.

Evoked potentials of all types (sensory or motor) are described in terms of latency and amplitude (Fig. 46-7). Latency is defined as the time measured from the application of the stimulus to the onset or peak (depending on convention used) of the response. The amplitude is simply the voltage of the recorded response. According to convention, deflections below the baseline are labeled "positive (P)," and deflections above the baseline are labeled "negative (N)." Because amplitude and latency change with recording circumstances, normal values must be established for each neurologic monitoring laboratory, and may differ from values recorded in other laboratories.

SERs used for intraoperative monitoring include SSEPs, BAEPs, and rarely VEPs. For all these techniques, cortical recording electrodes are placed on the scalp, using the same standard 10-20 system as for recording the EEG, whereas recordings for subcortical and peripheral signals are placed in various standardized anatomic locations. The surgical incision and the need for sterility may necessitate nonstandard electrode placements. Such deviations must be considered when interpreting baseline and subsequent SERs. In the case of MEPs, stimulating electrodes also are placed according to the 10-20 system of electrode placement, but over motor cortex instead. Recording electrodes may be

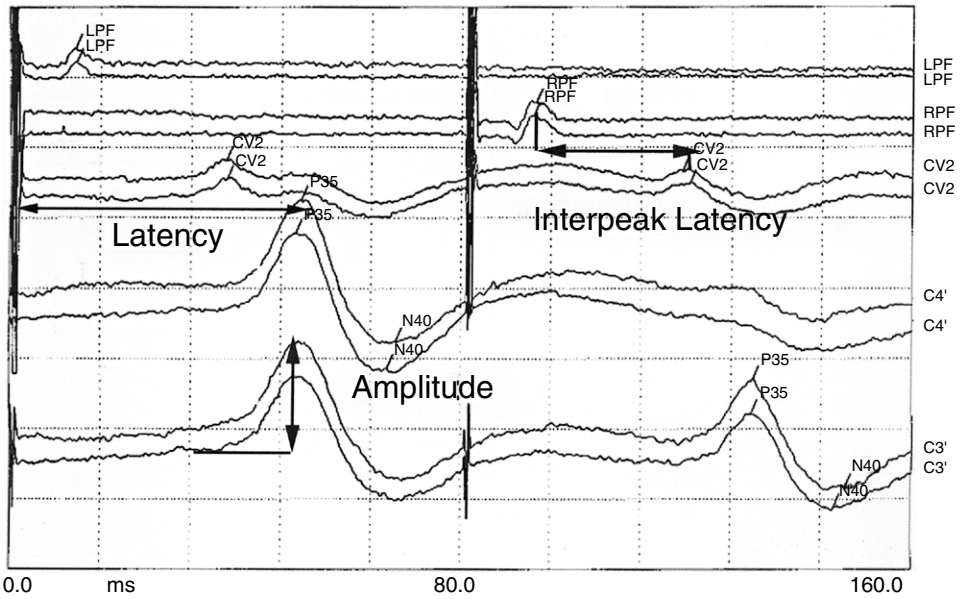

Figure 46-7 Sensory evoked responses are described in terms of latency and amplitude. Interpeak latency is the measured time between two peaks. Interpeak latency may be measured between two peaks in the same channel or between peaks in different channels (shown in figure). Note that the polarity of peaks is displayed contrary to standard convention (see text).

placed over the spinal column, peripheral nerve, and (most commonly) innervated muscle.

Intraoperative changes in evoked responses, such as decreased amplitude, increased latency, or complete loss of the waveform, may result from surgical trespass, such as retractor placement or ischemia, or they may reflect systemic changes, such as changes in anesthetic drug administration, temperature changes, or hypoperfusion. When these changes are detected and considered to be significant, the surgeon or anesthesiologist can make changes to relieve or lessen the insult to the monitored pathway (and presumably surrounding neural structures). Interventions by the anesthesiologist are directed at improving perfusion to the nervous tissue at risk and include increasing arterial blood pressure, especially if induced hypotension is used, or if the patient's pressure has decreased to below the preoperative level; transfusion, if significant anemia is present; volume expansion; augmentation of cardiac output; and normalization of arterial blood gas tensions if indicated. Changes in evoked potentials after retractor placement during a craniotomy or after compression of the blood supply to the spinal cord from spinal column distraction promptly allow the surgeon and the anesthesiologist to make appropriate changes to the operative procedure and anesthetic management that may prevent or minimize any postoperative neurologic deficit (Fig. 46-8).

Tolerance limits for degree of change in evoked response signals or duration of complete loss of waveform before permanent neurologic dysfunction occurs are not clearly defined, and this problem is especially true for transcranial MEPs. Such ambiguity is common among intraoperative monitors. Although we do know that increased frequency and duration of ST segment depression during coronary bypass surgery is associated with an increased risk of perioperative infarction, exact limits for degree and duration of ST segment depression for surgery do not exist, and likely vary significantly from patient to patient. The same problem may be exhibited with neurologic monitors.

Many centers using intraoperative SER monitoring define decreases in amplitude of 50% or more from baseline associated with a less than 10% prolongation in latency as clinically significant SER changes. Uncorrected, such changes are associated in clinical series and in case reports with onset of new postoperative neurologic deficits. As a result, such changes are immediately investigated. In practice, any SER changes directly associated with a surgical event are considered clinically significant, however, even if the magnitude of change is less than just described. Changes in SER that do not progress to complete loss of the waveform are less likely to be associated with a major new postoperative neurologic deficit. Complete loss of the SER waveform intraoperatively without recovery is highly likely to be associated with a major new deficit. If the SER recovers either spontaneously or after intraoperative interventions, the likelihood of neurologic injury depends on the procedure, the duration of the SER loss, and on whether the SER is mainly used to judge integrity of

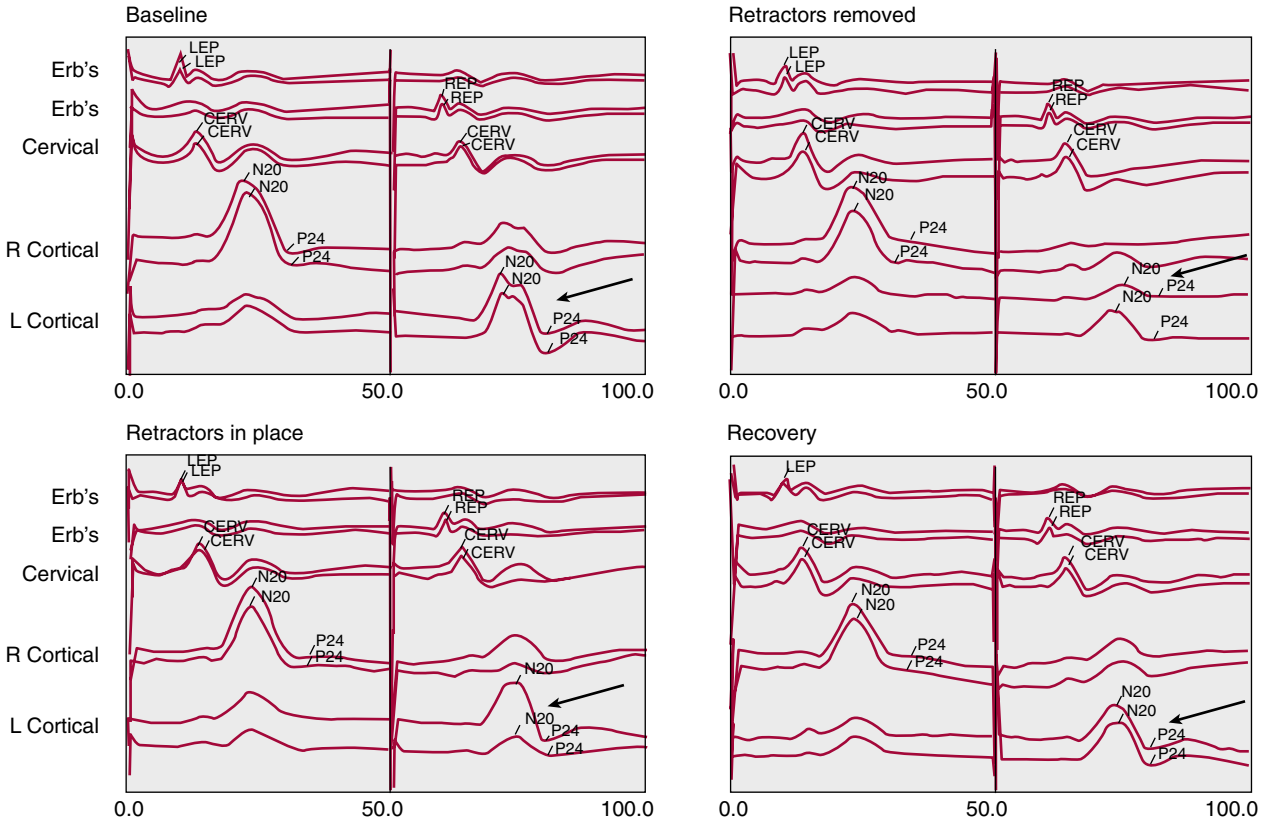

Figure 46-8 Somatosensory evoked potentials during an aneurysm clipping. Responses generated by the cortex at risk are indicated by *arrows*. Baseline, after retractor placement, after retractor removal, and recovery traces are shown. The initial evoked response change occurred 4 minutes after retractor placement. Note loss of voltage of cortical evoked response caused by inadvertent compression of the middle cerebral artery.

adjacent unmonitored structures. In one study of aortic vascular surgery in which SSEPs were monitored, loss of the SSEP waveform for less than 15 minutes was not associated with a new permanent neurologic deficit, whereas complete loss of the SSEP for longer periods was increasingly likely to reflect permanent neurologic injury, even if the response recovered completely to its intraoperative baseline during surgery.[46]

One of the most important principles of recording SERs intraoperatively is that reproducible, reliable tracings must be obtained at baseline before any intervention likely to cause changes in the evoked response. If good quality tracings with identifiable waveforms cannot be recorded and reproduced at baseline, evoked response monitoring would be of little use in monitoring the integrity of the CNS intraoperatively. If significant variability exists, or waveforms are difficult to identify, it would be impossible intraoperatively to distinguish SER changes that are clinically significant from a preexisting baseline variability of waveforms. When good, reproducible responses cannot be recorded at baseline, monitoring should not be used for clinical decision making.

Somatosensory Evoked Potentials. SSEPs are recorded after electric stimulation of a peripheral mixed nerve. Stimulation is provided most commonly with surface electrodes (e.g., electrocardiogram electrodes) placed on the skin above the nerve or with fine needle electrodes. A square wave stimulus of 50 to 250 μsec duration is delivered to the peripheral nerve, and the intensity is adjusted to produce a minimal muscle contraction. Increasing the stimulus intensity beyond the sum of the motor and sensory threshold does not influence the amplitude or latency of the recorded evoked potential. On a practical basis, however, many laboratories do not establish SSEP monitoring until after the patient is already anesthetized and paralyzed. In these cases, stimulus intensity is increased until no further increase in response size occurs at any recording site, typically constant current stimulation of 20 to 50 mA. For comparison, consider supramaximal stimulation used for the neuromuscular blockade monitor, commonly 80 mA. The rate of stimulation varies from 1 to 6 Hz. The common sites of stimulation include the median nerve at the wrist, the common peroneal nerve at the knee, and the posterior tibial nerve at the ankle.[47]

SSEP responses consist of short-latency and long-latency waveforms. Cortical short-latency SSEPs are most commonly recorded intraoperatively because they are less influenced by changes in anesthetic drug levels. The pathways involved in the generation of upper extremity short-latency SSEPs include large-fiber sensory nerves with their cell bodies in the dorsal root ganglia and central processes traveling rostrally in the ipsilateral posterior column of the spinal cord synapsing in the dorsal column nuclei at the cervicomedullary junction (first-order fibers), second-order fibers crossing and traveling to the contralateral thalamus via the medial lemniscus, and third-order fibers from the thalamus to the frontoparietal sensorimotor cortex. These primary cortical evoked responses, which are recordable with most anesthetic techniques, result from the earliest electric activity generated by the cortical neurons and are thought to arise from the postcentral sulcus parietal neurons. The longer latency secondary cortical waves are thought to arise in the association cortex. These responses have much greater variability in an awake patient,[45] habituate rapidly on repetitive stimulation,[44] and are only poorly reproducible during general anesthesia. Cortical SSEPs other than the primary cortical response are not monitored or interpreted intraoperatively because they are severely altered by general anesthesia.[44]

Although most evidence indicates that upper extremity evoked potentials are conducted rostrally in the spinal cord via dorsal column pathways, much data suggest that lower extremity SSEPs are conducted substantially by the lateral funiculus.[48] Stimulation of the posterior tibial nerve or common peroneal nerve at or above motor threshold activates group I fibers that synapse and travel rostrally through the dorsal spinocerebellar tract. After synapsing in nucleus Z at the spinomedullary junction, the pathway crosses and projects onto the ventral posterolateral thalamic nucleus.[49] Studies with dogs, cats, and monkeys support the concept that lower extremity SERs are conducted in all quadrants of the spinal cord, but primarily in the dorsal lateral funiculus.[50,51] This pathway difference is important because the dorsal lateral funiculus is supplied primarily by the anterior spinal artery, the artery that also supplies the descending motor pathway and neurons in the spinal cord. Manipulations, such as distraction of the spinal column to correct scoliosis, which may secondarily compress or distort radicular blood supply to the anterior spinal cord, should cause changes in the SSEP in the event blood supply is reduced to critical levels. This hypothesis is verified by the very low, but not zero, incidence of postoperative paraplegia on awakening without any intraoperative changes in SSEPs.

For SSEP recordings with median nerve stimulation, recording electrodes (usually electrocardiogram pads) are first placed at Erb's point, just above the midpoint of the clavicle. This point overlies the brachial plexus, and signals recorded here assure the clinician that the stimulus is actually being delivered properly to the patient. The next electrode (either an electrocardiogram pad or a gold cup electrode) is placed midline posteriorly over the neck at level of the second cervical vertebra, relatively near the dorsal column nuclei. Signals recorded here ensure proper transmission of the response from the peripheral nervous system into the spinal cord and rostral along the spinal cord to the lower medulla. The final electrodes (gold cup electrodes or needle electrodes) are placed on the scalp overlying the sensory (parietal) cortex contralateral to the stimulated limb. Signals recorded here ensure the integrity of the pathway through the brainstem, thalamus, and internal capsule, and may assess adequacy of CBF in this area of the cortex.[52-56]

To record SSEPs after posterior tibial nerve stimulation, electrodes (electrocardiogram pads) are placed first over the popliteal fossa to ensure proper stimulus delivery to the nervous system. Electrodes also may be placed over the lower lumbar spine to ensure proper transmission of the signal into the spinal cord itself, but this site is not commonly used because of the proximity of sterile surgical incisions. Cervical spine and scalp recording electrodes are placed in a similar fashion as described previously, although different locations may be used as required by the placement of the surgical incision. More invasive recording methods, such as epidural electrodes, also may be used intraoperatively.

Purported generators for short-latency SSEPs are listed in Table 46-1 and shown in Figure 46-9.[44,47] Induction of anesthesia and use of different recording electrode locations (montage), necessitated by the surgical incision, may significantly alter the appearance of the SSEP. In these cases, attribution of a particular generator to a given wave on the tracing may be quite difficult. During neurologic monitoring, such precision is not needed, and

Table 46-1 Generators of Somatosensory Evoked Potentials after Median Nerve Stimulation

Peak	Generators
N9 (EP)	Brachial plexus*
N11	Posterior columns or spinal roots
N13/P13	Dorsal column nuclei*
N14, 15	Brainstem or thalamus
N19/P22	Parietal sensory cortex*

*Indicates sites commonly recorded during surgery. All other waveforms indicated are not commonly monitored.

recorded waveforms are compared with tracings obtained at baseline and during earlier portions of the surgical procedure. After lower limb stimulation, absolute latencies are increased because of the greater distance the response to stimulation must travel along the peripheral sensory nerve and spinal cord. Interpeak latencies (see Fig. 46-7) also are evaluated to assess specific conduction times, such as N9 to N14 conduction time, reflecting transmission time from the brachial plexus to brainstem, or N14 to N19 conduction time, reflecting transmission time between the dorsal column nuclei and the primary sensory cortex.[57]

Brainstem Auditory Evoked Potentials. BAEPs are produced in the diagnostic laboratory by delivering repetitive clicks or tones via headphones. Headphones are not practical for surgical monitoring of neurosurgical procedures, and click stimuli are delivered using foam ear inserts attached to stimulus transducers (Fig. 46-10). Stimulus intensity is usually set at 60 to 70 dB above the patient's click-hearing threshold, although, practically speaking, many intraoperative laboratories establish monitoring after induction of anesthesia and instead begin with a stimulus intensity of 90 dB nHL (normal hearing level). The duration of the click is approximately 100 μsec, and the stimulus is given usually 10 to 15 times per second. Clicks are delivered using different "polarities"—that is, the click may cause initial movement of the tympanic membrane away from the transducer (rarefaction) or toward the transducer (condensation). Use of these two different methods commonly produces very different waveforms, amplitudes, and latencies in individual patients, and the method that produces the largest reproducible response is chosen. If stimulus artifact is a serious problem, clicks of alternating polarity may be used to decrease the artifact, but the waveforms produced are an average of those produced by either stimulating technique alone and may be more difficult to monitor.

Rate and intensity of stimulus delivery affect BAEPs.[44,58] Unilateral stimulation is used because responses from the other ear, which may remain normal during surgery, may obscure any abnormal responses from the monitored ear. Recording electrodes (usually gold cup electrodes) are placed on the lobe of the stimulated ear and on the top of the head (vertex).[58] White noise commonly may be delivered to the contralateral ear to prevent bone conduction from stimulation of the monitored ear from producing an evoked response from the contralateral ear. On average, 500 to 2000 repetitions are required because BAEPs recorded from the scalp are far-field potentials and extremely small (often <0.3 μV).[44,58]

Peaks in recordings of BAEPs are labeled I through VII; the purported neural generators for these peaks and the auditory pathway are shown in Figure 46-11. The anatomic auditory pathway would predict that BAEP monitoring would be most useful for surgical procedures in the posterior fossa that risk hearing or structures in the upper medulla, pons, and midbrain. As with other SERs, amplitude, absolute latencies, and interpeak latencies are evaluated to assess integrity of the auditory system,

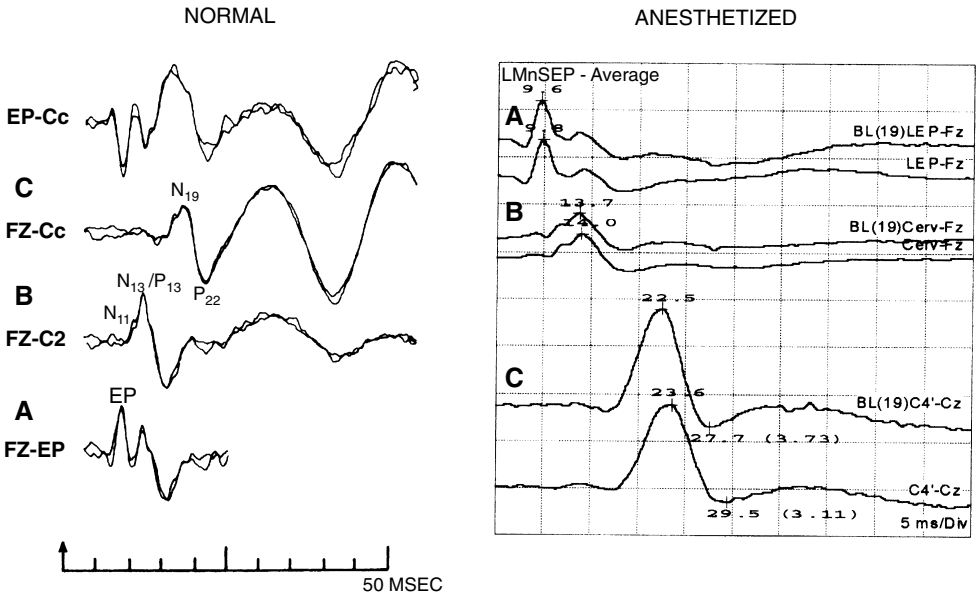

Figure 46-9 Short-latency somatosensory evoked potentials produced by stimulation of the median nerve at the wrist. The ability to identify each of the labeled peaks shown in the tracing from the awake patient is compromised by the anesthetic state and use of different recording electrode locations (**A** to **C**). Corresponding tracings are labeled with the same letter. *(From Chiappa KH, Ropper AH: Evoked potentials in clinical medicine. N Engl J Med 306:1205, 1982.)*

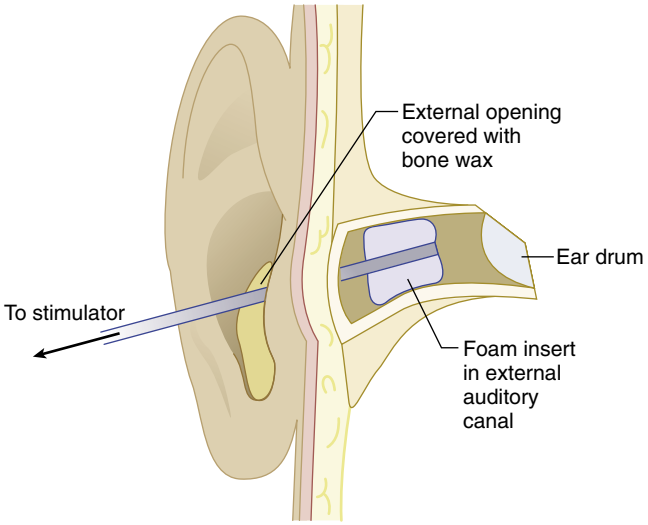

Figure 46-10 Schematic of brainstem auditory evoked potential stimulating apparatus. Loud click stimuli are delivered directly to the eardrum through the ear insert.

localize the functional defect when it occurs, and assess peripheral and central conduction times. Because waves VI and VII are inconsistent and variable, they are not routinely monitored,[58] and most articles reporting use of BAEP for surgical monitoring in the operating room monitor waves only up to wave V.[59-61]

Visual Evoked Potentials. VEPs are recorded after monocular stimulation with recording electrodes over the occipital, parietal, and central scalp.[60] Flash stimulation of the retina using light-emitting diodes embedded in soft plastic goggles through closed eyelids or as needed via contact lenses with built-in light-emitting diodes is provided. VEPs are cortical SERs, which vary with the type of stimulus, part of the retina stimulated, degree of pupil dilation, and patient's attention level.[44] Because some of these factors change commonly and even constantly during the course of every anesthetic, VEPs would be expected to be highly variable during surgery even when no surgical trespass on the visual system occurs. VEPs are the least commonly used evoked response monitoring technique intraoperatively.

Motor Evoked Potentials. MEPs are generated most commonly by the application of a transcranial train of electric stimuli, and responses are recorded at various points along the spinal column, peripheral nerve, and innervated muscle.

Transcranial Motor Evoked Potentials. Monitoring of the integrity of the motor tracts within the spinal cord is a technique with great potential benefit, and even during the relative short history of MEP monitoring, there are reported cases of loss of MEPs with preservation of the SSEP.[62-67] This technique has potential applications in spinal surgery, in which transmission across the operative field can be assessed, and in aortic surgery, with the potential for impairment of the blood supply to the vulnerable anterior spinal cord. Relative to SER monitoring, MEP monitoring is quite invasive and, in the case of transcranial stimulation, uses much higher stimulus intensity (≥400 V).

Several variants of MEP monitoring exist. The first method involves transcranial stimulation, either electric or magnetic. During transcranial electric MEP monitoring, stimulating electrodes (usually small, metallic screw-type electrodes similar to those used in fetal monitoring) are placed into the scalp overlying the motor cortex, and a train of electric stimuli (usually around 400 to 500 V) is applied to the scalp. This stimulation definitely activates muscles of mastication, and bite-blocks must be placed to prevent serious damage to the tongue during stimulation. During magnetic stimulation, a powerful magnetic stimulator is placed on the scalp over the motor cortex. Magnetic stimulation is more difficult for two reasons. First, the magnetic stimulator must be fixed to the head to prevent movement because even a slight movement of the stimulator can substantially alter the

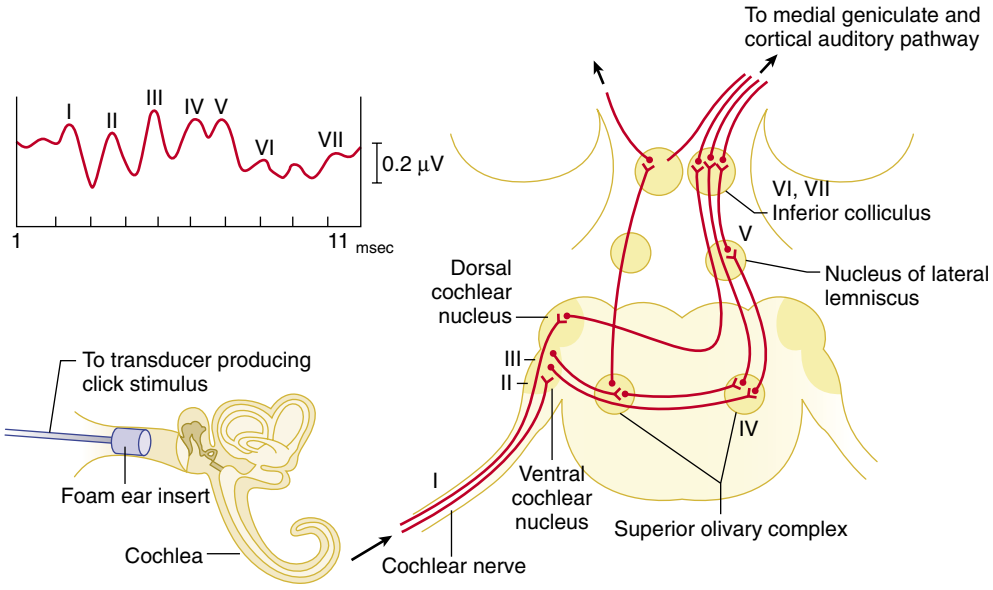

Figure 46-11 Schematic of auditory neural pathway. The brainstem auditory evoked potential is initiated by stimulation of the cochlea with a broadband click stimulus given via an ear insert in the external auditory canal. Neural generators of the brainstem auditory evoked potential peaks are shown.

stimulus applied to the motor cortex. Second, the stimulator is quite large and cannot practically be used intraoperatively if a craniotomy is performed. Brief repetitive applications of electric current or a strong magnetic field induce current in the motor cortex and produce an MEP.

These transcranial stimulating methods also may activate surrounding cortical structures and subcortical white matter pathways (sensory and motor). Distal antidromic propagation of the transcranially applied stimulus is blocked by synapses in all of the ascending sensory pathways. The stimulus is propagated easily orthodromically via descending motor pathways. The evoked responses may be recorded over the spinal cord, the peripheral nerve, and, most commonly, the muscle itself. To enhance the MEP, these responses may be averaged in the same manner as SERs, but averaging is almost always unnecessary.

Spinal Motor Evoked Potentials. Another method of producing the MEP involves electric stimulation of the spinal cord itself above the area of the cord at risk during surgery. Responses may be recorded over the distal spinal cord, peripheral nerve, and muscle.[68-70] Responses are recorded distally, usually over the peripheral nerve, and profound surgical muscle relaxation is used to prevent gross movement during surgery. This type of MEP is called a "neurogenic" MEP. Initially, investigators believed that this response, recorded over a peripheral nerve in the lower extremity (typically the tibial nerve in the popliteal fossa), was generated by stimulation of the descending motor tracts, activation of the anterior horn cells, and propagation of the nerve action potential via the peripheral nerve. Multiple clinical trials were conducted using this technique and comparing results of MEP monitoring with the SSEP with good results.[68-70] These responses also have the advantage that they do not show the same sensitivity to anesthetics that SSEPs do and may be recorded with any anesthetic technique.

Subsequent studies in animals and humans[71] have shown that neurogenic MEPs are, at best, mixed responses with a significant component of an antidromically conducted response along the sensory pathway. Stimulation of the dorsal column results in an antidromically conducted recordable signal peripherally because the somesthetic system does not synapse in the dorsal root ganglion, and fibers pass directly from the dorsal column through the cell body in the ganglion into the peripheral nerve. Because of this problem, use of neurogenic MEP monitoring has decreased significantly, replaced by the more invasive transcranial stimulation techniques, which produce responses that are exclusively produced by activation of the motor system.

Electromyography. Intraoperative monitoring of EMG responses generated by cranial and peripheral motor nerves allows early detection of surgically induced nerve damage and assessment of level of nerve function intraoperatively. In these cases, the ability of a nerve to produce a response in the innervated muscle is used to assess the health of a cranial or peripheral nerve at risk during surgery. Recordings are made from either surface (electrocardiogram or gold cup) electrodes or needle electrodes placed directly in the innervated muscle of interest. The most experience with this monitoring modality has been obtained during facial nerve monitoring.

EMG monitoring may be either active or passive. During active monitoring, a cranial or peripheral nerve is stimulated electrically, and the evoked EMG (compound muscle action potential) response from the muscle is recorded. Stimulation of the nerve proximal to the operative area or tumor can be used to assess functional integrity of the nerve.[72] Nerve function also may be assessed by noting the intensity of nerve stimulus needed to evoke a muscle response and by the morphology of the compound muscle action potential. Nerve function may be monitored passively during surgery with continuous recording of all generated responses from innervated muscle groups. "Popcorn" EMG discharges are produced by simple, benign contact with the monitored nerve. Response trains are produced with more significant nerve irritation. Neurotonic discharges are produced by significant nerve irritation or damage or both (Fig. 46-12).[72] These EMG responses, when they reach a certain voltage threshold, are usually converted into audible signals that provide immediate feedback to the surgeon and warn of impending nerve damage in real time. Real-time feedback is key because density and frequency of neurotonic discharges may correlate with degree of postoperative nerve dysfunction, as shown by data obtained from patients undergoing resection of acoustic tumors.[73]

Intraoperative monitoring of the motor component of other cranial nerves also has been successfully performed. EMG monitoring of the trigeminal nerve can be accomplished with electrodes placed over or in the temporalis or masseter muscles. Trigeminal nerve motor monitoring has been used during nerve section for tic douloureux to ensure preservation of the motor branch of the trigeminal nerve and in combination with facial nerve monitoring during resection of large posterior fossa lesions.[72] Using recording electrodes placed in or over the trapezius or sternocleidomastoid muscles, the spinal accessory nerve has been successfully monitored during resection of large meningiomas, glomus jugulare tumors, and neck carcinomas.[72] EMG monitoring of the hypoglossal nerve with needle electrodes placed in the tongue has been infrequently used for large posterior fossa lesions and clivus tumors.[72] Although EMG monitoring of the eye muscles can be performed using tiny hook wires for recording, it is rarely used.

Monitoring of peripheral motor nerves has been performed by placing needle electrodes in or over the muscles innervated by

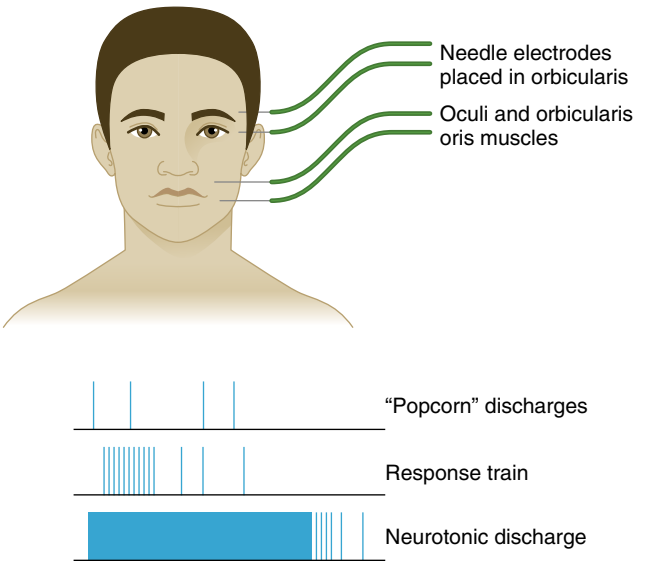

Figure 46-12 Schematic of facial nerve monitoring and typical responses seen during surgery.

nerves that traverse the operative area and are at risk from the planned surgical procedure. Auditory feedback from EMG monitoring can warn the surgeon of unexpected surgical trespass of the nerve, help locate a nerve within the field (e.g., during untethering of the spinal cord), and localize the level of any conduction block or delay. Because radiculopathies have been reported to occur after spine surgery, EMG monitoring of peripheral nerves has been used in patients undergoing spine surgery to decrease the risk of nerve root injury during the procedure.[72]

Clinical Applications of Neurologic Monitoring

Neurovascular Surgery (also see Chapter 63)

Extracranial Neurovascular Surgery: Carotid Vascular Surgery (Monitors: EEG, SSEPs, TCD, Cerebral Oximetry)

Electroencephalogram. The use of the EEG as a monitor of the adequacy of CBF during carotid endarterectomy has been established for many years. In a large series of patients undergoing carotid endarterectomy at the Mayo Clinic,[36] the EEG was compared with regional CBF using the ^{133}Xe washout method. This study validated the EEG as an indicator of the adequacy of regional CBF.

Normal CBF in gray and white matter averages 50 mL/100 g/min. With most anesthetic techniques, the EEG begins to become abnormal when CBF decreases to 20 mL/100 g/min. The threshold for EEG changes apparently is much lower (8 to 10 mL/100 g/min), however, when isoflurane is used.[74] Cellular survival is not threatened until CBF decreases to 12 mL/100 g/min (lower with isoflurane). The difference in blood flow between when the EEG becomes abnormal and the blood flow at which cellular damage begins to occur provides a rational basis for monitoring the EEG during carotid surgery. In many cases, prompt detection of EEG changes may allow intervention (e.g., shunting, increasing cerebral perfusion pressure) to restore CBF before onset of permanent neurologic damage. Standard hemodynamic monitoring provides no direct information about the adequacy of CBF. Blood pressure is not a specific indicator of the adequacy of CBF. Significant hypotension is not predictably associated with EEG evidence of cerebral ischemia. Severe anemia and decreases in oxygen saturation also decrease oxygen delivery. EEG activity becomes abnormal when increased blood flow cannot compensate for decreased arterial oxygen content.

Serious intraoperative reduction in cerebral oxygen supply may result from surgical factors (e.g., carotid cross-clamping) that are usually beyond the anesthesiologist's control, and from factors that the anesthesiologist can correct. Reduction in CBF produced by hyperventilation, hypotension, or temporary occlusion of major blood vessels may be corrected by reducing ventilation, by restoring normal blood pressure, or, in the case of temporary vessel occlusion, by increasing blood pressure above normal. Because the EEG may readily detect cerebral ischemia, continuous EEG monitoring may be used to evaluate the effectiveness of therapy instituted to correct ischemia.

If monitoring of the EEG could be proved scientifically to reduce the incidence of stroke during carotid vascular surgery, EEG monitoring would be established as a standard of care. Definitive data showing stroke reduction do not yet exist, however, and given the number of patients required to power a trial that would show a reduction in stroke rate from 2% to 1%, such studies are unlikely to be funded or forthcoming. What data are available do not provide a basis to recommend universal use of EEG monitoring during carotid surgery. In a large series of patients undergoing carotid endarterectomy with selective shunting who were monitored with 16-channel unprocessed EEG, no patient awakened with a new neurologic deficit that was not predicted by EEG.[75] Transient, correctable EEG changes were not associated with stroke. Persistent changes were associated with stroke. This study had no comparison group, however, analyzing stroke rate when EEG monitoring was not used during surgery.

In the North American Symptomatic Carotid Endarterectomy Trial and the European Carotid Surgery Trial, retrospective comparison of patients receiving EEG monitoring and patients not receiving EEG monitoring failed to show a significant difference in outcome.[76,77] Because the EEG detects reductions in CBF that would not otherwise be apparent in unmonitored patients, and permits intervention that may correct the problem (usually placing a shunt or increasing blood pressure), EEG monitoring should logically be useful in reducing the incidence of stroke when selective shunting is used. Data available from studies at this time bring us no closer to resolving this question, however, than we were 30 years ago. Advocates of monitoring and individuals who believe monitoring is of no value can cite multiple studies supporting each viewpoint.

Even more difficult to prove is that EEG monitoring is useful when all patients are shunted during carotid clamping. Such monitoring has detected correctable shunt malfunction, and investigators have described hypotension-related EEG changes in patients with critical stenoses and poor collateral circulation.[78] Advocates of selective shunting based on EEG (or other monitoring) criteria claim that inserting a shunt unnecessarily through a region of diseased vessel would surely increase embolization. A multicenter study of 1495 carotid endarterectomies provides some evidence that shunting of patients without evidence of decreased cerebral perfusion increases the incidence of stroke more than sixfold.[79] Although this study and other more recent studies[80-82] advocate that selective shunting using some form of monitoring of the adequacy of CBF should improve perioperative stroke rate, an analysis by the Cochrane Stroke Group[83] failed to show sufficient evidence to advocate for routine shunting, selective shunting, or even no shunting at all. Until compelling studies addressing this issue are done, it is unlikely that EEG monitoring during carotid vascular surgery would become a standard method.

Processed EEG also has been used during carotid vascular surgery. Two issues affect the efficacy and reliability of processed EEG as a monitor for cerebral ischemia. First, what is the minimum number of channels (or areas of the brain) to be monitored? The 16-channel unprocessed EEG is a reliable and sensitive monitor for intraoperative cerebral ischemia during carotid endarterectomy. In a series of more than 2000 patients monitored with 16-channel EEG at the Mayo Clinic, there were no false-negative EEGs[75]; in other words, no patient had undetected intraoperative cerebral injury. In operating rooms where carotid surgery is performed, however, 16-channel EEG monitored by a dedicated technician is unavailable. Processed EEG using less than 16 channels is used much more commonly. Clinical experience and clinical

investigations suggest that four channels (two per side) are the minimum number of channels for adequate sensitivity and specificity.[37] When a limited number of channels were compared with 16-channel EEG monitoring, 100% sensitivity and specificity were obtained using 2 channels per hemisphere, provided that those channels monitored the middle cerebral artery territory. These results were obtained with a frontoparietal channel combined with a frontotemporal channel.[37]

The second issue is the experience level of the observer monitoring the processed EEG. Is a dedicated, experienced technician or electroencephalographer needed? In a study addressing this question, the 16-channel unprocessed EEG monitored by a dedicated technician was compared with a processed EEG reviewed by three anesthesiologists of differing levels of experience with processed EEG.[38] The three anesthesiologists interpreted the tracings without knowledge of the case. They were presented only with the written trace with an indication of the point at which the carotid artery was clamped. In these cases, the most important interpretation pitfall to avoid is the "false-negative" pattern. If the clinician interprets the EEG as showing adequate CBF when in fact it does not, the surgeon may fail to shunt an ischemic patient. A false-positive result may be less of a problem because that patient is not ischemic but is given a shunt anyway. In this case, only the risk of emboli from the "unnecessary" shunt is incurred. The positive predictive value of the anesthesiologist correctly interpreting the trace as unchanged after clamping was 91% to 98%, which indicates that the device can be used by novice interpreters with fair accuracy to determine the presence of cerebral ischemia at the time of carotid occlusion. In this study, the review by the anesthesiologist was not done during the course of the procedure, but rather "off line," and does not address the issue of whether an anesthesiologist providing the intraoperative anesthetic management of the patient can provide adequate monitoring of the processed EEG simultaneously.

EEG monitoring has limitations. Despite the data available from the Mayo Clinic, immediately evident postoperative strokes have been reported in patients without any evidence of EEG changes intraoperatively. In our experience, such strokes result from emboli via the lenticulostriate arteries to subcortical structures that do not generate or affect the EEG, but are critically involved in the descending motor pathway. Overall, such events are rare.

Should the patient undergoing carotid endarterectomy have EEG monitoring? That question cannot be answered based on any available data. EEG monitoring provides information about CBF that would not otherwise be available. The clinician has an opportunity to intervene to increase inadequate blood flow when it occurs. Anecdotally, many clinicians have found such monitoring useful and use it routinely. Population studies do not support routine use, and it is up to the clinician to decide whether to use it.

Somatosensory Evoked Potentials. SSEP monitoring also has been used to gauge adequacy of CBF to the cerebral cortex and subcortical pathways during carotid vascular surgery.[56,84,85] SSEPs have been found in the laboratory to have a similar but slightly lower threshold for failure compared with the EEG. SSEPs are generally intact until the cortical blood flow decreases to less than 15 mL/100 g/min.[54] In a few comparison studies with the EEG, a similar sensitivity and specificity for postoperative neurologic function was found. These studies involved few patients, however, and are inadequate to support the hypothesis that SSEP monitoring may substitute for EEG monitoring of the adequacy of CBF.[84-86] Logic also would suggest that changes in SSEP are unlikely, for example, with ischemia involving the anterior portions of either the frontal or temporal lobe, which could readily be detected by an appropriately placed EEG electrode. Finally, a more recent meta-analysis does not support the use of SSEPs during carotid vascular surgery as a sole monitor of neurologic function.[87] There is even less outcome evidence to support the use of SSEPs during carotid surgery than there is for the EEG, but the authors and others have found SSEPs to be useful as a simultaneous monitor with EEG to detect subcortical ischemia.

Transcranial Doppler. TCD monitoring during carotid vascular surgery is based on measurement of two primary parameters—blood flow velocity in major conducting arteries leading to the cerebral cortex (most commonly middle cerebral artery) and the number of emboli detected in the same artery. The hypothesis justifying the use of this monitoring during carotid vascular surgery has two components: blood flow velocity correlates with CBF, and increasing numbers of emboli increase the likelihood of emboli related cerebral ischemia or stroke. The first component has not been well tested and shows variable results. An early study in a small group of patients undergoing carotid surgery did not show good correlation between CBF and blood flow velocity.[88] Subsequent studies in patients with varying intracranial pathology have yielded mixed results.[89-92]

The correlation between CBF and TCD-measured blood flow velocity remains good over time only when the artery being insonated does not change diameter, and when cortical blood flow in the distribution of the measured artery does not have significant collateral sources of blood flow. The relationship between emboli count and stroke is better established with multiple studies conducted in the preoperative, intraoperative, and postoperative periods indicating that higher emboli counts are associated with higher stroke risk and warrant intervention.[93-99]

Intraoperative use of TCD has not been widely adopted for many reasons. As previously noted, good TCD signals cannot be obtained in many individuals who could benefit from monitoring. Also, TCD probe motion during surgery causes major problems with loss of signal or with angle of insonance–induced changes in the relationship between blood flow velocity and blood flow. Nonetheless, multiple series of carotid endarterectomies with TCD monitoring have been reported with good success, quoting a critical blood flow velocity reduction around 50% as indicative of inadequate CBF requiring intervention (shunt or increased blood pressure or both).[93-99] There are no good outcome data supporting TCD use intraoperatively, but data regarding emboli count and risk of stroke suggest that if technical issues with probe attachment to the patient can be overcome, TCD may be useful as a predictor of impending stroke in the preoperative, postoperative, and perhaps intraoperative periods.

Cerebral Oximetry (Near-Infrared Spectroscopy). Near-infrared spectroscopy (NIRS) is an attractive monitor because of its ease of application and lack of training required for interpretation. The hypothesis governing its use is very simple: As oxygen delivery to the brain decreases, oxygen extraction from arterial blood increases, and the oxygen saturation in cerebral venous blood decreases. NIRS applied to cerebral monitoring measures

the oxygen saturation in the cerebral venous blood in the prefrontal cortex and promptly detects increases in oxygen extraction resulting from decreased oxygen delivery. Multiple case reports and series document the use of cerebral oximetry during neurovascular surgery, but several major questions surrounding use of NIRS during carotid surgery remain unanswered.

The first and most important question is what degree of decrease in oxygen saturation can be tolerated before intervention is necessary. Because most interventions involve some risk (e.g., shunt → emboli, increased BP → myocardial ischemia), the answer to this question is important. The answer does not yet exist, however, and may vary from patient to patient. Two more recent studies showed that in awake patients, the saturation value at which any patient would develop symptoms varied from patient to patient,[100,101] and an absolute value that required shunting could not be determined. Another study showed that cerebral oxygen saturation decreased before the EEG developed changes, and the authors used this observation to claim superiority for NIRS monitoring of the brain during carotid surgery.[102] This finding should not be surprising, however, because function of the brain (in this case, electric function) does not fail until increased extraction of oxygen no longer meets metabolic demands for the tissue. If metabolic demands are being met by increased extraction, it is unclear that intervention is needed.

Finally, a study by Friedell and colleagues[103] compared NIRS with EEG and SSEP monitoring during carotid surgery. In 24 of 323 patients, significant differences were observed between NIRS and monitors of electric function. Seventeen patients showed no changes in electric function with significant decreases in cerebral oxygen saturation. In seven patients, no change in cerebral oxygen saturation occurred despite significant change in the EEG and SSEP. These data in combination with the data from studies in awake patients suggest that use of NIRS alone during carotid vascular surgery may be inappropriate.

Intracranial Neurovascular Surgery (Monitors: SSEPs)

Somatosensory Evoked Potentials. SSEPs have been extensively studied during cerebral aneurysm surgery. During these procedures, the surgical incision and brain retraction precludes placement of scalp or brain surface electrodes that could detect cerebral ischemia in at-risk cortex. Recording electrodes placed on the surface of the brain have been used successfully, but they are commonly considered "in the way" by neurosurgeons. Scalp electrodes may be placed easily for SSEP monitoring, although the recording montage is frequently not the same as that used in an awake patient.

For aneurysms involving the anterior cerebral circulation, SSEP monitoring has an excellent, but not perfect, record for predicting postoperative neurologic function. Most patients without surgically induced SSEP changes during surgery awaken with an unchanged neurologic examination. Patients with significant SSEP changes that do not revert to normal awaken with a new neurologic deficit. Patients with SSEP changes that return to normal after a significant intraoperative change may show at least a transient postoperative deficit, with the severity and duration increasing as the duration of the SSEP change increases. Many authors have reported significant utility of SSEP monitoring in detecting improper aneurysm clip placement (see Fig. 46-8) and in guiding intraoperative blood pressure management, particularly in patients already showing or at significant risk for vasospasm after subarachnoid hemorrhage.[55,104-109] The same success cannot be reported, however, for posterior circulation aneurysms. In these cases, many areas of the cortex and subcortical structures are at risk for damage that cannot be monitored at all by somatosensory pathway function. A significant false-negative monitoring pattern exists for these patients, but changes can still be detected when a surgical insult is sufficiently severe to involve large portions of the brain.[110-113]

Supratentorial Intracranial Nonvascular Surgery (Monitors: Awake Patient, EEG, SSEPs)

During supratentorial procedures, neurologic monitoring can contribute to the precise localization of structures that need to be preserved or conversely supplement the anatomic information provided by imaging with functional data. Three techniques fall under this category: (1) Awake craniotomy can be a suitable approach for the resection of tumors and seizure foci. (2) Intraoperative electrocorticography (i.e., the recording from strategically placed subdural electrodes) is used to target more closely the resection of seizure foci. (3) Localization of the central sulcus and by extension the precentral motor cortex is sometimes helpful, if these structures have been displaced by a tumor.

The most comprehensive approach to the problem of functional localization of brain structures that need to be preserved to achieve a good outcome is to perform entire segments of a supratentorial craniotomy in an awake patient, who is undergoing repeated neurologic examinations targeted to assess the eloquent area at risk. Such procedures are typically divided into exposure, mapping, and resection phases, and can be done with the patient entirely awake or awake only during periods when the neurologic examination needs to be assessed.[114] Common to all these approaches is the need for meticulous locoregional anesthesia of the scalp at the craniotomy site and the pin sites of the head holder.[115] A second requirement is a patient who is well informed about the awake parts of the procedure and willing and able to cooperate. Dexmedetomidine, propofol, and remifentanil are the agents most frequently incorporated into the anesthetic regimens for awake craniotomy.[116] Complications of awake craniotomy include nausea and vomiting, respiratory problems, and "tight" brain, but are typically mild and occur in less than 10% of cases in experienced centers. Seizures triggered by cortical stimulation can be stopped by the application of iced saline to the exposed cortex or a small amount of barbiturate or propofol.

Seizure Focus Localization Surgery

Patients with epilepsy who have seizures that generalize from an anatomically distinct focus may benefit greatly from the surgical resection of that seizure focus.[117] Precise localization of a seizure focus is important for achieving the therapeutic objective of seizure control and for minimizing complications from the resection. With sensitive magnetic resonance tomography techniques, neuronavigation, and recordings of typical seizure activity in the awake patient after placement of subdural and depth electrodes, the anatomic location and the appropriate extent of the resection frequently can be determined preoperatively.[118] These developments have diminished the role of intraoperative recordings from the epileptogenic zone using electrocorticography.[119]

Neurologic monitoring during such a resection is performed using two different techniques. First, activity of the seizure focus can be recorded through electrocorticography. Second, eloquent brain areas next to the seizure focus can be monitored during an awake craniotomy as described in the previous section. Electrocorticography is done by placing a grid of subdural electrodes onto the exposed brain surface and recording spontaneous electric activity. Electrocorticography is constrained by several limitations. The time for such recordings is limited to a few minutes; recordings are limited to interictal discharges, which may not correlate with the epileptogenic focus; and recordings need to be obtained from a brain that is under the effects of general anesthetic agents, which alter the EEG.

To provide good conditions during the recording, the level of anesthesia is lightened (e.g., by use of a strict nitrous-narcotic technique or low concentrations of volatile agents). Provocative techniques, such as hyperventilation or administration of a small dose of methohexital, may be useful to activate the seizure focus. Intraoperative seizure mapping requires the involvement of an expert electroencephalographer familiar with this technique.

Motor Strip Localization

Electrophysiologic monitoring of the somatosensory system in anesthetized patients can provide a simple anatomic guide to the location of the rolandic fissure, which separates the parietal primary sensory and frontal primary motor cortex. The fissure is located by recording cortical SSEPs from a subdural strip electrode that is placed perpendicular to the presumed location of the fissure. The exact location of the fissure is characterized by a reversal in the polarity of the primary cortical response between the electrodes straddling the fissure, as illustrated in the clinical example in Figure 46-13.

Posterior Fossa Surgery (Monitors: BAEPs, Cranial Nerve Monitoring, SSEPs, MEPs)

Beside the cerebellum, the posterior fossa contains within the narrow space of the brainstem many crucial neural structures, including ascending and descending sensorimotor pathways; cranial nerve nuclei; cardiorespiratory centers; the reticular activating system; and the neural networks that underlie crucial protective reflexes, such as eye blink, swallowing, gag, and cough. Posterior fossa surgery is not undertaken lightly, and even small injuries can leave significant neurologic deficits. Although some of these neural structures, such as the sensory or auditory pathway, can be monitored consistently, intraoperative integrity of other neural structures is frequently only inferred from the well-being of neighboring structures amenable to monitoring.

Microvascular Decompression of Cranial Nerves V, VII, and IX

Microvascular decompression is done most frequently for trigeminal neuralgia (cranial nerve V) in patients who present acceptable medical risks for a posterior fossa craniotomy. More rarely, the same approach is used to treat hemifacial spasm or neurovascular compromise of lower cranial nerves. The surgery entails dissecting along the intracranial portion of the nerve, identifying offending blood vessels that encroach on the nerve, and placing an insulating Teflon pad between vessel and nerve. The surgery risks ischemic damage to perforating vessels coming off the offending arteries and cerebellar retraction–related damage to cranial nerves. The facial and vestibulocochlear nerves are at particular risk for stretch-induced injury caused by medial retraction of the cerebellum. Retraction-induced stretch produces a prolongation of the interpeak latency between peaks I and V of the BAEP waveform, ultimately leading to a complete loss of all waves beyond wave I (Fig. 46-14). Failure to release retraction in a timely manner results in postoperative hearing loss. Such monitoring increases the chances for preserved hearing after microvascular decompression.[120-124]

Vestibular Nerve Schwannoma

Vestibular nerve schwannomas are the most common tumors located in the cerebellopontine angle. Because of the common origin of the cochlear component of cranial nerve VIII and the essentially identical intracranial trajectory of the facial nerve, hearing loss and facial nerve palsy are concerns during surgical resection of these tumors. Size and preoperative auditory function are the best predictors of postoperative hearing.[125] For tumors up to about 2 to 3 cm in size, monitoring of BAEPs can increase the chances of preserving hearing.[126] In addition to BAEPs, the facial nerve is monitored through spontaneous and stimulated EMG. Prospective trials have shown a higher percentage of patients with a functional facial nerve 1 year after surgery if facial nerve monitoring was used as previously described. Tonic discharges warn of impending damage caused by stretch or heat (bovie). Sharp section of the nerve may elicit no discharge, and neuromuscular blockade may eliminate the ability to monitor. If the course of the nerve is displaced by the tumor, the surgeon can map its course with a hand-held stimulator and real-time auditory feedback.

Other Posterior Fossa Neoplasms

Monitoring for operations on other neoplasms located in the brainstem typically is individualized to each particular case or to the particular surgical approach. EMG may be recorded not only from the territory of the facial nerve, but also from the tongue to monitor the hypoglossal nerve, and from the glottis through electrodes embedded into a specialized endotracheal tube to monitor the vagus nerve. Such a setup can be used to map the floor of the fourth ventricle functionally, if it is distorted by a tumor.[127] Such monitoring may be insufficient to preserve vital reflexes because only the efferent limb of these reflexes is monitored by recording EMG from innervated muscle.

Use of neurologic monitoring for brainstem ischemia, although done in some centers, is not well documented or supported by clinical studies. Global well-being of the brainstem may be monitored by combining multiple modalities of evoked potentials, such as BAEPs, SSEPs, and MEPs. Each modality monitors a function whose integrity would be considered important in its own right for the functional outcome of an individual patient. As illustrated in Figure 46-15, the cross-section monitored by combining all these modalities still leaves out crucial areas. Given that perfusion occurs through perforating vessels, it is easy to see that monitoring may indicate that all is well or, more likely, that a therapeutic intervention was helpful in restoring function, when clinically the patient is still left with a significant deficit. This occurrence invalidates neither monitoring nor the therapeutic

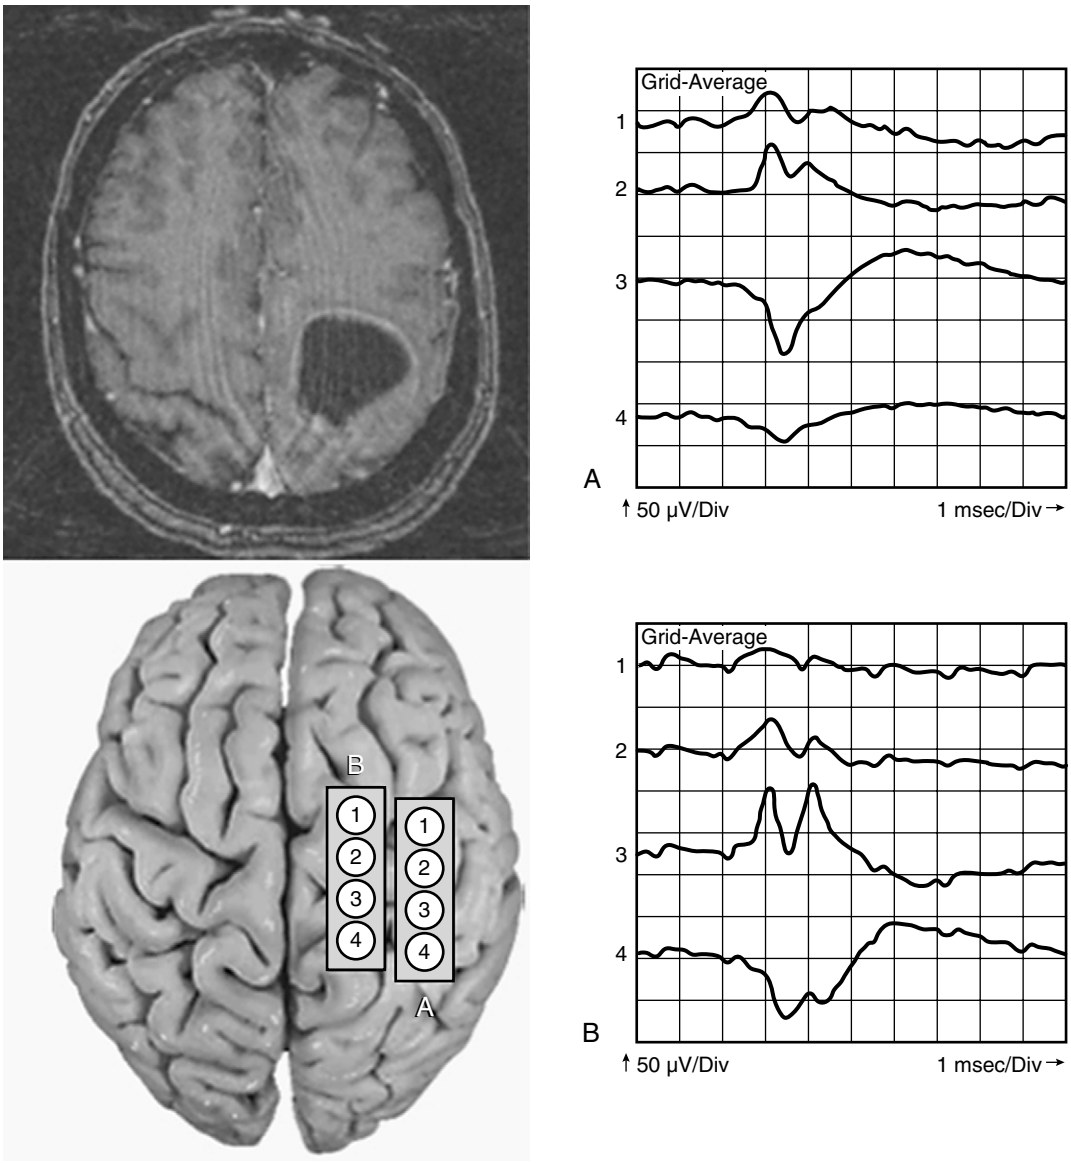

Figure 46-13 Intraoperative localization of the rolandic fissure separating the primary sensory and motor cortex. The clinical example is from a patient with a large parietal tumor shown in the scan. Two of the recordings made from a four-contact subdural electrode strip are shown. The relative positions of the strip electrode are labeled B and A. In recording A, the primary cortical response from the electrodes anterior to the rolandic fissure shows an upward deflection, whereas the response from electrodes posterior to the fissure shows a downward deflection. Moving the strip electrode anterior (recording B) moves this "phase reversal" between electrodes 3 and 4.

intervention, but indicates only that the monitored pathway was not located in an area at risk from the surgical procedure. Because of such obligatory "false-negatives," few studies address the utility of such monitoring. Because each individual monitoring modality comes with its own constraints, such an approach typically requires a dedicated neurophysiologist for interpretation and troubleshooting.

Spinal Column and Spinal Cord Surgery (Monitors: SSEPs, MEPs, EMG)

Intraoperative monitoring of SSEPs has been used most extensively in patients undergoing surgical procedures involving the spinal column or spinal cord, or both. Extensive experience has been gained in patients who have decompressive laminectomies or who have undergone corrective procedures for scoliosis. Intraoperative changes in SSEPs have been noted in 2.5% to 65% of patients undergoing surgical procedures on the spine or spinal cord.[128-131] When these changes are promptly reversed either spontaneously or with interventions by the surgeon or anesthesiologist (e.g., lessening the degree of spine straightening in scoliosis surgery or increasing arterial blood pressure), the patients most often have preserved neurologic function postoperatively. When these changes persisted, however, the patients most often awakened with worsened neurologic function.

False-negative (rare) and false-positive (common) results have been reported with SSEP monitoring during spine surgery. Patients with intact SSEPs throughout the procedure have awak-

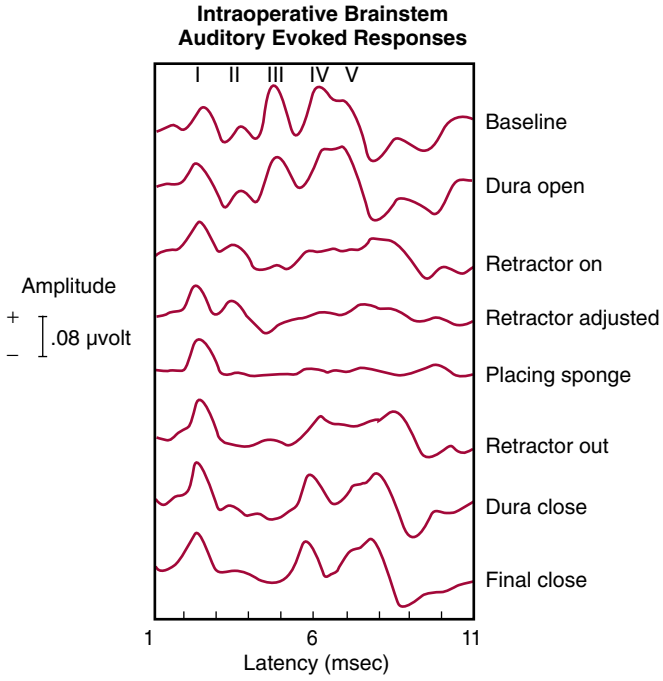

Figure 46-14 Intraoperative monitoring of brainstem auditory evoked responses during microvascular decompression. The baseline recording shows the typical five waves of the brainstem auditory evoked potential response. Intraoperative events are designated to the right of each trace. Placement of the retractor causes a severe increase in latency of wave V even after adjustment of retraction. During placement of the sponge, all waves subsequent to wave I, which originates in the inner ear, are nearly completely lost. Removal of the retractor causes brainstem auditory evoked potentials to revert toward baseline.

ened with a new significant neurologic deficit, but the total reported incidence of this finding is far less than 1% of all cases monitored. Patients with no postoperative neurologic deficit commonly experience significant changes in intraoperative SSEPs.[131] This monitoring pattern is most commonly caused by failure to control for other, nonpathologic factors that may alter the SSEP. Overall, the reliability of properly performed SSEP monitoring to predict the postoperative sensory and motor function has been reported to be excellent.[44,130,132] Motor tracts are not directly monitored by SSEPs, however. In addition, the blood supply to the dorsal columns of the spinal cord, which carries all of the upper extremity SSEPs and at least a portion of the lower extremity SSEPs, is derived primarily from the posterior spinal arteries. The blood supply to motor tracts and neurons is derived primarily from the anterior spinal artery. It is possible for a significant motor deficit to develop postoperatively in patients with intact SSEPs throughout the operative course. Such events have been reported.[133,134]

In operations on the spinal column and after acute spinal cord injury, the sensory and motor changes generally correlate well[44]; however, in patients with neurologic dysfunction after thoracic aortic vascular surgery, frequently posterior spinal cord function (proprioception, vibration, light touch) is left intact when motor and other sensory functions (pain, temperature) are impaired. This result occurred in 32% of patients with neurologic injury after aortic aneurysm repair in one series,[135] with similar results in many other series. Intraoperative SSEP monitoring in these patients carries a significant risk for false-negative results, and as a result, such monitoring is not widely used.

Multiple anecdotal reports and an increasing number of case series suggest that MEP monitoring during surgery on the spine or its blood supply is useful. Several series have reported significant changes in MEPs without changes in SSEPs. These series suggest that combined use of SSEP monitoring and MEP monitoring may eliminate false-negative monitoring patterns during spine surgery.[136-141] In the case of monitoring paraplegia risk during thoracoabdominal aneurysm surgery, the literature shows mixed but improving support for the use of MEP monitoring. Two earlier studies suggested that MEPs may not be as effective as hoped. The first study recorded MEPs from the lumbar spinal cord in dogs produced by transcranial electric stimulation.[135] Elmore and associates[142] found that these spinally recorded potentials did not accurately predict postoperative motor function. In a second study, Reuter and colleagues[143] recorded MEPs at the spinal cord and the peripheral nerve level in dogs produced by transcranial electric stimulation. They also found that the spinally recorded responses were inaccurate in predicting motor function postoperatively. The peripheral nerve responses disappeared in all animals and were not present 24 hours later regardless of whether the animal could move its lower extremities.

These studies suggest that the spinally recorded MEP likely represents a response generated by the descending corticospinal tract. This white matter pathway is resistant to ischemia compared

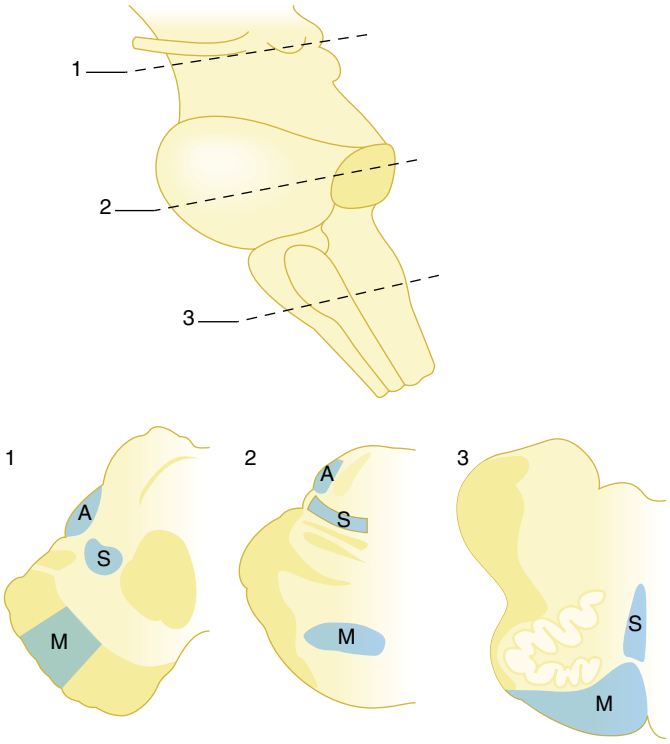

Figure 46-15 Monitoring of the brainstem with evoked potentials. Evoked potentials monitor specific tracts that encompass defined areas in the brainstem. This is shown in three transverse sections approximately at the levels indicated in the drawings. The areas directly monitored by a given modality are indicated in *blue* and labeled M (motor), S (somatosensory), and A (auditory). Conclusions about the well-being of the remainder of the brainstem are made by inference from the monitored areas.

with the more metabolically active anterior horn cells (gray matter). Recovery of this white matter–generated MEP response could occur after reperfusion of the cord, whereas the gray matter might not recover. Responses recorded from the peripheral nerve would reflect postsynaptic anterior horn cell function, but lower extremity ischemia occurring after aortic cross-clamping may preclude recording this or the response from muscles during surgery.

More recent clinical series have shown much greater success with MEP monitoring during aortic vascular surgery in correctly detecting inadequate spinal cord blood flow and in improving operative outcome. The technique has proven useful, particularly when operative strategies such as reimplantation of crucial intercostal vessels based on results of MEP monitoring, alteration of spinal cord perfusion pressure (blood pressure increase or cerebrospinal fluid drainage or both), spinal cord cooling, and other methods are used.[144-153] Although this monitoring technique holds promise in aortic surgery, much more clinical work is needed before MEP monitoring during aortic surgery becomes widely accepted and used.

Peripheral Nerve Surgery (Monitors: EMG, Nerve Action Potential)

Neurologic monitoring for surgeries involving peripheral nerves can be done in two different settings. In the first, the peripheral nerve is intact, but threatened by the surgery. Examples would be an intrinsic nerve tumor, such as a schwannoma or an extensive soft tissue tumor, particularly if it displaces the normal anatomic course of a nerve. Monitoring of spontaneous and stimulated muscle responses from muscle groups innervated by the nerve in question can be used to guide the resection. Spontaneous EMG discharges can be generated by stretch or compression of the nerve, by local heating from electrocautery, or from ischemia. Two caveats apply to the monitoring of spontaneous EMG. First, the neuromuscular junction is part of the monitored pathway, and muscle relaxation decreases/abolishes the sensitivity of monitoring in a dose-dependent manner. Second, sharp section of the nerve may not result in a noticeable discharge. To search out the course of the nerve intraoperatively, the surgeon may stimulate the wound area with a hand-held probe and listen for stimulated EMG or palpate for muscle contraction. The underlying concept should be familiar to anesthesiologists from the use of nerve stimulators in regional anesthesia.

A variation of this technique of monitoring that is gaining popularity is monitoring of pedicle screw placement during spinal instrumentation with the aim of avoiding nerve root injuries owing to malpositioned pedicle screws.[154,155] Typically, the shank of an implanted pedicle screw is stimulated repetitively with increasing current to determine the threshold for eliciting a dermatomal compound muscle potential. Because thresholds vary among cervical, thoracic, and lumbar spine, and between healthy and diseased nerve roots, this technique is currently not universally regarded as useful, but shows some promise.[156]

A second setting where monitoring of peripheral nerves is used is in patients with prolonged weakness and sensory loss after nerve injury undergoing nerve exploration.[157] The aim is to determine whether nerve reconstruction may improve outcome. The area of the lesion is determined by preoperative nerve conduction studies. Intraoperatively, the nerve is first stimulated proximal to the lesion, and a recording of the nerve action potential is made directly from the nerve distal to the lesion, as illustrated in Figure 46-16. If there is nerve conduction across the lesion, lysis of scar is performed, and the incision is closed. Natural recovery by means of axonal regrowth produces the best outcome. If conduction does not occur across the lesion, resection of the damaged nerve and nerve cable grafting is performed.[158-160]

Non-neurologic Surgery That Risks Damage to the Central Nervous System (Monitors: EEG, TCD, Cerebral Oximetry, $SjvO_2$)

Cardiopulmonary Bypass

Electroencephalogram. In humans, changes that occur with the institution of cardiopulmonary bypass (CPB) may alter the EEG via multiple different mechanisms. Plasma and brain levels of anesthetic drugs may be altered by CPB or by anesthetic drugs commonly given at the institution of CPB, alterations in arterial carbon dioxide tension and blood pressure may occur, and hemodilution with hypothermic perfusate nearly always occurs. These effects, all of which may produce EEG changes similar to pathologic changes seen with ischemia, make it difficult to interpret EEG changes occurring around the time of institution of CPB.

Levy and others[161,162] have tried to distinguish the normal effects of hypothermia from other events occurring at the institution of and conclusion of CPB. Initially, Levy concluded that only a qualitative relationship could be determined, but later, with the use of a much more sophisticated EEG analysis technique (approximate entropy), EEG changes associated with changes in temperature could be quantified.

Chabot and colleagues in Boston[163] and Edmonds and colleagues in Louisville[164] have attempted to use quantitative (processed, multiple-channel) EEG during CPB to detect cerebral hypoperfusion and relate these changes to postoperative neurologic function. In addition, some minimal work has been done with intervention after detection of cerebral hypoperfusion using quantitative EEG. Such monitoring techniques have not been widely adopted because although the data seem promising, only a few patients have been studied, and there are very few corroborating studies. In addition, this type of monitoring is extremely costly in time, personnel, and equipment costs, and given the lack of convincing outcome data, the cost-to-benefit ratio is unclear at best. Some other investigators failed to show any convincing relationship between intraoperative EEG parameters and postoperative neurologic function, especially in small infants and children.[165,166] Much work remains to be done studying use of the processed, quantitative EEG to provide information for clinical management of patients during CPB. None of the currently available studies and recommendations would support an evidence-based justification for their routine application.

Transcranial Doppler. TCD also has been used to monitor the cerebral circulation during CPB. Anecdotal reports and case series document the use of TCD for determining adequacy of CBF, detection of emboli, and detection of improper cannula placement.[167] Only very limited outcome data exist, and use of

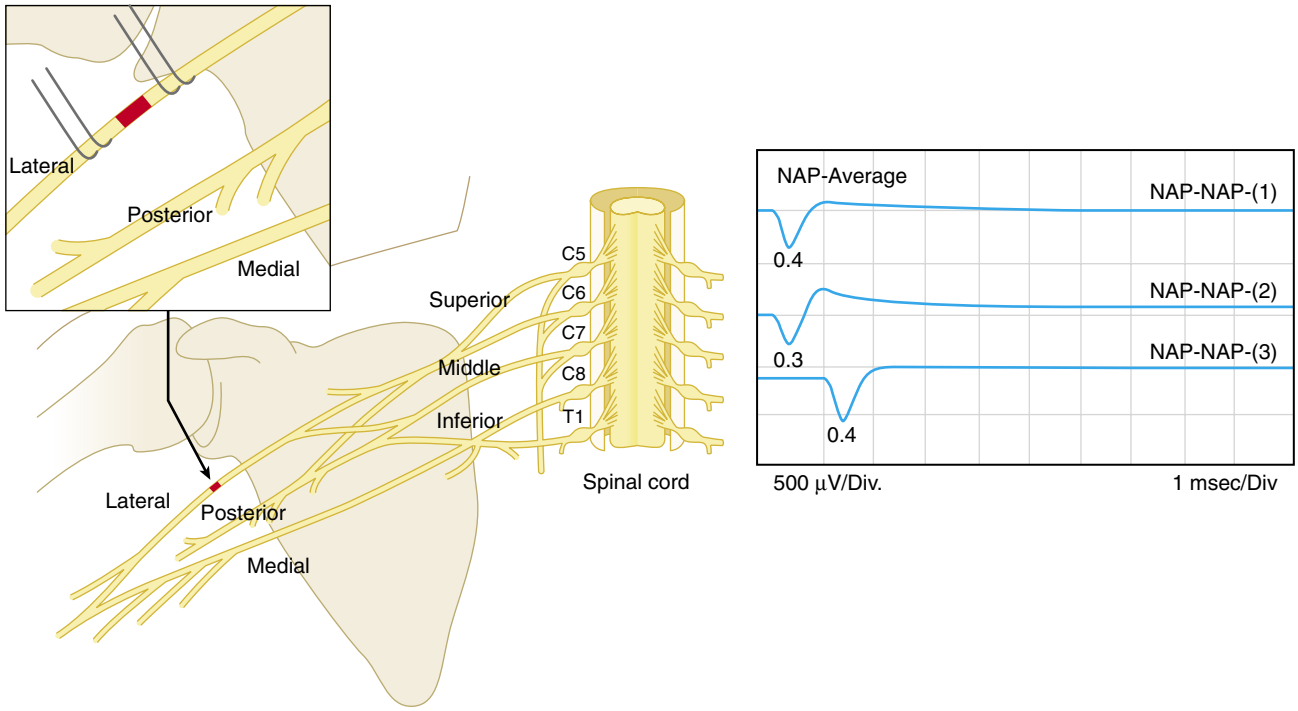

Figure 46-16 Recording a nerve action potential during a brachial plexus exploration. The site of the injury on the lateral fascicle is indicated in *red*. As shown in the *inset,* the surgeon places hook electrodes on either side of the exposed part of the nerve. If the injury is limited to an axonotmesis, proximal stimulation will result in a distal nerve action potential similar to the ones shown in the recording to the right. The delay in the response in the third tracing is simply due to a change in technical settings.

TCD during CPB does not stand up to evidence-based examination, primarily because of lack of information. Probe placement instability and inability to obtain signals in some patients also have limited the use of this monitor intraoperatively.

Cerebral Oximetry and Jugular Venous Oxygen Saturation. As is the case with EEG monitoring during CPB, there are multiple case reports and several series that advocate the use of NIRS or $Sjvo_2$ as indicators of adequate perfusion of the brain during CPB.[168,169] Incorrect placement of CPB cannulas has been detected clinically and in laboratory studies. One more recent series of patients undergoing CPB for coronary bypass surgery showed a higher incidence of major organ system dysfunction and longer hospital stays in patients with lower baseline and intraoperative cerebral oxygen saturation values.[170] The same questions exist for this application of NIRS, however, as do for the use of NIRS during carotid vascular surgery. Use of NIRS during CPB, although it provides information that would not otherwise be available, does not stand up to evidence-based examination, and much more work is needed before NIRS can be recommended as a standard of care during CPB.

$Sjvo_2$ is very invasive. Although data from case reports and studies suggest that $Sjvo_2$ may have utility in detecting inadequate CBF, lack of outcome data, lack of clearly defined critical values at different temperatures during CPB, and availability of more noninvasive modalities (EEG, cerebral oximetry) have resulted in only limited use of this monitoring method during CPB. Based on current information, no neurologic monitoring techniques either alone or in combination are clearly useful in improving outcome during surgery requiring CPB. Further research is needed before the cost in personnel and in equipment of neurologic monitoring during CPB can be justified.

Intensive Care Applications of Neurologic Monitoring (Monitors: EEG, Evoked Potentials, TCD, $Sjvo_2$)

Secondary injury to the CNS has been recognized in past decades as a major modifiable risk factor in patients with CNS disease. Aneurysmal subarachnoid hemorrhage, stroke, and traumatic brain injury are examples of CNS insults in which secondary injury has important implications for the ultimate functional outcome.[171-173] The same diseases frequently result in a primary insult to the CNS that severely constrains the utility of the clinical neurologic examination because of the need for mechanical ventilation and sedation. Many techniques of neurologic monitoring discussed earlier also have been used in the intensive care unit. Generally, however, techniques that require continued presence of skilled technologists, such as monitoring of evoked potentials, are prohibitively expensive and of less practical value than techniques that can be performed as a daily examination, or techniques that provide data easily integrated into the intensive care frame of mind. Along with monitoring, some of the techniques discussed previously also can provide important prognostic information in comatose patients and guide decision making.

Cerebral Ischemia

Cerebral ischemia is an important cause of secondary injury to the CNS. It can be difficult to detect in patients who are either

comatose or sedated, but can occur even in the face of an adequate cerebral perfusion pressure.[174,175] Three techniques may provide intensivists with additional information about cerebral perfusion. None of the monitors is considered "standard of care." As with all monitors, the impact of the monitor on outcome depends on the quality of the therapeutic interventions that result from integration of the additional data into the clinical management of a given patient.

$SjvO_2$ monitoring is used most extensively in the intensive care unit to monitor patients with traumatic brain injury. The data have been used to guide blood pressure and ventilatory management to optimize blood flow. $SjvO_2$ monitoring has had a major effect on ventilatory management of head-injured patients and has significantly reduced the routine use of hyperventilation in neurosurgical patients.[176-180] $SjvO_2$ values of less than 50% generally indicate cerebral ischemia. Increases in $SjvO_2$ may occur in response to therapy, or may be an ominous sign if the increase is caused by falling demand because of neuronal death.

Similar to $SjvO_2$ monitoring, monitoring of $P_{Br}O_2$ and blood flow is used most frequently in patients with traumatic brain injury. $P_{Br}O_2$ performs well in clinical practice. Decreases to less than 10 to 15 mm Hg are associated with worsening outcome,[27,180] whereas $P_{Br}O_2$-targeted treatment strategies may improve outcome.[181] The data for thermal diffusion CBF are not as comprehensive, perhaps reflecting the slightly less robust technology.[182] Nonetheless, in the setting of subarachnoid hemorrhage, thermal diffusion CBF less than 15 mL/100 g/min showed a sensitivity of 90% and a specificity of 75% for detecting symptomatic vasospasm.[19]

TCD is widely used in the intensive care unit to document the presence and severity of cerebral vasospasm after subarachnoid hemorrhage. As the major cerebral arteries narrow, flow velocity within the lumen must increase if blood flow is to be maintained. Such narrowing occurs 12 to 24 hours before the onset of clinical symptoms, allowing therapy to be initiated before the onset of clinical symptoms.[183-187] Mean flow velocities of more than 120 cm/sec seem to correlate well with angiographic vasospasm,[188,189] although intracranial pressure and concurrent therapy with hypertensive hypervolemic hemodilution modify the flow velocity. The latter two factors result in characteristic changes of the TCD waveform, however, preserving the utility of the examination.

Prognosis in Coma and Determination of Brain Death.

EEG monitoring may help to assess the clinical course and the prognosis of comatose patients. Assessment of prognosis must be separated from the insult that precipitated the coma by more than 24 hours. If not, the EEG may reflect predominantly the effect of the insult and may not predict prognosis. More than 24 hours after the insult, spontaneous sustained burst suppression correlates strongly with severe irreversible brain injury.[190] Absence of EEG variability portends a high likelihood of persistent vegetative state or death,[190,191] whereas spontaneous variability, reactivity to external stimuli, and typical sleep patterns are associated with more favorable outcomes.[192-194]

A specific indication for EEG monitoring is the therapeutic induction of a coma by barbiturate administration. Because neither blood nor cerebrospinal fluid concentrations of barbiturates reliably predict burst suppression and near-maximal reduction in cerebral metabolic rate of oxygen consumption,[195] and because barbiturate administration usually requires an increase in cardiovascular support, documentation of a burst suppression pattern on EEG allows the use of the minimal effective dose of barbiturate.

Similar to EEG, evoked potential studies have a place in predicting prognosis in comatose patients. The presence of normal SSEPs bilaterally is an excellent prognostic sign, whereas the absence of any SSEP cortical response is a poor prognostic indicator. The degree of bad outcome can be predicted by BAEPs. Intact and normal BAEPs with absent cortical SSEPs predict a best outcome of a chronic vegetative state. Outcome may be worse, however, because BAEPs commonly deteriorate later with rostral-to-caudal deterioration. Absent BAEP responses beyond wave I predict a high likelihood of brain death. Present but abnormal SSEPs are associated with outcomes intermediate between good/high function and a chronic vegetative state.[196-205]

TCD also has been used in the intensive care unit as an aid to the diagnosis of brain death. As intracranial pressure increases, the pulsatility of the TCD waveform increases, accentuating the systolic peak and diminishing flow during diastole. With further increases in intracranial pressure, a characteristic to-and-fro pattern of flow is established, which is consistent with clinical brain death.[206] TCD studies are easily performed at the bedside and can minimize the need for unnecessary transports of the patient for definitive radiologic studies.

Nonsurgical Factors Influencing Monitoring Results

Anesthesia and the Electroencephalogram

Anesthetic drugs affect the frequency and amplitude of EEG waveforms. Although each drug class and each specific drug has some specific, dose-related EEG effects (Table 46-2), some basic anesthesia-related EEG patterns may be described. Subanesthetic doses of intravenous and inhaled anesthetics usually produce an increase in frontal beta activity and abolish the alpha activity normally seen in the occipital leads in an awake, relaxed patient with the eyes closed. As the patient actually goes to sleep with general anesthesia, the brain waves become larger in amplitude and slower in frequency. In the frontal areas, small beta activity seen in an awake patient slows to the alpha range and increases in size. In combination with the loss of the occipital alpha activity, this phenomenon produces the appearance of a "shift" of the alpha activity from the posterior cortex to the anterior cortex. Further increases in the dose of the inhalation or intravenous agent produce further slowing of the EEG, and some agents have the capability to suppress EEG activity totally (see Table 46-2). Other agents never produce burst suppression or an isoelectric EEG, despite increasing dose, either because they are incapable of completely suppressing the EEG (e.g., opioids, benzodiazepines) or because cardiovascular toxicity of the drug (e.g., halothane) prevents administration of a large enough dose.

Intravenous Anesthetic Drugs

Barbiturates, Propofol, and Etomidate. Despite widely varying potencies and durations of action, barbiturates, propofol, and etomidate produce similar EEG patterns (Fig. 46-17 shows

Table 46-2 Anesthetic Drugs and Electroencephalogram (EEG)

Drug	Effect on EEG Frequency	Effect on EEG Amplitude	Burst Suppression?
Isoflurane			Yes, >1.5 MAC
Subanesthetic	Loss of alpha, ↑ frontal beta	↑	
Anesthetic	Frontal 4-13 Hz activity	↑	
Increasing dose >1.5 MAC	Diffuse theta and delta → burst suppression → silence	↑ → 0	
Desflurane	Similar to equi-MAC dose of isoflurane	Similar to equi-MAC dose of isoflurane	Yes, >1.5 MAC
Sevoflurane	Similar to equi-MAC dose of isoflurane	Similar to equi-MAC dose of isoflurane	Yes, >1.5 MAC
Nitrous oxide (alone)	Frontal fast oscillatory activity (>30 Hz)	↑, especially with inspired concentration >50%	No
Enflurane			Yes, >1.5 MAC
Subanesthetic	Loss of alpha, ↑ frontal beta	↑	
Anesthetic	↑ frontal 7-12 Hz activity	↑	
Increasing dose >1.5 MAC	Spikes/spike and slow waves → burst suppression; hypocapnia → seizures	↑↑ → 0	
Halothane			Not seen in clinically useful dosage range
Subanesthetic	↑ frontal 10-20 Hz activity	↑	
Anesthetic	↑ frontal 10-15 Hz activity	↑	
Increasing dose >1.5 MAC	Diffuse theta, slowing with increasing dose	↑	
Barbiturates			Yes, with high doses
Low dose	Fast frontal beta activity	Slight ↑	
Moderate dose	Frontal alpha frequency spindles	↑	
Increasing high dose	Diffuse delta → burst suppression → silence	↑↑↑ → 0	
Etomidate			Yes, with high doses
Low dose	Fast frontal beta activity	↑	
Moderate dose	Frontal alpha frequency spindles	↑	
Increasing high dose	Diffuse delta → burst suppression → silence	↑↑ → 0	
Propofol			Yes, with high doses
Low dose	Loss of alpha, ↑ frontal beta	↑	
Moderate dose	Frontal delta, waxing/waning alpha	↑	
Increasing high dose	Diffuse delta → burst suppression → silence	↑↑ → 0	
Ketamine			No
Low dose	Loss of alpha, ↑ variability	↑↓	
Moderate dose	Frontal rhythmic delta	↑	
High dose	Polymorphic delta, some beta	↑↑ (beta is low amplitude)	
Benzodiazepines			No
Low dose	Loss of alpha, increased frontal beta activity	↑	
High dose	Frontally dominant delta and theta	↑	
Opiates			No
Low dose	Loss of beta, alpha slows	↔ ↑	
Moderate dose	Diffuse theta, some delta	↑	
High dose	Delta, often synchronized	↑↑	
Dexmedetomidine	Moderate slowing, prominent spindles	↑↑	No

*delta = <4 Hz frequency; theta = 4-7 Hz frequency; alpha = 8-13 Hz frequency; beta = >13 Hz frequency.
MAC, minimum alveolar concentration.

EEG effects of thiopental). These drugs all follow the basic anesthesia-related EEG pattern described previously with initial EEG activation (see Fig. 46-17A), followed by dose-related depression. As the patient loses consciousness, characteristic frontal spindles are seen (see Fig. 46-17B), which are replaced by polymorphic 1- to 3-Hz activity (see Fig. 46-17C) as the drug dose is increased. Further increases in dose result in lengthening periods of suppression interspersed with periods of activity (burst suppression). With a very high dose, EEG silence results. All of these drugs have been reported to cause epileptiform activity in humans, but epi-

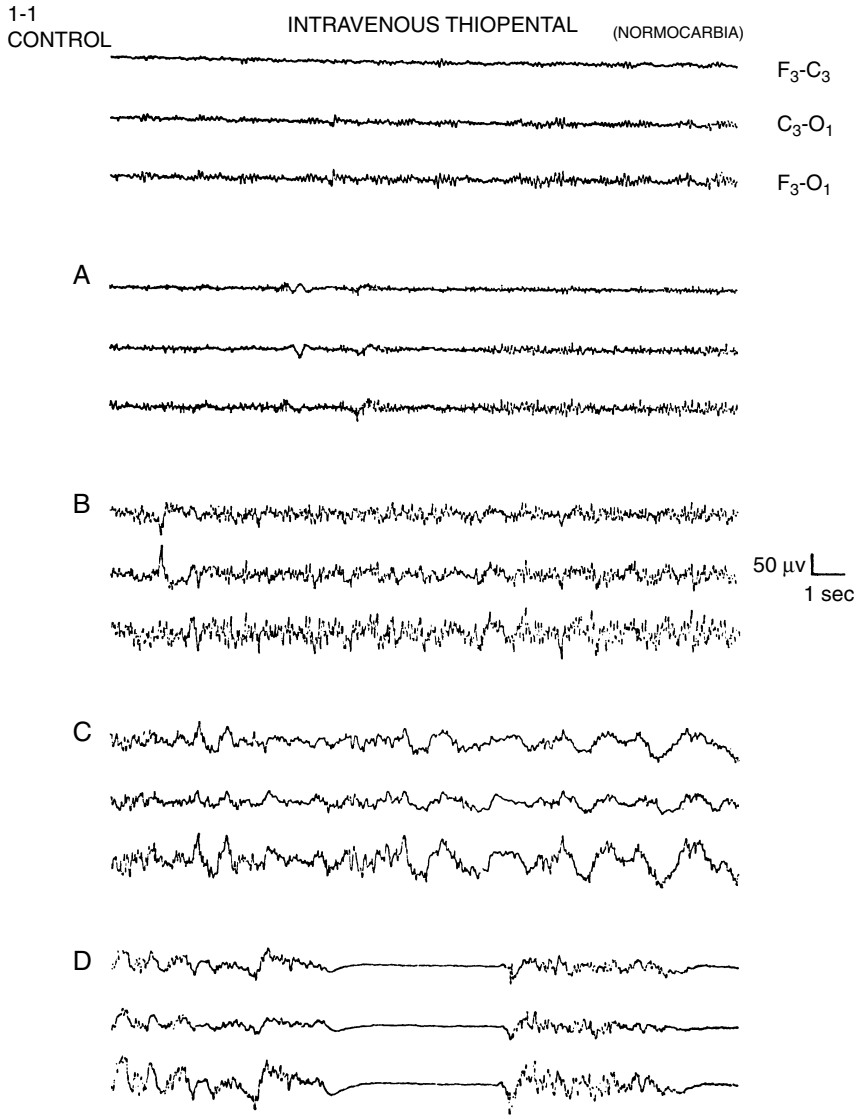

Figure 46-17 Electroencephalogram effects of intravenous administration of thiopental in humans. **A,** Rapid activity. **B,** Barbiturate spindles. **C,** Slow waves. **D,** Burst suppression. *(From Clark DL, Rosner BS: Neurophysiologic effects of general anesthetics. Anesthesiology 38:564, 1973.)*

leptiform activity is clinically significant only after methohexital and etomidate when given in subhypnotic doses.

Ketamine. Ketamine does not follow the basic anesthesia-related EEG pattern. Anesthesia with ketamine is characterized by frontally dominant rhythmic, high-amplitude theta activity. Increasing doses produce intermittent polymorphic delta activity of very large amplitude interspersed with low-amplitude beta activity.[207] Electrocortical silence cannot be produced with ketamine. EEG activity may be very disorganized and variable at all doses. This disorganization of the EEG with ketamine is responsible for the failure of the bispectral index to be useful in looking at the effect of ketamine on consciousness. Recovery of normal EEG activity even after a single bolus dose of ketamine is slow compared with barbiturates. There is no information available about the relationship between emergence reactions after ketamine and the EEG. Ketamine also has been associated with increased epileptiform activity.[207]

Benzodiazepines. Despite varying potencies and durations of action, benzodiazepines also follow the basic anesthesia-related EEG pattern. As a class, however, these drugs are incapable of producing burst suppression or an isoelectric EEG.

Opioids. As a class, opioids do not follow the basic anesthesia-related EEG pattern. Opioids generally produce a dose-related decrease in frequency and increase in amplitude of the EEG. If no further doses of opiates are given, alpha and beta activity return as drug redistribution occurs. The rapidity of return depends on the initial dose and on the drug. Remifentanil is associated with the most rapid return to normal.[208] Complete suppression of the EEG cannot be obtained with opioids. Epileptiform activity occurs in humans and in animals receiving large to supraclinical doses of opioids. Sharp wave activity is common after induction of anesthesia with fentanyl, with 20% of patients showing this phenomenon after 30 µg/kg; 60%, after 50 µg/kg; 58%, after 60 µg/kg; and 80%, after 70 µg/kg. Alfentanil bolus has

been used clinically to activate seizure foci during epilepsy surgery.[209] This epileptiform activity is mainly noted in the frontotemporal region.[210]

Dexmedetomidine. Dexmedetomidine is being increasingly used for sedation in the operating room and in the intensive care unit. EEG studies of patients undergoing sedation with dexmedetomidine alone show patterns similar to those seen in normal human sleep with increased slow-wave activity and sleep spindles prominent.[211] Burst suppression or an isoelectric EEG pattern cannot be produced even with high doses of the drug. Level of sedation with dexmedetomidine can be effectively monitored using processed EEG parameters and has been reported using bispectral index and entropy techniques.[212]

Inhaled Anesthetics

Nitrous Oxide. Used alone, nitrous oxide causes a decrease in amplitude and frequency of the dominant occipital alpha rhythm. With the onset of analgesia and depressed consciousness, frontally dominant fast oscillatory activity (>30 Hz) is frequently seen.[213] This activity may persist to some extent for 50 minutes after discontinuation of nitrous oxide. When nitrous oxide is used in combination with other agents, it increases the effects that would be associated with the agent alone clinically and with respect to the EEG pattern seen.

Isoflurane, Sevoflurane, Enflurane, Halothane, and Desflurane. Potent inhaled anesthetics follow the basic anesthesia-related EEG pattern. Isoflurane initially causes an activation of the EEG followed by a slowing of the EEG activity that is more marked with increasing dose. Isoflurane begins to produce periods of EEG suppression at 1.5 minimum alveolar concentration (MAC), which become longer with increasing dose until electric silence is produced at 2 to 2.5 MAC. Isolated epileptiform patterns sometimes can be seen during intersuppression activity at 1.5 to 2 MAC isoflurane.[214] Sevoflurane causes similar dose-dependent EEG effects. Equi-MAC concentrations of sevoflurane and isoflurane cause similar EEG changes.[215] Epileptiform activity has been induced by administration of sevoflurane in patients without epilepsy, and seizure activity on EEG, but not clinical seizure activity, has been reported in pediatric patients with a history of epilepsy during induction of anesthesia with sevoflurane.[216,217] Despite these observations, sevoflurane, similar to other inhalation agents, is not suitable for use during electrocorticography for localization of seizure foci.[218] EEG patterns seen with enflurane are similar to the patterns seen with isoflurane except that epileptiform activity is considerably more prominent. At 2 to 3 MAC, burst suppression is seen, but virtually all intersuppression activity consists of large spike/wave pattern discharges. Hyperventilation with high concentrations of enflurane increases the length of suppression, decreases the duration of bursts, but increases the amplitude and main frequency component of the intersuppression epileptiform activity. Frank EEG seizures also may occur with enflurane that produce the same cerebral metabolic effects as pentylenetetrazol, a known convulsant.

Halothane also produces EEG patterns similar to those of isoflurane, but dosages of halothane that would produce burst suppression in the EEG (3 to 4 MAC) are associated with profound cardiovascular toxicity. Desflurane produces EEG changes similar in nature to equi-MAC concentrations of isoflurane. In limited clinical studies, there has been no evidence of epileptiform activity with desflurane, despite hyperventilation and 1.6 MAC dosage,[219] and desflurane has been used as a treatment of refractory status epilepticus.[220]

Clinical studies have shown that the EEG effects of inhalational anesthetic agents are influenced by age and baseline EEG characteristics. Older patients and patients with EEG slowing at baseline were more sensitive to the EEG effects of isoflurane and desflurane. As anesthesia was deepened, similar EEG pattern changes were noted, but these changes occurred at lower end-tidal anesthetic concentrations.[221]

Anesthesia and Sensory Evoked Responses

Volatile Anesthetics

Multiple drugs used in the perioperative period can influence the ability to monitor SERs accurately (Table 46-3). A more recent review provides the interested clinician with a detailed analysis of all drug effects on SERs,[222] which is beyond the scope of this chapter. Table 46-3 does not quantify drug effects, but rather lists whether an individual drug is capable of producing a change in any part of an evoked response that could be mistaken for a surgically induced change. A "no" designation in this table does not mean that there are no effects of a given drug on SERs. The "no" designation indicates that any effects that do occur would not be called clinically significant by *clinicians experienced in intraoperative monitoring*. Several general concepts (Table 46-4) help the clinician who is trying to determine the best choice of drugs for use during monitored cases.

The volatile anesthetics isoflurane, sevoflurane, desflurane, enflurane, and halothane have similar effects in differing degrees on all types of SERs. VEPs are the most sensitive to the effects of volatile anesthetics, and BAEPs are the most resistant to anesthetic-induced changes. Spinal and subcortical SSEP responses are significantly less affected than cortical potentials.[223-225]

SSEPs, because they are the most widely used intraoperative SER technique, are the most completely studied with respect to the effects of anesthetic drugs. The effects of the currently used volatile agents on cortical SSEPs are dose-dependent increases in latency and conduction times and a decrease in amplitude of cortically, but not subcortically recorded signals.[223-227] When comparing the different volatile agents, studies have reported conflicting results.[223,225] One study suggests that halothane has a greater impact on cortical SSEPs than either isoflurane or enflurane,[225] whereas another published report supports a greater effect produced by enflurane and isoflurane than halothane.[223] None of these differences are clinically important and may be ignored by the practicing clinician. With respect to the newer agents, desflurane and sevoflurane seem to have qualitatively and quantitatively similar effects on SERs as isoflurane.[228-232] In neurologically normal patients, 0.5 to 1 MAC of any of the potent inhaled agents in the presence of nitrous oxide is compatible with monitoring of cortical SSEPs (Figs. 46-18, 46-19, and 46-20).[223,227] Neurologically impaired patients may show a significantly greater sensitivity to inhaled agents, even to the point of not tolerating any recordable level of inhaled agent. Generally, better monitoring conditions are obtained, however, with narcotic-based anesthetics with less than 1 MAC total (nitrous oxide plus potent agent) end-tidal inhaled anesthetic concentration.

Table 46-3 Ability of an Individual Anesthetic Drug to Produce a Change in Sensory and Motor Evoked Potentials That Could Be Mistaken for a Surgically Induced Change

	SSEPs		BAEPs		VEPs		Transcranial MEPs	
Drug	**LAT**	**AMP**	**LAT**	**AMP**	**LAT**	**AMP**	**LAT**	**AMP**

Note: This table is not quantitative in any way. "Yes" or "no" designations indicate whether an individual drug is capable of producing an effect on any portion of the evoked response that could be mistaken for a surgically induced change.
*Increases the effect of the agent(s) with which it is used.
(p): Use of this drug and any dose may render this type of monitoring impossible for a signifieant period of time.
AMP, amplitude; BAEPs, brainstem auditory evoked potentials; LAT, latency; MEPs, motor evoked potentials; ND, no data available from the literature; SSEPs, somatosensory evoked potentials; VEPs, visual evoked potentials.

The volatile anesthetics result in increases in latency of BAEPs without significantly affecting the amplitude.[227,233-235] Volatile anesthetics cause increases in latency and decreases in amplitude in the early (middle latency) cortical responses after auditory stimulation,[234] however, and these middle latency responses are now being used to monitor the hypnotic component of general anesthetics.[32] Adequate monitoring of BAEPs is possible with any clinically useful concentrations of inhaled agents (with or without nitrous oxide) (Figs. 46-21 and 46-22).[227,233-236]

Use of the volatile agents during monitoring of VEPs results in dose-dependent increases in latency with or without changes in amplitude.[227,237-240] Isoflurane results in dose-dependent increases in latency and decreases in amplitude up to 1.8% in 100% oxygen, at which time the waveform is lost.[227,237] Enflurane in the absence of hypocarbia also leads to decrease in amplitude.[237] Halothane causes increases in latency without changes in amplitude.[238,239] Although the data from these studies seem valid, the results are not clinically relevant because the variability of VEPs in anesthetized patients is so great that satisfactory monitoring, in the opinion of many experts, is impossible using any anesthetic technique.

Although volatile anesthetics cause significant changes in the SER waveforms, it is possible to provide adequate monitoring intraoperatively in the presence of anesthetic doses of volatile anesthetics. Doses of agents causing significant depression of the

Table 46-4 Guidelines for Choosing Anesthetic Techniques During Procedures in Which Sensory Evoked Responses Are Monitored

1. Intravenous agents have significantly less effect than "equipotent" doses of inhaled anesthetics
2. Combinations of drugs generally produce "additive" effects
3. Subcortical (spinal or brainstem) sensory evoked responses are very resistant to the effects of anesthetic drugs. If subcortical responses provide sufficient information for the surgical procedure, anesthetic technique is not important, and effects on cortically recorded responses may be ignored

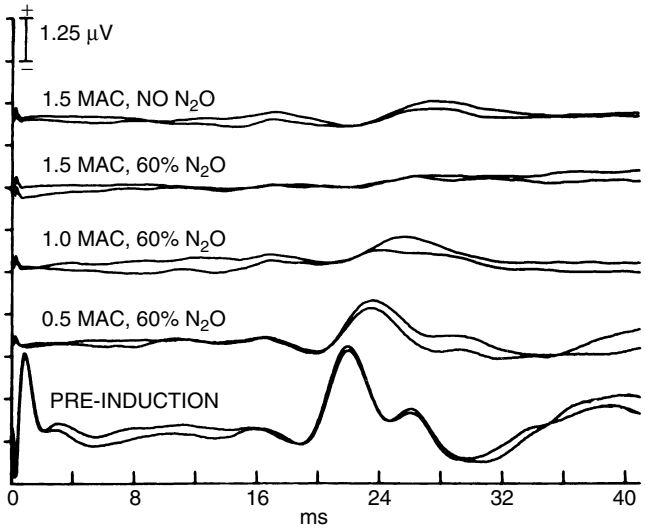

Figure 46-18 Representative somatosensory evoked potential cortical responses (C-3, C-4-FPz) at various minimum alveolar concentration (MAC) levels of isoflurane. *(From Peterson DO, Drummond JC, Todd MM: Effects of halothane, enflurane, isoflurane, and nitrous oxide on somatosensory evoked potentials in humans. Anesthesiology 65:35, 1986.)*

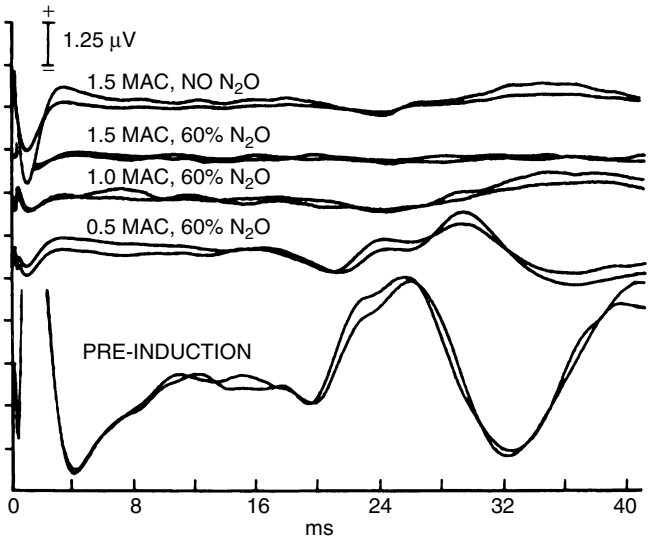

Figure 46-19 Representative somatosensory evoked potential cortical responses (C-3, or C-4-FPz) at various minimum alveolar concentration (MAC) levels of enflurane. *(From Peterson DO, Drummond JC, Todd MM: Effects of halothane, enflurane, isoflurane, and nitrous oxide on somatosensory evoked potentials in humans. Anesthesiology 65:35, 1986.)*

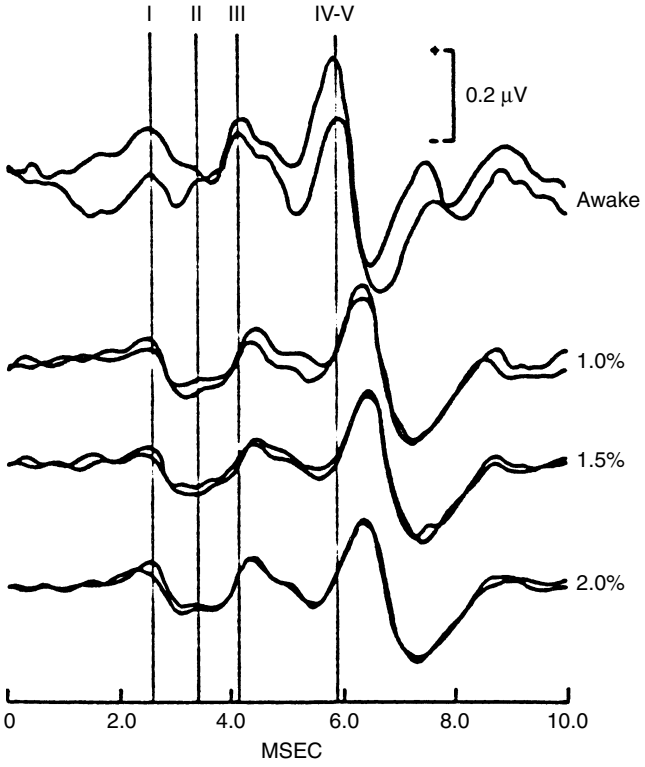

Figure 46-21 Influence of isoflurane alone on brainstem auditory evoked potential in a typical subject. Latency of peaks III and IV to V increased at 1.0%, but stabilized with increasing anesthetic depth. *(From Manninen PH, Lam AM, Nicholas JF: The effects of isoflurane–nitrous oxide anesthesia on brainstem auditory evoked potentials in humans. Anesth Analg 64:43, 1985.)*

response to be monitored must be prevented. In the authors' experience, end-tidal concentrations of inhaled agents totaling greater than 1.3 MAC have a dose-related, increasing probability of obliterating cortical SSEPs even in neurologically normal patients. Equally important, anesthetic concentration should not be changed during the critical periods of intraoperative monitoring. Critical periods are defined as periods in which surgical interventions are most likely to result in damage to neurologic tissue and changes in the SERs. Because the volatile anesthetic-induced changes in SERs are dose-dependent, increasing anesthetic dosage at a crucial point in the operative procedure can result in confusing changes in the SERs that potentially may be caused by the anesthetic, the surgical procedure, or both. The appropriate intervention is difficult to determine.

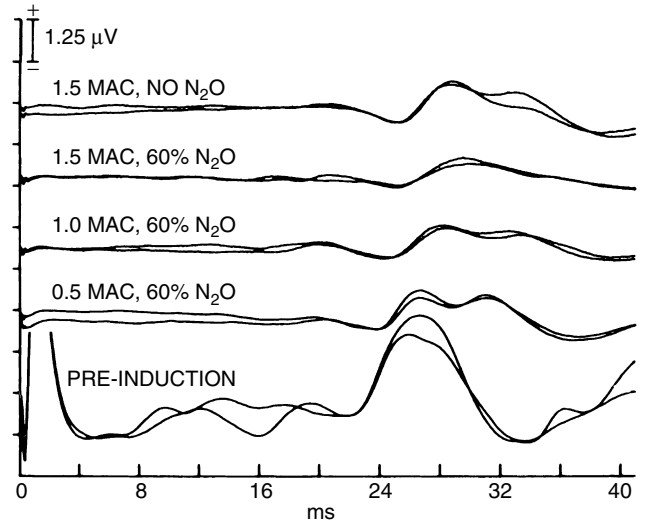

Figure 46-20 Representative somatosensory evoked potential cortical responses (C-3, C-4-FPz) at various minimum alveolar concentration (MAC) levels of halothane. *(From Peterson DO, Drummond JC, Todd MM: Effects of halothane, enflurane, isoflurane, and nitrous oxide on somatosensory evoked potentials in humans. Anesthesiology 65:35, 1986.)*

As with the volatile anesthetics, nitrous oxide causes differing effects on the SERs depending on the sensory system monitored. It causes decreases in amplitude without significant changes in latency in SSEPs when used alone or when added to a narcotic-based or volatile anesthetic.[223,224,241] The addition of nitrous oxide to a maintenance volatile anesthetic during the monitoring of BAEPs causes no further change.[233] Likewise, use of nitrous oxide alone causes no change in BAEPs, unless gas accumulates in the middle ear.[241] Use of nitrous oxide alone results in an increase in latency and a decrease in amplitude in VEPs, but when it is added to a volatile anesthetic technique, it causes no further changes in VEPs.[237,241]

Intravenous Agents

The effects of barbiturates on SERs have been studied in animal models and in humans. Increasing doses of thiopental in patients result in progressive dose-dependent increases in latency, decreases in amplitude of SSEPs, and progressive increases in latency of wave V in BAEPs. The changes in SSEPs are more pronounced than the changes in BAEPs, and waveforms beyond the initial primary cortical response are quickly obliterated. This finding is consistent with the theories that barbiturates affect synaptic transmission more than axonal conduction. Early wave-

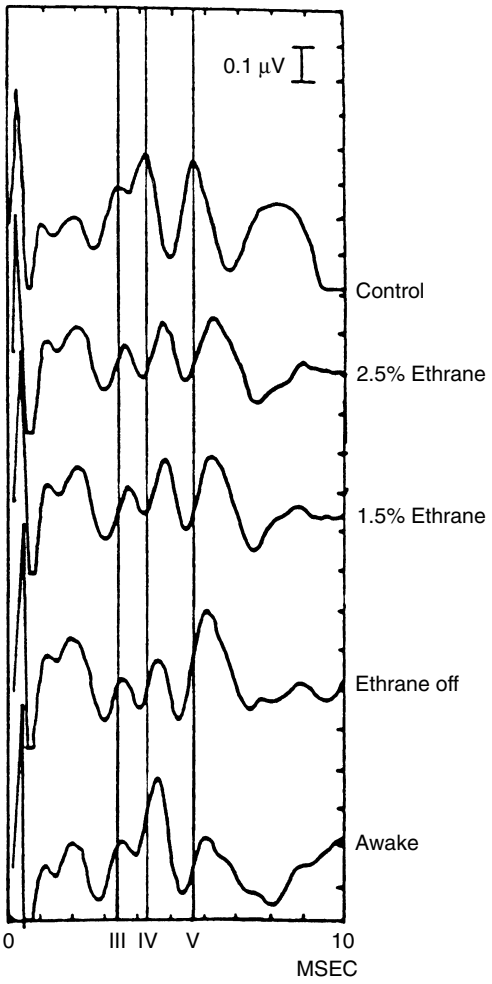

Figure 46-22 Brainstem auditory evoked potential recording obtained in one patient at different enflurane (Ethrane)-inspired concentrations. *(From Dubois MY, Sato S, Chassy J, et al: Effects of enflurane on brainstem auditory evoked responses in humans. Anesth Analg 61:898, 1982.)*

forms in SERs result primarily from axonal transmission, and later waves depend on multisynaptic pathways in addition to axonal transmission. At doses of thiopental far greater than doses producing an isoelectric EEG, adequate monitoring of early cortical and subcortical SSEPs and BAEPs was preserved.[242] Other barbiturate compounds show similar effects. Somatosensory and auditory SERs were never obliterated even at doses greater than those causing complete suppression of spontaneous EEG activity.[243] This observation is important, especially when attempting to monitor the adequacy of CBF during cerebrovascular surgery when the patient has been given large, "protective" doses of barbiturates. The EEG is isoelectric and not helpful for monitoring. The early cortical SSEP waveforms are still preserved, however, and may be very helpful in determining adequacy of CBF. Preserved ability to monitor SSEPs in head-injured patients receiving therapeutic thiopental infusions has been shown.[244] VEPs are much more sensitive to barbiturates. Low barbiturate doses obliterate all except the earliest waveforms. The early potentials persisted with increases in latency even to very high pentobarbital doses.[245] Except for VEPs, adequate perioperative monitoring of SERs is possible even in the presence of high-dose barbiturate therapy as long as the effects of the drug (increased latency with moderately decreased amplitude) are considered.

After bolus administration and intravenous infusions, etomidate causes increases in latency of all waves and prolongation of central conduction time in SSEPs. In contrast to virtually all other commonly used anesthetics, etomidate causes increases in amplitude of the cortical SSEP.[246,247] This effect may be due to an alteration in the balance of inhibitory and excitatory influences or an increase in the irritability of the CNS. This effect seems to be present in the cortex, but not in the spinal cord.[247] Etomidate infusions have been used to enhance SSEP recording in patients when it was impossible to obtain reproducible responses at the beginning of intraoperative monitoring because of the patients' pathology (Fig. 46-23). Following baseline responses that could not be monitored, the etomidate augmentation of the SSEP allowed adequate monitoring and detection of intraoperative

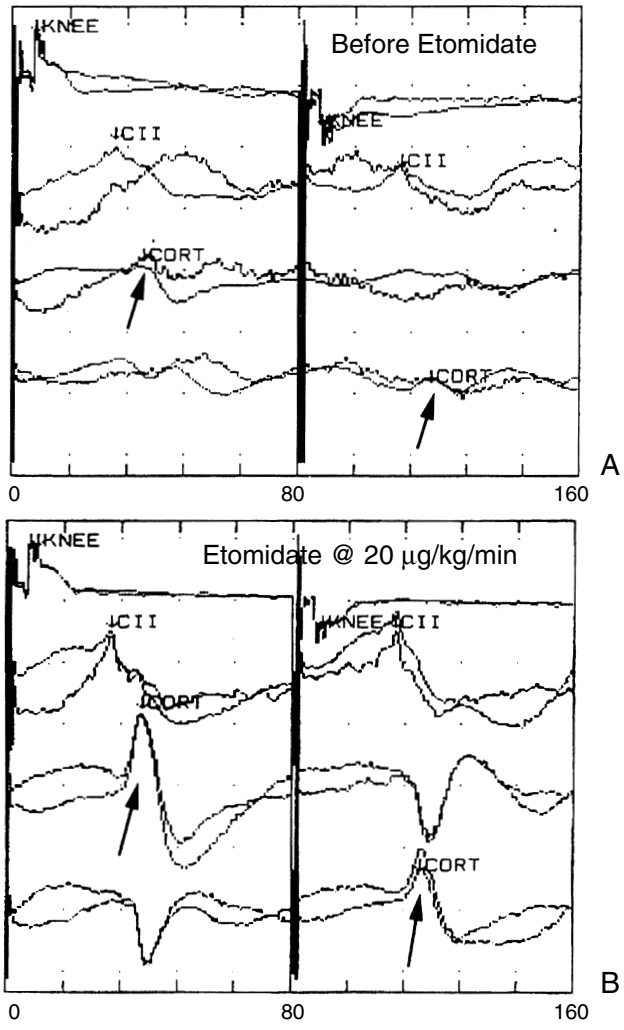

Figure 46-23 Effects of etomidate on somatosensory evoked potential. **A,** The *top tracings* were obtained from a mildly mentally impaired patient with severe kyphoscoliosis during the early maintenance phase of anesthesia using isoflurane and fentanyl. **B,** The *bottom tracings* were obtained after discontinuing isoflurane and instituting an etomidate infusion at 20 μg/kg/min. Note dramatically increased amplitude and clarity of the signal in the cortical channels (marked by *arrows*), which both are recorded with the same amplification scale.

events leading to compromise of the spinal cord.[247] The effects of etomidate on BAEPs are dose-dependent increases in latency and decreases in amplitude that are not clinically significant.[248]

Droperidol in premedicant doses has been shown to have varying effects on SSEPs. In most patients, decreases in amplitude and loss of late waves were noted. In a few patients, increases in amplitude were noted. In all patients, conduction time was prolonged.[249] Effects were not clinically significant. Benzodiazepines also can cause changes in SERs.[250,251] Diazepam causes increases in latency and decreases in amplitude of SSEPs, increases in latency in the cortical response after auditory stimulation, and no change in BAEPs.[250,251] Midazolam causes decreases in amplitude without changes in latency of SSEPs.[246]

Generally, opioids cause small dose-dependent increases in latency and decreases in amplitude of SSEPs. These changes are not clinically significant. Effects on amplitude are more variable than the latency increases.[252,253] Even at large doses of fentanyl (60 μg/kg), reproducible SSEPs can be recorded.[253] Other opiates cause similar dose-dependent changes in SSEPs.[252,254] Opioids can be used even in high doses in patients requiring intraoperative SSEP monitoring without impairment of ability to monitor neurologic function adequately. Opioid-induced changes must be taken into account, however, when evaluating the recordings. Large intravenous bolus administration of opioids should be avoided at times of potential surgical compromise to neurologic function to prevent confusing the interpretation of SEP changes if they develop. BAEPs were resistant to doses of fentanyl of 50 μg/kg with no changes observed in absolute latency, interpeak latency, or amplitude.[255]

Based on several case reports and small series, dexmedetomidine seems to be compatible with all types of evoked potential monitoring (including MEPs), and does not produce changes that would be mistaken for a surgically induced change. Data are limited, and large studies are lacking entirely. As the use of this drug increases, more data should become available, but at this time, use of dexmedetomidine does not seem to be problematic.

Anesthesia and Motor Evoked Potentials

Except in the case of neurogenic MEPs, effects of anesthetics are surprisingly profound, particularly on MEP recordings from muscle produced by either single pulse transcranial electric or especially magnetic stimulation (see Table 46-3).[256-261] Anesthetic techniques typically used by most anesthesiologists for spine surgery would produce prohibitive depression of the MEP.[262,263] Investigators showed in several studies that intravenous agents produce significantly less depression, and techniques using any of a combination of ketamine, opiates, etomidate, and propofol have been described.[264-270] The authors have had excellent experience with a combination of propofol and remifentanil, which also is supported in the literature.

Anesthetic effects on MEP responses recorded at spinal levels seem to be less serious. When responses are recorded from muscle, neuromuscular blocking agents should be monitored quantitatively, maintaining T1 twitch height at around 30% of control values to prevent excessive movement during the operation.[136,257] When responses are not recorded from muscle, profound relaxation is desirable because gross muscle movement produced by MEP stimulation is eliminated, facilitating the surgical procedure. More recent studies using rapid trains of stimuli with transcranial electric and magnetic stimulus techniques have produced responses that are more resistant to the effects of anesthetic agents, and more "traditional" techniques using inhaled agents and narcotics may be used.[271-273] Most studies support the use of total intravenous anesthesia as preferable to techniques using nitrous oxide or potent inhaled agents, however. Precise control of the anesthetic and avoidance of boluses during critical monitoring periods seem to be even more important than for SSEPs, and active cooperation of the anesthesia care team is essential for good, reproducible results. Figure 46-24 shows the dramatic effect of introduction of 0.3 MAC isoflurane to a total intravenous technique using propofol and remifentanil.

Pathophysiologic Effects on the Electroencephalogram

Hypoxia

Hypoxia may produce inadequate delivery of oxygen to the cerebral cortex generating EEG, and changes similar to those occurring with ischemia result. Initially, hypoxemia may not result in any EEG changes because the brain can increase blood flow to compensate. When the hypoxemia becomes severe enough, further increases in flow are impossible, and EEG changes occur. "Slowing" of the EEG during hypoxia is a nonspecific global effect. Fast frequencies are lost, and low frequencies dominate. Eventually, the EEG is abolished as the brain shuts down electric activity and diverts all oxygen delivered to maintenance of cellular integrity.

Hypotension

In a normal, awake patient, significant levels of hypotension seem to be needed to cause the earliest of CNS signs, as measured by discrimination tests such as the flicker-fusion test. This test examines the flicker rate at which the observer perceives the light to be continuous. In the early days of deliberate hypotension, this test was part of the preoperative evaluation to judge how far the pressure could be reduced during the operation. Clear signs of confusion and inability to concentrate or respond properly to simple commands generally represent very low levels of cerebral perfusion when caused by hypotension because the normal cerebral circulation has a large capacity to vasodilate and maintain normal flow in the face of significant hypotension.

The EEG changes associated with even this level of hypotension are not dramatic, although they are clear by comparison with a previously active recording. Herein lies the problem with using intraoperative EEG to determine whether a given level of hypotension has resulted in brain ischemia. EEG changes are not very pronounced and are bilateral. These changes also are nearly identical to the changes caused by increasing doses of many anesthetic drugs. EEG changes associated with hypotension can be detected, but when the hypotension is induced slowly and associated with changes in anesthetic drugs (e.g., use of isoflurane to reduce blood pressure), the changes are very difficult to interpret. EEG changes associated with acute, severe hypotension such as may be caused by sudden arrhythmias are easier to read. Many patients undergoing surgery do not have a normal cerebral circulation, however. In these individuals, even mild hypotension may result in significant cerebral ischemia. In these individuals, moni-

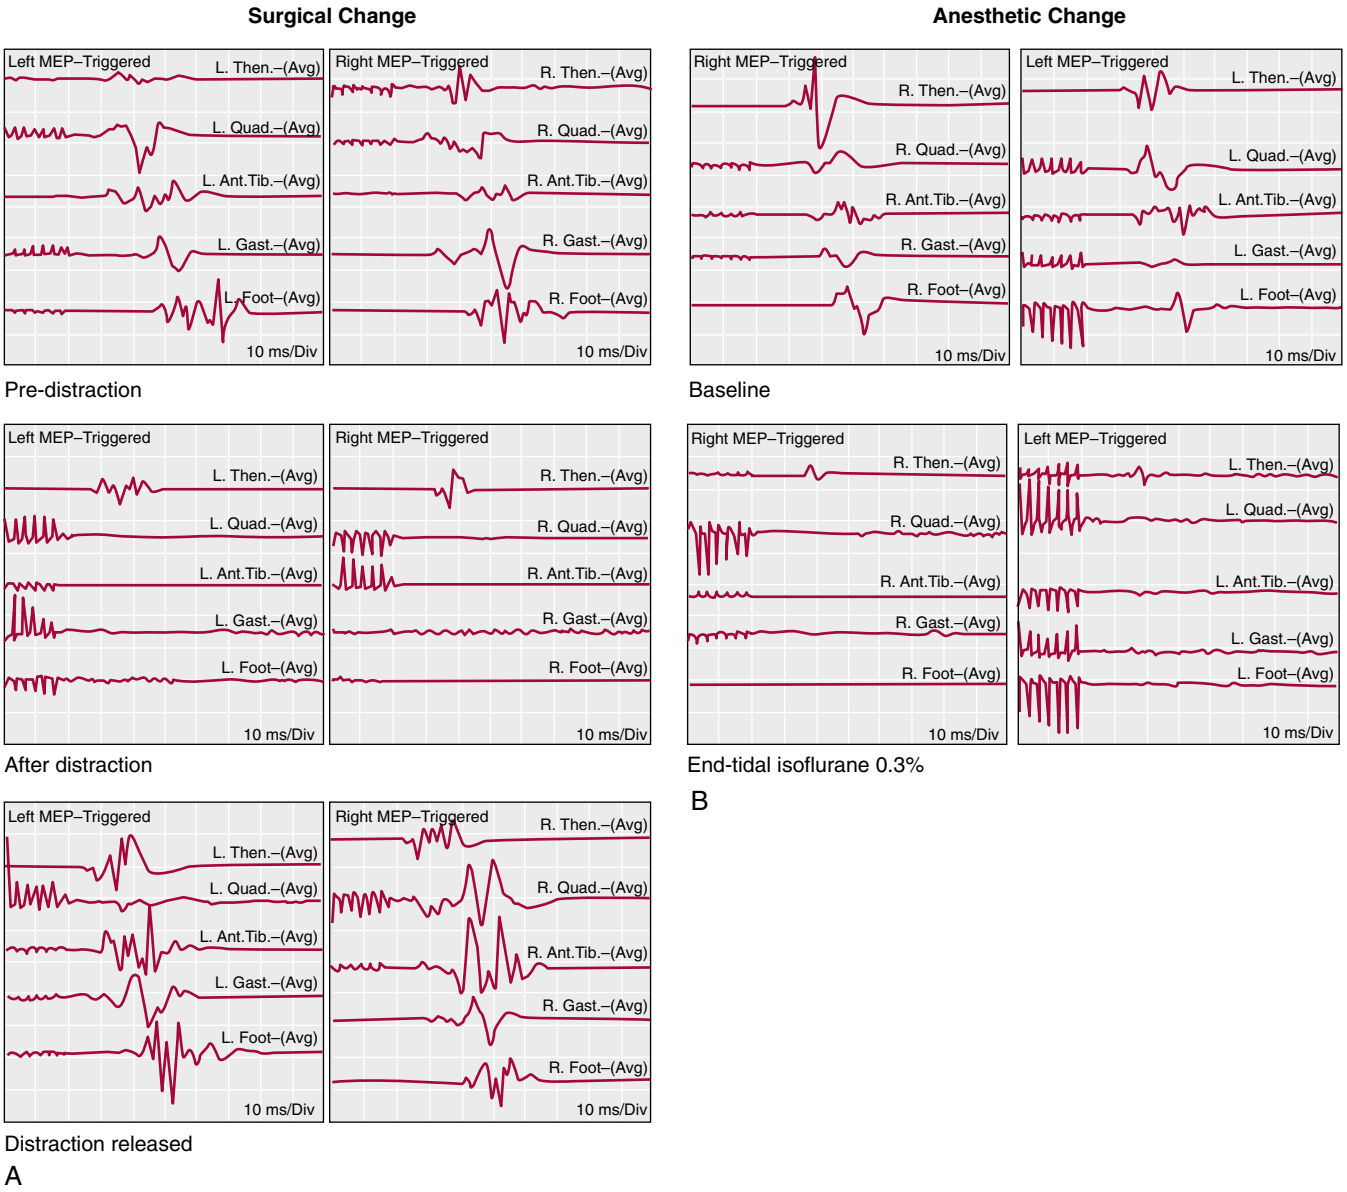

Figure 46-24 A, Transcranial electrical motor evoked potential recording showing surgically induced change during spine surgery (scoliosis repair). **B,** Motor evoked potential with an anesthetic-induced change. Note similarity of the change pattern except that in the anesthetic-induced change, the responses in the upper extremity also changed. Left-sided and right-sided responses are shown on the corresponding panel. A single upper extremity response is shown (*top tracing*) in each panel. Responses from four muscle groups in each lower extremity are shown directly below.

toring the EEG during planned hypotension may be helpful, provided that other causes of similar EEG changes may be carefully controlled. There remains little literature to support the use of EEG monitoring during hypotension, but in our opinion, when the EEG is being monitored (e.g., during carotid surgery), EEG changes secondary to hypotension really do represent cerebral ischemia of a significant degree and should be considered an important finding.

Hypothermia

During cooling on CPB, the total power and peak power frequency of the high-frequency band were highly correlated with temperature using Fourier analysis and spectral edge data; however, there was significant variability between subjects, especially during cooling.[274] Complete EEG suppression usually develops at 15°C to 18°C. Levy and colleagues[162] showed an improved ability to quantify the effects of hypothermia on the EEG using an EEG processing technique known as "approximate entropy."

Hypercarbia and Hypocarbia

Hypocapnia is known to activate excitable seizure foci, and in rare cases may produce EEG evidence of cerebral ischemia even in awake subjects.[275] Hypercapnia, unless severe and associated with hypoxemia, has only indirect effects secondary to increased CBF. In an anesthetized patient, hypercarbia-associated increases in

CBF may have similar effects to the effects seen with increasing end-tidal tension of volatile anesthetics.[276]

Untoward Events

One of the suggested reasons for monitoring the brain of an anesthetized patient is to enable detection of injuries to the nervous system that would not be otherwise apparent. Although there are hundreds of such case reports in the literature and many in the authors' experience, cost-effectiveness of such monitoring is unclear. In a more recent case at the authors' institution, severe EEG changes occurred at the beginning of a carotid endarterectomy, before surgical incision, and were unassociated with any other vital sign changes or hypotension. Immediate angiography revealed acute carotid occlusion and completely changed the operation performed with this patient, and the patient recovered completely. There are intraoperative events that could lead to CNS insult, which, if detected early, could be rapidly reversed or treated to prevent permanent injury. Given the rarity of such events, however, it is extremely unlikely that such monitoring would be shown to be beneficial in any foreseeable randomized trial. If the "at-risk" patient could be identified preoperatively, perhaps the EEG or other types of neuromonitoring could be useful in detecting untoward CNS events during anesthesia, such as a new stroke after elective general surgery.

Physiologic Factors Influencing Sensory Evoked Responses

Numerous physiologic variables, including systemic blood pressure, temperature (local and systemic), and blood gas tensions, can influence SEP recordings. With decreases in mean arterial blood pressure to below levels of cerebral autoregulation owing to either blood loss or vasoactive agents, progressive changes in SERs have been noted. SSEP changes observed are progressive decreases in amplitude until loss of the waveform with no changes in latency.[277,278] BAEPs are resistant to even profound levels of hypotension (mean arterial pressure of 20 mm Hg in dogs).[277] Cortical (synaptic) function necessary to produce cortical SERs seems to be more sensitive to hypoperfusion than spinal cord or brainstem, nonsynaptic transmission.[278] Rapid decreases in blood pressure to levels above the lower limit of autoregulation also have been associated with transient SSEP changes of decreased amplitude that resolve after several minutes of continued hypotension at the same level.[279] Reversible SSEP changes at systemic pressures within the normal range have been observed in patients undergoing spinal distraction during scoliosis surgery. These changes resolved with increases of systemic blood pressure to slightly above the patient's normal pressure, suggesting that the combina-

Table 46-5 Current Practices in Neurologic Monitoring

Procedure	Monitors	Current Practice
Carotid endarterectomy	Awake patient neurologic examination, EEG, SSEP, TCD	NIH recommends use of one of these four available monitors.
	CO	Threshold value not determined, inadequate normative population data
Scoliosis surgery	SSEP	Monitoring recommended, and may substitute for wake-up testing
	Wake-up test	Largely abandoned in centers using electrophysiologic monitoring. Monitoring is not continuous and false-negative monitoring patterns have been reported.
	MEP	Increased clinical use now that transcranial electrical stimulation is FDA approved. Useful in combination with SSEP
Acoustic neuroma	Facial nerve monitor	Facial nerve monitoring recommended
	BAEP	BAEP shows some clinical evidence of improved outcome in some procedures.
Intracranial aneurysm clipping	SSEP, EEG	Used routinely in some centers; limited clinical data on outcome, but appears clinically useful during anterior circulation procedures
Cranial nerve V decompression	BAEP	Used in some centers, reduces hearing loss
Cranial nerve VII decompression	BAEP	Data from small series show improved hearing preservation
Supratentorial mass lesions	SSEP	Used in some centers in selected high-risk procedures
Infratentorial mass lesions	BAEP/SSEP	BAEP to detect retractor-related cranial nerve VIII injury; SSEP in rare, high-risk lesions adjacent to ascending sensory pathways
Decompression of spinal stenosis	SSEP	Used in some centers in high-risk procedures (more often cervical)
Spinal cord trauma	SSEP/MEP	Used in some centers in high-risk procedures
Cardiopulmonary bypass	EEG, TCD, $SjvO_2$, CO	Used routinely in some centers, actively studied, but no outcome data as of yet
Aortic coarctation	SSEP	Used routinely in a few centers, no widespread acceptance
Aortic aneurysm repair	SSEP	Used routinely in a few centers, no widespread acceptance
	MEP	Used routinely in a few centers, no widespread acceptance

BAEP, brainstem auditory evoked potential; CO, cerebral oximetry; EEG, electroencephalogram; FDA, U.S. Food and Drug Administration; MEP, motor evoked potential; NIH, National Institutes of Health; $SjvO_2$, jugular bulb venous oxygen saturation; TCD, transcranial Doppler.

tion of surgical manipulation with levels of hypotension generally considered "safe" could result in spinal cord ischemia.[280]

Changes in temperature also affect SERs. Hypothermia causes increases in latency and decreases in amplitude of cortical and subcortical SERs after all types of stimulation.[281-283] Hyperthermia also alters SERs, with increases in temperature leading to decreases in amplitude in SSEPs and loss of SSEPs at 42°C during induced hyperthermia.[284]

Changes in arterial blood gas tensions have been reported to alter SERs, probably in relation to changes in blood flow or oxygen delivery to neural structures.[285,286] Hypoxia produces SSEP changes (decreased amplitude) similar to the changes seen with ischemia.[286] Decreased oxygen delivery associated with anemia during isovolemic hemodilution results in progressive increases in latency of SSEPs and VEPs that become significant at hematocrits less than 15%. Changes in amplitude were variable until very low hematocrits (approximately 7%) were reached, at which point the amplitude of all waveforms decreased.[287]

Summary

Regardless of the type of intraoperative neurologic monitor, several principles must be observed for neurologic monitoring to provide potential benefit to the patient. First, the pathway at risk during the surgical procedure must be amenable to monitoring. Second, if evidence of injury to the pathway is detected, there must be some intervention possible. If changes in the neurologic monitor are detected, and no intervention is possible, although the monitor may be of prognostic value, it does not have the potential to provide direct benefit to the patient from early detection of impending neurologic injury. Third, the monitor must provide reliable and reproducible data. If the data have a high degree of variability in the absence of clinical interventions, their utility for detecting clinically significant events is limited.

This chapter has reviewed the most common clinically used intraoperative neurologic monitors. Ideally, clinical studies would provide outcome data on the efficacy of a neurologic monitor in a given procedure to improve neurologic outcome. Although there is a wealth of clinical experience with many of these monitoring modalities, there is little in the way of randomized prospective studies evaluating the efficacy of neurologic monitoring. Based on clinical experience with neurologic monitoring and nonrandomized clinical studies in which neurologic monitoring is used and generally compared with historical controls, practice patterns for use of neurologic monitoring have developed. In certain procedures, neurologic monitoring is recommended and used by most centers; in other procedures, monitoring is used almost routinely in some centers, but not in others; and in some procedures, there is no clear clinical experience or evidence that would indicate that monitoring is useful at all (experimental use). Finally, there are procedures in which monitoring is used selectively for patients believed to be at higher-than-usual risk for intraoperative neurologic injury. Table 46-5 provides a summary of current clinical practice.

47 Neuromuscular Monitoring

Key Points

1. Residual postoperative neuromuscular blockade causes decreased chemoreceptor sensitivity to hypoxia, functional impairment of the pharyngeal and upper esophageal muscles, impaired ability to maintain the airway, and an increased risk for the development of postoperative pulmonary complications.
2. It is difficult and often impossible to exclude with certainty clinically significant residual curarization by clinical evaluation of recovery of neuromuscular function.
3. Absence of tactile fade in the response to train-of-four (TOF) stimulation, tetanic stimulation, and double-burst stimulation does not exclude significant residual blockade.
4. Adequate recovery of postoperative neuromuscular function cannot be guaranteed without objective neuromuscular monitoring.
5. Good evidence-based practice dictates that clinicians should always quantitate the extent of neuromuscular blockade by objective monitoring.
6. To exclude clinically significant residual neuromuscular blockade, the TOF ratio, when measured mechanically or by electromyography, must exceed 0.9.
7. Total twitch depression during surgery should be avoided. Whenever possible, one or two TOF responses should be maintained.
8. Antagonism of the neuromuscular block with a cholinesterase inhibitor should not be initiated before at least two or preferably three or four responses to TOF stimulation are observed.
9. If sufficient recovery (TOF ≥ 0.9) has not been documented objectively at the end of the surgical procedure, the neuromuscular block should be antagonized.

Quite often, the degree of neuromuscular blockade during and after anesthesia is evaluated with clinical criteria alone. However, clinically significant residual neuromuscular blockade (i.e., paralysis) may persist postoperatively.[1,2] Objective monitoring of the degree of neuromuscular block during and after anesthesia should reduce the problems of residual neuromuscular blockade.[3,4]

In awake patients, muscle power can be evaluated by tests of voluntary muscle strength, but during anesthesia and recovery from anesthesia this is not possible. Instead, the clinician uses clinical tests to assess muscle power directly and to estimate neuromuscular function indirectly (muscle tone; feel of the anesthesia bag as an indirect measure of pulmonary compliance, tidal volume, and inspiratory force). All these tests, however, are influenced by factors other than the degree of neuromuscular blockade. Therefore, whenever more precise information regarding the status of neuromuscular functioning is desired, the response of muscle to nerve stimulation should be assessed. This procedure also takes into account the considerable variation in individual response and sensitivity to muscle relaxants.

This chapter reviews the basic principles of peripheral nerve stimulation and the requirements for effective use of nerve stimulators. It also describes the response to nerve stimulation during depolarizing (phase I and phase II) and nondepolarizing neuromuscular blockade. Finally, methods of evaluating evoked neuromuscular responses with and without the availability of recording equipment are discussed.

Types of Peripheral Nerve Stimulation

Neuromuscular function is monitored by evaluating the muscular response to supramaximal stimulation of a peripheral motor nerve. Two types of stimulation can be used: electrical and magnetic. Electrical nerve stimulation is by far the most commonly used method in clinical practice and is described in detail in this chapter. In theory, magnetic nerve stimulation has several advantages over electrical nerve stimulation.[5,6] It is less painful and does not require physical contact with the body. However, the equipment required is bulky and heavy, it cannot be used for train-of-four (TOF) stimulation, and it is difficult to achieve

supramaximal stimulation with this method. Therefore, magnetic nerve stimulation is very seldom used in clinical anesthesia.

Principles of Peripheral Nerve Stimulation

The reaction of a single muscle fiber to a stimulus follows an all-or-none pattern. In contrast, the response of the whole muscle depends on the number of muscle fibers activated. If a nerve is stimulated with sufficient intensity, all fibers supplied by the nerve will react, and the maximum response will be triggered. After administration of a neuromuscular blocking drug, the response of the muscle decreases in parallel with the number of fibers blocked. The reduction in response during constant stimulation reflects the degree of neuromuscular blockade.

For the preceding principles to be in effect, the stimulus must be truly maximal throughout the period of monitoring; therefore, the electrical stimulus applied is usually at least 20% to 25% above that necessary for a maximal response. For this reason the stimulus is said to be supramaximal; however, supramaximal electrical stimulation hurts, which is not a concern during anesthesia, but during recovery the patient may be awake enough to experience the discomfort of nerve stimulation. Therefore, some researchers advocate stimulation with submaximal current during recovery. Although several investigations indicate that testing of neuromuscular function can be reliably performed postoperatively with submaximal stimulation,[7,8] the accuracy of such monitoring is unacceptable with low current.[9]

Patterns of Nerve Stimulation

For evaluation of neuromuscular function, the most commonly used patterns of electrical nerve stimulation are single-twitch, TOF, tetanic, post-tetanic count (PTC), and double-burst stimulation (DBS).

Single-Twitch Stimulation

In the single-twitch mode of stimulation, single supramaximal electrical stimuli are applied to a peripheral motor nerve at frequencies ranging from 1.0 Hz (once every second) to 0.1 Hz (once every 10 seconds) (Fig. 47-1). The response to single-twitch stimulation depends on the frequency at which the individual stimuli are applied. If the rate of delivery is increased to greater than 0.15 Hz, the evoked response will gradually decrease and settle at a lower level. As a result, a frequency of 0.1 Hz is generally used. Because 1-Hz stimulation shortens the time necessary to determine supramaximal stimulation, this frequency is sometimes used during induction of anesthesia; however, the apparent time of onset and length of neuromuscular blockade depend on the pattern and duration of stimulation. Therefore, results obtained with 1-Hz single-twitch stimulation cannot be compared with results obtained by using, for instance, 0.1-Hz single-twitch stimulation or TOF stimulation.[10]

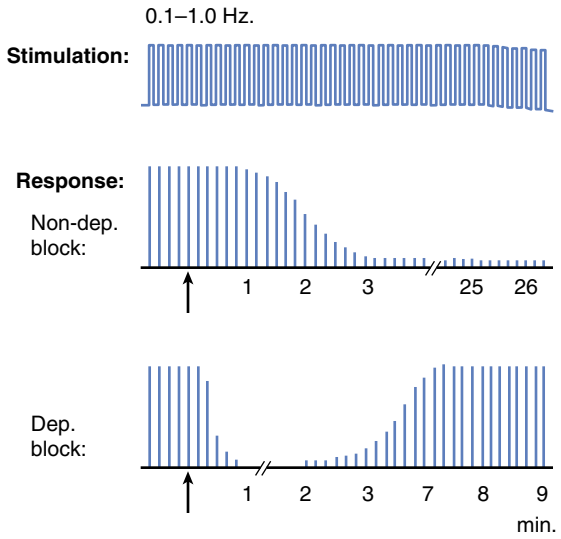

Figure 47-1 Pattern of electrical stimulation and evoked muscle responses to single-twitch nerve stimulation (at frequencies of 0.1 to 1.0 Hz) after injection of nondepolarizing (Non-dep.) and depolarizing (Dep.) neuromuscular blocking drugs (*arrows*). Note that except for the difference in time factors, no differences in the strength of the evoked responses exist between the two types of block.

Train-of-Four Stimulation

In TOF nerve stimulation, introduced by Ali and associates[11,12] during the early 1970s, four supramaximal stimuli are given every 0.5 second (2 Hz) (Fig. 47-2). When used continuously, each set (train) of stimuli is normally repeated every 10th to 20th second. Each stimulus in the train causes the muscle to contract, and "fade" in the response provides the basis for evaluation. That is, dividing the amplitude of the fourth response by the amplitude of the first response provides the TOF ratio. In the control response (the response obtained before the administration of a muscle relaxant), all four responses are ideally the same: the TOF

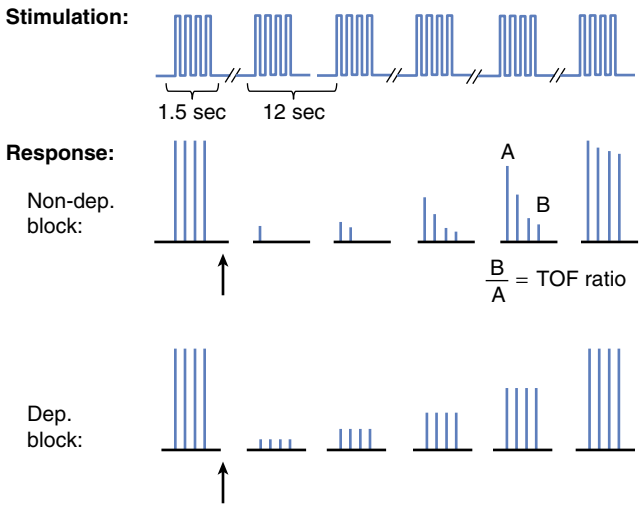

Figure 47-2 Pattern of electrical stimulation and evoked muscle responses to TOF nerve stimulation before and after injection of nondepolarizing (Non-dep.) and depolarizing (Dep.) neuromuscular blocking drugs (*arrows*).

ratio is 1.0. During a partial nondepolarizing block, the ratio decreases (fades) and is inversely proportional to the degree of blockade. During a partial depolarizing block, no fade occurs in the TOF response; ideally, the TOF ratio is approximately 1.0. Fade in the TOF response after injection of succinylcholine signifies the development of a phase II block (discussed later in the section on depolarizing neuromuscular blockade).

The advantages of TOF stimulation are greatest during nondepolarizing blockade because the degree of block can be read directly from the TOF response even though a preoperative value is lacking. In addition, TOF stimulation has some advantages over tetanic stimulation: it is less painful and, unlike tetanic stimulation, does not generally affect the degree of neuromuscular blockade.

Tetanic Stimulation

Tetanic stimulation consists of very rapid (e.g., 30-, 50-, or 100-Hz) delivery of electrical stimuli. The most commonly used pattern in clinical practice is 50-Hz stimulation given for 5 seconds, although some investigators have advocated the use of 50-, 100-, and even 200-Hz stimulation for 1 second. During normal neuromuscular transmission and a pure depolarizing block, the muscle response to 50-Hz tetanic stimulation for 5 seconds is sustained. During a nondepolarizing block and a phase II block after the injection of succinylcholine, the response will not be sustained (i.e., fade occurs) (Fig. 47-3).

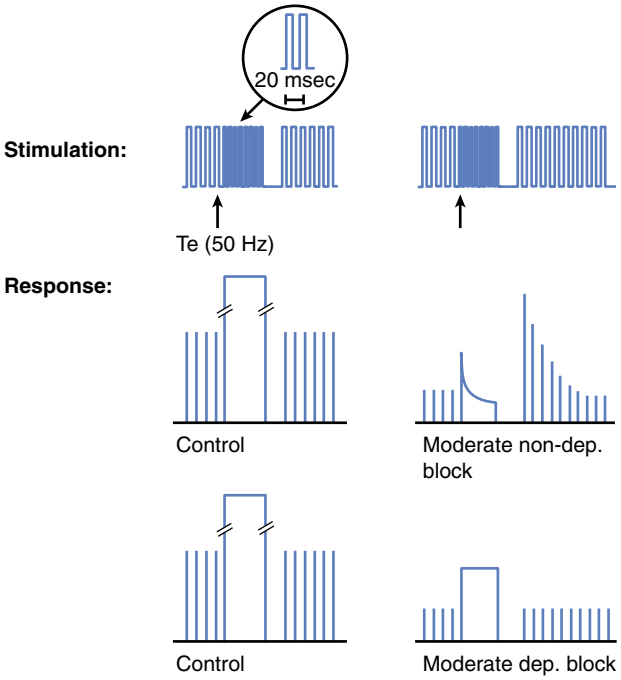

Figure 47-3 Pattern of stimulation and evoked muscle responses to tetanic (50-Hz) nerve stimulation for 5 seconds (Te) and post-tetanic twitch stimulation (1.0-Hz) (*arrows*). Stimulation was applied before the injection of neuromuscular blocking drugs and during moderate nondepolarizing (non-dep.) and depolarizing (dep.) blocks. Note the fade in the response to tetanic stimulation, plus the post-tetanic facilitation of transmission during nondepolarizing blockade. During depolarizing blockade, the tetanic response is well sustained, and no post-tetanic facilitation of transmission occurs.

Fade in response to tetanic stimulation is normally considered a presynaptic event; the traditional explanation is that at the start of tetanic stimulation, large amounts of acetylcholine are released from immediately available stores in the nerve terminal. As these stores become depleted, the rate of acetylcholine release decreases until equilibrium between mobilization and synthesis of acetylcholine is achieved. Despite this equilibrium, the muscle response caused by tetanic stimulation of the nerve at, for example, 50 Hz is maintained (given normal neuromuscular transmission) simply because the acetylcholine released is many times greater than the amount necessary to evoke a response. When the "margin of safety"[13] at the postsynaptic membrane (i.e., the number of free cholinergic receptors) is reduced by nondepolarizing neuromuscular blocking drugs, a typical reduction in twitch height is seen with a fade during, for instance, repetitive stimulation. In addition to this postsynaptic block, nondepolarizing neuromuscular blocking drugs may also block presynaptic neuronal-type acetylcholine receptors, thereby leading to impaired mobilization of acetylcholine within the nerve terminal.[14] This effect substantially contributes to fade in the response to tetanic (and TOF) stimulation. Although the degree of fade depends primarily on the degree of neuromuscular blockade, fade also depends on the frequency (Hz) and the length (seconds) of stimulation and on how often tetanic stimuli are applied. Unless these variables are kept constant, results from different studies using tetanic stimulation cannot be compared.

During partial nondepolarizing blockade, tetanic nerve stimulation is followed by a post-tetanic increase in twitch tension (i.e., post-tetanic facilitation of transmission) (see Fig. 47-3). This event occurs because the increase in mobilization and synthesis of acetylcholine caused by tetanic stimulation continues for some time after discontinuation of stimulation. The degree and duration of post-tetanic facilitation depend on the degree of neuromuscular blockade, with post-tetanic facilitation usually disappearing within 60 seconds of tetanic stimulation. Post-tetanic facilitation is evident in electromyographic, acceleromyographic, and mechanical recordings during partial nondepolarizing neuromuscular blockade. In contrast, post-tetanic twitch potentiation, which sometimes occurs in mechanical recordings before any neuromuscular blocking drug has been given, is a muscular phenomenon that is not accompanied by an increase in the compound muscle action potential.

Tetanic stimulation is very painful and therefore not normally acceptable to an unanesthetized patient. Furthermore, especially in the late phase of neuromuscular recovery, tetanic stimulation may produce lasting antagonism of neuromuscular blockade in the stimulated muscle such that the response of the tested site may no longer be representative of other muscle groups.[15]

Traditionally, tetanic stimulation has been used to evaluate residual neuromuscular blockade but is too painful to use in an unanesthetized patient. Except in connection with the technique of PTC (see later), tetanic stimulation has very little place in everyday clinical anesthesia. If the response to nerve stimulation is recorded, all the information required can be obtained from the response to TOF nerve stimulation. In contrast, if the response to nerve stimulation is evaluated only by tactile evaluation[16,17] or by eye (Viby-Mogensen and colleagues, unpublished observation), even experienced observers are unable to judge the response of tetanic stimulation with sufficient certainty to exclude residual neuromuscular blockade.

Post-Tetanic Count Stimulation

Injection of a nondepolarizing neuromuscular blocking drug in a dose sufficient to ensure smooth tracheal intubation causes intense neuromuscular blockade of the peripheral muscles. Because no response to TOF and single-twitch stimulation occurs under these conditions, these modes of stimulation cannot be used to determine the degree of blockade. It is possible, however, to quantify intense neuromuscular blockade of the peripheral muscles by applying tetanic stimulation (50 Hz for 5 seconds) and observing the post-tetanic response to single-twitch stimulation given at 1 Hz starting 3 seconds after the end of tetanic stimulation.[18] During intense blockade, there is no response to either tetanic or post-tetanic stimulation (Fig. 47-4). However, when the intense neuromuscular blockade dissipates and before the first response to TOF stimulation reappears, the first response to post-tetanic twitch stimulation occurs. As the intense block dissipates, more and more responses to post-tetanic twitch stimulation appear. For a given neuromuscular blocking drug, the time until return of the first response to TOF stimulation is related to the number of post-tetanic twitch responses present at a given time (i.e., the PTC) (Fig. 47-5).[18-22]

The PTC method is mainly used to assess the degree of neuromuscular blockade when there is no reaction to single-twitch or TOF nerve stimulation, as may be the case after injection of a large dose of a nondepolarizing neuromuscular blocking drug. However, PTC can also be used whenever sudden movements must be eliminated (e.g., during ophthalmic surgery). The necessary level of blockade of the adductor pollicis muscle to ensure paralysis of the diaphragm depends on the type of anesthesia and, in the intensive care unit, on the level of sedation. To ensure elimination of any bucking or coughing in response to tracheobronchial stimulation, neuromuscular blockade of the peripheral muscles must be so intense that no response to post-tetanic twitch stimulation can be elicited (PTC 0) (Fig. 47-6).[19-23]

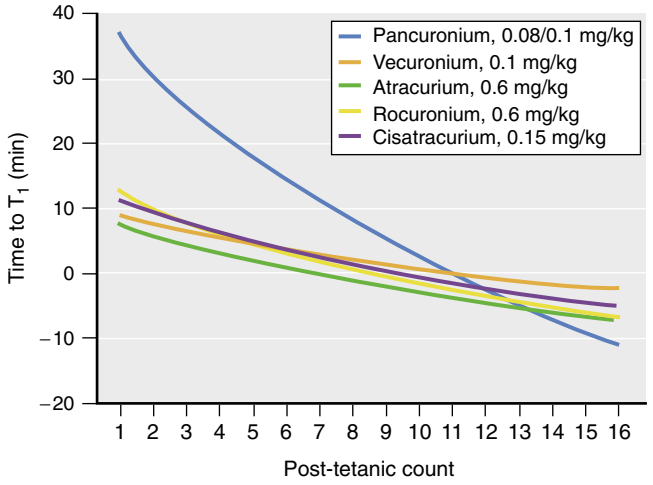

Figure 47-5 Relationship between the post-tetanic count and time when onset of train-of-four (T_1) is likely to be elicited for various neuromuscular blocking agents. *(From El-Orbany MI, Joseph JN, Salem MR: The relationship of post-tetanic count and train-of-four responses during recovery from intense cisatracurium-induced neuromuscular blockade. Anesth Analg 97:80, 2003.)*

The response to PTC stimulation depends primarily on the degree of neuromuscular blockade. It also depends on the frequency and duration of tetanic stimulation, the length of time between the end of tetanic stimulation and the first post-tetanic stimulus, the frequency of the single-twitch stimulation, and also (probably) the duration of single-twitch stimulation before tetanic stimulation. When the PTC method is used, these variables should be kept constant. In addition, because of possible antagonism of neuromuscular blockade in the hand, tetanic stimulation should not be performed more often than every 6 minutes.[18] If the hand muscles undergo antagonism of neuromuscular blockade while the rest of the body is still paralyzed, the hand muscles are no longer useful for monitoring.

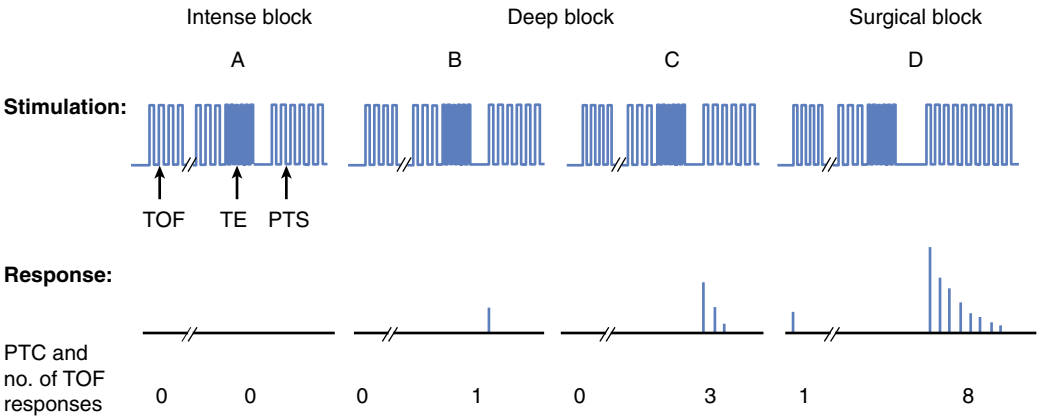

Figure 47-4 Pattern of electrical stimulation and evoked muscle responses to train-of-four (TOF) nerve stimulation, 50-Hz tetanic nerve stimulation for 5 seconds (TE), and 1.0-Hz post-tetanic twitch stimulation (PTS) during four different levels of nondepolarizing neuromuscular blockade. During intense blockade of peripheral muscles (**A**), no response to any of the forms of stimulation occurs. During less pronounced blockade (deep blockade, **B** and **C**), there is still no response to TOF stimulation, but post-tetanic facilitation of transmission is present. During surgical blockade (**D**), the first response to TOF appears and post-tetanic facilitation increases further. The post-tetanic count (see text) is 1 during very deep block (**B**), 3 during less deep block (**C**), and 8 during surgical (or moderate) block (**D**).

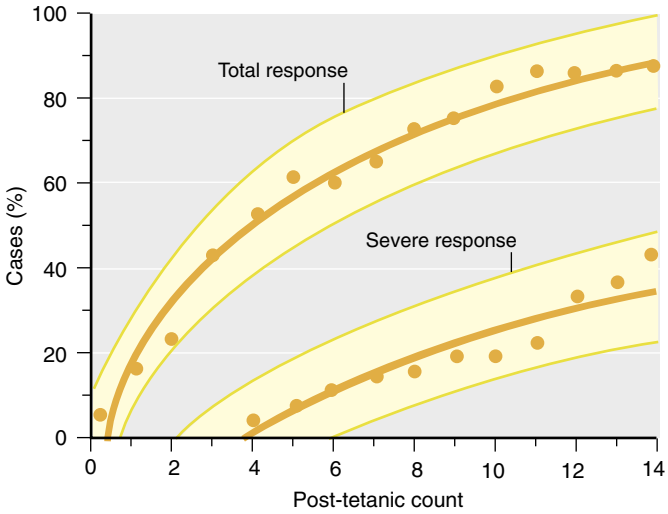

Figure 47-6 Relationship between the rate of muscle response to stimulation of the tracheal carina and the degree of neuromuscular blockade of peripheral muscles, as evaluated by post-tetanic count (PTC). The subjects were 25 patients anesthetized with thiopental, nitrous oxide, and fentanyl and given vecuronium (0.1 mg/kg) for tracheal intubation. For comparison, the first response to train-of-four stimulation usually occurs when the PTC is approximately 10 (range, 6 to 16). The carina was stimulated with a soft sterile rubber suction catheter introduced via the endotracheal tube. The total response consisted of mild responses plus severe responses. A mild response was said to occur if stimulation of the carina induced only slight bucking that did not interfere with surgery. A severe response was said to occur if stimulation elicited bucking that interfered with surgery and required intervention. Elimination of severe responses requires an intense neuromuscular blockade; PTC must be less than 2 to 3, and elimination of all reactions requires that PTC be 0. *(From Fernando PUE, Viby-Mogensen J, Bonsu AK, et al: Relationship between post-tetanic count and response to carinal stimulation during vecuronium-induced neuromuscular blockade. Acta Anaesthesiol Scand 31:593, 1987. Copyright 1987, Munksgaard International Publishers, Ltd. Copenhagen, Denmark.)*

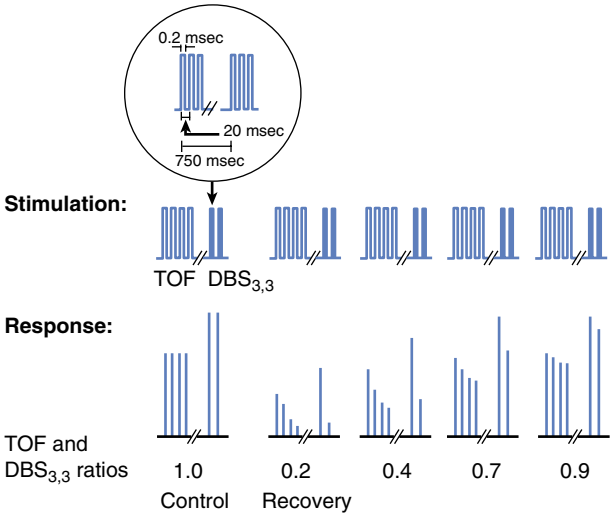

Figure 47-7 Pattern of electrical stimulation and evoked muscle responses to train-of-four (TOF) nerve stimulation and double-burst nerve stimulation (i.e., three impulses in each of two tetanic bursts, $DBS_{3,3}$) before injection of muscle relaxants (control) and during recovery from nondepolarizing neuromuscular blockade. The TOF ratio is the amplitude of the fourth response to TOF divided by the amplitude of the first response. The $DBS_{3,3}$ ratio is the amplitude of the second response to $DBS_{3,3}$ divided by the amplitude of the first response. (See text for further explanation.)

Double-Burst Stimulation

DBS consists of two short bursts of 50-Hz tetanic stimulation separated by 750 msec. The duration of each square wave impulse in the burst is 0.2 msec (Fig. 47-7). Although the number of impulses in each burst can vary, DBS with three impulses in each of the two tetanic bursts ($DBS_{3,3}$) is most commonly used.[24-26]

In nonparalyzed muscle, the response to $DBS_{3,3}$ is two short muscle contractions of equal strength. In a partly paralyzed muscle, the second response is weaker than the first (i.e., the response fades) (see Fig 47-7). Measured mechanically, the TOF ratio correlates closely with the $DBS_{3,3}$ ratio. DBS was developed with the specific aim of allowing manual (tactile) detection of small amounts of residual blockade under clinical conditions,[24] and during recovery and immediately after surgery, tactile evaluation of the response to $DBS_{3,3}$ is superior to tactile evaluation of the response to TOF stimulation.[26,27] However, as shown in Figure 47-8, absence of fade in the manually evaluated response to $DBS_{3,3}$ (and TOF) does not exclude residual neuromuscular blockade.[28]

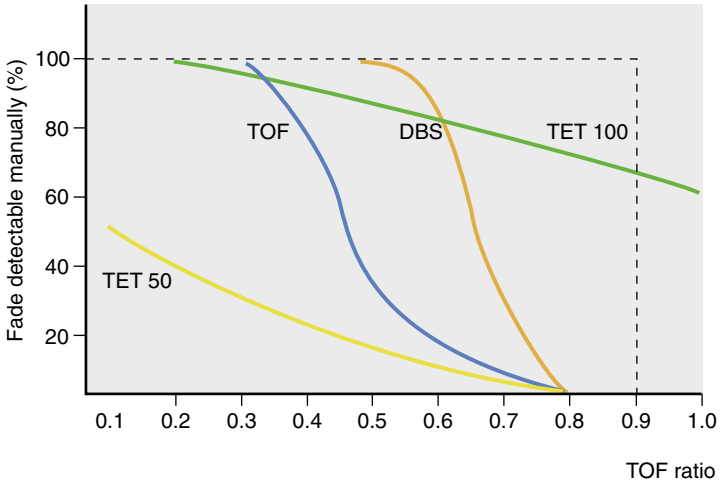

Figure 47-8 Fade detectable by feel in the response to train-of-four (TOF), double-burst stimulation ($DBS_{3,3}$), and 50- and 100-Hz tetanic stimulation (TET 50 and TET 100) in relation to the true TOF ratio, as measured mechanically. The axis indicates the percentage of instances in which fade can be felt at a given TOF ratio.[17,25,26] It appears that it is not possible to exclude residual neuromuscular block by any of the methods, regardless of whether a TOF ratio of 0.7 or 0.9 is taken to reflect adequate recovery of neuromuscular function. (See text for further explanation.)

The Nerve Stimulator

Although many nerve stimulators are commercially available, not all meet the basic requirements for clinical use. The stimulus should produce a monophasic and rectangular waveform, and the length of the pulse should not exceed 0.2 to 0.3 msec. A pulse exceeding 0.5 msec may stimulate the muscle directly or cause repetitive firing. Stimulation at a constant current is preferable to stimulation at a constant voltage because current is the determinant of nerve stimulation. Furthermore, for safety reasons, the nerve stimulator should be battery operated, include a battery check, and be able to generate 60 to 70 mA, but not higher than 80 mA. Many commercially available stimulators can deliver just 25 to 50 mA and provide a constant current only when skin resistance ranges from 0 to 2.5 kΩ. These limitations are a disadvantage; during cooling, skin resistance may increase to approximately 5 kΩ, which may cause the current delivered to the nerve to fall below the supramaximal level and lead to a decrease in the response to stimulation. As a result, the anesthesiologist may misjudge the degree of neuromuscular blockade. Ideally, the nerve stimulator should have a built-in warning system or a current level display that alerts the user when the current selected is not delivered to the nerve.

The ideal nerve stimulator should have other features as well. The polarity of the electrodes should be indicated, and the apparatus should be capable of delivering the following modes of stimulation: TOF (as both a single train and in a repetitive mode, with TOF stimulation being given every 10 to 20 seconds), single-twitch stimulation at 0.1 and 1.0 Hz, and tetanic stimulation at 50 Hz. In addition, the stimulator should have a built-in time constant system to facilitate PTC. The tetanic stimulus should last 5 seconds and be followed 3 seconds later by the first post-tetanic stimulus. If the nerve stimulator does not allow objective measurement of the response to TOF stimulation, at least one DBS mode should be available, preferably $DBS_{3,3}$. Single-twitch stimulation at 1 Hz is useful during initiation of monitoring because it shortens the time necessary to determine supramaximal stimulation. Most investigators agree that there is no need for tetanus at 100 or 200 Hz because 50-Hz tetanic stimulation stresses neuromuscular function to the same extent as maximal voluntary effort does. Furthermore, in contrast to 100- and 200-Hz stimulation, 50-Hz tetanic stimulation does not cause fatigue (fade) in nonparalyzed muscle.

The Stimulating Electrodes

Electrical impulses are transmitted from stimulator to nerve by means of surface or needle electrodes, the former being the more commonly used in clinical anesthesia. Normally, disposable pregelled silver or silver chloride surface electrodes are used. The actual conducting area should be small, approximately 7 to 11 mm in diameter.[29] Otherwise, the current produced in the underlying nerve may not be adequate. The skin should always be cleansed properly and preferably rubbed with an abrasive before application of the electrodes. When a supramaximal response cannot be obtained with surface electrodes, needle electrodes should be used. Although specially coated needle electrodes are commercially available, ordinary steel injection needles can be used. The needles should be placed subcutaneously but never in a nerve.

Sites of Nerve Stimulation and Different Muscle Responses

In principle, any superficially located peripheral motor nerve may be stimulated. In clinical anesthesia, the ulnar nerve is the most popular site; the median, posterior tibial, common peroneal, and facial nerves are also sometimes used. For stimulation of the ulnar nerve, the electrodes are best applied to the volar side of the wrist (Fig. 47-9). The distal electrode should be placed about 1 cm proximal to the point at which the proximal flexion crease of the wrist crosses the radial side of the tendon to the flexor carpi ulnaris muscle. The proximal electrode should preferably be placed so that the distance between the centers of the two electrodes is 3 to 6 cm (see Fig. 47-9). With this placement of the electrodes, electrical stimulation normally elicits only finger flexion and thumb adduction. If one electrode is placed over the ulnar groove at the elbow, thumb adduction is often pronounced because of stimulation of the flexor carpi ulnaris muscle. When this latter placement of electrodes (sometimes preferred in small children) is used, the active negative electrode should be at the wrist to ensure maximal response. Polarity of the electrodes is less crucial when both electrodes are close to each other at the volar side of the wrist; however, placement of the negative electrode distally normally elicits the greatest neuromuscular response.[30] When the temporal branch of the facial nerve is stimulated, the negative electrode should be placed over the nerve, and the positive electrode should be placed somewhere else over the forehead.

Because different muscle groups have different sensitivities to neuromuscular blocking agents, results obtained for one muscle cannot be automatically extrapolated to other muscles. The diaphragm is among the most resistant of all muscles to both depo-

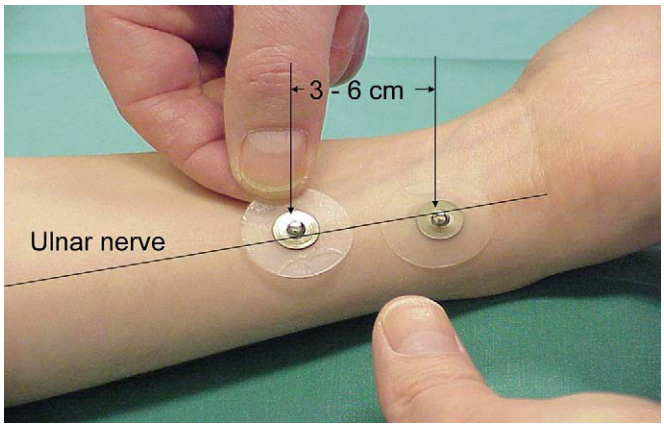

Figure 47-9 Stimulating electrodes with the appropriate contact area in the correct position over the ulnar nerve of the left forearm. *(From Fuchs-Buder T, Claudius C, Skovgaard LT, et al: Good clinical research practice in pharmacodynamic studies of neuromuscular blocking agents II: The Stockholm revision. Acta Anaesthesiol Scand 51:789, 2007.)*

larizing[31] and nondepolarizing neuromuscular blocking drugs.[32] In general, the diaphragm requires 1.4 to 2.0 times as much muscle relaxant as the adductor pollicis muscle for an identical degree of blockade (Fig. 47-10).[32] Also of clinical significance is that onset time is normally shorter for the diaphragm than for the adductor pollicis muscle and the diaphragm recovers from paralysis more quickly than the peripheral muscles do (Fig. 47-11).[33] The other respiratory muscles are less resistant than the diaphragm, as are the larynx and the corrugator supercilii muscles.[34-36] Most sensitive are the abdominal muscles, the orbicularis oculi muscle, the peripheral muscles of the limbs, and the geniohyoid, masseter, and upper airway muscles.[37-40] From a practical clinical point of view, it is worth noting that (1) the response of the corrugator supercilii to facial nerve stimulation reflects the extent of neuromuscular blockade of the laryngeal adductor muscles and abdominal muscles better than the response of the adductor pollicis to ulnar nerve stimulation does[34,41] and (2) the upper airway muscles seem to be more sensitive than the peripheral muscles.[37,38] Although three investigations using acceleromyography have indicated small differences in the response to TOF nerve stimulation in the arm (adductor pollicis muscle) and the leg (flexor hallucis brevis muscle), these differences are probably of little clinical significance.[42,43]

Even though the precise source of these differences is unknown, variations in acetylcholine receptor density, acetylcholine release, acetylcholinesterase activity, fiber composition, innervation ratio (number of neuromuscular junctions), blood flow, and muscle temperature may be possible explanations.

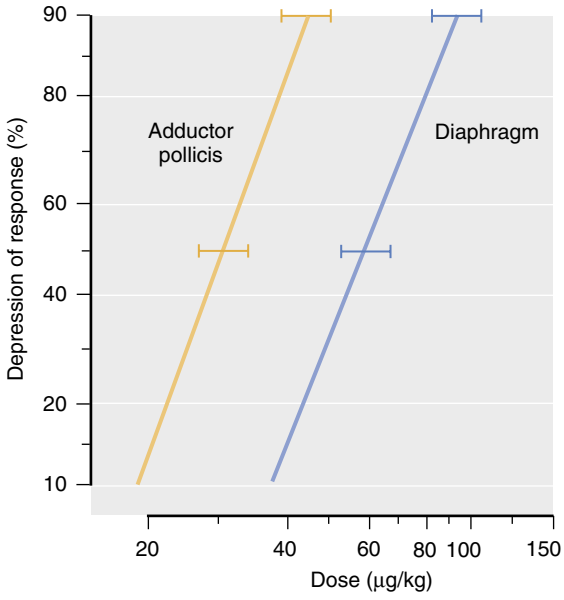

Figure 47-10 The mean cumulative dose-response curve for pancuronium in two muscles shows that the diaphragm requires approximately twice as much pancuronium as the adductor pollicis muscle for the same amount of neuromuscular blockade. The depression in muscle response to the first stimulus in train-of-four nerve stimulation (probit scale) was plotted against dose (log scale). The force of contraction of the adductor pollicis was measured on a force-displacement transducer; response of the diaphragm was measured electromyographically. *(From Donati F, Antzaka C, Bevan DR: Potency of pancuronium at the diaphragm and the adductor pollicis muscle in humans. Anesthesiology 65:1, 1986.)*

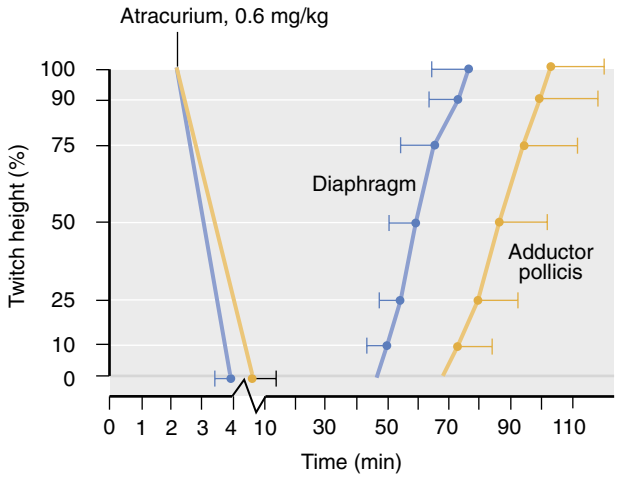

Figure 47-11 Evolution of twitch height (mean ± SD) of the diaphragm (*blue circles*) and the adductor pollicis muscle (*yellow circles*) in 10 anesthetized patients after the administration of atracurium, 0.6 mg/kg. *(From Pansard J-L, Chauvin M, Lebrault C, et al: Effect of an intubating dose of succinylcholine and atracurium on the diaphragm and the adductor pollicis muscle in humans. Anesthesiology 67:326, 1987.)*

In assessing neuromuscular function, use of a relatively sensitive muscle such as the adductor pollicis of the hand has both disadvantages and advantages. Obviously, during surgery it is a disadvantage that even total elimination of the response to single-twitch and TOF stimulation does not exclude the possibility of movement of the diaphragm, such as hiccupping and coughing. PTC stimulation, however, allows evaluation of the intense blockade necessary to ensure total paralysis of the diaphragm. On the positive side, the risk of overdosing the patient decreases if the response of a relatively sensitive muscle is used as a guide to the administration of muscle relaxants during surgery. In addition, during recovery, when the adductor pollicis has recovered sufficiently, it can be assumed that no residual neuromuscular blockade exists in the diaphragm or in other resistant muscles.

Recording of Evoked Responses

The choice of recording method is a practical decision. Five methods are available: measurement of the evoked mechanical response of the muscle (mechanomyography [MMG]), measurement of the evoked electrical response of the muscle (electromyography [EMG]), measurement of acceleration of the muscle response (acceleromyography [AMG]), measurement of the evoked electrical response in a piezoelectric film sensor attached to the muscle (piezoelectric neuromuscular monitor [P_ZEMG], and phonomyography [PMG]).

Mechanomyography

A requirement for correct and reproducible measurement of evoked tension is that the muscle contraction be isometric. In clinical anesthesia, this condition is most easily achieved by measuring thumb movement after the application of a resting tension

of 200 to 300 g (a preload) to the thumb. When the ulnar nerve is stimulated, the thumb (the adductor pollicis muscle) acts on a force-displacement transducer. The force of contraction is then converted into an electrical signal, which is amplified, displayed, and recorded. The arm and hand should be rigidly fixed, and care should be taken to prevent overloading of the transducer. In addition, the transducer should be placed in correct relation to the thumb (i.e., the thumb should always apply tension precisely along the length of the transducer). It is important to remember that the response to nerve stimulation depends on the frequency with which the individual stimuli are applied and that the time used to achieve a stable control response may influence subsequent determination of the onset time and duration of blockade.[29] Generally, the reaction to supramaximal stimulation increases during the first 8 to 12 minutes after commencement of the stimulation. Therefore, in clinical studies, recording of the control response (before injection of muscle relaxant) should not be made until the response has stabilized for 8 to 12 minutes or a 2- or 5-second 50-Hz tetanic stimulation has been given.[44] Even then, twitch response often recovers to 110% to 150% of the control response after paralysis with succinylcholine. This increase in response, thought to be caused by a change in the contractile response of the muscle, normally disappears within 15 to 25 minutes.

Although numerous methods for mechanical recording of evoked mechanical responses exist, not all meet the criteria outlined.

Electromyography

Evoked EMG records the compound action potentials produced by stimulation of a peripheral nerve. The compound action potential is a high-speed event that for many years could be picked up only by means of a preamplifier and a storage oscilloscope. Modern neuromuscular transmission analyzers are able to make on-line electronic analyses and graphic presentations of the EMG response.

The evoked EMG response is most often obtained from muscles innervated by the ulnar or the median nerves. Stimulating electrodes are applied as in force measurements. Although both surface and needle electrodes may be used for recording, no advantage is obtained by using the latter. Most often, the evoked EMG response is obtained from the thenar or hypothenar eminence of the hand or from the first dorsal interosseous muscle of the hand, preferably with the active electrode over the motor point of the muscle (Fig. 47-12). The signal picked up by the analyzer is processed by an amplifier, a rectifier, and an electronic integrator. The results are displayed either as a percentage of control or as a TOF ratio.

Two new sites for recording the EMG response have been introduced: the larynx and the diaphragm.[45,46] By using a noninvasive disposable laryngeal electrode attached to the tracheal tube and placed between the vocal cords, it is possible to monitor the onset of neuromuscular blockade in the laryngeal muscles. Thus far, however, the method is mainly of interest in clinical research when investigating onset times of the laryngeal muscles. In paravertebral surface diaphragmatic EMG, the recording electrodes are placed on the right of vertebrae T12/L1 or L1/L2 for monitoring the response of the right diaphragmatic crux to transcutaneous stimulation of the right phrenic nerve at the neck.[45-47] As is the case with surface laryngeal EMG, surface diaphragmatic EMG is mainly of interest in clinical research because of difficulties connected with stimulation of the phrenic nerve transcutaneously at the neck.

Evoked electrical and mechanical responses represent different physiologic events. Evoked EMG records changes in the electrical activity of one or more muscles, whereas evoked MMG records changes associated with excitation-contraction coupling and contraction of the muscle as well. For these reasons, the results obtained with these methods may differ.[48,49] Although evoked EMG responses generally correlate well with evoked mechanical responses,[50] marked differences may occur, especially in the response to succinylcholine and in the TOF ratio during recovery from a nondepolarizing block.[48-50]

In theory, recording of evoked EMG responses has several advantages over recording of evoked mechanical responses. Equipment for measuring evoked EMG responses is easier to set up, the response reflects only factors influencing neuromuscular transmission, and the response can be obtained from muscles not accessible to mechanical recording. However, evoked EMG does entail some difficulties. Although high-quality recordings are possible in most patients, the results are not always reliable. For one thing, improper placement of electrodes may result in inadequate pickup of the compound EMG signal. If the neuromuscular transmission analyzer does not allow observation of the actual waveform of the compound EMG, determining optimal placement of the electrodes is difficult. Another source of unreliable results may be that fixation of the hand with a preload on the thumb might be more important than is generally appreciated[50] inasmuch as changes in the position of the electrodes in relation to the muscle may affect the EMG response. In addition, direct muscle stimulation sometimes occurs. If muscles close to the stimulating electrodes are stimulated directly, the recording electrodes may pick up an electrical signal even though neuromuscular transmission is completely blocked. Another difficulty is that the EMG response often does not return to the control value. Whether this situation is the result of technical problems, inadequate fixation of the hand, or changes in temperature is unknown (Fig. 47-13). Finally, the evoked EMG response is very sensitive to electrical interference, such as that caused by diathermy.

Acceleromyography

The technique of AMG is based on Newton's second law: force equals mass times acceleration.[51] If mass is constant, acceleration is directly proportional to force. Accordingly, after nerve stimulation, one can measure not only the evoked force but also acceleration of the thumb.

AMG uses a piezoelectric ceramic wafer with electrodes on both sides. Exposure of the electrode to a force generates an electrical voltage proportional to acceleration of the electrode. Consequently, when an accelerometer is fixed to the thumb and the ulnar nerve is stimulated, an electrical signal is produced whenever the thumb moves. This signal can be analyzed in a specially designed analyzer[52] or perhaps displayed on a recording system. At least one detached monitor based on measurement of acceleration is commercially available: the TOF-Watch (Organon, part of Schering-Plough Corp.) (Fig. 47-14).

AMG is a simple method of analyzing neuromuscular function, both in the operating room and in the intensive care

unit. However, although good correlation exists between the TOF ratio measured by this method and the TOF ratio measured with a force-displacement transducer or EMG,[51,53,54] measurements made via AMG are not directly comparable with results obtained by the other two methods.[54-58] When AMG is used with a free-moving thumb, as originally suggested,[51] wide limits of agreements in twitch height (T1) and TOF ratio and differences in the onset and recovery course of blockade between AMG and MMG have been found. Moreover, the AMG control TOF ratio is consistently higher than when measured with a force-displacement transducer. In accordance with this, several studies have indicated that when using AMG, the TOF ratio indicative of sufficient postoperative neuromuscular recovery is 1.0 rather than 0.9 as when measured by MMG or EMG in the adductor pollicis muscle.[2,17,59,60]

One reason for the wide limits of agreement between AMG and MMG is probably and paradoxically connected with one of the originally claimed advantages of the method, that fixation of the hand could be reduced to a minimum as long as the thumb could move freely.[51] However, in daily clinical practice it is often not possible to ensure that the thumb can move freely and that the position of the hand does not change during a surgical procedure. The evoked response may therefore vary considerably. Several solutions have been proposed, and on-going clinical research indicates that the use of an elastic preload on the thumb may improve the agreement between results obtained with AMG and MMG (Fig. 47-15). Despite these reservations, it is my opinion that AMG at the thumb is a valuable clinical tool that when used with intelligence, may eliminate the problem of postoperative residual neuromuscular blockade.[61,62]

When the thumb is not available for monitoring during surgery, some clinicians prefer to monitor the AMG response of the orbicularis oculi or the corrugator supercilii in response to facial nerve stimulation.[41] However, neuromuscular monitoring of both these sites with AMG is subject to large uncertainty regarding the extent of paralysis, and it therefore cannot be recommended for routine monitoring. It provides only a rough estimate of the degree of block of the peripheral muscles.[63,64]

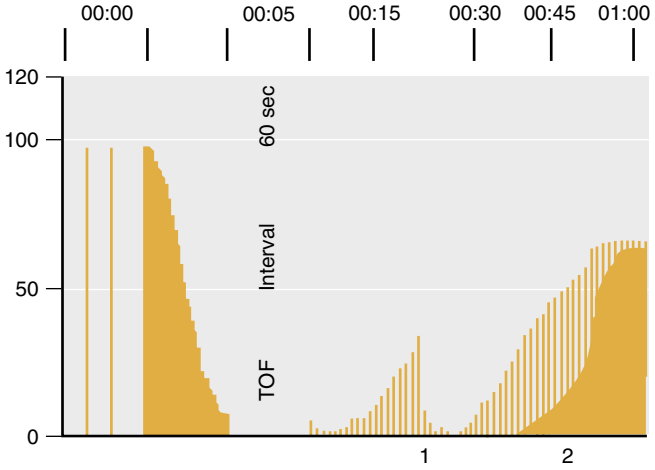

Figure 47-13 Evoked electromyographic printout from a Relaxograph. Initially, single-twitch stimulation was given at 0.1 Hz, and vecuronium (70 µg/kg) was administered intravenously for tracheal intubation. After approximately 5 minutes, the mode of stimulation was changed to train-of-four (TOF) stimulation every 60 seconds. At a twitch height (first twitch in the TOF response) of approximately 30% of control (marker 1), 1 mg of vecuronium was given intravenously. At marker 2, 1 mg of neostigmine was given intravenously, preceded by 2 mg of glycopyrrolate. The printout also illustrates the common problem of failure of the electromyographic response to return to the control level. *(Courtesy of Datex-Ohmeda, Helsinki, Finland.)*

Piezoelectric Neuromuscular Monitors

The technique of the piezoelectric monitor is based on the principle that stretching or bending a flexible piezoelectric film (e.g., one attached to the thumb) in response to nerve stimulation generates a voltage that is proportional to the amount of stretching or bending.[65,66] At least two devices based on this principle are available commercially: the ParaGraph Neuromuscular Blockade Monitor (Vital Signs, Totowa, NJ) and the M-NMT MechanoSensor, which is a part of the Datex AS/3 monitoring system (Datex-Ohmeda, Helsinki, Finland) (Fig. 47-16).

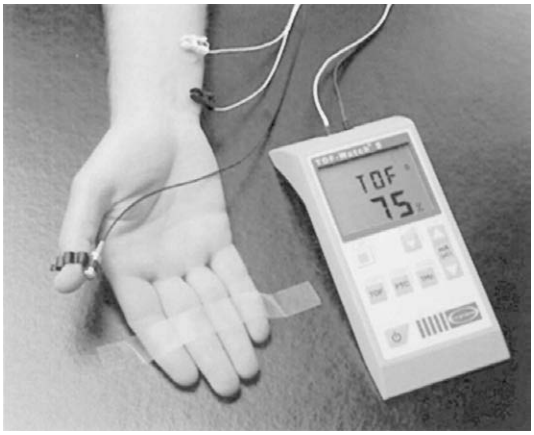

Figure 47-14 TOF-Watch (Organon, part of Schering-Plough, Corp.). This neuromuscular transmission monitor is based on measurement of acceleration with a piezoelectric transducer.[51,52] Note that the transducer is fastened to the thumb and the stimulating electrodes. On the display of the TOF-Watch, the train-of-four (TOF) ratio is given in percentage.

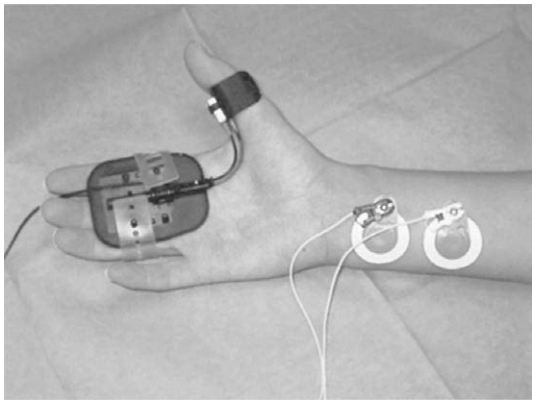

Figure 47-15 Hand adaptor (elastic preload) for the TOF-Watch transducer (Organon, part of Schering-Plough, Corp.).

Few studies have evaluated the function of these monitors.[65-67] The scarce data indicate a good relationship between results obtained with P_ZEMG, AMG, and MMG, but also wide limits of agreement between the methods. Therefore, although P_ZEMG may be a valuable clinical tool, the values obtained in an individual patient with this method may vary from those obtained with MMG or AMG.

Phonomyography

PMG (acoustic myography) is a relatively new method of monitoring neuromuscular function.[68-72] Contraction of skeletal muscles generates intrinsic low-frequency sounds, which can be recorded with special microphones. This method has been evaluated for clinical and research purposes. Several reports indicate good correlation between evoked acoustic responses and those obtained with more traditional methods of recording, such as MMG, EMG, and AMG. However, it is uncertain whether PMG will ever be used for monitoring neuromuscular blockade during routine anesthesia. What does make PMG interesting, however, is that in theory the method can be applied not only to the adductor pollicis muscle but also to other muscles of interest such as the diaphragm, larynx, and eye muscles. In addition, the ease of application is attractive.

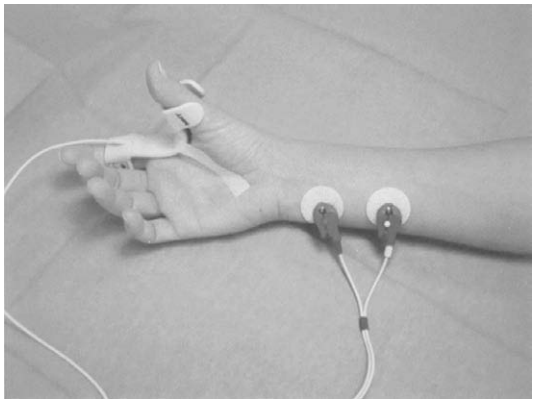

Figure 47-16 Datex-Engstrøm M-NMT MechanoSensor (a piezoelectric neuromuscular monitor).

For further information on recording evoked responses, the reader is referred to guidelines for good clinical research practice in pharmacodynamic studies of neuromuscular blocking drugs, published in *Acta Anaesthesiologica Scandinavica*.[29]

Evaluation of Recorded Evoked Responses

Nerve stimulation in clinical anesthesia is usually synonymous with TOF nerve stimulation. Therefore, the recorded response to this form of stimulation is used to explain how to evaluate the degree of neuromuscular blockade during clinical anesthesia.

Nondepolarizing Neuromuscular Blockade

After injection of a nondepolarizing neuromuscular blocking drug in a dose sufficient for smooth tracheal intubation, TOF recording demonstrates four phases or levels of neuromuscular blockade: intense blockade, deep blockade, moderate or surgical blockade, and recovery (Fig. 47-17).

Intense Neuromuscular Blockade

Intense neuromuscular blockade occurs within 3 to 6 minutes of injection of an intubating dose of a nondepolarizing muscle relaxant, depending on the drug and the dose given. This phase is also called the "period of no response" because no response to any pattern of nerve stimulation occurs. The length of this period varies, again depending primarily on the duration of action of the muscle relaxant and the dose given. The sensitivity of the patient to the drug also affects the period of no response.

Deep Neuromuscular Blockade

Intense neuromuscular blockade is followed by a period of deep block, characterized by absence of response to TOF stimulation, but presence of post-tetanic twitches (i.e., PTC ≥ 1; compare with Figure 47-4). Although it is not possible during this phase to determine exactly how long deep neuromuscular blockade will last, correlation does exist between PTC stimulation and the time until reappearance of the first response to TOF stimulation (see Fig. 47-5).

Moderate or Surgical Blockade

Moderate or surgical blockade begins when the first response to TOF stimulation appears. This phase is characterized by a gradual return of the four responses to TOF stimulation. Furthermore, good correlation exists between the degree of neuromuscular blockade and the number of responses to TOF stimulation. When only one response is detectable, the degree of neuromuscular blockade (the depression in twitch tension) is 90% to 95%. When the fourth response reappears, neuromuscular blockade is usually 60% to 85%.[73,74] The presence of one or two responses in the TOF pattern normally indicates sufficient relaxation for most surgical procedures. During light anesthesia, however, patients may move, buck, or cough. Therefore, when elimination of sudden movements is crucial, a deeper block (or a deeper level of anesthesia) may be necessary. The deep block can then be evaluated by PTC (see Fig. 47-6).

Antagonism of neuromuscular blockade with a cholinesterase inhibitor should not normally be attempted when the blockade is intense or deep because reversal will often be inadequate, regardless of the dose of antagonist administered.[75] Furthermore, after the administration of large doses of muscle relaxants, reversal of the block to clinically normal activity is not always possible if only one TOF response is present. In general, antagonism with cholinesterase inhibitors should not be initiated before at least two and preferably three or four responses are observed.

Recovery

Return of the fourth response in the TOF heralds the recovery phase. During neuromuscular recovery, a reasonably good correlation exists between the actual TOF ratio measured by MMG and clinical observation, but the relationship between the TOF ratio and signs and symptoms of residual blockade varies greatly

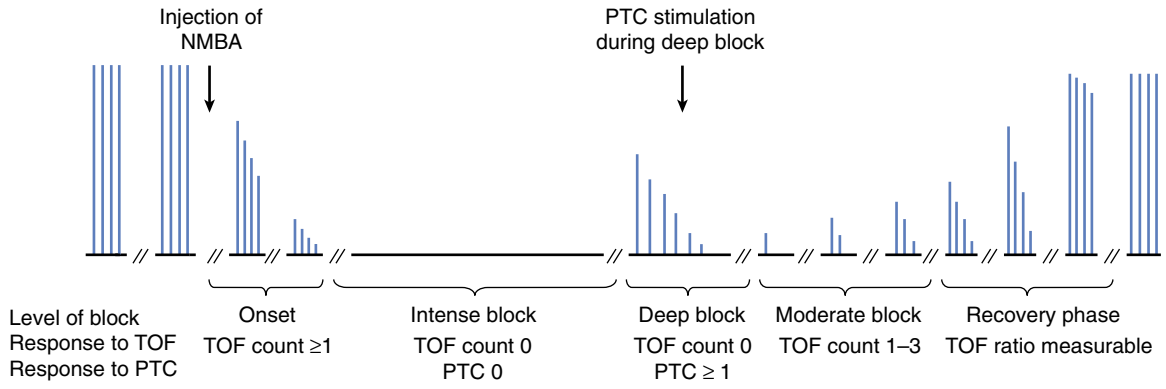

Figure 47-17 Levels of block after a normal intubating dose of a nondepolarizing neuromuscular blocking agent (NMBA) as classified by post-tetanic count (PTC) and train-of-four (TOF) stimulation. During intense (profound) block, there are no responses to either TOF or PTC stimulation. During deep block, there is response to PTC but not to TOF stimulation. Intense (profound) block and deep block together constitute the "period of no response to TOF stimulation." Reappearance of the response to TOF stimulation heralds the start of moderate block. Finally, when all four responses to TOF stimulation are present and a TOF ratio can be measured, the recovery period has started. *(From Fuchs-Buder T, Claudius C, Skovgaard LT, et al: Good clinical research practice in pharmacodynamic studies of neuromuscular blocking agents II: The Stockholm revision. Acta Anaesthesiol Scand 51:789, 2007.)*

among patients.[75] When the TOF ratio is 0.4 or less, the patient is generally unable to lift the head or arm. Tidal volume may be normal, but vital capacity and inspiratory force will be reduced. When the ratio is 0.6, most patients are able to lift their head for 3 seconds, open their eyes widely, and stick out their tongue, but vital capacity and inspiratory force are often still reduced. At a TOF ratio of 0.7 to 0.75, the patient can normally cough sufficiently and lift the head for at least 5 seconds, but grip strength may still be as low as about 60% of control.[76] When the ratio is 0.8 and higher, vital capacity and inspiratory force are normal.[12,77-79] The patient may, however, still have diplopia and facial weakness (Table 47-1).[75]

In clinical anesthesia, a TOF ratio of 0.70 to 0.75, or even 0.50, has been thought to reflect adequate recovery of neuromuscular function.[79] However, the TOF ratio, whether recorded mechanically or by EMG, must exceed 0.80 or even 0.90 to exclude clinically important residual neuromuscular blockade.[40,50,59,80-85] Moderate degrees of neuromuscular blockade decrease chemoreceptor sensitivity to hypoxia and thereby lead to insufficient response to a decrease in oxygen tension in blood.[80,81,83,85] Moreover, residual blockade (TOF < 0.90) is associated with functional impairment of the pharyngeal and upper esophageal muscles, which most probably predisposes to regurgitation and aspiration of gastric contents.[40] Recently, Eikerman and colleagues documented that partial neuromuscular blockade, even to a degree that does not evoke dyspnea or oxygen desaturation, may decrease inspiratory upper airway volume and can evoke partial inspiratory airway collapse.[86] Accordingly, residual blockade (TOF < 0.70) caused by the long-acting muscle relaxant pancuronium is a significant risk factor for the development of postoperative pulmonary complications (Table 47-2 and Fig. 47-18).[82] Even in volunteers without sedation or impaired consciousness, a TOF ratio of 0.9 or less may impair the ability to maintain the airway.[76] Adequate recovery of neuromuscular function requires return of an MMG or EMG TOF ratio to 0.90 or greater, which cannot be guaranteed without objective neuromuscular monitoring.[61,62,87-90]

Table 47-1 Clinical Signs and Symptoms of Residual Paralysis in Awake Volunteers After Mivacurium-Induced Neuromuscular Blockade

Train-of-Four Ratio	Signs and Symptoms
0.70-0.75	Diplopia and visual disturbances
	Decreased handgrip strength
	Inability to maintain apposition of the incisor teeth
	"Tongue depressor test" negative
	Inability to sit up without assistance
	Severe facial weakness
	Speaking a major effort
	Overall weakness and tiredness
0.85-0.90	Diplopia and visual disturbances
	Generalized fatigue

Table 47-2 Relationship between Train-of-Four Ratio at the First Postoperative Recording and Postoperative Pulmonary Complications*

	Pancuronium (*n* = 226)			Atracurium or Vecuronium (*n* = 450)		
	No. of Patients	Patients with POPC		No. of Patients	Patients with POPC	
		n	%		*n*	%
TOF ≥ 0.70	167	8	4.8	426	23	5.4
TOF < 0.70	59	10	16.9†	24	1	4.2

*Results from a prospective, randomized, and blinded study of postoperative pulmonary complications (POPC) in a total of 691 adult patients undergoing abdominal, gynecologic, or orthopedic surgery and receiving either pancuronium, atracurium, or vecuronium.[82] In 4 of the 46 patients with POPC (1 in the pancuronium group and 3 in the atracurium and vecuronium groups), the train-of-four (TOF) ratio was not available. Because there were no significant differences in the two groups of patients given the intermediate-acting muscle relaxants, the data from these groups are pooled.
†$P < .02$ versus patients in the same group with a TOF ratio of 0.70 or greater.

Depolarizing Neuromuscular Blockade (Phase I and II Blocks)

Patients with normal plasma cholinesterase activity who are given a moderate dose of succinylcholine (0.5 to 1.5 mg/kg) undergo a typical depolarizing neuromuscular block (phase I block; i.e., the response to TOF or tetanic stimulation does not fade, and no post-tetanic facilitation of transmission occurs). In contrast, some patients with genetically determined abnormal plasma cholinesterase activity who are given the same dose of succinylcholine undergo a nondepolarizing-like block characterized by fade in the response to TOF and tetanic stimulation and the occurrence of post-tetanic facilitation of transmission (Fig. 47-19). This type of block is called a phase II block (dual, mixed, or desensitizing block). In addition, phase II blocks sometimes occur in genetically normal patients after repetitive bolus doses or a prolonged infusion of succinylcholine.

From a therapeutic point of view, a phase II block in normal patients must be differentiated from a phase II block in patients with abnormal cholinesterase activity. In normal patients, a phase II block can be antagonized by administering a cholinesterase inhibitor a few minutes after discontinuation of succinylcholine. In patients with abnormal genotypes, however, the effect of intravenous injection of an acetylcholinesterase inhibitor (e.g., neostigmine) is unpredictable. For example, neostigmine can potentiate the block dramatically, temporarily improve neuromuscular transmission, and then potentiate the block or partially reverse the block, all depending on the time elapsed since administration of succinylcholine and the dose of neostigmine given. Therefore, unless the cholinesterase genotype is known to be normal, antagonism of a phase II block with a cholinesterase inhibitor should be undertaken with extreme caution. Even if neuromuscular function improves promptly, patient surveillance should continue for at least 1 hour.

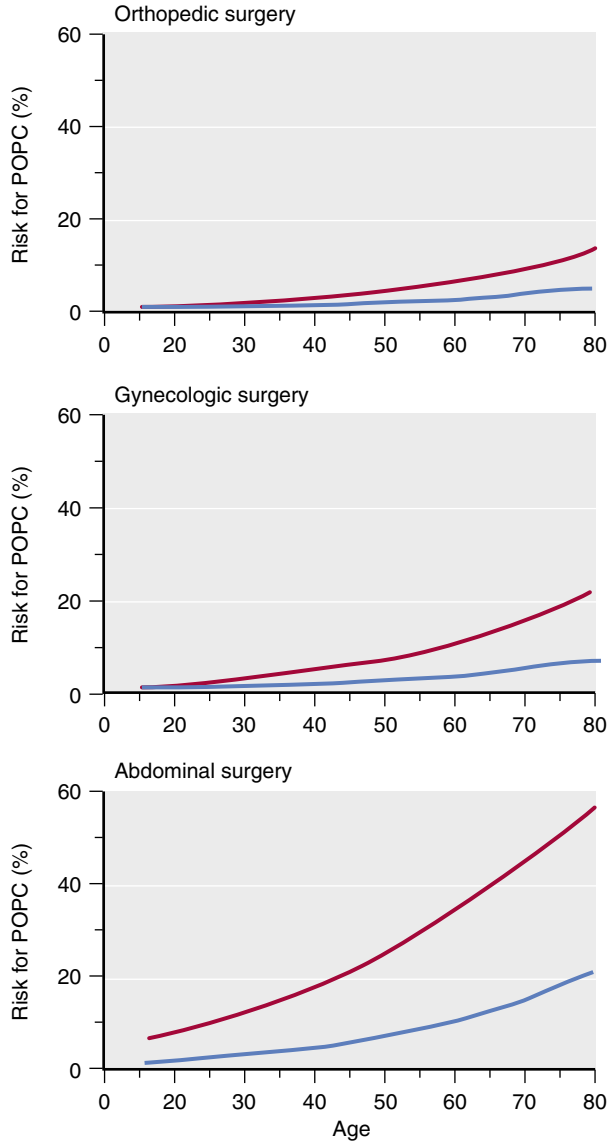

Figure 47-18 Predicted probabilities of a postoperative pulmonary complication (POPC) in different age groups in orthopedic, gynecologic, and major abdominal surgery with a duration of anesthesia of less than 200 minutes. The *red lines* represent patients with residual neuromuscular block (train-of-four [TOF] < 0.70) after the administration of pancuronium; the *blue lines* represent patients with a TOF of 0.70 or greater after the administration of pancuronium, as well as all patients after the administration of atracurium and vecuronium, independent of the TOF ratio at the end of anesthesia.[82]

Use of Nerve Stimulators Without Recording Equipment

Whenever a neuromuscular blocking drug is administered to a patient, tactile or visual evaluation of the evoked response is still the most common form of clinical neuromuscular monitoring. The following is a description of how this is best done.

First, for supramaximal stimulation, careful cleansing of the skin and proper placement and fixation of electrodes are essential. Second, every effort should be taken to prevent central cooling, as well as cooling of the extremity being evaluated. Both central and local surface cooling of the adductor pollicis muscle may reduce twitch tension and the TOF ratio.[91-93] Peripheral cooling may affect nerve conduction, decrease the rate of release of acetylcholine and muscle contractility, increase skin impedance, and reduce blood flow to muscles, thus decreasing the rate of removal of muscle relaxant from the neuromuscular junction. These factors may account for the occasional very pronounced difference in muscle response between a cold extremity and the contralateral warm extremity.[94] Third, when possible, the response to nerve stimulation should be evaluated by feel and not by eye, and the response of the thumb (rather than response of the fifth finger) should be evaluated. Direct stimulation of the muscle often causes subtle movement of the fifth finger when no response is present at the thumb. Finally, the different sensitivities of various muscle groups to neuromuscular blocking agents should always be kept in mind. Figure 47-20 shows which modes of nerve stimulation can be used at various perioperative times.

Use of a Peripheral Nerve Stimulator During Induction of Anesthesia

The nerve stimulator should be attached to the patient before induction of anesthesia but should not be turned on until after the patient is unconscious. Single-twitch stimulation at 1 Hz may be used initially when seeking supramaximal stimulation. However, after supramaximal stimulation has been ensured and before muscle relaxant is injected, the mode of stimulation should be changed to TOF (or 0.1-Hz twitch stimulation). Then, after the response to this stimulation has been observed (the control response), the neuromuscular blocking agent is injected. Although the trachea is often intubated when the response to TOF stimulation disappears, postponement of this procedure for 30 to 90

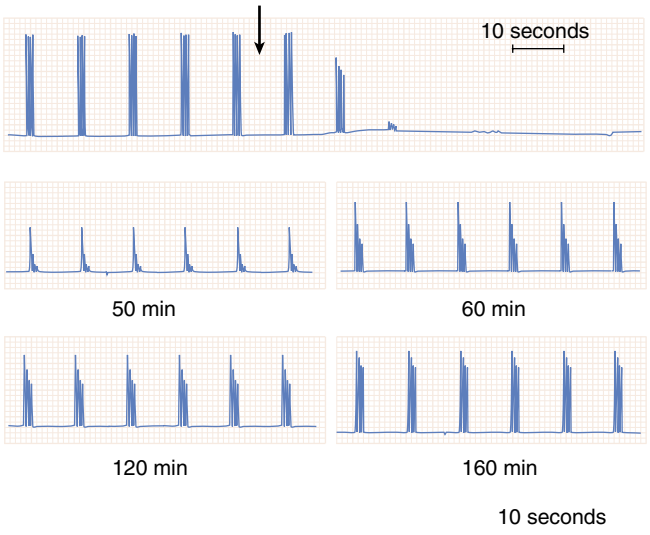

Figure 47-19 Typical recording of the mechanical response (Myograph 2000) to train-of-four ulnar nerve stimulation after injection of 1 mg/kg of succinylcholine (*arrow*) in a patient with genetically determined abnormal plasma cholinesterase activity. The prolonged duration of action and the pronounced fade in the response indicate a phase II block.

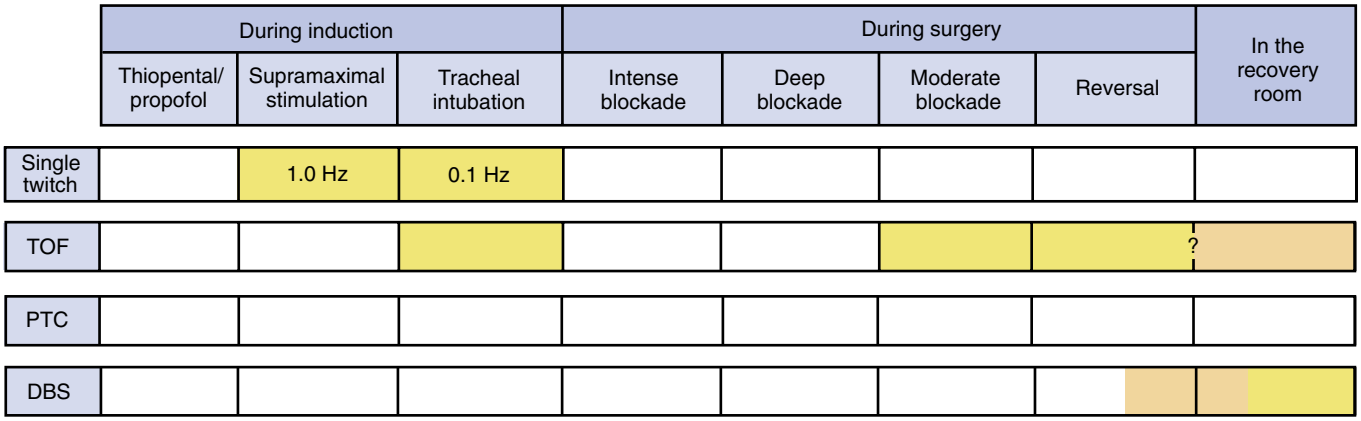

Figure 47-20 Diagram showing when the different modes of electrical nerve stimulation can be used during clinical anesthesia. *Dark areas* indicate appropriate use and *light areas*, less effective use. Modes of nerve stimulation are train-of-four (TOF) stimulation; post-tetanic count (PTC); double-burst stimulation (DBS); and the question mark (?), indicating that TOF is less useful in the recovery room unless measured with mechanomyography, electromyography, or acceleromyography. (See text for further explanation.)

seconds, depending on the muscle relaxant used, usually produces better conditions.

Use of a Peripheral Nerve Stimulator During Surgery

If tracheal intubation is facilitated by the administration of succinylcholine, no more muscle relaxant should be given until the response to nerve stimulation reappears or the patient shows other signs of returning neuromuscular function. If plasma cholinesterase activity is normal, the muscle response to TOF nerve stimulation reappears within 4 to 8 minutes.

When a nondepolarizing neuromuscular drug is used for tracheal intubation, a longer-lasting period of intense blockade usually follows. During this period of no response to TOF and single-twitch stimulation, the time until return of response to TOF stimulation may be evaluated by PTC (see Fig. 47-5).

For most surgical procedures requiring muscle relaxation, twitch depression of approximately 90% will be sufficient, provided that the patient is adequately anesthetized. If a nondepolarizing relaxant is used, one or two of the responses to TOF stimulation can be felt. However, because the respiratory muscles (including the diaphragm) are less sensitive to neuromuscular blocking agents than the peripheral muscles are, the patient may breathe, hiccup, or even cough at this depth of blockade. To ensure paralysis of the diaphragm, neuromuscular blockade of the peripheral muscles must be so intense that the PTC is zero in the thumb.

An added advantage of keeping the neuromuscular blockade at a level of one or two responses to TOF stimulation is that antagonism of the block is facilitated at the end of surgery.

Use of a Peripheral Nerve Stimulator during Reversal of Neuromuscular Blockade

Antagonism of nondepolarizing neuromuscular blockade with a cholinesterase inhibitor such as neostigmine should probably not be initiated before at least two responses to TOF stimulation are present or before obvious clinical signs of returning neuromuscular function are seen. Certainly, reversal of neuromuscular blockade will not be hastened and may possibly be delayed by giving neostigmine when no response to peripheral nerve stimulation is present. Conversely, to achieve rapid reversal (within 10 minutes) to a TOF ratio of 0.7 in more than 90% of patients, three and preferably four responses should be present at the time of neostigmine injection.[95] To achieve a TOF ratio of 0.9 in all patients with this method is not possible, but critical episodes of postoperative residual blockade should be an infrequent occurrence.[96]

During recovery of neuromuscular function, when all four responses to TOF stimulation can be felt, an estimation of the TOF ratio may be attempted. However, manual (tactile) evaluation of the response to TOF stimulation (see Fig. 47-8) is not sensitive enough to exclude the possibility of residual neuromuscular blockade.[25,88,97] Greater sensitivity is achieved with $DBS_{3,3}$, but even absence of manual fade in the $DBS_{3,3}$ response does not exclude clinically significant residual blockade.[27] Therefore, manual evaluation of responses to nerve stimulation should always be considered in relation to reliable clinical signs and symptoms of residual neuromuscular blockade (Box 47-1).

When to Use a Peripheral Nerve Stimulator

At some institutions, nerve stimulators are used routinely whenever a neuromuscular blocking drug is administered. In most cases, the response is evaluated by touch, and only in selected cases are the responses recorded. Many anesthesiologists do not agree with extensive use of nerve stimulators and argue that they manage quite well without these devices. However, the question is not how little an experienced anesthetist can manage with but rather how to ensure that all patients receive optimal treatment.

In daily clinical practice, significant residual blockade can be excluded with certainty only if objective methods of neuromuscular monitoring are used.[61,62] In my opinion[3] and those of others,[4] good evidence-based practice dictates that clinicians

Box 47-1 Clinical Tests of Postoperative Neuromuscular Recovery

Unreliable

Sustained eye opening

Protrusion of the tongue

Arm lift to the opposite shoulder

Normal tidal volume

Normal or nearly normal vital capacity

Maximum inspiratory pressure less than 40 to 50 cm H_2O

Most Reliable

Sustained head lift for 5 seconds

Sustained leg lift for 5 seconds

Sustained handgrip for 5 seconds

Sustained "tongue depressor test"

Maximum inspiratory pressure 40 to 50 cm H_2O or greater

should always quantitate the extent of neuromuscular recovery by objective monitoring. At a minimum, the TOF ratio should be measured during recovery whenever a nondepolarizing neuromuscular block is not antagonized.[3]

However, in many departments clinicians do not have access to equipment for measuring the degree of block. How then to evaluate and, as far as possible, exclude a clinically significant postoperative block? First, long-acting neuromuscular blocking agents should not be used. Second, the tactile response to TOF nerve stimulation should be evaluated during surgery. Third, if possible, total twitch suppression should be avoided. The block should be managed so that there is always one or two tactile TOF responses. Fourth, the block should be antagonized at the end of the procedure, but reversal should not be initiated before at least two and preferably three or four responses to TOF stimulation are present. Fifth, during recovery, tactile evaluation of the response to DBS is preferable to tactile evaluation of the response to TOF stimulation because it is easier to feel fade in the DBS than in the TOF response. Sixth, the clinician should recognize that absence of tactile fade in both the TOF and DBS responses does not exclude significant residual blockade.[28,87,88,97] Finally, reliable clinical signs and symptoms of residual blockade (see Box 47-1) should be considered in relation to the response to nerve stimulation.

In view of the uncertainty connected with the use of clinical tests of postoperative neuromuscular recovery and tactile evaluation of the response to nerve stimulation, at a minimum, every anesthesia department and every recovery room should have at least one apparatus for recording evoked responses. Whether the functioning of such a neuromuscular transmission analyzer is based on EMG, MMG, AMG, P_ZEMG, or PMG is not crucial, as long as the physician knows how to use the apparatus in question.

48 Temperature Regulation and Monitoring

Key Points

1. General anesthetics decrease the thresholds (triggering core temperatures) for vasoconstriction and shivering by 2°C to 3°C.
2. Anesthetic-induced impairment of thermoregulatory control, combined with a cool operating room environment, makes most patients hypothermic.
3. The major initial cause of hypothermia in most patients is core-to-peripheral redistribution of body heat.
4. Neuraxial anesthesia impairs both central and peripheral thermoregulatory control and is associated with substantial hypothermia.
5. Large randomized trials have proved that even mild hypothermia (i.e., 1.5°C to 2.0°C) causes adverse outcomes, including a threefold increase in morbid myocardial outcomes, a threefold increase in risk for wound infection, coagulopathy and need for allogeneic transfusion, prolonged recovery, and prolonged hospitalization.
6. Body temperature should be monitored in patients undergoing surgery lasting longer than 30 minutes, and core temperature should be maintained at 36°C or higher whenever possible. Forced-air warming currently offers the best combination of high efficacy, low cost, and remarkable safety.

Mammals and birds are homeothermic and require a nearly constant internal body temperature. When internal temperature deviates significantly from normal, metabolic functions usually deteriorate, and death may result. The thermoregulatory system generally maintains core body temperature within a few tenths of a degree centigrade of "normal," which is about 37°C in humans. Anesthetic-induced inhibition of thermoregulation combined with exposure to a cold operating room environment makes most unwarmed patients hypothermic. In recent years, major outcome studies have shown that mild hypothermia (≈1°C to 2°C): (1) triples the incidence of morbid cardiac outcomes, (2) triples the incidence of surgical wound infections, (3) increases surgical blood loss and the need for allogeneic transfusion by about 20%, and, (4) prolongs postanesthesia recovery and the duration of hospitalization. An understanding of normal and anesthetic-influenced thermoregulation will facilitate prevention and management of these and numerous other temperature-related complications.

Normal Thermoregulation

Thermoregulation is based on multiple, redundant signals from nearly every type of tissue. Processing of thermoregulatory information occurs in three phases: *afferent thermal sensing*, *central regulation*, and *efferent responses*.

Afferent Input

Information on temperature is obtained from thermally sensitive cells throughout the body. Cold-sensitive cells are anatomically and physiologically distinct from those that detect warmth. Warm receptors increase their firing rates when temperature increases, whereas cold receptors do so when temperature decreases. Cutaneous warm receptors rarely depolarize at normal skin temperatures and are probably important only during heat stress. The actual sensors appear to be a recently discovered class of transient receptor potential (TRP) protein receptors.[1]

Cold signals travel primarily via Aδ nerve fibers, and warm information, by unmyelinated C fibers, although there is some overlap.[2] C fibers also detect and convey pain sensation, which is why intense heat cannot be distinguished from sharp pain. Most ascending thermal information traverses the spinothalamic tracts in the anterior spinal cord, but no single spinal tract is critical for conveying thermal information. Consequently, the entire anterior cord must be destroyed to ablate thermoregulatory responses.

The hypothalamus, other parts of the brain, the spinal cord, deep abdominal and thoracic tissues, and the skin surface each

contribute roughly 20% of total thermal input to the central regulatory system.[3]

Central Control

Temperature is regulated by central structures (primarily the hypothalamus) that compare integrated thermal input from the skin surface, neuraxis, and deep tissues with *threshold* temperatures for each thermoregulatory response. Although integrated by the hypothalamus, most thermal information is "preprocessed" in the spinal cord and other parts of the central nervous system. This hierarchic arrangement presumably developed when the evolving thermoregulatory control system co-opted previously existing mechanisms (e.g., shivering from muscles previously used for posture and locomotion). Some thermoregulatory responses can be mounted by the spinal cord alone.[4] For example, animals and patients with high spinal cord transection regulate temperature better than might be expected.

The slope of response intensity versus core temperature defines the *gain* of a thermoregulatory response. Response intensity no longer increasing with further deviation in core temperature identifies the *maximum intensity*. This system of thresholds and gains is a model for a thermoregulatory system that is further complicated by interactions between other regulatory responses (i.e., vascular volume control) and time-dependent effects.

How the body determines absolute threshold temperatures is unknown, but the mechanism appears to be mediated by norepinephrine, dopamine, 5-hydroxytryptamine, acetylcholine, prostaglandin E_1, and neuropeptides. The thresholds vary daily in both sexes (circadian rhythm) and monthly in women by approximately 0.5°C. Exercise, food intake, infection, hypothyroidism and hyperthyroidism, anesthetic and other drugs (including alcohol, sedatives, and nicotine), and cold and warm adaptation all alter threshold temperatures.

Control of autonomic responses is approximately 80% determined by thermal input from core structures (Fig. 48-1).[5] In contrast, a large fraction of the input controlling behavioral responses is derived from the skin surface. The *interthreshold range* (core temperatures *not* triggering autonomic thermoregulatory responses) is a few tenths of a degree centigrade.[6] This range is bounded by the sweating threshold at its upper end and by vasoconstriction at the lower end. Because energy cost and nutrients are conserved without excessive autonomic control within this range, some animals such as camels and desert rats use this strategy extensively and exhibit core temperature changes of up to 10°C each day. However, most mammals—including humans—normally regulate core temperature tightly.

Both sweating and vasoconstriction thresholds are 0.3°C to 0.5°C higher in women than in men, even during the follicular phase of the menstrual cycle (first 10 days).[7] These differences are even greater during the luteal phase.[8] Central thermoregulatory control is apparently intact even in somewhat premature infants.[9] In contrast, thermoregulatory control is sometimes impaired in the elderly.[10]

Efferent Responses

The body responds to thermal perturbations (body temperatures differing from the appropriate threshold) via effector mechanisms that increase metabolic heat production or alter environmental heat loss. Each thermoregulatory effector has its own threshold and gain, so there is an orderly progression of responses and response intensities in proportion to need. In general, energy-efficient effectors such as vasoconstriction are maximized before metabolically costly responses such as shivering are initiated. Figure 48-2 shows the normal values for the major autonomic response thresholds.

Effectors determine the ambient temperature range that the body will tolerate while maintaining a normal core temperature. When specific effector mechanisms are inhibited (e.g., when shivering is prevented by the administration of muscle relaxants), the

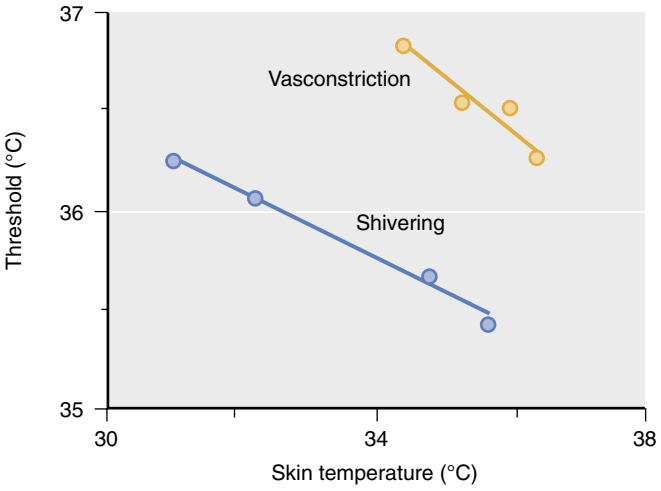

Figure 48-1 There is a linear relationship between mean skin temperature and the core temperature triggering vasoconstriction and shivering. Skin temperature contributes about 20% to control of each thermoregulatory defense. *(From Cheng C, Matsukawa T, Sessler DI, et al: Increasing mean skin temperature linearly reduces the core-temperature thresholds for vasoconstriction and shivering in humans. Anesthesiology 82:1160-1168, 1995.)*

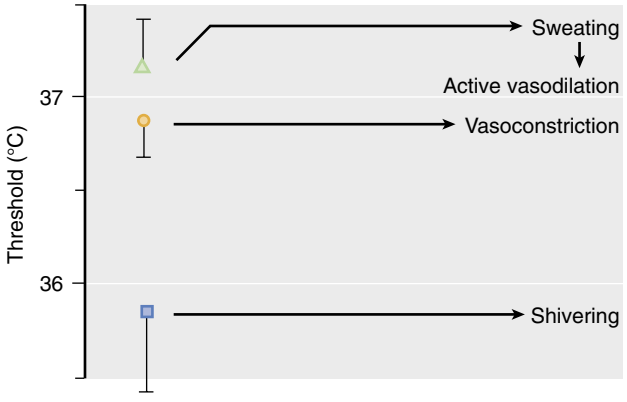

Figure 48-2 A core temperature below the threshold for response to cold provokes vasoconstriction, nonshivering thermogenesis, and shivering. A core temperature exceeding the hyperthermic threshold produces active vasodilation and sweating. No thermoregulatory responses are initiated when the core temperature is between these thresholds; these temperatures identify the interthreshold range, which in humans is usually only about 0.2°C. *(Threshold data from Lopez M, Sessler DI, Walter K, et al: Rate and gender dependence of the sweating, vasoconstriction, and shivering thresholds in humans. Anesthesiology 80:780-788, 1994.)*

tolerable range is decreased. Still, temperature will remain normal unless other effectors cannot compensate for the imposed stress. Quantitatively, *behavioral regulation* is the most important effector mechanism. Behavioral compensations include dressing appropriately, modifying environmental temperature, assuming positions that oppose skin surfaces, and voluntary movement.

Infants regulate their temperature remarkably well. In contrast, advanced age, infirmity, or medications can diminish the efficacy of thermoregulatory responses and increase the risk for hypothermia. For example, decreased muscle mass, neuromuscular diseases, and muscle relaxants all inhibit shivering, which increases the minimum tolerable ambient temperature. Similarly, anticholinergic drugs inhibit sweating, which decreases the maximum tolerable temperature.

Cutaneous vasoconstriction is the most consistently used autonomic effector mechanism. Metabolic heat is lost primarily via convection and radiation from the skin surface, and vasoconstriction reduces this loss. Total digital skin blood flow is divided into nutritional (mostly capillary) and thermoregulatory (mostly arteriovenous shunt) components.[11] The arteriovenous shunts are anatomically and functionally distinct from the capillaries supplying nutritional blood to the skin (thus vasoconstriction does not compromise the needs of peripheral tissues).

Control of blood flow through arteriovenous shunts tends to be "on" or "off." In other words, the gain of this response is high, with digital flow increasing from trivial to maximal levels after changes in core temperature of only a few tenths of a degree centigrade. Local α-adrenergic sympathetic nerves mediate constriction in the thermoregulatory arteriovenous shunts, and flow is minimally affected by *circulating* catecholamines. Roughly 10% of cardiac output traverses the arteriovenous shunts; consequently, shunt vasoconstriction increases mean arterial pressure approximately 15 mm Hg.[12]

Nonshivering thermogenesis increases metabolic heat production (measured as whole-body oxygen consumption) without producing mechanical work. It doubles heat production in infants[13] but increases it only slightly in adults.[14] The intensity of nonshivering thermogenesis increases in linear proportion to the difference between mean body temperature and its threshold. Skeletal muscle and brown fat tissue are the major sources of nonshivering heat in adults. The metabolic rate in both tissues is controlled primarily by norepinephrine released from adrenergic nerve terminals and is further mediated locally by an uncoupling protein.[15]

Sustained shivering augments metabolic heat production by 50% to 100% in adults. This increase is small in comparison to that produced by exercise (which can, at least briefly, increase metabolism by 500%) and thus is surprisingly ineffective. Shivering does not occur in newborn infants and probably is not fully effective until children are several years old. The rapid tremor (up to 250 Hz) and unsynchronized muscular activity of thermogenic shivering suggest no central oscillator. However, superimposed on the fast activity, there is usually a slow (4 to 8 cycles/min), synchronous "waxing-and-waning" pattern that presumably is centrally mediated.[16]

Sweating is mediated by postganglionic, cholinergic nerves.[17] It thus is an active process that is prevented by nerve block or administration of atropine.[18] Sweating is the only mechanism by which the body can dissipate heat in an environment exceeding core temperature. Fortunately, the process is remarkably effective, with 0.58 kcal dissipated per gram of evaporated sweat.

Active vasodilation is apparently mediated by nitric oxide.[19] Because active vasodilation requires intact sweat gland function, it is also largely inhibited by nerve blockade. The threshold for active vasodilation is usually similar to the sweating threshold, but the gain may be less. Consequently, maximum cutaneous vasodilation is generally delayed until core temperature is well above that provoking maximum sweating intensity.

Thermoregulation During General Anesthesia

Behavioral regulation is not relevant during general anesthesia because patients are unconscious and frequently paralyzed. All general anesthetics tested thus far markedly impair normal autonomic thermoregulatory control and cause slightly elevated warm-response thresholds, whereas cold-response thresholds are markedly reduced. Consequently, the interthreshold range is increased from its normal value near 0.3°C to about 2°C to 4°C.[20-24] The gain and maximum intensity of some responses remain normal,[7] whereas others are reduced by general anesthesia.[25,26]

Response Thresholds

Propofol,[20] alfentanil,[21] and dexmedetomidine[22] all produce a slight linear increase in the sweating threshold combined with a marked and linear decrease in the vasoconstriction and shivering thresholds. Isoflurane[24] and desflurane[23] also slightly increase the sweating threshold; however, they decrease the cold-response threshold nonlinearly. Consequently, the volatile anesthetics inhibit vasoconstriction and shivering less than propofol does at low concentrations but more than propofol does at typical anesthetic doses. In all cases (except during meperidine[27] and nefopam[28] administration), vasoconstriction and shivering decrease synchronously and thus maintain their normal approximate 1°C difference.

The dose-dependent response thresholds for four anesthetic drugs are shown in Figure 48-3. The combination of increased sweating thresholds and reduced vasoconstriction thresholds increases the interthreshold range about 20-fold, from its normal value near 0.2°C to approximately 2°C to 4°C. Temperatures within this range do *not* trigger thermoregulatory defenses, and patients are thus by definition poikilothermic within this temperature range.

Isoflurane,[24] desflurane,[23,25] enflurane,[29] halothane,[30] and the combination of nitrous oxide and fentanyl[31] decrease the vasoconstriction threshold 2°C to 4°C from its normal value near 37°C. The dose dependence is nonlinear; that is, greater concentrations produce disproportionate threshold reductions. The shivering thresholds decrease synchronously. In contrast, these drugs increase the sweating threshold only slightly.

Clonidine synchronously decreases cold-response thresholds[32] while slightly increasing the sweating threshold.[33] Nitrous oxide decreases the vasoconstriction[34] and shivering[35] thresholds less than equipotent concentrations of volatile anesthetics do. In

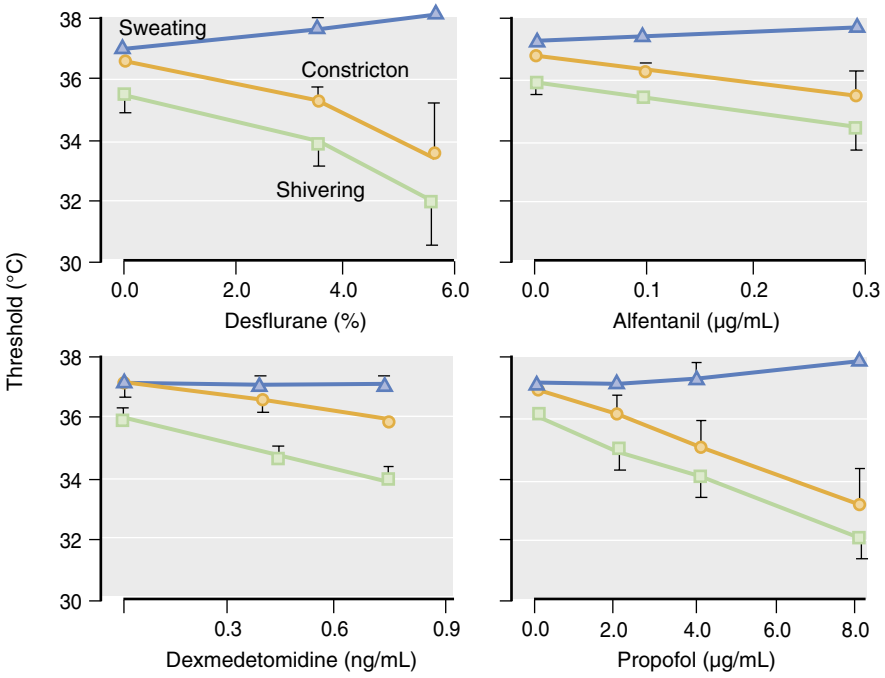

Figure 48-3 Major autonomic thermoregulatory response thresholds in volunteers given desflurane, alfentanil, dexmedetomidine, or propofol. All the anesthetics slightly increase the sweating threshold (triggering core temperature) while markedly and synchronously decreasing the vasoconstriction and shivering thresholds. Standard deviation bars smaller than the data markers have been deleted. *(From Annadata RS, Sessler DI, Tayefeh F, et al: Desflurane slightly increases the sweating threshold, but produces marked, non-linear decreases in the vasoconstriction and shivering thresholds. Anesthesiology 83:1205-1211, 1995; Kurz A, Go JC, Sessler DI, et al: Alfentanil slightly increases the sweating threshold and markedly reduces the vasoconstriction and shivering thresholds. Anesthesiology 83:293-299, 1995; Talke P, Tayefeh F, Sessler DI, et al: Dexmedetomidine does not alter the sweating threshold, but comparably and linearly reduces the vasoconstriction and shivering thresholds. Anesthesiology 87:835-841, 1997; and Matsukawa T, Kurz A, Sessler DI, et al: Propofol linearly reduces the vasoconstriction and shivering thresholds. Anesthesiology 82:1169-1180, 1995.)*

contrast, midazolam only slightly impairs thermoregulatory control.[36,37] Painful stimulation slightly increases the vasoconstriction thresholds[29]; consequently, thresholds will be somewhat lower when surgical pain is prevented by simultaneous local or regional anesthesia.

Responses in Infants and the Elderly

Thermoregulatory vasoconstriction is comparably impaired in infants, children, and adults given isoflurane[38] or halothane (Fig. 48-4).[39] In contrast, the vasoconstriction threshold is about 1°C less in patients aged 60 to 80 years than in those between 30 and 50 years (see Chapters 69, 71, 82, and 84).

Nonshivering thermogenesis does not occur in anesthetized adults,[40] but it is an important thermoregulatory response in animals and human infants. However, nonshivering thermogenesis in animals is inhibited by volatile anesthetics,[41] and it fails to increase the metabolic rate in infants anesthetized with propofol (Fig. 48-5).[42]

Gain and Maximum Response Intensity

Both the gain and maximum intensity of sweating remain normal during isoflurane[7] and enflurane anesthesia.[43] However, the gain of arteriovenous shunt vasoconstriction is reduced threefold during desflurane anesthesia (Fig. 48-6),[25] even though the maximum vasoconstriction intensity remains normal.[44]

Shivering is rare at surgical levels of general anesthesia, which is consistent with its threshold being roughly 1°C less than the vasoconstriction threshold.[20-24] (Vasoconstriction usually prevents additional hypothermia,[45] so even unwarmed patients rarely become cold enough to shiver.) Nonetheless, shivering can be induced by sufficient active cooling.

Gain and maximum shivering intensity remain normal during both meperidine and alfentanil administration.[46] Gain also remains nearly intact during nitrous oxide administration, although maximum intensity is reduced.[47] Isoflurane changes the macroscopic pattern of shivering to such an extent that it is no longer possible to easily determine gain. The drug does, however, reduce maximum shivering intensity.[26]

In summary, sweating is the best preserved major thermoregulatory defense during anesthesia. Not only is the

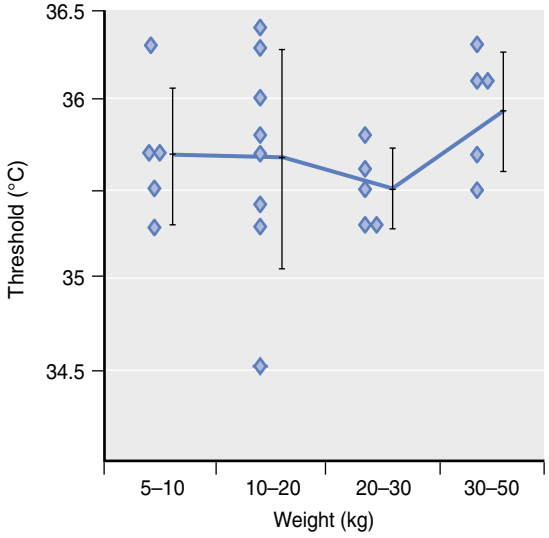

Figure 48-4 Core thermoregulatory threshold in 23 healthy children and infants undergoing abdominal surgery with halothane anesthesia. Differences among the groups are not statistically significant. Results are presented as means ± SD. *(From Bissonnette B, Sessler DI: Thermoregulatory thresholds for vasoconstriction in pediatric patients anesthetized with halothane or halothane and caudal bupivacaine. Anesthesiology 76:387-392, 1992.)*

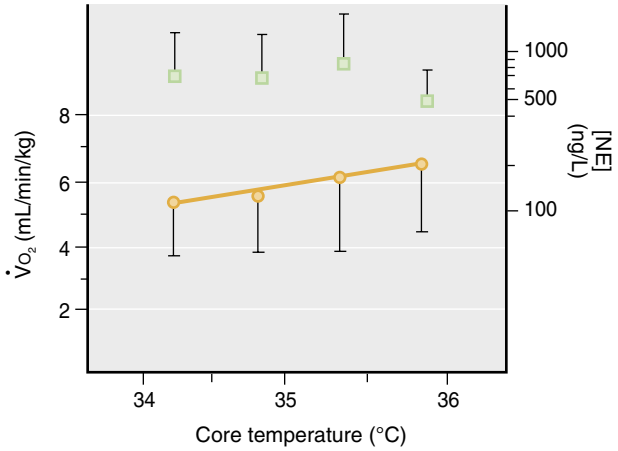

Figure 48-5 Progressive reduction in core temperature did not trigger an increase in oxygen consumption ($\dot{V}O_2$) that might indicate nonshivering thermogenesis. Instead, hypothermia decreased systemic oxygen consumption: $\dot{V}O_2 = 0.83$ (Core temperature) – 23.3 ; $r^2 = .92$. Intraoperative plasma norepinephrine concentrations ([NE]) were variable but did not change significantly as a function of core temperature. Data are presented as means ± SD. *(From Plattner O, Semsroth M, Sessler DI, et al: Lack of nonshivering thermogenesis in infants anesthetized with fentanyl and propofol. Anesthesiology 86:772-777, 1997.)*

threshold only slightly increased, but the gain and maximum intensity also remain normal. In contrast, the thresholds for vasoconstriction and shivering are markedly reduced, and furthermore, the efficacy of these responses is diminished even after being activated.

Development of Hypothermia During General Anesthesia

Inadvertent hypothermia is by far the most common perioperative thermal disturbance during anesthesia. Hypothermia results from a combination of anesthetic-impaired thermoregulation and exposure to a cold operating room environment. Of these two causes, impaired thermoregulation is much more important.

Heat Transfer

Heat can be transferred from a patient to the environment in four ways: radiation, conduction, convection, and evaporation. Among these mechanisms, radiation and convection contribute most to perioperative heat loss.

All surfaces with a temperature above absolute zero radiate heat; similarly, all surfaces absorb heat radiating from surrounding surfaces. Heat transfer via this mechanism is proportional to the difference of the fourth power of the absolute temperature difference between the surfaces. It is likely that radiation is the major type of heat loss in most surgical patients.[48]

Conductive heat loss is proportional to the temperature difference between two adjacent surfaces and the strength of the thermal insulation separating them. In general, conductive losses are negligible during surgery because patients usually only directly contact the foam pad (an excellent thermal insulator) covering most operating room tables.

Conductive loss of heat directly to air molecules is limited by the development of a layer of still air adjacent to the skin that serves as an insulator. When this layer is disturbed by air currents, the insulating properties diminish substantially, thereby increasing heat loss. This increase is termed convection and is proportional to the square root of the air speed; this is the basis of the familiar "wind chill" factor. Air speed in operating rooms—even those with high rates of air turnover—is typically only approximately 20 cm/sec, which only slightly increases loss when compared with still air. Nonetheless, convective loss is usually the second most important mechanism by which heat is transferred from patients to the environment. Presumably, convective loss increases substantially in operating rooms equipped to provide laminar flow. However, the actual augmentation has not been quantified and may be less than expected from the increase in air speed because surgical draping provides considerable thermal insulation.

Sweating increases cutaneous evaporative loss enormously but is rare during anesthesia. In the absence of sweating, evaporative loss from the skin surface is limited to less than 10% of metabolic heat production in adults. In contrast, infants lose a higher fraction of their metabolic heat from transpiration of water through thin skin. The problem becomes especially acute in

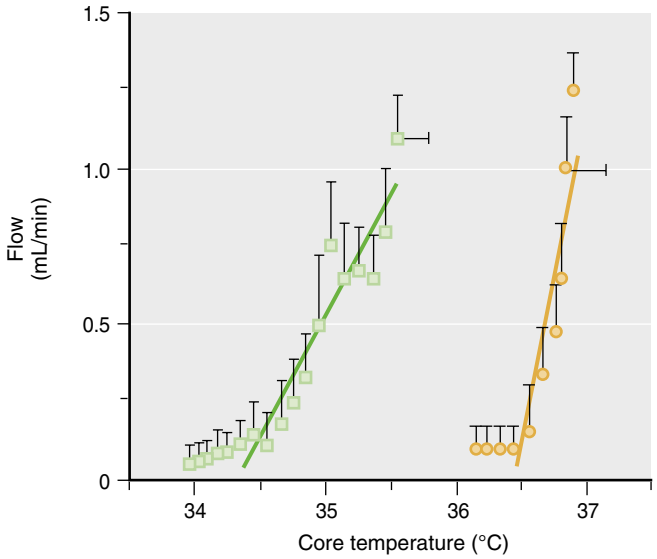

Figure 48-6 Finger blood flow without (*circles*) and with (*squares*) desflurane administration. Values were computed relative to the thresholds (finger flow = 1.0 mL/min) in each subject. Flows of exactly 1.0 mL/min are not shown because flows in each individual were averaged over 0.1°C or 0.05°C increments; each data point thus includes both higher and lower flows. The horizontal standard deviation bars indicate variability in the thresholds among the volunteers; although error bars are shown only at a flow near 1.0 mL/min, the same temperature variability applies to each data point. Slopes of the flow-versus–core temperature relationships (1.0 to ≈0.15 mL/min) were determined by linear regression. These slopes defined the gain of vasoconstriction with and without desflurane anesthesia. Gain was reduced by a factor of 3, from 2.4 to 0.8 mL/min/°C ($P < .01$). *(From Kurz A, Xiong J, Sessler DI, et al: Desflurane reduces the gain of thermoregulatory arterio-venous shunt vasoconstriction in humans. Anesthesiology 83:1212-1219, 1995.)*

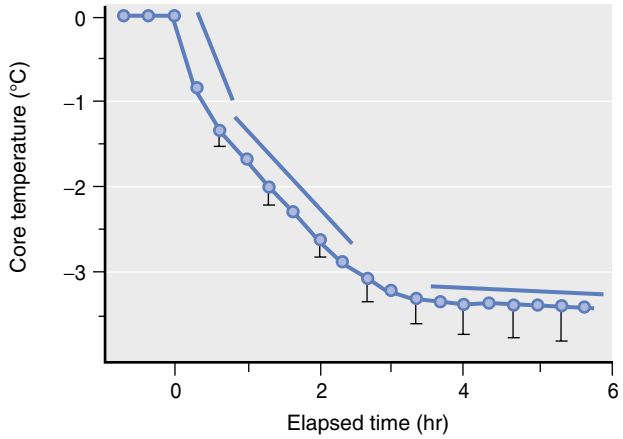

Figure 48-7 Hypothermia during general anesthesia develops with a characteristic pattern. An initial rapid decrease in core temperature results from a core-to-peripheral redistribution of body heat. This is followed by a slow, linear reduction in core temperature that results simply from heat loss exceeding heat production. Finally, core temperature stabilizes and subsequently remains virtually unchanged. This plateau phase may be a passive thermal steady state or result when sufficient hypothermia triggers thermoregulatory vasoconstriction. Results are presented as means ± SD.

premature infants, who may lose one fifth of their metabolic heat production via transcutaneous evaporation.[49] Simple thermodynamic calculations and clinical measurements indicate that only trivial amounts of heat are lost from the respiratory system.[50] Evaporation inside surgical wounds may contribute substantially to total heat loss[51] but has never been quantified in humans.

Patterns of Intraoperative Hypothermia

Hypothermia during general anesthesia develops with a characteristic pattern. An initial rapid decrease in core temperature is followed by a slow, linear reduction in core temperature. Finally, core temperature stabilizes and subsequently remains virtually unchanged (Fig. 48-7). Each component of this typical pattern has a different etiology.

Volatile anesthetics cause vasodilation via direct peripheral action.[52] More importantly, they also inhibit tonic thermoregulatory vasoconstriction, thereby resulting in arteriovenous shunt dilation.[20-24] Nonetheless, anesthetic-induced vasodilation increases cutaneous heat loss only slightly.[53] Anesthetics reduce the metabolic rate 20% to 30%.[54] However, even the combination of increased heat loss and reduced heat production is insufficient to explain the 0.5°C to 1.5°C decrease in core temperature generally observed during the first hour of anesthesia.

The key to understanding the initial decrease in core temperature is to appreciate that body heat is not normally distributed evenly. Core temperature represents only about half the body mass (mostly the trunk and head); the remaining mass is typically 2°C to 4°C cooler than the core. This core-to-peripheral tissue temperature gradient is normally maintained by tonic thermoregulatory vasoconstriction. Anesthetic-induced vasodilation, however, allows core heat to flow peripherally. This warms the arms and legs but does so at the expense of the core (Figs. 48-8 and 48-9).[55] The extent to which redistribution reduces core temperature depends on the core-to-peripheral tissue temperature gradient at the time of induction. This gradient, in turn, depends

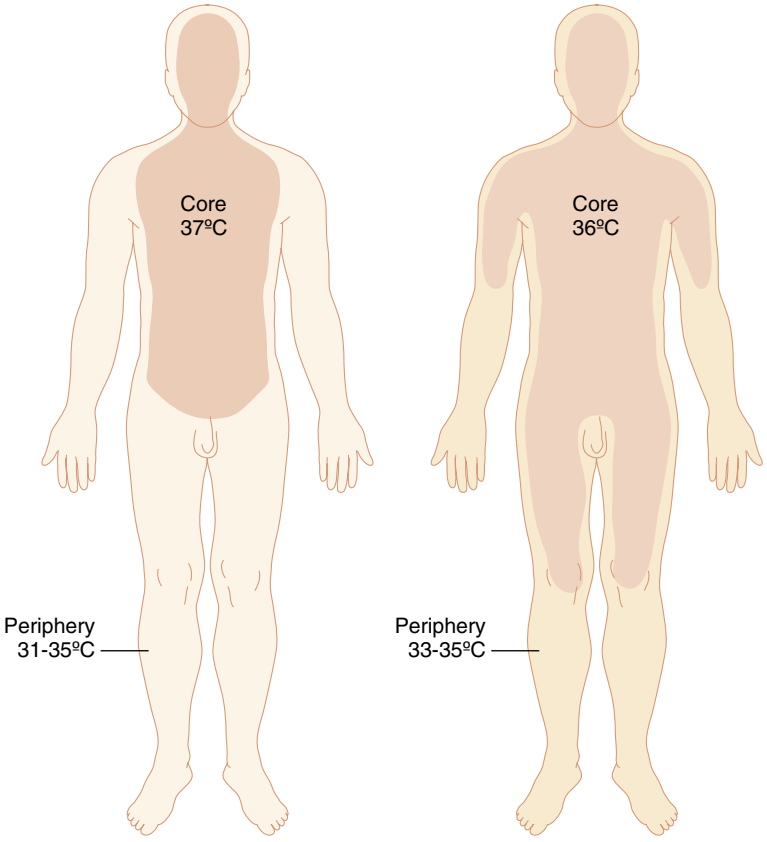

Figure 48-8 Drawing illustrating internal redistribution of body heat after induction of general anesthesia. Hypothermia after induction of spinal or epidural anesthesia results similarly, but redistribution is restricted to the legs.

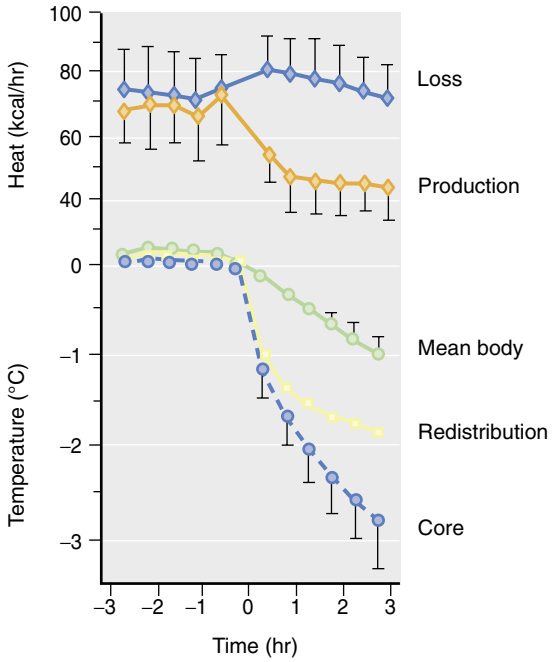

Figure 48-9 Changes in body heat content and distribution of heat within the body during induction of general anesthesia (at elapsed time zero). Subtraction of the change in mean body temperature from the change in core (tympanic membrane) temperature leaves the core hypothermia specifically resulting from redistribution. Redistribution hypothermia was thus not a measured value; instead, it is defined by the decrease in core temperature not explained by the relatively small decrease in systemic heat content. After 1 hour of anesthesia, core temperature had decreased 1.6 ± 0.3°C, with redistribution contributing 81% to the decrease. Even after 3 hours of anesthesia, redistribution contributed 65% to the entire 2.8 ± 0.5°C decrease in core temperature. Results are presented as means ± SD. *(Modified from Matsukawa T, Sessler DI, Sessler AM, et al: Heat flow and distribution during induction of general anesthesia. Anesthesiology 82:662-673, 1995.)*

on the patient's prior thermal environment and thermoregulatory status, both of which are difficult to determine clinically.

After initial redistribution hypothermia, core temperature usually decreases in a slow, linear fashion for 2 to 4 hours. This reduction results simply from heat loss exceeding metabolic heat production,[56] and the rate at which core temperature decreases depends on the difference and size of the patient. After 3 to 4 hours of anesthesia, core temperature usually reaches a plateau and remains virtually constant for the duration of surgery.[31] The core temperature plateau may simply represent a thermal steady state (heat production equaling heat loss) in patients remaining relatively warm. In others, however, the plateau phase is associated with peripheral thermoregulatory vasoconstriction triggered by core temperatures of 33°C to 35°C.

Thermoregulatory vasoconstriction during anesthesia decreases cutaneous heat loss,[44] but this decrease alone is usually insufficient to produce a thermal steady state. Furthermore, neither adults[40] nor infants[42] appear to be able to increase intraoperative heat production in response to hypothermia. An additional mechanism must therefore contribute to the core temperature plateau. Evidence suggests that a primary factor is constraint of metabolic heat to the core thermal compartment. In this scenario, distribution of metabolic heat (which is largely produced centrally) is restricted to the core compartment, thereby maintaining its temperature. Peripheral tissue temperature, in contrast, continues to decrease because it is no longer being supplied with sufficient heat from the core.[45] A core temperature plateau resulting from thermoregulatory vasoconstriction is thus not a thermal steady state, and body heat content continues to decrease even though core temperature remains nearly constant.

Neuraxial Anesthesia

Autonomic thermoregulation is impaired during regional anesthesia, and the result is typically intraoperative core hypothermia. Interestingly, this hypothermia is often not consciously perceived by patients but nonetheless triggers shivering. The result is frequently a potentially dangerous clinical paradox: a hypothermic patient who denies feeling cold (see Chapters 51, 52 and 87).

Thermoregulation

Epidural[57,58] and spinal[58,59] anesthesia each decrease the thresholds triggering vasoconstriction and shivering (above the level of the block) by about 0.6°C (Fig. 48-10). Presumably, this decrease does not result from recirculation of neuraxially administered local anesthetic because impairment is similar during epidural and spinal anesthesia,[57-59] although the amount and location of administered local anesthetic differ substantially. Furthermore, lidocaine administered intravenously in doses producing plasma concentrations similar to those occurring during epidural anesthesia has no thermoregulatory effect.[60] Finally, neuraxial administration of 2-choloprocaine, a local anesthetic with a plasma half-life of only about 20 seconds, also impairs thermoregulatory control.[61]

The vasoconstriction and shivering thresholds are comparably decreased during regional anesthesia,[59] suggesting an alteration in central, rather than peripheral control. The mechanism by

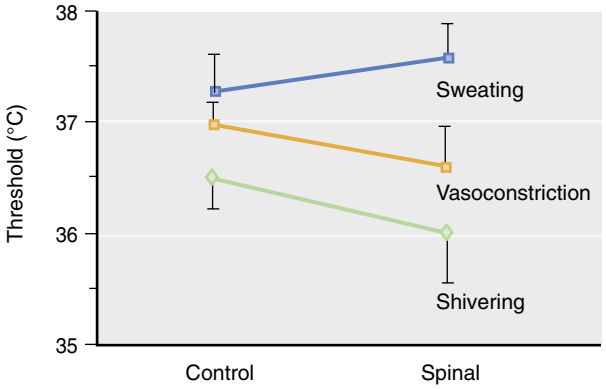

Figure 48-10 Spinal anesthesia increased the sweating threshold but reduced the thresholds for vasoconstriction and shivering. Consequently, the interthreshold range increased substantially. The vasoconstriction-to-shivering range, however, remained normal during spinal anesthesia. Results are presented as means ± SD. *(From Kurz A, Sessler DI, Schroeder M, Kurz M: Thermoregulatory response thresholds during spinal anesthesia. Anesth Analg 77:721-726, 1993.)*

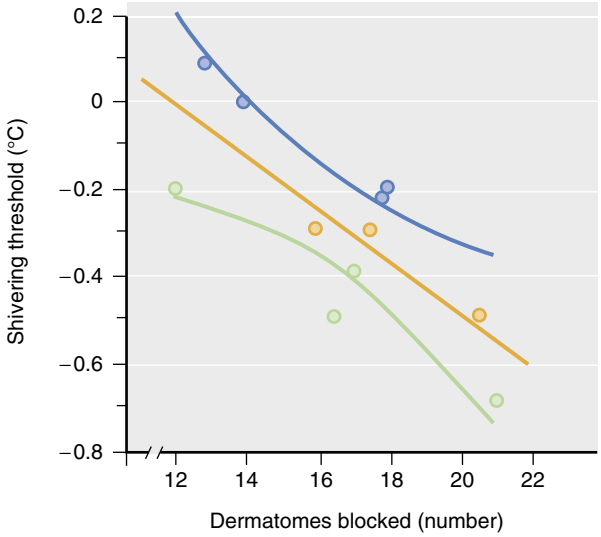

Figure 48-11 The number of dermatomes blocked (sacral segments = 5; lumbar segments = 5; thoracic segments = 12) versus reduction in the shivering threshold (difference between the control shivering threshold and the spinal shivering threshold). The shivering threshold was reduced more by extensive spinal blocks than by less extensive ones (Δ threshold = 0.74 – 0.06 [dermatomes blocked]; $r^2 = .58$, $P < .006$). The *curved lines* indicate 95% confidence intervals for the slope. *(From Leslie K, Sessler DI: Reduction in the shivering threshold is proportional to spinal block height. Anesthesiology 84:1327-1331, 1996.)*

which peripheral administration of local anesthesia impairs centrally mediated thermoregulation may involve alteration of afferent thermal input from the legs. The key factor here is that tonic cold signals dominate thermal input at leg skin temperatures in typical operating room environments.[2] Regional anesthesia blocks all thermal input from the blocked regions, which in the typical case is primarily cold information. The brain may then interpret decreased cold information as relative leg warming. This appears to be an unconscious process in that perceived temperature does not increase.[62] Because skin temperature is an important input to the thermoregulatory control system, leg warming proportionately reduces the vasoconstriction and shivering thresholds. Consistent with this theory, a leg skin temperature near 38°C is required to produce the same reduction in cold-response thresholds in an unanesthetized subject as produced by regional anesthesia.[63] Moreover, the reduction in thresholds is proportional to the number of spinal segments blocked (Fig. 48-11).[64] Major conduction anesthesia may thus reduce the vasoconstriction and shivering thresholds by producing an abnormal elevation in *apparent* (as opposed to actual) leg temperature. However, this explanation remains speculative.

Because neuraxial anesthesia prevents vasoconstriction and shivering in blocked regions, it is not surprising that epidural anesthesia decreases the maximum intensity of shivering. However, epidural anesthesia also reduces the gain of shivering, which suggests that the regulatory system is unable to compensate for lower body paralysis (Fig. 48-12).[26] Thermoregulatory defenses, once triggered, are thus less effective than usual during regional anesthesia.

Neuraxial anesthesia is frequently supplemented with sedative and analgesic medications that impair thermoregulatory control.[20,21,27] Such inhibition may be severe when combined with the intrinsic impairment produced by regional anesthesia and other factors, including advanced age and preexisting illness.

Interestingly, core hypothermia during regional anesthesia may not trigger a perception of cold.[57,65] The reason is that thermal perception (behavioral regulation) is largely determined by skin rather than core temperature. During regional anesthesia, core hypothermia is accompanied by a real increase in skin temperature. The result is typically a perception of continued or increased warmth accompanied by activation of autonomic thermoregulatory responses including shivering (Fig. 48-13).[57,65]

Taken together, these data indicate that neuraxial anesthesia inhibits numerous aspects of thermoregulatory control. The vasoconstriction and shivering thresholds are reduced by regional anesthesia[57-59,63,64] and further reduced by adjuvant drugs[21,36] and advanced age.[10] Even once triggered, the gain and maximum response intensity of shivering are about half-normal. Finally, behavioral thermoregulation is impaired.[65] The result is that cold defenses are triggered at a lower temperature than normal during regional anesthesia, defenses are less effective once triggered, and patients frequently do not recognize that they are hypothermic. Because core temperature monitoring remains rare during regional anesthesia, substantial hypothermia often goes undetected in these patients.[66]

Heat Balance

Hypothermia is common during regional anesthesia and may be nearly as severe as during general anesthesia.[67] Core temperature

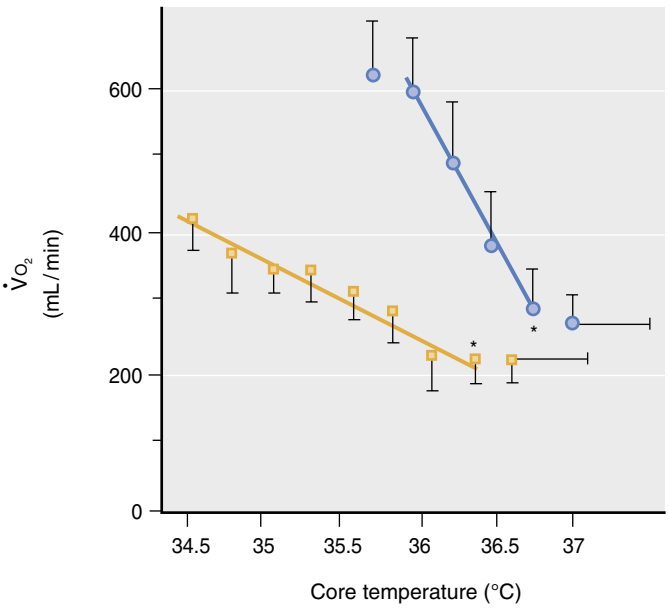

Figure 48-12 Systemic oxygen consumption without (*circles*) and with (*squares*) epidural anesthesia. The horizontal standard deviation bars indicate variability in the thresholds among the volunteers; although error bars are shown only once in each series, the same temperature variability applies to each data point. Slopes of the oxygen consumption–versus–core temperature relationships (*solid lines*) were determined by linear regression. These slopes defined the gain of shivering with and without epidural anesthesia. Gain was reduced 3.7-fold, from –412 mL/min/°C ($r^2 = .99$) to –112 mL/min/°C ($r^2 = .96$). *(From Kim J-S, Ikeda T, Sessler D, et al: Epidural anesthesia reduces the gain and maximum intensity of shivering. Anesthesiology 88:851-857, 1998.)*

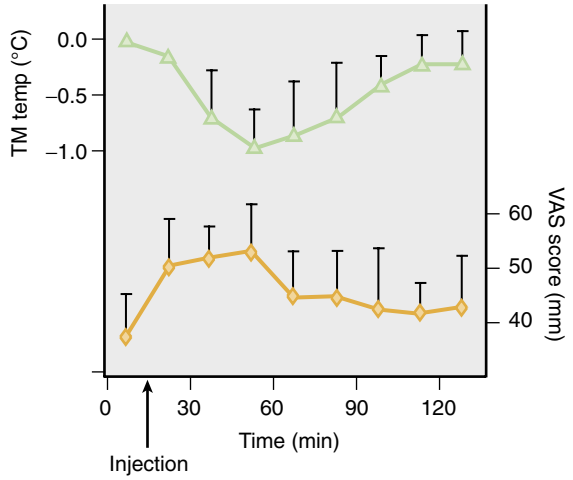

Figure 48-13 Induction of epidural anesthesia at an elapsed time of 15 minutes decreased core temperature and increased thermal comfort as determined by a 100-mm visual analog scale (VAS). Interesting, however, that maximal thermal comfort coincided with *minimum* core temperature. The results are presented as means ± SD. TM, tympanic membrane. *(Modified from Sessler DI, Ponte J: Shivering during epidural anesthesia. Anesthesiology 72:816-821, 1990.)*

typically decreases 0.5°C to 1.0°C shortly after induction of anesthesia. However, the vasodilation induced by regional anesthesia only slightly increases cutaneous heat loss. Furthermore, metabolic heat production remains constant or increases because of shivering thermogenesis. This rapid decrease in core temperature, similar to that seen after induction of general anesthesia, also results from an internal core-to-peripheral redistribution of body heat.[68] As during general anesthesia,[69,70] redistribution hypothermia during regional anesthesia can be minimized by cutaneous warming before induction.[71]

Subsequent hypothermia results simply from heat loss exceeding metabolic heat production. Unlike patients given general anesthesia, however, core temperature does not necessarily plateau after several hours of surgery. Not only is the vasoconstriction threshold centrally impaired by regional anesthesia,[58,59] but more importantly, vasoconstriction in the legs is also directly prevented by nerve block.[72] Because the legs constitute the bulk of the peripheral thermal compartment, an effective plateau cannot develop without vasoconstriction in the legs and the resulting decrease in cutaneous heat loss and constraint of metabolic heat to the core.

The importance of intraoperative leg vasoconstriction is illustrated during combined regional/general anesthesia. Consistent with the impairment of thermoregulatory responses with regional anesthesia alone,[58,59] vasoconstriction during combined regional/general anesthesia is triggered at a core temperature approximately 1°C lower than during general anesthesia alone. Moreover, once triggered, vasoconstriction produces a core temperature plateau during general anesthesia alone but not during combined regional/general anesthesia. The result is that core temperature during combined regional/general anesthesia continues to decrease throughout surgery.[73] Consequently, core temperature monitoring and thermal management are especially important in patients given simultaneous regional and general anesthesia.

Shivering

Shivering-like tremor in volunteers given neuraxial anesthesia is always preceded by core hypothermia and vasoconstriction (above the level of the block).[57] Furthermore, electromyographic analysis indicates that the tremor has the 4- to 8-cycle/min waxing-and-waning pattern that characterizes normal shivering.[61] The tremor is thus apparently normal thermoregulatory shivering, triggered when redistribution hypothermia decreases core temperature.

Spinal thermal receptors have been detected in every mammal and bird tested. Experimental stimulation of these receptors reliably produces shivering in animals. Stimulation of these putative receptors in humans by epidural anesthetic injection could theoretically initiate thermoregulatory responses, including shivering. However, epidural administration of large amounts of ice-cold saline does not trigger shivering in volunteers.[74] In addition, the incidence of shivering is comparable in volunteers[57] and patients[75] given warm or cold epidural anesthetic injections. These data indicate that the temperature of an injected local anesthetic does not influence the incidence of shivering during major conduction anesthesia.

The risk of shivering during neuraxial anesthesia is markedly diminished by maintaining strict normothermia.[57] However, there is a distinct incidence of low-intensity, shivering-like tremor that occurs in normothermic patients and is not thermoregulatory.[76] The cause of this muscular activity remains unknown, but it is associated with pain[77] and may thus result from activation of the sympathetic nervous system (Fig. 48-14).

Shivering during neuraxial anesthesia can sometimes be treated by warming sentient skin. This augments cutaneous

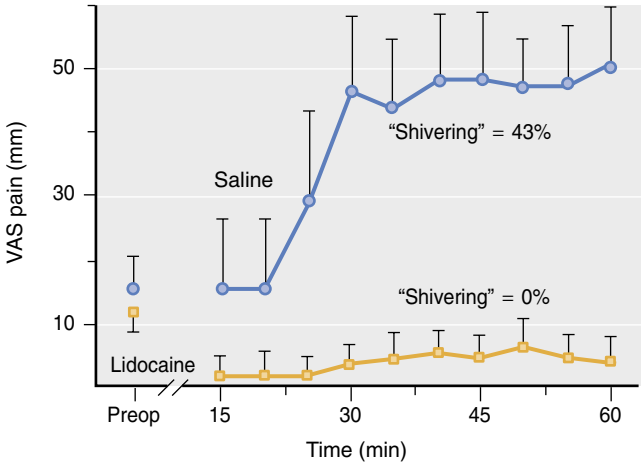

Figure 48-14 Visual analog pain scores (VAS) in normothermic patients given intra-articular lidocaine or saline after knee surgery. Pain was assessed postoperatively by an investigator blinded to the group assignment. Time zero indicates discontinuation of anesthesia. Data are presented as means ± SD. Patients receiving a local anesthetic block (lidocaine) had significantly less postoperative pain than those given saline; all values after 10 elapsed minutes differed significantly in the two groups. Shivering-like tremor was observed in 43% of the patients given saline versus 0% of those given lidocaine, thus indicating that the tremor is related to pain. *(From Horn E-P, Schroeder F, Wilhelm S, et al: Postoperative pain facilitates non-thermoregulatory tremor. Anesthesiology 91:979-984, 1999.)*

thermal input to the central regulatory system and thus increases the degree of core hypothermia tolerated. Because the entire skin surface contributes 20% to thermoregulatory control[5] and the lower body contributes about 10%,[63] sentient skin warming is likely to compensate for only small reductions in core temperature. The same drugs that are effective for postanesthetic tremor are also useful for shivering during regional anesthesia; such drugs include meperidine (25 mg intravenously [IV] or epidurally),[78] clonidine (75 μg IV),[79] dexmedetomine,[80] ketanserin (10 mg IV),[79] and magnesium sulfate (30 mg/kg IV).[81]

Consequences of Mild Intraoperative Hypothermia

Perianesthetic hypothermia produces potentially severe complications, as well as distinct benefits. Thermal management thus deserves the same thoughtful analysis of potential risks and benefits as other therapeutic decisions do.

Benefits

Substantial protection against cerebral ischemia and hypoxia is provided by hypothermia of just 1°C to 3°C in animals.[82,83] Protection was initially thought to result from the approximate 8%/°C linear reduction in tissue metabolic rate. However, the efficacy of mild hypothermia far exceeds that of treatments such as high-dose isoflurane or barbiturate coma, which comparably reduce the metabolic rate.[84] These data suggest that other actions (e.g., decreased release of excitatory amino acids) explain the protective action of hypothermia.[85] Accordingly, there is no reason to expect protection to augment linearly with temperature, and in animals it appears that much of the total benefit from moderate hypothermia takes place within the first couple of degrees.

Therapeutic hypothermia has twice been shown to improve outcomes after out-of-hospital cardiac arrest.[86,87] Rapid induction of hypothermia is thus becoming routine for patients after recovery from arrest and for asphyxiated neonates.[88-90]

The potential protection afforded by mild hypothermia is so great that reduced core temperature (i.e., ≈34°C) is increasingly being used during neurosurgery and other procedures in which tissue ischemia can be anticipated. The difficulty is that there are currently few outcome data substantiating an extrapolation from animal data to clinical practice. Furthermore, the appropriate target temperature for therapeutic hypothermia has yet to be established.

Hypothermia for brain trauma was initially claimed to be therapeutic based on a post hoc subgroup analysis of a study that overall showed no benefit.[91] A subsequent large randomized trial was unable to demonstrate any benefit overall or in subgroups—although interpretation of the study was limited by violations in the fluid administration protocol in some patients.[92] Most recently, hypothermia was shown to be beneficial in a nonrandomized study in which brain trauma patients with elevated intracranial pressure refractory to conventional treatment were assigned to therapeutic hypothermia. Despite being sicker than the comparison patients (who had low intracranial pressure), the hypothermic patients demonstrated improved outcomes.[93]

Small nonrandomized series suggested that mild hypothermia might improve the outcome after stroke.[94] A small feasibility trial for treatment of stroke with hypothermia has been published,[95] but no large trial is currently in progress.

Although the initial feasibility trials were encouraging,[95,96] a subsequent large outcome trial failed to demonstrate any improvement with therapeutic hypothermia in patients undergoing surgery for subarachnoid hemorrhage.[97] This result was especially disappointing because surgery is one of the few times in humans that hypothermia can be instituted before the onset of ischemia.

Hypothermic protection against ischemia may extend to other organs. For example, mild hypothermia markedly reduces infarct size in experimental acute myocardial infarction in human-sized pigs,[98] and a preliminary study in patients was encouraging.[99] However, a subsequent major outcome trial in humans failed to demonstrate convincing benefit (unpublished).

A limitation of most therapeutic hypothermia studies is that cooling began well after the ischemic insult and that patients typically took many hours to cool. It thus remains possible that benefit will yet be identified in future studies that initiate hypothermia earlier and use recently developed systems to cool patients faster. Table 48-1 lists selected major studies that have evaluated the potential benefits of mild perioperative hypothermia.

Complications

Coagulation is impaired by mild hypothermia. The most important factor is a cold-induced defect in platelet function.[107] Interestingly, the defect in platelet function is related to local temperature, not core temperature. Wound temperature, however, is largely determined by core temperature and will be distinctly higher in normothermic patients. Perhaps as important, hypothermia directly impairs enzymes of the coagulation cascade. This will not be apparent during routine coagulation screening because the tests are performed at 37°C. When these tests are performed at hypothermic temperatures, however, the defect becomes apparent.[108]

Consistent with these in vitro defects, nearly all randomized trials indicate that mild hypothermia increases blood loss during hip arthroplasty and increases allogeneic transfusion requirements.[109] Similarly, nearly all randomized trials report an increased transfusion requirement in hypothermic patients. Meta-analyses indicate that both blood loss and transfusion requirements are significantly increased by hypothermia.[106] The treatment effect is substantial, with just 1°C of core hypothermia increasing each by about 20%.

Wound infections are among the most common serious complications of anesthesia and surgery and probably cause more morbidity than all other anesthetic complications combined.[110] Hypothermia can contribute to wound infections both by directly impairing immune function[111] and by triggering thermoregulatory vasoconstriction, which in turn decreases oxygen delivery to wounds.[112] It is well established that fever is protective and that infections are aggravated when naturally occurring fever is prevented.[113] Similarly, mild hypothermia, maintained only during anesthesia, impairs subsequent resistance to both *Escherichia coli* and *Staphylococcus aureus* dermal infections in guinea pigs. As

Table 48-1 Major Complications of Mild Perioperative Hypothermia in Humans

Consequence	First Author	Year	*N*	ΔT_{core} (°C)	Normothermic	Hypothermic	*P*

Only prospective, randomized human trials are included; subjective responses were evaluated by observers blinded to the treatment group and core temperature. ***N*** = total number of subjects. ΔT_{core} = difference in core temperature between the treatment groups. Different outcomes of some studies are shown in separate rows. VAS is a 100-mm-long visual analog scale (0 mm = intense cold; 100 mm = intense heat). The study by Just and colleagues is but one of dozens of studies showing that hypothermia provokes shivering. The results are presented as means ± SD or median (interquartile range) unless otherwise specified. NS = not significant. For the effects of hypothermia on perioperative blood loss and transfusion requirement, see the meta-analysis by Rajagopalan and coworkers.[106]

might be expected from these in vitro and animal data, a prospective, randomized clinical trial indicated that mild intraoperative hypothermia triples the incidence of surgical wound infection in patients undergoing colon surgery. Furthermore, hypothermia delayed wound healing and prolonged the duration of hospitalization 20% even in patients without infection. Consistent with poor wound healing, urinary nitrogen excretion remains elevated for several postoperative days in patients allowed to become hypothermic during surgery.

Thermal comfort is markedly impaired by postoperative hypothermia, a feeling that persists for several hours in patients who are several degrees centigrade hypothermic at the beginning of recovery (Fig. 48-15).[104] Patients, asked years after surgery, often identify feeling cold in the immediate postoperative period as the worst part of their hospitalization—sometimes rating it worse than surgical pain. Postoperative thermal discomfort is also physiologically stressful in that it elevates blood pressure, heart rate, and plasma catecholamine concentrations.[103] These factors presumably contribute to what may be the most important consequence of mild perioperative hypothermia: a threefold increase in morbid myocardial outcomes. Given that myocardial ischemia is among the leading causes of unanticipated perioperative death, the results of this prospective, randomized trial must be taken extremely seriously. Drug metabolism is markedly decreased by perioperative hypothermia. For further information see Chapters 26 and 29. Table 48-2 lists the major studies that have evaluated complications caused by mild perioperative hypothermia.

Postanesthetic Shivering

The incidence of postoperative shivering-like tremor is reportedly about 40% but now appears to be less as more patients are kept normothermic and opioids are administered more frequently and in larger doses than in the past. It is a potentially serious complication that increases oxygen consumption roughly 100% in proportion to intraoperative heat loss.[116] Interestingly, though, myocardial ischemia is poorly correlated with shivering, suggesting that an increased metabolic rate is not the primary cause of this complication. In addition to increasing intraocular and

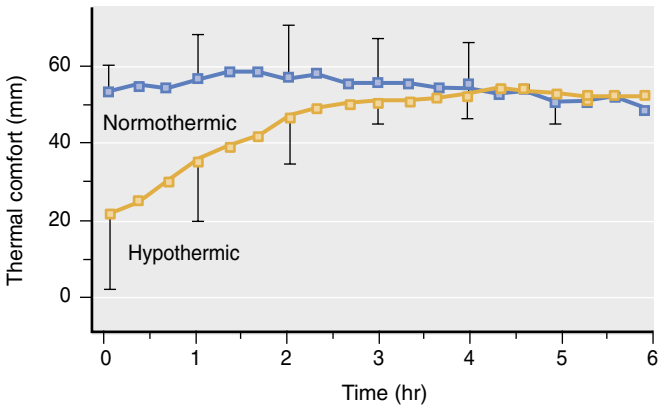

Figure 48-15 Patients who started recovery while about 2°C hypothermic reported feeling unpleasantly cold, and the sensation persisted longer than 2 hours. Only a few of the warmed patients shivered at any time during the recovery period. In contrast, most of the hypothermic patients demonstrated grade 2 or 3 tremor during the first postoperative hour. By the end of the first elapsed hour, however, shivering was rare, even in the hypothermic patients. Error bars indicate standard deviations. Thermal comfort is shown on a 100-mm visual analog scale, where 0 mm is the worst possible cold sensation, 50 mm is neutral, and 100 mm is extreme heat. *(From Kurz A, Sessler DI, Narzt E, et al: Postoperative hemodynamic and thermoregulatory consequences of intraoperative core hypothermia. J Clin Anesth 7:359-366, 1995.)*

Table 48-2 Potential Benefits of Mild Perioperative Hypothermia in Humans

Consequence	First author	Year	*N*	ΔT_{core} (°C)	Normothermic	Hypothermic	*P*

intracranial pressure, postoperative shivering possibly aggravates wound pain by stretching incisions. The most important determinants of shivering risk are young age and low core temperature.[117]

Unfortunately, the etiology of postanesthetic shivering-like tremor is unclear. Certainly, much postoperative tremor is simply normal shivering. As early as 1972, however, investigators recognized the existence of at least two distinct tremor patterns.[118] That perceptive observation was subsequently confirmed in a study that used electromyography to demonstrate that postoperative tremor has (1) a tonic pattern resembling normal shivering, typically with a 4- to 8-cycle/min waxing-and-waning component, and (2) a phasic, 5- to 7-Hz bursting pattern resembling pathologic clonus.[119] The clonic pattern was consistent with the previous observation that pathologic spinal cord responses, including clonus, nystagmus, and exaggerated deep tendon reflexes, were common during recovery from general anesthesia.[120] This combined tonic and clonic pattern is thermoregulatory; that is, it is always preceded by core hypothermia and arteriovenous shunt vasoconstriction.[121] The tonic pattern consistently demonstrated the 4- to 8-cycle/min waxing-and-waning pattern of normal shivering[16] and apparently is a simple thermoregulatory response to intraoperative hypothermia. In contrast, the clonic pattern is not a normal component of thermoregulatory shivering and appears to be specific to recovery from volatile anesthetics. Although the precise etiology of this tremor pattern remains unknown, it may result from anesthetic-induced disinhibition of normal descending control over spinal reflexes. Earlier data in surgical patients, however, belie the simple conclusion from a volunteer study[121] that all postanesthetic tremor is thermoregulatory. Instead, there appears to be a distinct incidence of non-thermoregulatory tremor in normothermic postoperative patients[122]; similar non-thermoregulatory tremor has been observed in women during labor.[76] The etiology of this tremor and why volunteers and patients should respond differently remain unknown, but surgical pain appears to be a key factor.[77]

Postanesthetic shivering can be treated by skin surface warming because the regulatory system tolerates more core hypothermia when cutaneous warm input is augmented. However, the skin surface contributes only 20% to control of shivering,[5] and available skin surface warmers increase mean skin temperature only a few degrees centigrade.[123] Consequently, cutaneous warming compensates for only small amounts of core hypothermia and will not usually prove effective in most patients with core temperatures much below 35°C.[124]

Postanesthetic shivering can also be treated with a variety of drugs, including clonidine (75 μg IV),[79] ketanserin (10 mg IV),[79] tramadol,[125] physostigmine (0.04 mg/kg IV),[126] nefopam (0.15 mg/kg),[127] dexmedetomidine, and magnesium sulfate (30 mg/kg IV).[81] The specific mechanisms by which ketanserin, tramadol, physostigmine, and magnesium sulfate stop shivering remain unknown. Similarly, how clonidine arrests shivering also remains unknown, but clonidine[32] and dexmedetomidine[22] comparably reduce the vasoconstriction and shivering thresholds, thus suggesting that they act on the central thermoregulatory system rather than preventing shivering peripherally. Postoperative shivering has been reviewed in detail[128] and treatment options have been subjected to a systematic review.[129]

Alfentanil, a pure μ-receptor agonist, significantly impairs thermoregulatory control.[21] However, meperidine is considerably more effective in treating shivering than equi-analgesic doses of other μ-agonists are.[130] Clinically, this efficacy is manifested as a shivering threshold that is reduced twice as much as the vasoconstriction threshold[27] without a decrease in the gain or maximum intensity of shivering.[46] The efficacy of meperidine is at least partially preserved during the administration of moderate doses of naloxone (0.5 μg/kg/min) but virtually obliterated by enormous doses (5.0 μg/kg/min).[131] These data suggest that the action of this

drug is in part mediated by non–μ-opioid receptors. Meperidine possesses considerable κ activity[132] and also has central anticholinergic activity. However, neither mechanism appears to mediate meperidine's special antishivering activity.

Perioperative Thermal Manipulations

Intraoperative thermoregulatory vasoconstriction, once triggered, is remarkably effective in preventing further core hypothermia.[39,45] Nonetheless, most patients are poikilothermic during surgery because they do not become sufficiently hypothermic to trigger thermoregulatory responses.[20,21,23,24] Therefore, intraoperative hypothermia can be minimized by any technique that limits cutaneous heat loss to the environment, such as loss caused by cold operating rooms, evaporation from surgical incisions, or conductive cooling produced by the administration of cold intravenous fluids. The efficacy of various approaches differs enormously, however.

Mean body temperature will decrease when heat loss to the environment exceeds metabolic heat production. Heat production during anesthesia is approximately 0.8 kcal/kg/hr. Because the specific heat of the human body is about 0.83 kcal/kg,[133] body temperature decreases approximately 1°C/hr when heat lost to the environment exceeds metabolic production by a factor of 2. Normally, about 90% of metabolic heat is lost through the skin surface. During anesthesia, additional heat is also lost directly from surgical incisions and by the administration of cold intravenous fluids.

Effects of Vasomotor Tone on Heat Transfer

Thermoregulatory vasodilation causes the initial core-to-peripheral redistribution of body heat[55]; similarly, re-emergence of vasoconstriction in patients becoming sufficiently hypothermic produces a core temperature plateau.[45] It is thus evident that vasomotor tone alters intercompartmental heat transfer. In addition to thermoregulatory arteriovenous shunt status, arteriolar tone is directly modulated by anesthetics per se.[52] Both factors potentially influence the speed with which peripherally applied heat reaches the core thermal compartment.

Thermoregulatory vasoconstriction slightly impairs induction of therapeutic hypothermia during neurosurgery.[134] However, arteriovenous shunt tone has little effect on intraoperative cooling[135] or heating.[136] Intraoperative vasoconstriction thus only slightly impedes peripheral-to-core transfer of cutaneous heating and cooling. Little clinical effect presumably results because intraoperative thermoregulatory vasoconstriction is opposed by direct anesthetic-induced peripheral vasodilation.

During postanesthetic recovery, however, the situation differs markedly. Here, dissipation of anesthetic-induced peripheral dilation[52,137] leaves thermoregulatory vasoconstriction unopposed. As might be expected, this vasoconstriction then becomes an important factor and significantly impairs transfer of peripherally applied heat to the core thermal compartment. Patients with residual spinal anesthetic block thus warm considerably faster than those recovering from general anesthesia alone

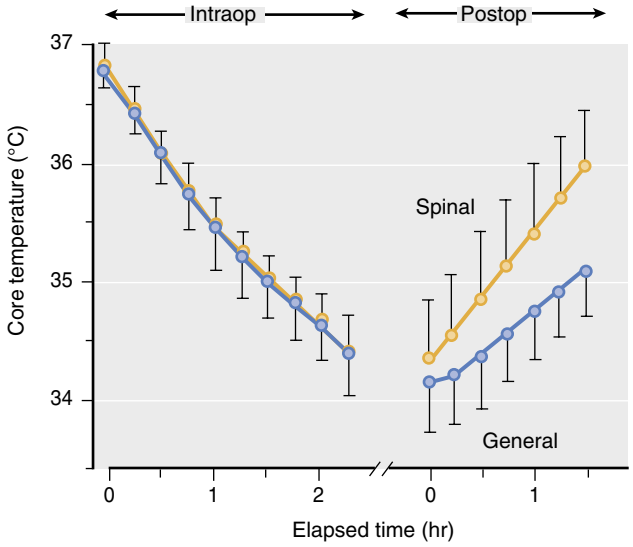

Figure 48-16 Intraoperative and postoperative core temperatures in patients assigned to general anesthesia ($n = 20$) and spinal anesthesia ($n = 20$). All patients were warmed with forced air during the postoperative period. Core temperature did not differ significantly during surgery but increased significantly faster postoperatively in patients given spinal anesthesia (1.2 ± 0.1°C/hr versus 0.7 ± 0.2°C/hr, means ± SD). *(From Szmuk P, Ezri T, Sessler DI, et al: Spinal anesthesia only minimally increases the efficacy of postoperative forced-air rewarming. Anesthesiology 87:1050-1054, 1997.)*

(Fig. 48-16).[138] Heat balance studies indicate that core warming is slowed because vasoconstriction constrains up to 30 kcal in peripheral tissues.[139]

Furthermore, it is easier to maintain intraoperative normothermia (when most patients are vasodilated) than rewarm patients postoperatively (when virtually all hypothermic patients are vasoconstricted). In addition to being more effective, intraoperative warming is more appropriate than postoperative treatment of hypothermia because it prevents the complications resulting from hypothermia.[109] Patients unavoidably becoming hypothermic during surgery should nonetheless be actively heated postoperatively to increase thermal comfort, decrease shivering, and hasten rewarming.

Preventing Redistribution Hypothermia

The initial 0.5°C to 1.5°C reduction in core temperature is difficult to prevent because it results from redistribution of heat from the central thermal compartment to cooler peripheral tissues.[55] Consequently, surface warming usually fails to prevent hypothermia during the first hour of anesthesia.[56] Lack of efficacy during this period results both because the central-to-peripheral flow of heat is massive and because transfer of applied cutaneous heat to the core requires nearly an hour, even in vasodilated patients.

Although redistribution is difficult to treat,[56] it can be prevented. Redistribution results when anesthetic-induced vasodilation allows heat to flow peripherally down the normal temperature gradient. Skin surface warming before induction of anesthesia does not significantly alter core temperature (which remains well regulated), but it does increase body heat content. Most of the increase is in the legs, the most important component of the

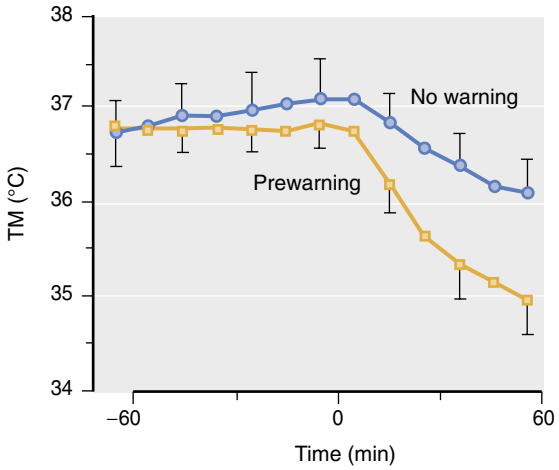

Figure 48-17 During the preinduction period (–120 to 0 minutes), volunteers were either actively warmed or passively cooled (no warming). At induction of anesthesia (time = 0 minutes), active warming was discontinued and volunteers were exposed to the ambient environment. Initial tympanic membrane (TM) temperatures were similar before each preinduction treatment. During the 60 minutes after induction of anesthesia, core temperature decreased less when volunteers were prewarmed. ($\Delta T = -1.1 \pm 0.3°C$) than when the same volunteers were not warmed ($\Delta T = -1.9 \pm 0.3°C$). Data are presented as means ± SD. *(From Hynson JM, Sessler DI, Moayeri A, et al: The effects of pre-induction warming on temperature and blood pressure during propofol/nitrous oxide anesthesia. Anesthesiology 79:219-228, 1993.)*

peripheral thermal compartment. When peripheral tissue temperature is sufficiently increased, subsequent inhibition of normal tonic thermoregulatory vasoconstriction produces little redistribution hypothermia because heat can flow only down a temperature gradient (Fig. 48-17).[69,70] Although substantial amounts of heat must be transferred across the skin surface, active prewarming for as little as 30 minutes probably prevents considerable redistribution.[140]

The "afterdrop" associated with discontinuation of cardiopulmonary bypass is a type of redistribution hypothermia that results from a substantial core-to-peripheral tissue temperature gradient. As might be expected, it is more impressive after bypass at 17°C[141] than at 27°C to 31°C.[142] Cutaneous warming during and after bypass reduces core temperature afterdrop by 60%. However, heat balance data indicate that this reduction results primarily because cutaneous warming prevents the typical decrease in body heat content after discontinuation of bypass rather than by reducing redistribution.[143]

Airway Heating and Humidification

Simple thermodynamic calculations indicate that less than 10% of metabolic heat production is lost via the respiratory tract. The loss results from both heating and humidifying inspiratory gases, but humidification requires two thirds of the heat.[50] Because little heat is lost via respiration, even active airway heating and humidification minimally influence core temperature.[56]

Because respiratory heat loss remains virtually constant during anesthesia, the fraction of total heat lost via the respiratory tract decreases dramatically during large operations in which substantial heat is lost from evaporation within surgical incisions.[51] Consequently, airway heating and humidification are even less effective than usual in patients most in need of effective warming.

Intravenous Fluids

Patients cannot be warmed by administering heated fluids because the fluids cannot (much) exceed body temperature. On the other hand, heat loss from cold intravenous fluids becomes substantial when large amounts of crystalloid solution or blood are administered. One unit of refrigerated blood or 1 L of crystalloid solution administered at room temperature each decreases mean body temperature approximately 0.25°C. (The blood is twice as cold, but only half the volume.) Fluid warmers minimize these losses and should be used when large amounts of intravenous fluid or blood are administered. In smaller cases, though, they contribute little.

For routine cases, there are no clinically important differences among the available fluid warmers. Although most warmers allow fluid to cool in the tubing between the heater and the patient, this cooling is of little consequence in adults: at high flow there is little cooling, and at low flow the amount of fluid given is trivial.[144] Special high-volume systems with powerful heaters and little resistance to flow facilitate care of trauma victims and are useful in other cases in which a large amount of fluid must be administered quickly.

Cutaneous Warming

Operating room temperature is the most critical factor influencing heat loss because it determines the rate at which metabolic heat is lost by radiation and convection from the skin and by evaporation from within surgical incisions. Consequently, increasing room temperature is one way to minimize heat loss. However, room temperatures exceeding 23°C are generally required to maintain normothermia in patients undergoing all but the smallest procedures[145]; most operating room personnel find such temperatures uncomfortably warm. Infants may require ambient temperatures exceeding 26°C to maintain normothermia. Such temperatures are sufficiently high to impair the performance of operating room personnel and decrease their vigilance.

The easiest method of decreasing cutaneous heat loss is to apply passive insulation to the skin surface. Insulators readily available in most operating rooms include cotton blankets, surgical drapes, plastic sheeting, and reflective composites ("space blankets"). A single layer of each reduces heat loss approximately 30%, and there are no clinically important differences among the types of insulation. The reduction in heat loss from all the commonly used passive insulators is similar because most of the insulation is provided by the layer of still air trapped beneath the covering. As a result, adding additional layers of insulation further reduces heat loss only slightly. For example, one cotton blanket reduces heat loss by about 30%, but three cotton blankets reduces heat loss only by 50%. Furthermore, warming the cotton blankets provides little benefit, and the benefit is short-lived.[146] These data indicate that simply adding additional layers of passive insulation or warming the insulation before application will usually be insufficient in patients becoming hypothermic while covered with a single layer of insulation.

Cutaneous heat loss is roughly proportional to surface area throughout the body.[147] (The popular perception that a large fraction of metabolic heat is lost from the head is false in adults. Loss from the head can be substantial in small infants,[148] but the loss is high mostly because the head represents a large fraction of the total surface area.) Consequently, the amount of skin covered is more important than which surfaces are insulated. It does not make sense, for example, to cover the head and leave the arms exposed because the arms have more surface area than the head and account for more heat loss.

Passive insulation alone is rarely sufficient to maintain normothermia in patients undergoing large operations; active warming will be required in such cases. Because about 90% of metabolic heat is lost via the skin surface, only cutaneous warming will transfer sufficient heat to prevent hypothermia. Consequently, for intraoperative use, circulating water and forced air are the two major systems requiring consideration.

Studies consistently report that circulating-water mattresses are nearly ineffective.[149] Presumably, they are unable to maintain normothermia because little heat is lost from the back into the 5 cm of foam insulation covering most operating room tables. Moreover, the combination of heat and decreased local perfusion (resulting when the patient's weight reduces capillary blood flow) increases the propensity for pressure/heat necrosis ("burns"). Such tissue injury can occur even when the water temperature does not exceed 40°C.[150] Circulating water is more effective—and safer—when placed *over* patients rather than *under* them and, in that position, can almost completely eliminate metabolic heat loss. Metabolic heat production will increase mean body temperature approximately 1°C/hr when cutaneous heat loss is eliminated. Recently developed circulating-water garments transfer large amounts of heat by increasing the warmed surface area or using materials that facilitate conduction.[151,152]

The most common perianesthetic warming system is forced air. The best forced-air systems completely eliminate heat loss from the skin surface.[123] Forced air usually maintains normothermia even during the largest operations[56] and is superior to circulating-water mattresses.[153] It is also remarkably safe, with few if any injuries reported with proper use.

Induction of Mild Therapeutic Hypothermia

There remains a paucity of evidence supporting the application of therapeutic hypothermia for indications other than out-of-hospital cardiac arrest and asphyxiated neonates. Nonetheless, hypothermia is occasionally used during neurosurgery or acute myocardial infarction. Typically, target core temperatures are 32°C to 34°C, and it is thought that reaching the target temperature quickly is important.

Passive cooling is far too slow for induction of therapeutic hypothermia. Immersion in cold water is the quickest noninvasive method of actively cooling patients. However, immersion is difficult under clinical conditions and poses a substantial electrical safety risk. Administration of refrigerated intravenous fluids is also effective and reduces mean body temperature 0.5°C/L.[154] However, this method may be impractical in neurosurgical patients, in whom fluids must be restricted.

Forced-air cooling is easy to implement but relatively slow in that it takes about 2.5 hours to cool neurosurgical patients to 33°C.[134] Conventional circulating-water mattresses are unlikely to be efficient because relatively little skin surface contacts the mattress and the patient's own body weight reduces blood-borne convection of heat to the back. Newer circulating-water systems include garment-like covers or "energy exchange pads" that cover far more skin surface and transfer large amounts of heat, and they are fairly effective.[155]

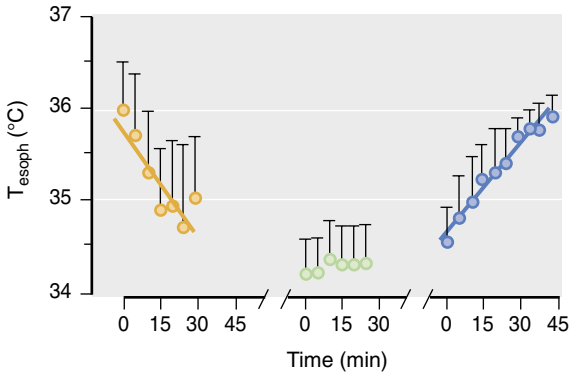

Figure 48-18 Average (±SD) intraoperative esophageal temperatures (T_{esoph}) during the cooling, temperature maintenance, and rewarming periods in eight neurosurgical patients who were cooled with endovascular heat-exchanging catheters in the vena cava. Time zero identified the beginning of each thermal management period; the duration of these periods differed in individual patients, depending on the duration of surgery and other factors. Regression lines are shown for the cooling and rewarming periods. *(From Doufas AG, Akça O, Barry A, et al: Initial experience with a novel heat-exchanging catheter in neurosurgical patients. Anesth Analg 95:1752-1756, 2002.)*

The best way to rapidly induce therapeutic hypothermia is probably endovascular cooling. These systems consist of a heat-exchanging catheter, usually inserted into the inferior vena cava via the femoral artery, and a servocontroller. They can decrease core temperatures at rates approaching 4°C/hr (Fig. 48-18).[156]

Inducing therapeutic hypothermia during surgery is relatively easy because anesthetics profoundly impair thermoregulatory responses. In contrast, unanesthetized patients—even those who have suffered a stroke—vigorously defend core temperature by vasoconstriction and shivering.[157] It is thus necessary to pharmacologically induce tolerance to hypothermia. The best method thus far identified is the combination of buspirone and meperidine, drugs that synergistically reduce the shivering threshold to around 34°C without provoking excessive sedation or respiratory toxicity.[158] The combination of dexmedetomidine and meperidine may also be helpful, although the interaction is simply additive in this case.[80] In contrast, ondansetron,[159] doxapram,[160] and magnesium sulfate[161] only slightly reduce the shivering threshold in humans. Although initially reported to be effective,[162] neither arm nor face warming reduces the shivering threshold by clinically important amounts.[163]

Deliberate Severe Intraoperative Hypothermia

Severe hypothermia may be induced deliberately to confer protection against tissue ischemia, specifically during cardiac surgery and, occasionally, neurosurgery. Drugs such as barbiturates and volatile anesthetics provide considerably less protection than

even mild hypothermia does.[84] Because many organs compensate poorly for hypothermia, temperatures as low as those deliberately induced are usually lethal when unintentional. Deliberate hypothermia is safe only because anesthesiologists understand and treat the physiologic changes caused by core temperatures 10°C to 15°C below normal.

Although deep hypothermia (i.e., 28°C) has been used to facilitate cardiopulmonary bypass for decades, recent evidence suggests that this degree of hypothermia is either unhelpful or simply harmful. For example, hypothermia may be associated with prolonged ventricular dysfunction[164] and does not limit cognitive impairment after bypass.[165] Consequently, cardiac surgery is increasingly being performed at either "tepid" temperatures (i.e., 33°C) or normothermia. There is increasing evidence that outcomes after bypass surgery, whether on- or off-pump, are improved by maintaining normothermia or near-normothermia.[166,167] Deep hypothermia (i.e., 18°C) remains routine for intentional circulatory arrest cases.[141]

Organ Function

Hypothermia decreases the whole-body metabolic rate by approximately 8%/°C[40] to approximately one half the normal rate at 28°C.[168] Whole-body oxygen demand diminishes, and oxygen consumption in tissues that have higher than normal metabolic rates, such as the brain, is especially reduced. Brain oxygenation is thus improved by hypothermia.[169] Low metabolic rates allow aerobic metabolism to continue during periods of compromised oxygen supply; toxic waste production declines in proportion to the metabolic rate. Although a decreased metabolic rate certainly contributes to the observed protection against tissue ischemia, other effects of hypothermia, including "membrane stabilization" and decreased release of toxic metabolites and excitatory amino acids, appear to be most important.[85]

Cerebral blood flow also decreases in proportion to the metabolic rate during hypothermia because of an autoregulatory increase in cerebrovascular resistance.[85] The arteriovenous Po_2 difference thus remains constant, and the venous lactate concentration does not increase. Cerebral function is well maintained until core temperatures reach approximately 33°C, but consciousness is lost at temperatures below 28°C. Primitive reflexes such as the gag, pupillary constriction, and monosynaptic spinal reflexes remain intact until approximately 25°C. Nerve conduction decreases, but peripheral muscle tone increases and results in rigidity and myoclonus at temperatures near 26°C. Somatosensory and audio evoked potentials are temperature dependent, but not significantly modified at core temperatures of 33°C or higher.

Hypothermic effects on the heart include a decrease in heart rate, increased contractility, and well-maintained stroke volume.[170] Cardiac output and blood pressure both decrease. At temperatures below 28°C, sinoatrial pacing becomes erratic and ventricular irritability increases. Fibrillation usually occurs between 25°C and 30°C, and electrical defibrillation is generally ineffective at these temperatures. Because coronary artery blood flow decreases in proportion to cardiac work, hypothermia per se does not cause myocardial ischemia. However, even mild hypothermia decreases tissue damage in response to experimental cardiac ischemia.[98]

Hypothermia decreases blood flow to the kidneys by increasing renovascular resistance. Inhibition of tubular absorption maintains normal urinary volume. As temperature decreases, reabsorption of sodium and potassium is progressively inhibited and thereby results in an antidiuretic hormone–mediated "cold diuresis." Despite increased excretion of these ions, plasma electrolyte concentrations usually remain normal. Kidney functions return to normal when patients are rewarmed. Respiratory strength is diminished at core temperatures lower than 33°C, but the ventilatory CO_2 response is minimally affected. Hepatic blood flow and function also decrease and thus significantly inhibit the metabolism of some drugs.

Acid-Base Changes

The pH of neutral water ($[OH^-] = [H^+]$) increases 0.017 unit for each 1°C reduction in temperature[171]; the pH of blood in a closed system (e.g., test tube or artery) changes similarly (see Chapter 49). Cold-blooded animals allow pH to vary with body temperature as it would in vitro (i.e., blood becomes more alkalotic as temperature decreases); in contrast, homeotherms, which decrease body temperature during hibernation, maintain an arterial pH near 7.4, a process known as pH-stat management. Interpretation of arterial pH in hypothermic humans is difficult because it is unclear which strategy is optimal.[172]

To mimic the compensatory mechanisms used by hibernating homeotherms, blood pH (which is measured by electrodes at 37°C) has traditionally been "corrected" to the patient's actual body temperature. Without correction, tissue oxygen availability decreases because hemoglobin's affinity for oxygen increases about 1.7%/°C. This effect is small in comparison to the 5.7%/°C increase in oxyhemoglobin affinity caused by hypothermia itself. Fortunately, the combined increases in affinity are offset by the 8%/°C reduction in metabolic rate caused by hypothermia. Tissue hypoxia is thus unlikely, with or without correction, and has not been demonstrated experimentally.

Ectothermic strategy is also known as "alpha-stat" because the dissociation constant of the α-imidazole group in histidine changes in parallel with that of water. Maintaining constant imidazole ionization results in optimal enzyme function as temperature changes. In contrast, homeothermic dynamics significantly decreases metabolic function, and animals are essentially anesthetized by cold. Constant relative alkalinity also maintains a stable intracellular-to-extracellular gradient that promotes the removal of acidic products of intracellular metabolism, which might be salutary.[173]

Both alpha- and pH-stat management seem to work well, and physiologic differences between them appear to be subtle. However, there is increasing evidence that pH-stat management better preserves neurons in the context of ischemic stress.[174-176] Furthermore, clinical outcomes seem to be improved by pH-stat management[177]—or at least not worsened.[178] Nonetheless, alpha-stat management remains common, and there is no consensus that either strategy markedly influences the outcome of cardiac surgery.

Hyperthermia and Fever

Hypothermia is by far the most common perianesthetic thermal perturbation. However, hyperthermia is probably more dangerous than a comparable degree of hypothermia, and hyperthermia

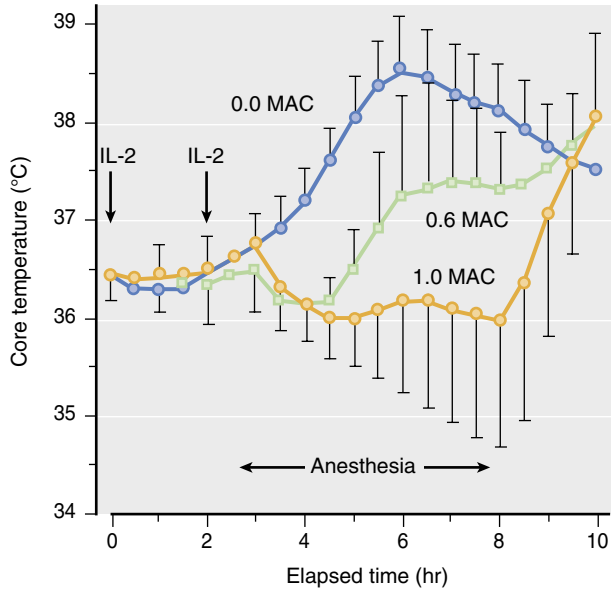

Figure 48-19 Change in core temperature after the administration of 50,000 IU/kg of interleukin-2 (IL-2), followed by a second dose of 100,000 IU/kg 2 hours later. The first dose of IL-2 defined elapsed time zero; anesthesia was started after 3 elapsed hours and continued for 5 hours. Data are presented as means ± SD. *(From Negishi C, Lenhardt R, Sessler DI, et al: Desflurane reduces the febrile response to interleukin-2 administration. Anesthesiology 88:1162-1169, 1998.)*

is certainly more dangerous when perturbations exceed a few degrees centigrade. Hyperthermia is a generic term simply indicating a core body temperature exceeding normal values. In contrast, fever is a regulated increase in the core temperature targeted by the thermoregulatory system. Hyperthermia can result from a variety of causes and usually indicates a problem of sufficient severity that physician intervention is required.

Passive Hyperthermia

Passive intraoperative hyperthermia results from excessive patient heating and is most common in infants and children. It is especially frequent when effective active warming is used without adequate core temperature monitoring. Passive hyperthermia, by definition, does not result from thermoregulatory intervention. Consequently, it can easily be treated by discontinuing active warming and removing excessive insulation.

For information on malignant hyperthermia, see Chapter 37.

Fever

Normal body temperature is neither set nor maintained by circulating factors. In contrast, fever results when endogenous pyrogens increase the thermoregulatory target temperature ("set point"). Endogenous pyrogens identified include interleukin-1, tumor necrosis factor, interferon-α, and macrophage inflammatory protein-1.[179] Although it was initially believed that these factors act directly on hypothalamic thermoregulatory centers,[180] there is increasing evidence of a more complicated system involving vagal afferents.[181] Most endogenous pyrogens have peripheral actions (e.g., activation of the immune system) in addition to their central generating capabilities.

Fever is relatively rare during general anesthesia even though febrile stimuli are frequently present. It is rare because volatile anesthetics per se inhibit expression of fever (Fig. 48-19),[182] as do opioids.[183] Infection is by far the most common cause of fever. However, perioperative fever also occurs in response to mismatched blood transfusions, blood in the fourth cerebral ventricle, and allergic reactions. Some degree of fever is also typical after surgery.[184] The causes of fever are sufficiently diverse—and potentially serious—that a search for a specific etiology is usually warranted.

Treatment of hyperthermia depends on the cause, with the critical distinction being between fever and other causes of hyperthermia. (In general, patients with fever and increasing core temperature will have constricted fingertips, whereas those with other types of hyperthermia will be vasodilated.) It is always appropriate to treat the underlying causes, but nonfebrile hyperthermia will also improve with cooling.

The first- and second-line treatments of fever are amelioration of the underlying cause and administration of antipyretic medications. The first treatment strategy often fails because the etiology of the fever remains unknown; alternatively, the source may be known but unresponsive. The second strategy also often fails or is only partially effective, perhaps because some fever is mediated by mechanisms that bypass conventional antipyretics.[179] It is in these patients that third-line treatment is most likely to be implemented: active cooling (Table 48-3). Active cooling of febrile

Table 48-3 Active Cutaneous Cooling as Treatment of Fever

	Control	Cooling	Warming
Integrated core temperature (°C/hr)	6.0 ± 1.6	5.7 ± 2.2	6.4 ± 1.2
Oxygen consumption (mL/min)	330 ± 50	430 ± 40*	310 ± 30
Duration of shivering (min)	33 ±11	229 ± 35	20 ± 0
Mean arterial pressure (mm Hg)	90 ± 4	98 ± 6*	86 ± 6†
Mean [norepinephrine] (nM)	1.0 ± 0.4	1.4 ± 0.7*	1.1 ± 0.5†
Baseline [epinephrine] (nM)	0.3 ± 0.1	0.3 ± 0.1	0.3 ± 0.1
Mean [epinephrine] during treatment (nM)	0.3 ± 0.1	0.5 ± 0.1*	0.4 ± 0.1
Severe cold sensation (% of time)	27	89*	11

Volunteers were given 30,000 IU/kg of interleukin-2 (IL-2), followed 2 hours later by an additional dose of 70,000 IU/kg. The first dose of IL-2 defined elapsed time zero; thermal management started after 3 elapsed hours and continued for 5 hours. Each volunteer participated on 3 separate days: no warming or cooling, active cooling, and active warming. Mean and integrated values are presented over the treatment period, from 3 to 8 elapsed hours. Times are presented in terms of hours elapsed since the first injection of IL-2. Data are presented as means ± SD.
*Statistically significant differences from control.
†Statistically significant differences from the cooling day.

patients is intuitive. However, it frequently fails to reduce core temperature—while simultaneously worsening the situation by triggering thermoregulatory defenses, including intense discomfort, shivering, and activation of the autonomic nervous system.[185] Active cooling of febrile patients should thus be instituted with considerable care to be sure that the putative benefits outweigh the stress induced by the activation of thermoregulatory defenses.

Hyperthermia During Epidural Analgesia

Hyperthermia frequently complicates epidural analgesia for labor and delivery[186] and in nonpregnant postoperative patients.[187] It is more likely during prolonged labor (i.e., >8 hours). A clinical consequence of this hyperthermia is that women given epidural analgesia are more often administered antibiotics than those treated conventionally are, and their offspring are more commonly treated for sepsis.[188]

Because passive hyperthermia and excessive heat production are unlikely causes, elevated body temperature in laboring and postoperative patients is presumably true fever (i.e., a regulated increase in core temperature) resulting from infection or inflammation.[189] For example, Dashe and coworkers concluded that "Epidural analgesia is associated with intrapartum fever, but only in the presence of placental inflammation. This suggests that the fever reported with epidural analgesia is due to infection rather than the analgesia itself."[189]

The conventional assumption is that hyperthermia is *caused* by the technique, although no convincing mechanism has been proposed. It is worth remembering, though, that pain in "control" patients is usually treated with opioids—which themselves attenuate fever.[178] Fever associated with infection or tissue injury might then be suppressed by the low doses of opioids that are usually given to the "control" patients while being expressed normally in patients given epidural analgesia (Fig. 48-20).[190] The extent to which this mechanism contributes remains to be determined and has been disputed,[191] but no convincing alternative explanation has been advanced.

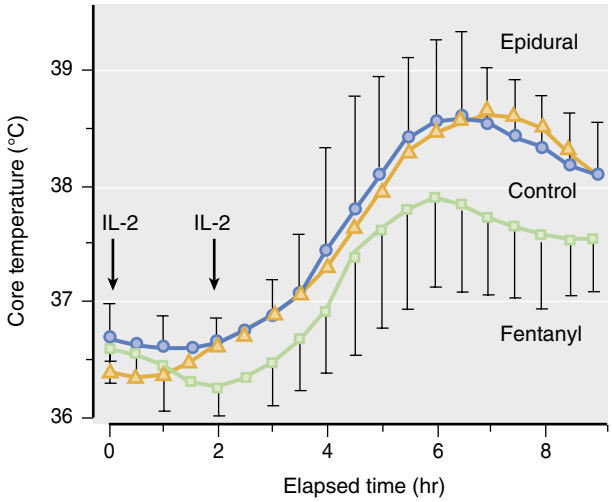

Figure 48-20 Core temperatures after the administration of 50 IU/g of interleukin-2 (IL-2), followed by a second dose of 100 IU/g 2 hours later. The first dose of IL-2 defined elapsed time zero. Data are presented as means ± SD. Error bars for the epidural days are omitted for clarity but were similar to those shown for control and intravenous fentanyl. *(From Negishi C, Lenhardt R, Ozaki M, et al: Opioids inhibit febrile responses in humans, whereas epidural analgesia does not: An explanation for hyperthermia during epidural analgesia. Anesthesiology 94:218-222, 2001.)*

Temperature Monitoring

Core temperature measurements (e.g., tympanic membrane measured with a thermocouple, pulmonary artery, distal part of the esophagus, and nasopharynx) are used to monitor intraoperative hypothermia, prevent overheating, and facilitate detection of malignant hyperthermia. Muscle or skin surface temperatures may be used to evaluate vasomotion[192] and ensure the validity of peripheral neuromuscular monitoring.[193]

Both core and skin surface temperature measurements are required to determine the thermoregulatory effects of different anesthetic drugs. The combination of core and mean skin temperature can be used to estimate mean body temperature—and therefore body heat content—with remarkable accuracy.[194] Temperatures are not uniform within the body; consequently, temperatures measured at each site have different physiologic and practical significance.

Thermometers

Mercury-in-glass thermometers are slow and cumbersome and thus have universally been replaced with electronic systems. The most common electronic thermometers are thermistors and thermocouples. Both devices are sufficiently accurate for clinical use and inexpensive enough to be disposable. Also sufficiently accurate for clinical use are "deep tissue" thermometers that are based on actively reducing the cutaneous heat flux to zero[195]; unfortunately, "deep tissue" thermometers are not currently available in Europe or the United States. Infrared monitors that extrapolate tympanic membrane temperature from outer ear temperature are unreliable,[196] as are infrared systems that scan forehead skin.[197]

Temperature-Monitoring Sites

The core thermal compartment is composed of highly perfused tissues whose temperature is uniform and high in comparison to the rest of the body. Temperature in this compartment can be evaluated in the pulmonary artery, distal part of the esophagus, tympanic membrane, or nasopharynx.[198,199] Temperature probes incorporated into esophageal stethoscopes must be positioned at the point of maximal heart sounds, or even more distally, to provide accurate readings. Even during rapid thermal perturbations such as cardiopulmonary bypass, these temperature-monitoring sites remain reliable. Core temperature can be estimated with reasonable accuracy by using oral, axillary, rectal, and bladder temperatures, except during extreme thermal perturbations.[198,199]

Skin surface temperatures are considerably lower than core temperature. Skin surface temperatures—when adjusted with an appropriate offset—nonetheless reflect core temperature reasonably well.[200] However, skin temperatures fail to reliably confirm

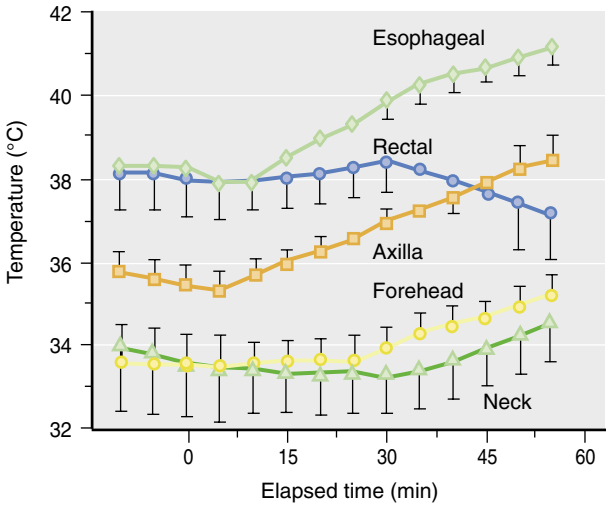

Figure 48-21 Axillary and esophageal temperatures correlated well during acute malignant hyperthermia in swine, but forehead and neck skin temperatures did not. Rectal temperature also failed to promptly identify the onset of malignant hyperthermia. Elapsed time zero indicates an end-tidal P_{CO_2} of 70 mm Hg. These data indicate that forehead and neck skin surface temperatures will not adequately confirm other clinical signs of malignant hyperthermia. Valid core temperature–monitoring sites include the distal part of the esophagus, pulmonary artery, nasopharynx, and tympanic membrane. Except during cardiopulmonary bypass, body temperature can also be measured in the mouth, axilla, and bladder. Data are presented as means ± SD. *(Modified from Iaizzo PA, Kehler CH, Zink RS, et al: Thermal response in acute porcine malignant hyperthermia. Anesth Analg 82:803-809, 1996.)*

the clinical signs of malignant hyperthermia (tachycardia and hypercapnia) in swine[201] and have not been evaluated for this purpose in humans (Fig. 48-21). Rectal temperature also normally correlates well with core temperature[198,199] but fails to increase appropriately during malignant hyperthermia crises[201] and under other documented situations.[202] Consequently, rectal and skin surface temperatures must be used with considerable caution.

Even during cardiopulmonary bypass, the core temperature–monitoring sites (e.g., tympanic membrane, nasopharynx, pulmonary artery, and esophagus) remain useful. In contrast, rectal temperatures lag behind those measured in core sites. Consequently, rectal temperature is considered an "intermediate" temperature in deliberately cooled patients. During cardiac surgery, bladder temperature is equal to rectal temperature (and therefore intermediate) when urine flow is low, but it is equal to pulmonary artery temperature (and thus core) when flow is high.[203] Because bladder temperature is strongly influenced by urine flow, it may be difficult to interpret in these patients. Adequacy of rewarming is best evaluated by considering both "core" and "intermediate" temperatures.

When Temperature Monitoring Is Required

Core hypothermia is as common during epidural and spinal anesthesia as during general anesthesia and can be nearly as severe.[66] Therefore, core temperature should be measured during regional anesthesia in patients likely to become hypothermic, which at the very least includes those undergoing body cavity surgery.

Core temperature monitoring is appropriate during most general anesthetics both to facilitate detection of malignant hyperthermia and to quantify hyperthermia and hypothermia. By far the most common perioperative thermal disturbance is inadvertent hypothermia. Core temperature usually decreases 0.5°C to 1.5°C in the first 30 minutes after induction of anesthesia. Hypothermia results from internal redistribution of heat and a variety of other factors whose importance in individual patients is hard to predict.[55,68] Core temperature perturbations during the first 30 minutes of anesthesia are thus difficult to interpret, and measurements are not usually required. Body temperature should, however, be monitored in patients undergoing general anesthesia exceeding 30 minutes in duration and in all patients whose surgery lasts longer than 1 hour.

Temperature-Monitoring and Thermal Management Guidelines

The objective of temperature monitoring and perioperative thermal management is to detect thermal disturbances and maintain appropriate body temperature during anesthesia. The data available suggest the following guidelines:

1. Core body temperature should be measured in most patients given general anesthesia for longer than 30 minutes.
2. Temperature should also be measured during regional anesthesia when changes in body temperature are intended, anticipated, or suspected.
3. Unless hypothermia is specifically indicated (e.g., for protection against ischemia), effort should be made to maintain intraoperative core temperature higher than 36°C.*

Various organizations have also proposed temperature-monitoring and thermal management strategies. The ASA standards requires only that "every patient receiving anesthesia shall have temperature monitored when clinically significant changes in body temperature are intended, anticipated or suspected." For office-based sedation, regional anesthesia, or general anesthesia, the ASA also requires that "the body temperature of pediatric patient shall be measured continuously."

The state of New Jersey has stronger requirements, specifically that the body temperature of each patient under general or regional anesthesia shall be continuously monitored. Italy probably has the strongest standards, which require, among other things, that (1) core temperature is measured in adults undergoing general anesthesia for longer than 30 minutes (and all children), (2) ambient operating room temperature exceeds 21°C, (3) patients are kept normothermic, and (4) patients who become hypothermic remain in the postanesthesia care unit until normothermia is restored.

In 2007, the American College of Cardiology and American Heart Association published guidelines for the care of patients undergoing noncardiac surgery. The guidelines include a class 1 recommendation that "maintenance of body temperature in a

*Opinions are the author's and not necessarily shared by the American Society of Anesthesiologists (ASA), but they should be.

normothermic range is recommended for most procedures other than during periods in which mild hypothermia is intended to provide organ protection (e.g., during high aortic cross-clamping)."[204] Based on overwhelming evidence of hypothermia-induced complications, maintaining perioperative normothermia is likely to be among the first anesthetic "pay-for-performance" measures.

Summary

Body temperature is normally controlled by a negative-feedback system in the hypothalamus that integrates thermal information from most tissues. Approximately 80% of this thermal input is derived from core body temperature, which can be measured with distal esophageal, nasopharyngeal, or tympanic membrane thermometer probes. The hypothalamus coordinates increases in heat production (nonshivering thermogenesis and shivering), increases in environmental heat loss (sweating), and decreases in heat loss (vasoconstriction) as needed to maintain normothermia.

Thermal steady state requires that heat loss to the environment equals metabolic heat production; hypothermia occurs when heat loss exceeds production. Mild core hypothermia is common during surgery and anesthesia and results initially from redistribution of body heat from the core to peripheral tissues and subsequently from heat loss exceeding metabolic heat production. Clinical doses of general anesthetics decrease the threshold for response to hypothermia from approximately 37°C (normal) to 33°C to 35°C. Anesthetized patients whose core temperatures exceed these values are usually poikilothermic and do not actively respond to thermal perturbations. Patients becoming sufficiently hypothermic do trigger thermoregulatory vasoconstriction, and the vasoconstriction is remarkably effective in minimizing further core hypothermia.

Mild intraoperative hypothermia provides significant protection against tissue ischemia and hypoxia in animals. Nonetheless, the only situations in which improved outcome has been demonstrated with therapeutic hypothermia in humans is out-of-hospital cardiac arrest and neonatal asphyxia. Hypothermia also decreases triggering of malignant hyperthermia and reduces the severity of the syndrome, once triggered. However, most consequences of inadvertent hypothermia are harmful. Major adverse effects include morbid myocardial outcomes, reduced resistance to surgical wound infections, increased blood loss and transfusion requirements, prolonged duration of drug action, shivering, and decreased postoperative thermal comfort.

Little metabolic heat is lost via the respiratory tract. Consequently, even active airway heating and humidification are of little benefit. Administration of sufficient volumes of cold intravenous fluid can produce substantial hypothermia. Fluids therefore should be warmed in patients requiring intravenous administration of more than several liters per hour; however, fluid warming should always be secondary to active cutaneous warming. Among the clinically available active systems, forced air offers the best combination of efficacy, safety, and price. Forced air can usually maintain normothermia even during the largest operations.

Regional anesthesia produces both peripheral and central inhibition of thermoregulatory control. Peripheral inhibition results when local anesthetics block nerves that are required for thermoregulatory defenses. Hypothermia during neuraxial anesthesia results initially from core-to-peripheral redistribution of body heat and subsequently from heat loss exceeding heat production. Hypothermia during major conduction anesthesia may be as severe as that during general anesthesia.

Increased core temperature can result from augmented thermogenesis (malignant hyperthermia), excessive heating (passive hyperthermia), or a specific increase in the thermoregulatory target temperature (fever). Because the causes of hyperthermia are varied and often serious, the etiology of observed increases in core temperature should be sought and appropriate treatments should be instituted.

A reasonable strategy for detecting and preventing thermal disturbances is to monitor core temperature in patients in whom general anesthesia will last longer than 30 minutes and in those undergoing major surgery with regional anesthesia. Unless hypothermia is specifically indicated (i.e., for protection against cerebral ischemia), core temperature should be maintained above 36°C.

49 Perioperative Acid-Base Balance

Key Points

1. The presence of a significant acid-base abnormality often signals a serious underlying problem.
2. All acid-base abnormalities result from alterations in the dissociation of water.
3. Only three factors independently affect acid-base balance—the $Paco_2$, the strong ion difference (SID), and the total concentration of weak acids (A_{TOT}).
4. Respiratory acidosis is caused by hypercarbia, and respiratory alkalosis is caused by hypocarbia.
5. Metabolic acidosis is caused by decreased SID or increased A_{TOT}. Decreased SID results from accumulation of metabolic anions (shock, ketoacidosis, and renal failure), hyperchloremia, and free water excess. Increased A_{TOT} results from hyperphosphatemia.
6. Metabolic alkalosis is caused by increased SID or decreased A_{TOT}. SID increases as a result of sodium gain, chloride loss, or free water deficit. A_{TOT} decreases in hypoalbuminemia and hypophosphatemia. This is particularly common in critical illness.
7. Most acid-base disorders are treated by reversal of the cause.

The chemical composition of the extracellular and intracellular spaces is tightly controlled; this includes, but is not limited to, hydrogen and hydroxyl moieties. Alterations in the relative concentrations of these ions, widely described as disorders of acid-base chemistry, are associated with significant clinical problems. Consequently, the detection, interpretation, and treatment of acid-base abnormalities has become a core element of clinical care. Many clinicians struggle to understand acid-base chemistry because traditional educational approaches have focused on interpretation of laboratory data, rather than an understanding of underlying biophysical chemistry. The "modern" physical-chemical approach to acid-base balance has significantly enhanced understanding of these problems and simplified the clinical approach.[1-4]

A key to understanding acid-base chemistry is the realization that acid-base abnormalities are secondary phenomena; they result from other biochemical changes in the extracellular environment.[5] Alterations in the relative concentrations of hydronium and hydroxyl are less important than the chemical abnormalities causing them. Hydrogen (hydronium) and hydroxyl are the ion dissociation products of water and are modulated to maintain electric neutrality in response to changes in the local concentration of strong ions, weak acids, and carbon dioxide (CO_2). This chapter first explores the physical chemistry of water, then examines the evolution of acid-base medicine, and finally applies clinical approaches to acid-base conundrums.

Physical Chemistry of Water

The human body contains a large quantity of water. Consequently, the physical properties of water have enormous implications for maintenance of homeostasis. Water is a simple triatomic molecule. Its chemical formula is H_2O, and its structural formula is H—O—H. The charge distribution of each covalent bond is unequal. The molecule has a polar conformation and the H—O—H bond angle is 105 degrees. Water molecules attract and form hydrogen bonds with one another. These bonds are fundamental to the existence of life on Earth. Water molecules are in continuous motion. Occasionally, when molecules collide, enough energy is produced to transfer a proton from one water molecule to another. Water slightly dissociates into a negatively charged hydroxyl (OH^-) ion and a positively charged hydronium (H_3O^+) ion. Conventionally, this self-ionization of water is written as follows:

$$H_2O \leftrightarrow H^+ + OH^-$$

The symbol H^+ is convenient because, although protons dissociating from water have many aliases (e.g., H_3O^+ and $H_9O_4^+$), most physicians and chemists refer to them as hydrogen ions.

The extent to which water self-ionizes is minuscule. In pure water at 25°C, the $[H^+]$ and $[OH^-]$ are 1×10^{-7} mmol/L. The tendency for water to dissociate into its component parts is represented by the following:

$$K_{eq}H_2O = [H^+][OH^-]$$

The molarity of water is extremely high—55.5M ("there is a lot of water in water"). Because the concentration of water and the K_{eq} are constants, the ion-product dissociation constant for water can be expressed as follows:

$$K_{eq}H_2O = K_{eq}(55.5) = K_W{}' = [H^+][OH^-]$$

The implication is that the relative concentrations of hydroxyl and hydrogen are constant, so when there is an increase in the concentration of hydrogen ions, there is a concomitant decrease in the concentration of hydroxyl ions, and vice versa.

Pure water is considered neutral because the relative concentrations of hydrogen and hydroxyl are equal. A solution is considered acidic if the concentration of hydrogen ions exceeds that of hydroxyl ions ($[H^+] > 1.0 \times 10^{-7}$ mmol/L, $[OH^-] < 1.0 \times 10^{-7}$ mmol/L). A solution is considered alkaline if the hydroxyl ion concentration exceeds the hydrogen ion concentration.

Acids and Bases

The concept of acids and bases is relatively new. In the early part of the 20th century, it was known that in critical illness the CO_2 content of the blood decreased. In 1831, O'Shaughnessy identified loss of "carbonate of soda" from the blood as a fundamental disturbance in patients dying of cholera.[2] We now know that the loss of bicarbonate was related to hyperventilation and buffering of free hydrogen ions in dysoxic or dysmetabolic states. In 1909, Henderson[6] coined the term *acid-base balance*. He was able to define this process in terms of carbonic acid equilibrium, work that later was refined by Hasselbalch in 1916.[7] Essentially, their method described acid-base balance in terms of the hydration equation for CO_2,[4] the only clinical chemistry test available at that time:

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow H^+ + HCO_3^-$$

$$pH = pK_a + \log\left[[HCO_3^-]/[H_2CO_3]\right]$$

$$\text{Total } CO_2 = [HCO_3^-] + [\text{dissolved } CO_2] + [\text{carbamino } CO_2] + [H_2CO_3]$$
$$\approx P_{CO_2} \times 0.03 \text{ mmol } CO_2/\text{L/mm Hg}$$

so, substituting into the previous equation:

$pH = 6.1 + \log\left[[HCO_3^-]/P_{CO_2} \times 0.03\right]$: the Henderson-Hasselbalch equation

In 1903, the revolutionary theory of Arrhenius (1859-1927) established the foundations of acid-base chemistry. In an aqueous solution, an Arrhenius acid is any substance that delivers a hydrogen ion into the solution.[2] A base is any substance that delivers a hydroxyl ion into the solution. Because of its high dielectric constant, water is a highly ionizing solution. Substances with polar bonds dissociate into their component parts (dissolve) in water. Hydrogen chloride (HCl) is an acid, and potassium hydroxide (KOH) is a base.

The degree of dissociation of substances in water determines whether they are strong acids or strong bases. Lactic acid, which has an ion dissociation constant (pK_a) of 3.4, is completely dissociated at physiologic pH and is a strong acid. Conversely, carbonic acid, which has a pK_a of 6.4, is incompletely dissociated and is a weak acid. Similarly, ions such as sodium, potassium, and chloride that do not easily bind other molecules are considered strong ions—they exist free in solution. In any solution, the ion dissociation constant for water, K_W', dictates that the relative ratio of $[H^+]$ to $[OH^-]$ must always be constant, and electric neutrality must always hold. Consequently, strong cations—Na^+, K^+, Ca^{2+}, Mg^{2+}—act as Arrhenius bases (because they drive hydroxyl out of, and hydrogen into, solution, to maintain electric neutrality), and strong anions—Cl^-, LA^-, ketones, sulfate and formate—act as Arrhenius acids.

Aqueous solutions, such as ammonia (NH_3), sodium carbonate (Na_2CO_3), and sodium bicarbonate ($NaHCO_3$), are bases, but none are hydroxides. In 1923, Brønsted and Lowry proposed an expanded theory of acids and bases. They defined acids as proton donors and bases as proton acceptors. All Arrhenius acids and bases were also Brønsted-Lowry acids and bases. The Brønsted-Lowry approach accounts for the peculiar behavior of CO_2 and ammonia, as follows:

$$NH_3 + H_2O \leftrightarrow NH_4^+ + OH^-$$

In this situation, water is the proton donor, the Brønsted-Lowry acid, and ammonia is the proton acceptor, the Brønsted-Lowry base. Conversely, consider the following reaction:

$$HCl + H_2O \rightarrow H_3O^+ + Cl^-$$

In this reaction, hydrogen chloride acts as a Brønsted-Lowry acid, and water acts as a Brønsted-Lowry base:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

In this reaction, CO_2 is hydrated to carbonic acid, a Brønsted-Lowry acid, which subsequently dissociates to hydrogen and bicarbonate.

Stewart Approach

Determinants of Acidity or Alkalinity of a Solution

The extracellular fluid (ECF) is a solution containing many different molecules that directly influence the dissociation of water. It is inconvenient to use the molar concentration of hydrogen/hydroxide to reflect the relative acidity and alkalinity of a solution. The pH scale, developed by Sorenson in the 1920s, is a simple device for acid-case quantification. The pH scale was developed by using the negative logarithm of the hydrogen ion concentration. Neutral pH for pure water is 7.0 (1.0×10^{-7} mmol/L). Physiologic pH, for the ECF, is 7.4, which is alkaline. Conventionally, we refer to relative acidity and alkalinity from this starting point. If pH is greater than 7.4, the ECF is alkaline (relative to normal), and if pH is less than 7.4, the ECF is acidic (relative to normal). The pH of the intracellular space is 6.8 to 7.0, and remains constant despite dramatic changes in extracellular pH. The reason for the difference in acidity between the spaces is unclear.[8,9]

To determine the hydrogen ion concentration of ECF, the investigator must look at the dissociation equilibriums for all fully dissociated and partially dissociated ionic compounds and apply three simple rules, as follows:

1. Electric neutrality: in aqueous solutions, in any compartment, the sum of all of the positive charged ions must equal the sum of all of the negative charged ions.

2. Dissociation equilibriums: the dissociation equilibriums of all incompletely dissociated substances, as derived from the law of mass action, must be satisfied at all times.
3. Mass conservation: the amount of a substance remains constant unless it is added, removed, generated, or destroyed. The total concentration of an incompletely dissociated substance is the sum of concentrations of its dissociated and undissociated forms.

To determine the acid-base status of a fluid, all substances to which these rules might be applied must be accounted for. A discussion of key groups follows.

Strong Ions

The first group of ions, the strong ions, is simple to incorporate because they dissociate completely. The most abundant strong ions in the extracellular space are Na^+ and Cl^-. Other important strong ions include K^+, SO_4^{2-}, Mg^{2+}, and Ca^{2+}. In a solution containing strong ions created using specified concentrations of NaOH and HCl, the hydrogen ion concentration can calculated by solving for electric neutrality:

$$([Na^+]-[Cl^-])+([H^+]-[OH^-])=0$$

This creates two separate, simultaneous equations, as follows:

$$[H^+]=\sqrt{K_W{}'+([Na^+]-[Cl^-])^2/4}-([Na^+]-[Cl^-])/2$$

and

$$[OH^-]=\sqrt{K_W{}'+([Na^+]-[Cl^-])^2/4}-([Na^+]-[Cl^-])/2$$

These equations tell us that hydrogen and hydroxyl concentrations are determined by the $K_W{}'$ and the difference in charge between sodium and chloride. Because the former is constant, in this system, ($[Na^+] - [Cl^-]$) must determine $[H^+]$ and $[OH^-]$. Because the concentrations of sodium and chloride are known, the net positive charge minus net negative charge can be quantified. It is the strong ion difference (SID). Logically, in any solution, the sum total of the charges imparted by strong cations minus the charges from strong anions represents the SID. SID independently influences hydrogen ion concentration (Fig. 49-1). In human ECF, SID is positive:

$$\begin{aligned}SID&=([Na^+]+[K^+]+[Ca^{2+}]+[Mg^{2+}])-([Cl^-]+[A^-])\\&=40\text{-}44\ mEq\end{aligned}$$

Stewart's pioneering work revealed several facts regarding $[H^+]$ that had not previously been understood. SID is always positive in human ECF, and hydroxyl ions almost always exceed hydrogen ions quantitatively in solution. The relationship between SID and $[H^+]$ is nonlinear in these conditions. Any change in SID changes $[H^+]$ and $[OH^-]$ concentrations. Because of the water dissociation constant, this relationship is inverted: As $[H^+]$ increases, $[OH^-]$ decreases. SID is an independent variable; $[H^+]$ and $[OH^-]$ are dependent, meaning that the addition of hydrogen ions alone (without strong corresponding anions), cannot influence the pH of the solution.

Weak Acid "Buffer" Solutions

The degree of water dissociation—and the hydrogen ion concentration—also is influenced by charges derived from weak acids.

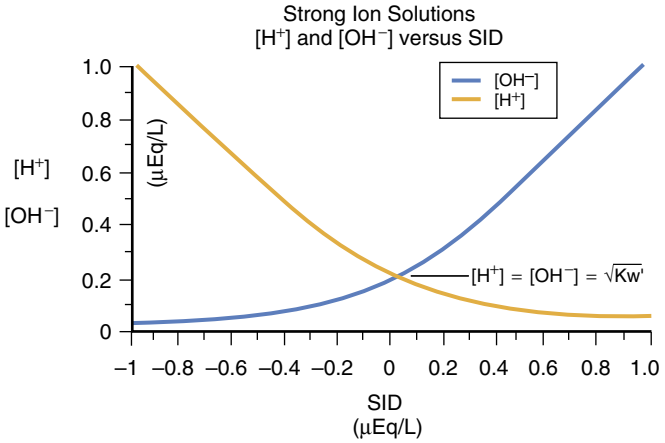

Figure 49-1 Effect of changes in the strong ion gap (strong ion difference [SID]) on hydrogen and hydroxyl ion concentration. *(Adapted from Stewart PA: Modern quantitative acid-based chemistry. Can J Physiol Pharmacol 61:1444-1461, 1983.)*

These weak acids are partially dissociated compounds whose degree of dissociation is determined by the prevailing temperature and pH. The predominant molecules in this group are albumin and phosphate. Stewart used the term A_{TOT} to represent the total concentration of weak ions that influenced acid-base balance.[10]

The acid HA only partly dissociates, represented by the following equilibrium:

$$[HA]=K_A[H^+][A^-]$$

K_A is the weak acid dissociation constant. If we assume that HA and A^- play no further part in this reaction (the law of mass conservation), the amount of A^- present in the solution must equal the amount initially present, so:

$$[HA][A^-]=[A_{TOT}]$$

where $[A_{TOT}]$ is the total weak acid concentration.

To calculate the effect of weak acid dissociation on $[H^+]$, we must take into account water dissociation and electric neutrality:

$$[H^+][OH^-]=K_W{}'\ (\text{water dissociation})$$
$$[SID]+[H^+]-[A^-]-[OH^-]=0\ (\text{electric neutrality})$$

These four simultaneous equations determine the $[H^+]$ in this solution containing strong ions and weak acids. SID and A_{TOT} are independent variables whose concentration was determined during the production of the system. $K_W{}'$ and K_A are constants. Consequently, the other variables [HA], $[H^+]$, $[OH^-]$, and $[A^-]$ must adjust to satisfy the equations. They are dependent variables.

Carbon Dioxide

Along with strong ions and weak bases, ECF contains CO_2. The concentration of CO_2 in ECF is determined by tissue production and alveolar ventilation. CO_2, when in solution, exists in four forms: CO_2 [denoted $CO_2(d)$], carbonic acid (H_2CO_3), bicarbonate ions (HCO_3^-), and carbonate ions (CO_3^{2-}).

The concentration of $CO_2(d)$ is determined by the solubility coefficient of CO_2 (S_{CO_2}), which depends on body temperature, P_{CO_2}, and other factors. Several equilibrium equations can be derived from the hydration of CO_2:

$$[CO_2(d)] = [S_{CO_2}] \times P_{CO_2}$$

The tendency for CO_2 to hydrate to H_2CO_3, and subsequently dissociate to H^+ and HCO_3^-, is reflected by the following equation:

$$[CO_2(d)] \times [OH^-] = K_1 \times [HCO_3^-]$$

These equations can be combined together and with water equilibrium as follows:

$$[H^+] \times [HCO_3^-] = K_c \times P_{CO_2}$$

Bicarbonate also dissociates to release hydrogen ions and carbonate, the equilibrium reaction for which is represented by:

$$[H^+] \times [CO_3^{2-}] = K_3 [HCO_3^-]$$

Factors Independently Influencing Water Dissociation

Now that we have looked at the different factors that may influence the concentration of hydrogen ions in a solution, strong ions, weak acids, and CO_2, we can combine the derived equations to solve for $[H^+]$:

Water dissociation equilibrium:	$[H^+] \times [OH^-] = K_W'$
Weak acid dissociation equilibrium:	$[H^+] \times [A^-] = K_A \times [HA]$
Conservation of mass for weak acids:	$[HA] + [A^-] = [A_{TOT}]$
Bicarbonate ion formation equilibrium:	$[H^+] \times [HCO_3^-] = K_C \times P_{CO_2}$
Carbonate ion formation equilibrium:	$[H^+] \times [CO_3^{2-}] = K_3 \times [HCO_3^-]$
Electric neutrality:	$[SID] + [H^+] - [HCO_3^-] - [A^-] - [CO_3^{2-}] - [OH^-] = 0$

There are six independent simultaneous equations, and just six unknown, dependent variables determined by them: $[HA]$, $[A^-]$, $[HCO_3^-]$, $[CO_3^{2-}]$, $[OH^-]$, and $[H^+]$. There are three known independent variables: SID, $[A_{TOT}]$, and P_{CO_2}

Although the above-listed equations look simple, they require fourth-order polynomials for solution. This is impossible without computer technology.

Solving the equations for $[H^+]$ is as follows:

$$[SID] + [H^+] - K_C \times P_C / [H^+] - K_A - [A_{TOT}] / (K_A + [H^+]) - K_3 \times K_C P_C / [H^+]^2 - K_W' / [H^+] = 0$$

In other words, $[H^+]$ is a function of SID, A_{TOT}, P_{CO_2}, and numerous constants. All other variables, most notably $[H^+]$, $[OH^-]$, and $[HCO_3^-]$, are dependent, and cannot independently influence acid-base balance.

Acid-Base Abnormalities

The value of the Stewart approach is that it allows us to use a simple model for explaining acid-base disturbances because all abnormalities can be explained in terms of SID, A_{TOT}, or P_{CO_2}. Traditionally, acid-base disturbances have been classified as being due to either alterations in arterial carbon dioxide ($Paco_2$) tension—respiratory acidosis or alkalosis—or alterations in blood chemistry—metabolic acidosis or alkalosis. This remains a useful classification, although respiratory or metabolic abnormalities rarely occur independently of one another.

Respiratory Acid-Base Abnormalities

Respiratory acidosis occurs when there is an acute increase in $Paco_2$ principally resulting from respiratory failure. Clinically, there are signs of CO_2 retention, including cyanosis, vasodilation, and narcosis. Respiratory alkalosis occurs when there is an acute decrease in $Paco_2$ as a result of hyperventilation. The patient presents with symptoms and signs of vasoconstriction, including lightheadedness, visual disturbances, dizziness, and perhaps hypocalcemia owing to increased binding of calcium to albumin. The last-mentioned is caused by an increase in the available negative charge on albumin in alkaline states. Acute hypocalcemia is associated with paresthesias and tetany.

Respiratory acidosis causes a rapid increase in $[H^+]$. Compensation for hypercarbia is slow, requiring increased urinary excretion of chloride.[8] There is a concomitant increase in the serum bicarbonate, reflecting higher total CO_2 load, rather than compensation. The acuity of respiratory failure can be deduced by looking at the relative ratio of CO_2 to HCO_3^- (Table 49-1). Many investigators have suggested that respiratory acidosis may not be harmful. There has been extensive clinical experience with "permissive hypercapnia" for acute respiratory failure, which seems to be well tolerated.[9,11,12]

Metabolic Acid-Base Disturbances

Metabolic acid-base abnormalities are caused by alterations in the SID or A_{TOT}, or both. An increase in the SID causes alkalemia; a decrease in the SID causes acidemia. The alteration may be caused by a change in the total or relative concentration of strong ions. A decrease in the SID (i.e., more anions relative to cations) causes acidosis; this may occur because of a net increase in anions (e.g., hyperchloremia, lactacidemia) or an increase in the volume of distribution of the same quantity of ions (e.g., dilutional acidosis) (Table 49-2).

Metabolic acidosis is of clinical significance for two reasons: (1) pathologies arising from the acidosis itself and (2) pathologies arising from the cause of the acidosis. Acidosis is associated with

Table 49-1 Changes in $Paco_2$ and $[HCO_3^-]$ in Response to Acute and Chronic Acid-Base Disturbances

Disturbances	$[HCO_3^-]$ versus $Paco_2$
Acute respiratory acidosis	$\Delta HCO_3^- = 0.2\ \Delta Paco_2$
Acute respiratory alkalosis	$\Delta HCO_3^- = 0.2\ \Delta Paco_2$
Chronic respiratory acidosis	$\Delta HCO_3^- = 0.5\ \Delta Paco_2$
Metabolic acidosis	$\Delta Paco_2 = 1.3\ \Delta HCO_3^-$
Metabolic alkalosis	$\Delta Paco_2 = 0.75\ \Delta HCO_3^-$

Δ, change in value; $[HCO_3^-]$, concentration of bicarbonate ion; P_{CO_2}, partial pressure of carbon dioxide.
Modified from Narins RB, Emmett M: Simple and mixed acid-base disorders: A practical approach. Medicine (Baltimore) 59:161-187, 1980.

Table 49-2 Classification of Primary Acid-Base Abnormalities

Abnormalities	Acidosis	Alkalosis
Respiratory	Increased P_{CO_2}	Decreased P_{CO_2}
Metabolic		
Abnormal SID		
Caused by water excess or deficit	Water excess = dilutional ↓ SID + ↓[Na^+]	Water deficit = contraction ↑ SID ↑[Na^+]
Caused by electrolytes	Chloride excess	Chloride deficit
Chloride (measured)	↓ SID ↑[Cl^-]	↑ SID + ↓[Cl^-]
Other (unmeasured) anions, such as lactate and keto acids	↓ SID ↑[UMA^-]	—
Abnormal A_{TOT}		
Albumin [Alb]	↑[Alb] (rare)	↓[Alb]
Phosphate [Pi]	↑[Pi]	

[Alb], concentration of serum albumin; A_{TOT}, total concentration of weak ions; [Cl^-], concentration of chloride ions; [Na^+], concentration of sodium ions; P_{CO_2}, partial pressure of carbon dioxide; [Pi], concentration of inorganic phosphate; SID, strong ion difference; [UMA^-], unmeasured anions.
Adapted from Fencl V, Jabor A, Kazda A, Figge J: Diagnosis of metabolic acid-base disturbances in critically ill patients. Am J Respir Crit Care Med 162:2246-2251, 2000.

alterations in transcellular ion pumps and increased ionized calcium. The result is vasodilation, diminished muscular performance (particularly myocardial), and arrhythmias. The oxyhemoglobin dissociation curve shifts rightward to increase oxygen offload into the tissues. Rapid-onset metabolic acidosis may be associated with profound hypotension, cardiac arrhythmias, and death. The malignancy of the acidosis is strongly related to the underlying disease process; lactic acidosis caused by circulatory shock is more malevolent than hyperchloremic acidosis caused by excessive administration of 0.9% saline solution.[13] The body is hyper-responsive to acidosis. Increasing hydrogen ion content in cerebrospinal fluid activates the respiratory center to stimulate respiration. Alveolar ventilation increases, reducing arterial CO_2 content, reducing the total body [H^+]. Bicarbonate concentration simultaneously decreases, owing to buffering activity, and owing to the reduction in total CO_2; this prevents abrupt reductions in plasma pH in acute metabolic acidosis.

Metabolic alkalosis rarely occurs as a result of acute illness. Symptoms and signs of metabolic alkalosis include widespread vasoconstriction, lightheadedness, tetany, and paresthesia. The main compensatory mechanism is hypoventilation, which may delay weaning from mechanical ventilation in critically ill patients.

An understanding of the mechanisms by which alterations in SID affect acid-base balance clarifies many of the abnormalities that have remained unexplained by traditional teaching. Of key importance is the ability to differentiate the change in the SID that results from altered free water balance from that arising from altered concentrations of measured and unmeasured electrolytes.

The following examples illustrate the theoretical basis of fluctuations in acid-base chemistry associated with alterations in the relative ratio of water and electrolytes in the extracellular space. An average man weighing 70 kg has a total body water of approximately 45 L, two thirds of which is in the intracellular space. Approximately 15 L is extracellular. The [Na^+] in this compartment is 140 mEq/L, [Cl^-] is 100 mEq/L, and [K^+] is 4 mEq/L. For simplicity, let us ignore magnesium, calcium, other strong ions, and CO_2. In this system, the SID is 44 mEq, this positive charge being balanced principally by weak acids. Anything that increases the SID increases the relative concentration of strong cations to strong anions, and alkalinizes the solution. Anything that decreases the SID decreases the relative concentration of cations to anions, and acidifies the solution.

If the volume of this compartment is expanded by 2 L, as would occur with rapid infusion of 5% dextrose, [Na^+] decreases to 123 mEq/L, [K^+] decreases to 3.5 mEq/L, and [Cl^-] decreases to 88 mEq/L. The relative ratio of cations to anions also decreases, and SID decreases to 38.5. The system becomes more acidic; this is the basis behind the concept of "dilutional acidosis."

Conversely, if 2 L of free water is removed from the system, the total amount of ions would remain unchanged (e.g., as would occur with profuse sweating or dehydration), and an opposite effect would occur. [Na^+] would increase to 161 mEq/L, [K^+] would increase to 4.6 mEq/L, and [Cl^-] would increase to 115 mEq/L. The relative ratio of cations to anions increases, and SID increases to 50.6. The system becomes more alkaline; this is the basis behind "contraction alkalosis."

In perioperative medicine, we commonly administer "normal saline" (NaCl 0.9%), containing 154 mEq of sodium and 154 mEq of chloride. The SID of this solution is 0. A patient who loses 5 L of ECF and is given 5 L of NaCl as replacement would be expected to have a net gain in sodium and chloride. In this scenario, [Na^+] increases to 144 mEq/L, [K^+] decreases to 2.6 mEq/L, and [Cl^-] increases to 118 mEq/L. The SID decreases to 29; this is the basis behind "hyperchloremic acidosis."[14]

Any process that leads to dilution of the total number of ions in the solution would be expected to cause acidosis. Consider the therapeutic use of mannitol (before the diuresis), hyperglycemia, or ethylene glycol or methanol poisoning. The presence of each of these osmotically active particles in the ECF results in an increase in the volume of extracellular water without changing the net charge; the consequence is a reduction in SID and a temporary dilutional acidosis.

Any process that removes chloride without sodium, such as aggressive nasogastric suctioning with loss of hydrogen chloride, causes metabolic alkalosis (hypochloremic alkalosis) as a result of an increase in SID. The alkalosis is caused by chloride loss and not hydrogen ions. There is a finite quantity of Cl^-, which is governed by the law of conservation of mass, whereas there is an effectively unlimited supply of hydrogen ions available from water, and conservation of mass does not apply. Severe diarrhea, which is associated with loss of potassium and sodium, reduces the SID, and is associated with metabolic acidosis. Aggressive use of diuretics causes a net loss of free water over sodium and chloride, and causes contraction alkalosis.

The most malignant form of metabolic acidosis is associated with a net gain of "unmeasured" (i.e., electrolytes not conventionally measured on serum chemistry analysis) anions, and, consequently, a decreased SID:

1. In dysoxia and states of severe stress, lactate is produced, reducing the SID and causing acidosis.
2. In uncontrolled diabetes, ketoacids—β-hydroxybutyrate and acetoacetate—are produced, reducing the SID and causing acidosis.

3. In severe renal failure, SO_4^{2-} and PO_4^{3-} ("fixed renal acids") are not excreted, causing acidosis.

The mechanism of acidosis is similar to before. If we add an additional anion (e.g., lactate) at a concentration of 10 mEq/L to the ECF of a patient with $[Na^+]$ of 140 mEq/L, $[Cl^-]$ of 100 mEq/L, and $[K^+]$ of 4 mEq/L, the SID decreases to 34 mEq/L, and the system becomes more acidemic.

The total weak acid pool, principally serum albumin and phosphate, also is an important determinant of acid-base status. Hyperphosphatemia has long been associated with the acidosis of renal failure. Hypoalbuminemia is common in clinical practice. There is a strong association between hypoalbuminemia and severity of critical illness. This association occurs as a result of hepatic reprioritization of visceral protein production toward acute-phase reactants, capillary leak, breakdown of preexisting albumin (so that its constituent amino acids can be used for protein synthesis), and hemodilution with isotonic fluids. Hypoalbuminemia decreases A_{TOT} and is associated with metabolic alkalosis.[15]

The impact of hypoalbuminemia on acid-base balance has been grossly underestimated. Stewart's original theory was subsequently modified by Figge and colleagues.[16] The serum albumin concentration is the core negative charge offsetting the net positive charge of the SID.[17] Consequently, the presence of hypoalbuminemia may mask the detection of acidosis[18] caused by unmeasured anions, when conventional tools of acid-base chemistry, pH, base deficit, and the anion gap are used.[19] The presence of hypoalbuminemia has significant implications, not least for its association with adverse outcomes.[18,20] Hyperalbuminemia is very unusual; nonetheless, in cholera, when associated with hemoconcentration, it is associated with acidosis.[21]

Fencl and colleagues[18] neatly categorized acid-base disturbances along respiratory and metabolic lines (see Table 49-2). This categorization elegantly explains all known acid-base disturbances.

There are significant differences between the mechanisms causing acid-base imbalances. It would be reasonable to predict significantly different outcomes for patients developing acidosis from dilution, poisoning, hyperchloremia, excessive use of normal saline infusions, or dysoxia owing to increased production of lactate. The acid-base abnormalities themselves may be of less clinical significance than previously thought.[9]

Regulation of Acid-Base Balance

Extracellular hydrogen ion concentration apparently is tightly controlled by the body. This control should be viewed in terms of volatile and metabolic acids. We have evolved various intracellular and extracellular weak acid buffering systems to prevent rapid changes in the extracellular electrochemical balance that may interfere with transcellular ion pumps. A buffer is a solution of two or more chemicals that minimizes changes in pH in response to the addition of an acid or base. Most buffers are weak acids. Ideally, a buffer has a pK_a that is equal to the pH, and an ideal body buffer has a pK_a between 6.8 and 7.2.

The major source of acid in the body is CO_2. CO_2 production from metabolism results in the generation of 12,500 mEq of H^+ daily; this is excreted by the lungs. By contrast, only 20 to 70 mEq of hydrogen ion–promoting anions are excreted through the kidney each day. Volatile acid is principally buffered by hemoglobin. Deoxygenated hemoglobin is a strong base, and there would be a huge increase in the pH of venous blood if hemoglobin did not bind hydrogen ions that are produced by metabolism.

CO_2 easily passes through cell membranes. Within the erythrocyte, CO_2 combines with H_2O, under the influence of carbonic anhydrase, to form H_2CO_3. This ionizes to hydrogen and bicarbonate. Hydrogen ions bind to histidine residues on deoxyhemoglobin (the "Haldane" effect), and bicarbonate is actively pumped from cells. Chloride moves inward to maintain electroneutrality (chloride shift) and to ensure the continued production of carbonic acid. CO_2 also is buffered directly by hemoglobin (carbaminohemoglobin) and by plasma proteins (carbamino proteins). Venous blood contains 1.68 mmol/L of extra CO_2 over arterial blood: 65% as HCO_3^- and H^+ bound to hemoglobin, 27% as carbaminohemoglobin (CO_2 bound to hemoglobin), and 8% dissolved.

When respiratory failure occurs, the principal CO_2 buffering system, hemoglobin, becomes overwhelmed. This leads to the rapid development of acidosis. In response, the kidney excretes an increased chloride load using NH_4^+, a weak cation, for electrochemical balance. ECF osmolality is maintained. This process is conventionally referred to as "metabolic compensation."[22] Chronic respiratory acidosis is associated with an increase in total body CO_2 content, reflected principally by an increase in serum bicarbonate. Mathematically, $\Delta HCO_3^- = 0.5\ \Delta Paco_2$.[23] $[HCO_3^-]$ is a dependent variable that increases or decreases with Pco_2. The rate of conversion of CO_2 to HCO_3^- depends on carbonic anhydrase activity and occurs slowly. It is possible to determine mathematically whether an increase in $Paco_2$ is acute or long-standing (see Table 49-1).

Hypercapnia is associated with a progressive increase in cerebrospinal fluid bicarbonate, reflecting an overall increase in total CO_2 load. Compensation of this hypercarbia is a reduction in cerebrospinal fluid chloride[24] and an increase in cerebrospinal fluid SID.[25-27] This is probably controlled by active transport mechanisms across the blood-brain barrier or at the level of the choroid plexus and can be blocked by furosemide and acetazolamide.[28-31]

Metabolic acid is buffered principally by increased alveolar ventilation producing respiratory alkalosis and extracellular weak acids. These weak acids include plasma proteins, phosphate, and bicarbonate. The bicarbonate buffering system (92% of plasma buffering and 13% overall) is probably the most important extracellular buffer. The pK_a of bicarbonate is low (6.1), but the system is extremely important because of the enormous quantity of CO_2 in the body. The coupling of bicarbonate and H_2O produces CO_2 that is excreted through the lungs via an increase in alveolar ventilation. Physicians must be aware of the importance of this compensatory mechanism. Anesthetized or critically ill patients on controlled mechanical ventilation lose the capacity to regulate their own Pco_2. Consequently, the combination of acute metabolic and respiratory acidosis can cause a devastating reduction in pH.

The major effect of the kidney on acid-base balance relates to renal handling of sodium and chloride ions. Because dietary intake of sodium and chloride is roughly equal, the kidney excretes a net chloride load using NH_4^+, a weak cation, to accompany chloride (electrochemically) in the urine.[22]

In metabolic acidosis, chloride is preferentially excreted by the kidney. In metabolic alkalosis, chloride is retained, while sodium and potassium are excreted. The presence of bicarbonate in the urine reflects the needs to maintain electric neutrality. Abnormalities in the renal handling of chloride may be responsible for several inherited acid-base disturbances. In renal tubular acidosis, there is inability to excrete Cl^- in proportion to Na^+.[32] The diagnosis can be made by observing a hyperchloremic metabolic acidosis with inappropriately low levels of Cl^- in the urine: The urinary SID is positive. If the urinary SID is negative, the process is nonrenal. Similarly, pseudohypoaldosteronism seems to be due to high reabsorption of chloride.[33] Bartter syndrome is caused by a mutation in the gene encoding the chloride channel—CLCNKB—that regulates the Na-K-2Cl cotransporter (NKCC2).[34] The other causes of hyperchloremic metabolic acidosis are gastrointestinal losses (diarrhea, small bowel or pancreatic drainage), parenteral nutrition, excessive administration of saline, and the use of carbonic anhydrase inhibitors.

Analytic Tools Used in Acid-Base Chemistry

Textbooks and clinical practice have tended to overestimate the importance of isolated changes in hydrogen or bicarbonate ion concentration. The clinical significance of acid-base perturbations is determined by the underlying cause, rather than the serum concentration of hydrogen and hydroxyl ions themselves. Nevertheless, acid-base chemistry remains a mainstay of clinical data interpretation because of ubiquitous availability, low cost, and universal acceptance. The accuracy of acid-base measurements is not determined, however, by the blood gas, which measures volatile acid and pH, alone. Measurement of all of the strong and weak ions that influence water dissociation, although cumbersome, is essential.

Acid-base abnormalities are best described by alterations in P_{CO_2}, SID, and A_{TOT}. Many approaches used to teach and describe the acid-base status of a patient fail to explain adequately many commonly seen perioperative acid-base abnormalities (e.g., dilutional or hyperchloremic acidosis) and are misleading with regard to the cause of the problem (e.g., dilutional acidosis is caused by reduced SID, not dilution of bicarbonate). Although it is important to consider historically used approaches, modern approaches to acid-base interrogation focus on physical chemistry either to calculate the magnitude of the disturbance in SID (strong ion gap [SIG]) or to recalculate the base deficit or excess using SID and A_{TOT} (see Fig. 49-4). In this section, we consider some of the tools that have evolved over the past 50 years to assist with interpretation of acid-base conundrums. None are entirely accurate, and each has a dedicated group of followers.[35]

Carbon Dioxide–Bicarbonate (Boston) Approach

Schwartz and colleagues, at Tufts University in Boston, developed an approach to acid-base chemistry using acid-base maps and the mathematical relationship between CO_2 tension and serum bicarbonate (or total CO_2), derived from the Henderson-Hasselbalch equation to predict the nature of acid-base disturbances (see Table 49-1). Patients with known acid-base disturbances, at steady states of compensation, were evaluated. The degree of compensation from what was considered normal was measured for each disease state. The investigators described six primary states of acid-base imbalance, using linear equations or maps, relating hydrogen ion concentration to P_{CO_2} for respiratory disturbances, and P_{CO_2} to HCO_3^- concentration for metabolic disturbances (Fig. 49-2). For any given acid-base disturbance, an expected HCO_3^- concentration was determined. For most simple disturbances, this is a reasonable approach.

Using these maps and equations, physicians have been able to determine the nature of most respiratory and metabolic acid-base disturbances. Although there is a mathematical relationship in place, alterations in H^+ and HCO_3^- do not reflect cause and effect. Chronic hypoventilation is associated with an increase in P_{CO_2} and HCO_3^-. Many physicians have incorrectly assigned the increase in HCO_3^- as compensation for increased P_{CO_2}. It is not. The increased HCO_3^- concentration reflects increased total CO_2 in the body. Alterations in HCO_3^- reflect its role as a buffer, CO_2 by-product, and weak acid.

Although the P_{CO_2}-HCO_3^- approach is accurate for most disturbances, there are several inherent pitfalls, particularly in relation to the metabolic component. First, the approach is not as simple as it seems. It requires the clinician to refer to confusing maps or to learn formulas and perform mental arithmetic. Second, the system neither explains nor accounts for many of the complex acid-base abnormalities seen in perioperative and critically ill patients. These include acute acidosis in the setting of hypoalbuminemia, hyperchloremic acidosis, and dilutional acidosis or lactic acidosis in the setting of chronic respiratory acidosis.

Base Deficit/Excess (Copenhagen) Approach

Singer and Hastings[36] pioneered an alternative approach to acid-base chemistry in 1948. Their method moved away from the Henderson-Hasselbalch equation and attempted to quantify the

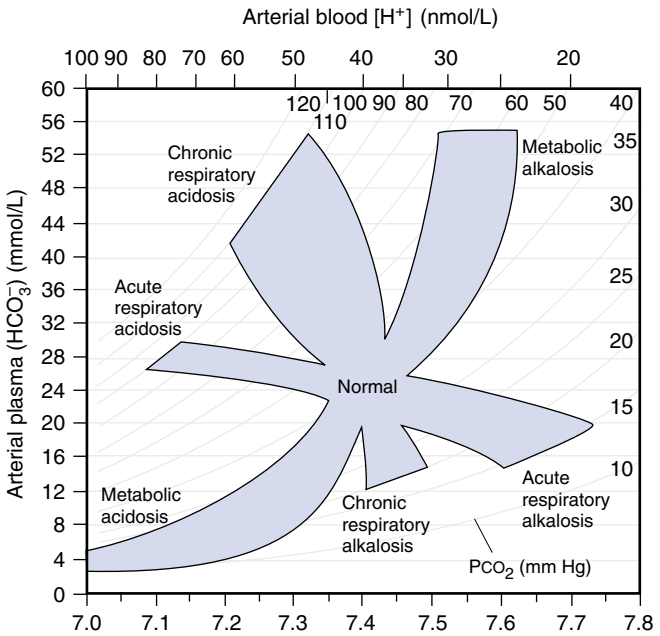

Figure 49-2 Acid-base nomogram using the Boston approach. Different acid-base disturbances can be distinguished based on the relative values of partial pressure of carbon dioxide (P_{aCO_2}) and concentration of bicarbonate ion ($[HCO_3^-]$). *(Adapted from Brenner BM, Rector FC: The Kidney, 3rd ed. Philadelphia, WB Saunders, 1986, p 473.)*

metabolic component. They proposed that the whole-blood buffer base could be used for this purpose. The buffer base represented the sum of the bicarbonate and the nonvolatile buffer ions (essentially serum albumin, phosphate, and hemoglobin). Applying the law of electric neutrality, the buffer base was forced to equal the electric charge difference between strong (fully dissociated) ions. Normally, buffer base = $[Na^+] + [K^+] - [Cl^-]$. Alterations in buffer base essentially represented changes in strong ion concentrations (these could not be easily measured in 1948). Buffer base increases in metabolic alkalosis and decreases in metabolic acidosis. The major drawback of the use of buffer base measurements is the potential for changes in buffering capacity associated with alterations in hemoglobin concentration.

In 1948, Siggard-Andersen* developed a simpler measure of metabolic acid-base activity, the base deficit/excess. This is defined as the amount of strong acid or base required to return pH to 7.4, assuming a P_{CO_2} of 40 mm Hg and temperature of 38°C. The initial use of whole-blood base excess was criticized because of the dynamic activity of red blood cells within the acid-base paradigm of gas and electrolyte exchange. This approach was modified in the 1960s to use only serum base excess, and the calculation became the *standardized* base excess. Similar to the Boston group, the Siggard-Andersen approach was based on data derived from a large population of patients that led to the development of nomograms (Fig. 49-3 and Table 49-3). Current algorithms for computing the standardized base excess are derived from the Van Slyke equation.[37] This base deficit excess (BDE) approach to acid-base chemistry has been successfully validated by Schlichtig et al.[38] The standardized base excess (SBE) is computed by blood gas analyzers as follows:

$$SBE = 0.9287\left[HCO_3^- - 24.4 + (pH - 7.4)\right]$$

Simple mathematical rules can be applied for using the BDE in each of the common acid-base disturbances. In acute respiratory acidosis or alkalosis, BDE does not change. Conversely, in acute metabolic acidosis, the magnitude of change of the P_{CO_2} (in mm Hg) is the same as that of the BDE (in mEq/L)

There has been considerable discussion over the past 30 years about the merits and demerits of the BDE compared with the CO_2-HCO_3^- system. In reality, there is little difference between the two; both equations and nomograms were derived from in vivo patient data and abstracted backward. Consequently, for most patients, either approach is relatively accurate but misleading. Using measures of buffer base as a means of quantifying acid-base disturbances does not allow the clinician to distinguish between acidosis caused by lactate or chloride or alkalosis caused by dehydration or hypoalbuminemia. These measures may miss the presence of an acid-base disturbance entirely; for example, a hypoalbuminemic (metabolic alkalosis), critically ill patient with a lactic acidosis may have a normal-range pH, bicarbonate, and base excess. This may lead to inappropriate or inadequate therapy.

Anion Gap Approach

The most widely used tool for investigating metabolic acidosis is the anion gap developed by Emmett and Narins.[39] The anion gap

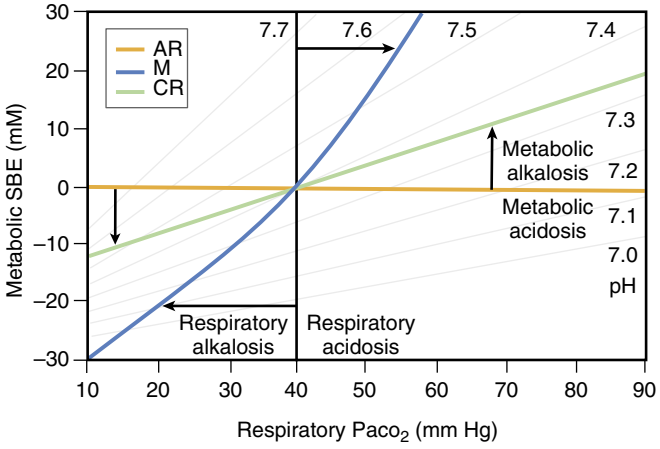

Figure 49-3 Acid-base nomogram using the Copenhagen approach as revised by Schlichtig. The various acid-base disturbances can be distinguished based on partial pressure of carbon dioxide (P_{aCO_2}) and base deficit or excess, here referred to as standard base excess (SBE). *Arrows* represent changes as the body compensates for acute acidosis or alkalosis. AR, acute respiratory acidosis or alkalosis; CR, chronic respiratory acidosis or alkalosis; M, metabolic acidosis or alkalosis. *(From Schlichtig R, Grogono AW, Severinghaus JW: Human P_{aCO_2} and standard base excess compensation for acid-base imbalance. Crit Care Med 26:1173-1179, 1998.)*

is based on the law of electric neutrality and is entirely consistent with the work of Stewart and Fencl. The system is based on data that were not easily available or known at the time of publication: the contribution to electric neutrality ascribed to weak acids (phosphate and albumin) and unmeasured anions. The sum of the difference in charge of the common extracellular ions reveals an unaccounted for "gap" of −10 to −12 mEq/L (anion gap = $(Na^+ + K^+ - (Cl^- + HCO_3^-))$ (Fig. 49-4). If the patient develops a metabolic acidosis, and the gap "widens" to −16 mEq/L, the acidosis is caused by unmeasured anions: lactate or ketones. If the gap does not widen, the anions are being measured, and the acidosis has been caused by hyperchloremia (bicarbonate cannot independently influence acid-base status).

Although the anion gap is a useful tool, it is weakened by the assumption of what is or is not a "normal gap."[40] Most critically ill patients are hypoalbuminemic, and many are also hypophosphatemic.[41] Consequently, the gap may be normal in the presence of unmeasured anions. This situation has been exten-

Table 49-3 Changes in Standardized Base Deficit or Excess in Response to Acute and Chronic Acid-Base Disturbances

Disturbance	BDE versus P_{aCO_2}
Acute respiratory acidosis	ΔBDE = 0
Acute respiratory alkalosis	ΔBDE = 0
Chronic respiratory acidosis	$\Delta BDE = 0.4\ \Delta P_{aCO_2}$
Metabolic acidosis	$\Delta P_{aCO_2} = \Delta BDE$
Metabolic alkalosis	$\Delta P_{aCO_2} = 0.6\ \Delta BDE$

BDE, base deficit or excess; Δ, change in value; P_{aCO_2}, partial pressure of arterial oxygen.
Modified from Narins RB, Emmett M: Simple and mixed acid-base disorders: A practical approach. Medicine (Baltimore) 59:161-187, 1980.

*Astrup P, Siggard-Andersen O: Micromethods for measuring acid-base values of blood. Adv Clin Chem 69:1-28, 1963.

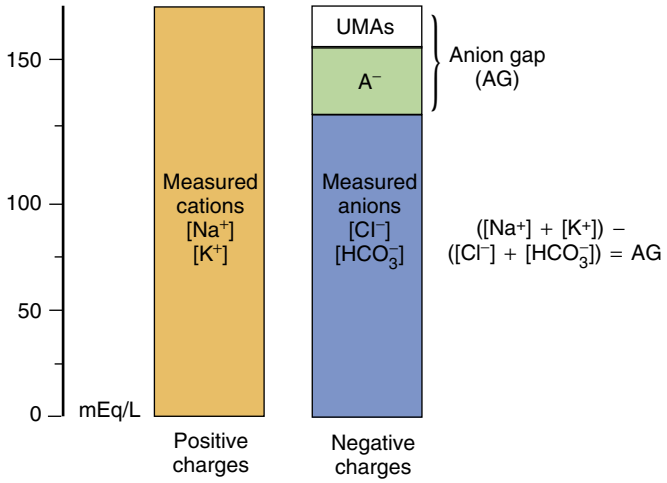

Figure 49-4 The anion gap represents the difference in charge between measured cations and measured anions. The missing negative charge is composed of weak acids (A^-), such as albumin and phosphate, and strong unmeasured anions (UMAs), such as lactate. The strong ion gap (SIG) approach is probably the most accurate method for evaluating acid-base anomalies and predicting outcomes.[42-45] The weakness of this system is that the SIG does not represent unmeasured strong anions, but rather all anions that are unmeasured. It is unclear whether this weakness is clinically significant because there is an emerging body of evidence that "stress acidosis" is associated with a medley of metabolic by-products, often in the absence of elevated serum lactate. The presence of a widened SIG is associated with worse outcomes.[46,47] This is important because many critical care practitioners continue to overestimate the importance of lactate in the evaluation and prognostication of major injury.[48]

sively studied by Figge and colleagues,[19] who have provided us with a variant known as the "corrected anion gap":

$$\text{Anion gap corrected (for albumin)} = \text{calculated anion gap} + 2.5\left(\text{normal albumin g/dL} - \text{observed albumin g/dL}\right)$$

The second weakness with this approach is the use of bicarbonate in the equation. An alteration in $[HCO_3^-]$ concentration can occur for reasons independent of metabolic disturbance (e.g., hyperventilation). The base deficit and anion gap frequently underestimate the extent of the metabolic disturbance.[18] The anion gap is nonetheless useful in discriminating acidosis from unmeasured anions from hyperchloremic acidosis in a previously healthy patient (e.g., in acute trauma).

Stewart-Fencl Approach

A more accurate reflection of true acid-base status can be derived using the Stewart-Fencl approach.[1,2] This approach is based on the concept of electric neutrality, a small advance from the anion gap. There exists, in plasma, a SID $[(Na^+ + Mg^{2+} + Ca^{2+} = K^+) - (Cl^- + A^-]$ of 40 to 44 mEq/L, balanced by the negative charge on bicarbonate and A_{TOT} (the buffer base). There is a small difference between apparent SID (apparent SID = $([Na^+]+ [K^+]+ [Mg^{2+}]+ [Ca^{2+}]) - [Cl^-]$) and buffer base. This effective SID = $[HCO_3^-]$ + [charge on albumin] + [charge on Pi] (in mmol/L). Because weak acids such as albumin and phosphate have known degrees of ionization, one can calculate the SIG, which quantifies the amount of unmeasured anion present (Fig. 49-5):

$$[\text{alb}^-] = [\text{alb g/L}] \times (0.123 \times \text{pH} - 0.631)$$

$$[\text{Pi}]\ (\text{in mg/dL}) = [\text{Pi}]/10 \times \text{pH} - 0.47$$

$$\text{SIG} = \text{apparent SID} - \text{effective SID}$$

SID changes quantitatively in absolute and relative terms when there are changes in plasma water concentration. Fencl and colleagues[18] addressed this by correcting the chloride concentration for free water (Cl^- *corr*) using the following equation:

$$[Cl^-]\ corr = [Cl^-]\ \text{observed} \times ([Na^+]\ \text{normal}/[Na^+]\ \text{observed}$$

This corrected chloride concentration may be inserted into the apparent SID equation. Likewise, the derived value for unmeasured anions should be corrected for free water using unmeasured anions instead of Cl^- in the previous equation.[18] In a series of nine normal subjects Fencl and colleagues[18] estimated the "normal" SIG as 8 ± 2 mEq/L.

Although accurate, the SIG is cumbersome and expensive, requiring measurement of multiple ions and albumin. An alternative approach, used by Gilfix and colleagues[49] and subsequently by Balasubramanyan and associates[45] and Story and associates,[50] is to calculate the base deficit-excess gap. This allows recalculation of BDE using strong ions, free water, and albumin. The resulting base deficit-excess gap should mirror the SIG and anion gap. We find the simplified calculation of Story and associates[50] to be most useful (Table 49-4). These investigators use two equations to calculate the BDE for sodium, chloride, and free water (BDE_{NaCl}) and for albumin.

It is probable that no single number will ever allow investigators to make sense of complex acid-base disturbances. Fencl and colleagues[18] suggested that, rather than focusing on anion gap or BDE, physicians should address each blood gas in terms of all alkalinizing and acidifying effects: respiratory acidosis or alkalosis, the presence or absence of abnormal SID (owing to water excess or deficit, measured electrolytes or unmeasured electrolytes), and abnormal A_{TOT}.

Although this approach may seem inelegant, it has the advantage of being comprehensive. Consider the following

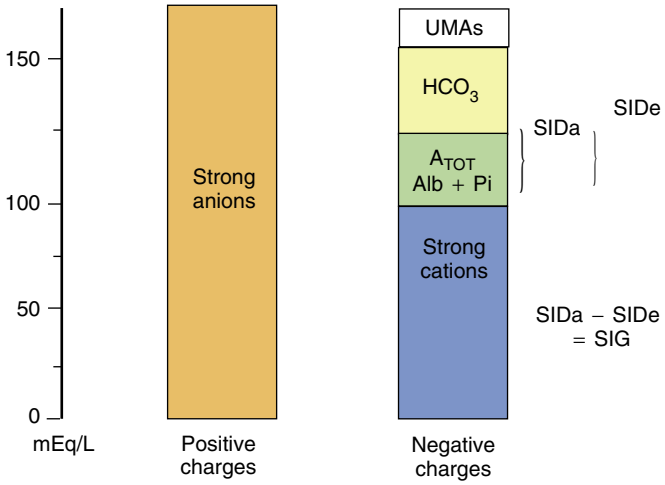

Figure 49-5 The strong ion gap. Apparent strong ion difference (SIDa) is the sum of the total concentration of weak ions (A_{TOT}) plus concentration of bicarbonate ion ($[HCO_3^-]$). Effective strong ion difference (SIDe) is the real SID. The difference between the two is composed of unmeasured anions (UMA).

Table 49-4 Calculation of Base Deficit or Excess of Sodium, Chloride, and Free Water, and Albumin

$BDE_{NaCl} = ([Na^+]–[Cl^-]) – 38$
$BDE_{Alb} = 0.25\ (42 – \text{albumin g/L})$
$BDE_{NaCl} – BDE_{Alb} = BDE_{calc}$
$BDE – BDE_{calc} = BDE\ gap = \text{the effect of unmeasured anions or cations}$
These calculations simplify the framework for "eyeballing" a chemistry series:
Normal Na = 140 mEq/L
For every 1 mEq/L increase in Na from 140, base excess increases by +1 (Na 150 = BDE +10 = contraction alkalosis)
For every 1 mEq/L decrease in Na from 140, base deficit increases by –1 (Na 130 = BDE –10 = dilutional acidosis)
Normal Cl = 102 mEq/L
For every 1 mEq/L increase in Cl from 102, base deficit increases by +1 (Cl 110 = BDE – 8 = hyperchloremic acidosis)
For every 1 mEq/L decrease in Cl from 102, base excess increases by +1 (Cl 90 = BDE +12 = hypochloremic, chloride sensitive, alkalosis)
Normal albumin = 42 g/L or 4.2 g/dL
For every 0.4 g/dL decrement in albumin from 4.0, there is a 1.0 mEq/L increase in base excess

Note: This approach involves calculating the base deficit or excess for sodium, chloride, and free water (BDE_{NaCl}), and that for albumin (BDE_{Alb}). The result is the calculated BDE (BDE_{calc}). This is subtracted from the measured BDE to find the BDE gap.

patient, described by Fencl and colleagues[18] (data in mEq/L unless otherwise stated):

> *Sodium 117, potassium 3.9, calcium 3, magnesium 1.4, chloride 92, inorganic phosphate 0.6 mmol/L, albumin 6 g/L, pH 7.33, P_{CO_2} 30 mm Hg, HCO_3 15, anion gap 13, corrected anion gap 23, base excess −10, SID 18, corrected chloride 112, corrected unmeasured anions 18.*

Using traditional methodology, one would describe this as a nongap metabolic acidosis, and look for causes of bicarbonate wasting, such as renal tubular acidosis or gastrointestinal losses. The degree of respiratory alkalosis is appropriate for the degree of acidosis ($\Delta BD = \Delta P_{CO_2}$). Fencl-Stewart methodology reveals a much more complex situation. SID is reduced to 18 mEq/L—caused by free water excess, unmeasured anions, and hyperchloremia (see the corrected chloride). The degree of acidosis does not mirror this metabolic disturbance, however, owing to the alkalizing force at play: hypoalbuminemia. The corrected anion gap mirrors the change in SID, but this is grossly underestimated by the base deficit. This patient has a dilutional acidosis, a hyperchloremic acidosis, and a lactic acidosis.

For most patients presenting to the emergency department or operating suite, who have been previously healthy, the use of tools such as the base deficit or anion gap to assess metabolic disturbances remains reasonable. For critically ill patients, the most effective method of interpreting acid-base conundrums involves unraveling synchronous acidifying and alkalinizing processes and using calculations or rules of thumb to distinguish between the various forces at play. A clinician's ability to interpret such information depends on the amount of available data. A simple blood gas alone may camouflage a significant acid-base disturbance. In the next section, we look at the causes of many commonly seen acid-base disturbances in different clinical settings.

Acid-Base Problems in Different Clinical Settings

Simple acid-base disturbances can be evaluated using the following strategy:

Step 1. Look at the pH (three possibilities):
- <7.35—acidosis
- 7.35-7.45—normal or compensated acidosis
- >7.45—alkalosis

Step 2. Look for respiratory component (volatile acid = CO_2):
- P_{CO_2} <35 mm Hg—respiratory alkalosis or compensation for metabolic acidosis (if so, BD* > −5)
- P_{CO_2} 35-45 mm Hg—normal range
- P_{CO_2} >45 mm Hg—respiratory acidosis (acute if pH <7.35, chronic if pH in normal range and BE† > +5)

Step 3. Look for a metabolic component (i.e., buffer base utilization):
- BD >−5—metabolic acidosis
- BE −5 to +5—normal range
- BE >5—alkalosis

Put this information together. Options:
1. Acidosis, CO_2 <35 mm Hg, ± BD >−5—acute metabolic acidosis
2. Normal range pH CO_2 <35, BD >−5—acute metabolic acidosis plus compensation
3. Acidosis, P_{CO_2} >45 mm Hg, normal range BE—acute respiratory acidosis
4. Normal range pH, P_{CO_2} >45 mm Hg, BE >+5—prolonged respiratory acidosis
5. Alkalosis, P_{CO_2} >45 mm Hg, BE >+5—metabolic alkalosis
6. Alkalosis, P_{CO_2} <35 mm Hg, BDE normal range—acute respiratory alkalosis
7. If the acid-base picture does not conform to any of these, a mixed picture is present.

Acid-Base Disturbances in the Emergency Setting

Acid-base disturbances are an important part of the laboratory investigation of acutely ill patients. Common disturbances are acute respiratory acidosis or alkalosis and acute metabolic acidosis. Acute metabolic alkalosis is unusual. Mixed respiratory acidosis/metabolic acidosis is seen in severely injured or infected patients.

Acute respiratory acidosis, as discussed earlier, results from hypoventilation. The hypoventilation may be due to loss of respiratory drive, neuromuscular or chest wall disorders, or rapid,

*Base deficit (BD) = amount of strong cation required to bring pH back to 7.4, with P_{CO_2} corrected at 40 mm Hg.

†Base excess (BE) = amount of strong anion required to bring pH back to 7.4, with P_{CO_2} corrected at 40 mm Hg.

shallow breathing that increases the fraction of dead space ventilation. Causes include neurologic injury (e.g., stroke, spinal cord injury, botulism, tetanus), toxic suppression of the respiratory center (e.g., opioids, barbiturates, benzodiazepines), neuromuscular disorders (e.g., Guillain-Barré syndrome, myasthenia gravis), abdominal hypertension, flail chest, hydrohemopneumothorax, pulmonary edema, and pneumonia.

Acute respiratory alkalosis is caused by hyperventilation. The hyperventilation most often results from anxiety, central respiratory stimulation (as occurs early in salicylate poisoning), or excessive artificial ventilation. Acute respiratory alkalosis often occurs in compensation for acute metabolic acidosis. In such cases, the reduction in P_{CO_2} from baseline (usually 40 mm Hg) is equal to the magnitude of the base deficit. In a patient with an acute lactic acidosis of 10 mEq/L, the base deficit should be −10, and the P_{CO_2} should be 30 mm Hg. If the P_{CO_2} is higher than expected, there is a problem with respiration. This situation is seen in a multitrauma patient, in whom there is massive blood loss causing lactic acidosis plus a flail chest causing respiratory acidosis.

Acute metabolic acidosis is caused by an alteration in the SID or A_{TOT}. An altered SID reflects a change in the relative ratio of strong anions to strong cations. This change can be caused by anion gain, as occurs with lactic acidosis, renal acidosis, ketoacidosis, or hyperchloremia. Alternatively, cations may be lost, as occurs with severe diarrhea or renal tubular acidosis. Acute acidosis also may reflect increased free water relative to strong ions—the so-called dilutional acidosis that may accompany excessive hypotonic fluid intake. Alcohols such as ethanol, methanol, isopropyl alcohol, and ethylene glycol are osmotically active molecules that expand extracellular water. Poisonings with these agents cause a dilutional acidosis. In addition, although hyperglycemia or administration of mannitol ultimately contracts ECF via an osmotic diuresis, the initial response is volume expansion.

To investigate acute metabolic acidosis in previously healthy patients, simple observational and mathematical tools, such as the anion gap and base deficit, are useful (Table 49-5). The base deficit shows the presence of an acid-base anomaly. The anion gap (anion gap = $[Na^+ + K^+ - (Cl^- + HCO_3^-)]$) distinguishes acidosis caused by hyperchloremia (renal tubular acidosis or excessive administration of "normal saline") from acidosis caused by "unmeasured" anions (many of which now are measurable) and dilution. When a patient presents with an acute metabolic upset (e.g., trauma, exsanguination, loss of consciousness, tachypnea), a blood gas, electrolyte panel, serum lactate, serum osmolality, and urinalysis are invaluable.

In acute metabolic acidosis, three diagnoses should be immediately investigated: (1) lactic acidosis (send a serum lactate—it should mirror the magnitude of base deficit); (2) ketoacidosis secondary to diabetes (the patient should be hyperglycemic and have positive urinary ketones); and, by exclusion, (3) acute renal failure, characterized by high serum urea and creatinine and low total CO_2.

Lactic acidosis in the presence of hypoxemia or hypoperfusion is termed type A lactic acidosis. When hypoxemia/hypoperfusion is absent, it is referred to as type B lactic acidosis, and is more often associated with inborn errors of metabolism and some drugs (e.g., biguanides and toxins). Another important source of lactate is administration of catecholamines, particularly epinephrine.

Table 49-5 Evaluation of a Patient with Metabolic Acidosis

1. Is acidosis being caused by measured or unmeasured anions (i.e., chloride)?
   - Look at blood chemistry
     - Calculate anion gap: Na + K − Cl = 10-12
     - If gap is normal, there is too much chloride present, owing to excessive administration, excess loss of sodium (diarrhea, ileostomy), or renal tubular acidosis
     - If gap is wide (>16), there are other unmeasured anions present, causing acidosis
   - Check serum lactate—if >2, probably lactic acidosis
     - If high lactate is explained by circulatory insufficiency (shock, hypovolemia, oliguria, under-resuscitation, anemia, carbon monoxide poisoning, seizures), then "type A" lactic acidosis
     - If not think about "type B (rare)" causes—biguanides, fructose, sorbitol, nitroprusside, ethylene glycol, cancer, liver disease
   - Look at creatinine and urine output
     - If patient is in acute renal failure, these may be renal acids
   - Look at blood glucose and urinary ketones
     - If patient is hyperglycemic and ketotic, this is diabetic ketoacidosis
     - If patient is ketotic (unmeasured anion) and normoglycemic, this is either alcoholic (check blood alcohol) or starvation ketosis
     - Check for presence of chronic alcohol abuse—high mean corpuscular volume, increased γ-glutamyl transferase on liver panel
2. If all of these tests are negative, think of intoxication
   - Send toxicology laboratory tests (particularly salicylates) and serum osmolality, and calculate osmolality using the formula: 2(Na + K) + Glucose/18 + BUN/2.8
   - Look for unmeasured source of osmoles: if gap between measured and calculated serum osmolality >12, think of alcohol, particularly ethylene glycol, isopropyl alcohol, and methanol

Diabetic ketoacidosis is characterized by ketosis and hyperglycemia. Ketone bodies are produced from β-hydroxylated fatty acids in states of starvation or insulin deficiency. They include acetate, acetoacetate, and β-hydroxybutyrate. These act as strong ions, causing metabolic acidosis. Patients with diabetic ketoacidosis have acidosis caused by ketones and lactate and hypoperfusion. They are characteristically dehydrated, owing to hyperglycemia induced diuresis.

Renal acidosis is caused by accumulation of strong ion products of metabolism, including sulfate and formate, excreted exclusively by the kidney. In addition, there is accumulation of a weak acid, phosphate; this is caused by relative deficiency of vitamin D. Lactic acidosis is treated with volume resuscitation and source control. Diabetic ketoacidosis is treated with volume resuscitation and insulin. Renal acidosis is treated with dialysis.

Finally, the presence of a low serum sodium (>135 mEq/L) should alert the clinician to the possibility of a dilutional acidosis, such as may be caused by alcohol poisoning. Alcohol poisoning is suspected by the presence of an osmolar gap, a difference between the measured and calculated serum osmolality of greater than 12 mOsm showing the presence of unmeasured osmoles. Toxicology laboratories can investigate for the presence of various toxic alcohols.

The use of sodium bicarbonate boluses or infusions is controversial in acute metabolic acidosis. There is little evidence of benefit using this agent in lactic acidosis or ketoacidosis.[9] The key to managing acid-base disturbances lies not in altering acid-base

balance, but rather in correcting the underlying defect. Sodium bicarbonate increases SID and can correct one cause of acidosis. Conversely, sodium bicarbonate is administered as an 8.4% hypertonic solution and has a plasma-expanding effect that can lead to a dilutional acidosis and increases $Paco_2$ as well. This expansion may provide a hemodynamic benefit in shock.[9] Sodium bicarbonate infusions, with the purpose of increasing SID, have been used in patients awaiting dialysis, to reduce patient symptoms and to prevent hyperkalemia.

Specific toxins require more specific treatment. Methanol is metabolized to formaldehyde and formate by alcohol dehydrogenase. These products are highly toxic, causing blindness, cardiovascular instability, and death. Treatment strategies include the use of ethanol, which competes for binding on alcohol dehydrogenase, and fomepizole, which inhibits the enzyme. Ethylene glycol poisoning causes central nervous system depression, lactic acidosis, formation of calcium oxalate urinary crystals leading to hypocalcemia and renal failure, cardiovascular depression, and death. Treatment is with fomepizole with or without hemodialysis.

Perioperative Acid-Base Disturbances

In addition to the acid-base disturbances seen in emergency situations, numerous acid-base conundrums are peculiar to perioperative and critically ill patients. These include respiratory acidosis and alkalosis associated with mechanical ventilation, acidosis secondary to hyperchloremia or contraction, and alkalosis owing to sodium gain or chloride loss. Perioperatively, respiratory acidosis likely is due to poorly chosen mechanical ventilation strategies, narcosis, or incomplete reversal of neuromuscular blockade. Respiratory alkalosis is caused by hyperventilation most often as a result of mechanical overventilation, or from pain or anxiety.

Metabolic acid-base disturbances are common perioperatively and often are iatrogenic. In particular, these disturbances reflect manipulation of SID by administration of electrolyte or osmotically imbalanced solutions.

Hyperchloremic acidosis is seen frequently in the operating suite. This usually follows administration of a large volume of 0.9% saline solution. This solution contains 154 mEq of Na^+ and Cl^- and has an SID of 0. Each liter of normal saline is associated with SID loss. Hyperchloremic acidosis also is associated with acute normovolemic hemodilution with 5% albumin solution or 6% hetastarch (both formulated in normal saline).[51] The key abnormality is chloride gain. Serum sodium may stay the same or increase. Dilutional acidosis refers to a condition in which there is an alteration in the relative quantity of sodium and chloride in free water such that serum sodium decreases. This condition most commonly reflects the perioperative administration of sodium-poor fluids. The perioperative stress response is associated with increased secretion of antidiuretic hormone and a reduced ability to excrete free water. Excessive administration of hypotonic fluids, such as dextrose 5% or 0.45% sodium chloride, leads to an expansion in free water, hyponatremia, and acidosis.

Case 1

A 45-year-old man is admitted after a motor vehicle crash. He is bleeding, and his pulse is thready. Blood pressure is 90/50 mm Hg, heart rate is 120 beats/min, respiratory rate is 36/min, and temperature is 35°C.

A serum chemistry and blood gas are taken. Does he have any acid-base disturbances?

Na^+ 144, K^+ 4, Cl^- 110, total CO_2 8, urea 10, creatinine 2, albumin 4, lactate 16, pH 7.28, Pco_2 24, HCO_3^- 8, BE –16

Anion gap = 26

Corrected anion gap = 27.25

Using traditional tools, the patient has a widened anion gap acidosis. This is a lactic acidosis, with appropriate respiratory compensation. The BDE and anion gap approach accurately detect the "unmeasured" anion, lactate.

The patient is aggressively volume resuscitated and brought to the operating room. A blood gas and serum chemistry are taken on the patient, now mechanically ventilated in the intensive care unit, 12 hours later.

Na^+ 148, K^+ 3, Cl^- 120, total CO_2 22, urea 10, creatinine 2, albumin 2, lactate 5, pH 7.33, Pco_2 35, HCO_3^- 18, BE –11

Is the patient still under-resuscitated? What intravenous fluid was used?

In this situation, traditional tools are unreliable. Using the Fencl-Gilfix[45,49] approach, correcting the base deficit excess for acidifying and alkalinizing processes reveals a complex situation.

Acidifying Process	Magnitude	BDC	Alkalinizing Process	Magnitude	BEC
Hyperchloremia	120 mEq/L	–17	Hypernatremia	148 mEq/L	+2.4
Lactacidemia	5 mEq/L	–5	Hypoalbuminemia	2 g/dL	+8.5
Total		–22	Total		+11.9

BDC – BEC = –10.1

(BDC = base deficit corrected; BEC = base excess corrected)

Using simple measures such as BDE to follow the resuscitation, one might assume, based on the base deficit, that serum lactate was significantly higher than it actually is, and that the patient is under-resuscitated. This is not so. The patient was resuscitated with "normal" saline.

The physiologic basis for dilutional acidosis is often misunderstood. It cannot truly be explained by dilution of bicarbonate because one would expect acids and bases to be equally effected.[52] Studies have failed to show reduced serum bicarbonate in "dilutional acidosis."[52,53] Bicarbonate concentration is determined by CO_2 equilibrium.[54] Alterations in pH reflect changes in the relative ratio of sodium and chloride. Morgan and coworkers[55] showed that in vitro hemodilution is associated with a simple linear relationship between diluent crystalloid SID and the rate and direction of change of plasma SID and whole-blood base excess.[55]

The presence of a hyperchloremia is associated with different outcomes than some other forms of acidosis. Brill and colleagues[13] found that hyperchloremic acidosis was associated with better outcomes than acidosis associated with lactic acidosis or ketoacidosis. This finding supports the contention that the underlying problem increases patient risk. Nonetheless, metabolic acidosis, regardless of origin, can depress myocardial contractility, reduce cardiac output, and impair tissue perfusion. Acidosis inactivates membrane calcium channels and inhibits the release of norepinephrine from sympathetic nerve fibers. This leads to vasodilation and maldistribution of blood flow. Additionally, metabolic acidosis is associated with an increased incidence of postoperative nausea and emesis.[56] Plasma chloride levels affect afferent arteriolar tone through calcium-activated chloride channels and modulate the release of renin.[57] Hyperchloremia can reduce renal and other splanchnic blood flow and glomerular filtration rate.[58,59] In a study of healthy volunteers, normal saline was associated with reduced urinary output compared with lactated Ringer solution.[60] Finally, in a study of fluid prehydration to prevent contrast nephropathy, the use of sodium bicarbonate was associated with a 11.9% absolute reduction in the risk of renal injury (defined as a 25% increase in creatinine).[61]

Hyperchloremic acidosis is treated by increasing the SID of infused fluids. This may be accomplished by infusing sodium without chloride. Although no such fluid is available commercially, isotonic sodium bicarbonate or sodium acetate solution can be administered.

Perioperative metabolic alkalosis most often is iatrogenic. Hyperventilation of patients with chronic respiratory failure results in acute metabolic alkalosis from chronic compensatory alkalosis associated with chloride loss in urine (Fig. 49-6).[8] More frequently, metabolic alkalosis is associated with increased SID owing to sodium gain. This results from administration of fluids in which sodium is "buffered" by weak ions, such as citrate (in blood products), acetate (in parenteral nutrition), and bicarbonate. Buffer ions such as citrate, acetate, gluconate, and lactate are rapidly cleared by the liver under normal conditions and do not contribute to acid-base balance. Sodium and chloride obey the law of conservation of mass. The so-called chloride-sensitive alkalosis really reflects sodium gain, treated by administration of net loads of chloride—0.9% sodium chloride or, perhaps more appropriately, potassium chloride, calcium chloride, and occasionally hydrogen chloride. It is important to correct chloride-sensitive alkalosis because the normal compensatory measure is hypoventilation, increasing $Paco_2$. This may lead to CO_2 narcosis, or failure to liberate from mechanical ventilation (Table 49-6).

Chloride loss can result in metabolic alkalosis in perioperative patients. Chloride most often is lost from the gastrointestinal tract as a result of continuous suctioning or vomiting. Gastric juice contains hydrochloric acid. The loss of chloride, not of H^+, causes the alkalosis, however, because chloride obeys the law of conservation of mass and alters the SID.

In maintaining perioperative patients, hypotonic and dextrose-containing fluids should be avoided. For patients receiving 1 or 2 L of perioperative fluid, the choice of fluids has little effect.

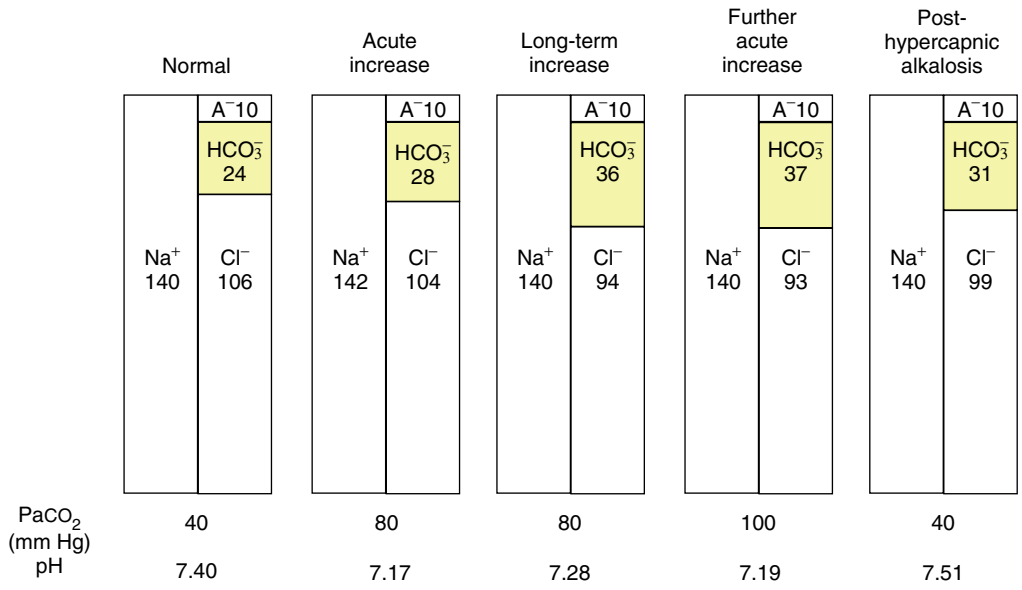

Figure 49-6 Changes in acid-base and electrolyte composition in patients with respiratory acidosis. *Left to right,* Normal acid-base status; adaptation to an acute increase in partial pressure of carbon dioxide ($Paco_2$) to 80 mm Hg; adaptation to a long-term increase in $Paco_2$ to 80 mm Hg; superimposition of an acute further increase in $Paco_2$ (to a level of 100 mm Hg) in the same patient; and post–hypercapnic alkalosis resulting from an abrupt reduction in $Paco_2$ to 40 mm Hg in the same patient. A^- denotes unmeasured plasma anions, and the numbers within the bars give ion concentrations in mmol/L. *(Adapted from Androgue H, Madias N: Management of life-threatening acid-base disorders: First of two parts. N Engl J Med 338:26-34, 1998.)*

Table 49-6 Acid-Base Disturbances Commonly Seen Perioperatively

Disorder	Cause
Respiratory acidosis	Hypoventilation—narcosis, incomplete reversal of neuromuscular blockade
Respiratory alkalosis	Hyperventilation—anxiety, pain
Metabolic acidosis secondary to unmeasured anions (widened gap acidosis)	Hypoperfusion—lactic acidosis; diabetic ketoacidosis; renal failure
Metabolic acidosis secondary to measured anions (non-gap hyperchloremic acidosis)	Hyperchloremia—"normal" saline, hetastarch, or albumin infusions; renal tubular acidosis; bladder reconstructions
Metabolic acidosis secondary to free water excess (hyponatremia, dilution acidosis)	Hypotonic fluid administration; sodium loss—diarrhea; administration of hyperosmolar fluids—mannitol, alcohol, hyperproteinemia
Metabolic alkalosis	Hyperventilation of patient with history of carbon dioxide retention (COPD); sodium gain (sodium bicarbonate, massive blood transfusion); chloride loss—nasogastric suctioning

COPD, chronic obstructive pulmonary disease.

If larger volumes of crystalloid are administered, it is important to use balanced buffered solutions that mirror the electrolyte content of ECF, such as lactated Ringer solution, Normosol, or Plasma-Lyte. Normal saline should be administered to a patient who has been on continuous nasogastric suctioning until the base deficit returns to zero. Likewise, normal saline should accompany large volumes of blood or frozen plasma. Care must be taken to avoid hypokalemia, hypocalcemia, hypomagnesemia, and hypophosphatemia. Patients who have received purgatives for bowel surgery should be treated with balanced buffer solutions. The same rules apply to colloid solutions. Human albumin solution, some hetastarches, and gelatins (available in Europe) are formulated in sodium chloride; large volumes cause hyperchloremic acidosis.

Acid-Base Disturbances in Critical Illness

Acid-base disturbances in critically ill patients may be complex and confounding (see Chapter 91). These may result in normal blood gases despite significant, off-setting perturbations of P_{CO_2}, SID, and A_{TOT}. Significant pathology may be overlooked.

The most important single disturbance in acid-base chemistry in critically ill patients is hypoalbuminemia.[15] This is ubiquitous and causes an unpredictable metabolic alkalosis that can mask significant alterations in SID, such as lactic acidemia. Although Figge and colleagues[19] have presented a mechanism for adjusting the anion gap for albumin, this implies that the physician is actually aware of an acid-base abnormality. Likewise, the use of base deficit to predict lactate is unreliable in critical illness.[18] Prolonged respiratory failure with associated hypercarbia leads to additional metabolic alkalosis as a result of chloride loss in urine.[8] Mechanical ventilation per se increases the circulating volume of atrial natriuretic hormone and antidiuretic hormone. The result is increased total body water and dilutional acidosis. This situation may be complicated further by renal insufficiency or renal failure, with concomitant accumulation of metabolic by-products, renal anions, and other unmeasured anions. Polyuric renal failure may be associated with significant contraction alkalosis, owing to loss of sodium, potassium, and free water.

Critically ill patients are vulnerable to significant changes in SID and free water. Nasogastric suctioning causes chloride loss, whereas diarrhea leads to sodium and potassium loss. Surgical drains placed in tissue beds may remove fluids with varying electrolyte concentrations (e.g., the pancreatic bed secretes fluid rich in sodium). Fever, sweating, oozing tissues, and inadequately humidified ventilator circuits lead to large-volume insensible loss and contraction alkalosis.

Infusions administered to patients may be responsible for unexpected alterations in serum chemistry. Many antibiotics, such as piperacillin-azobactam, are diluted in sodium-rich solutions. Others, such as vancomycin, are administered in large

Case 2

A 56-year-old man is chronically critically ill. A serum chemistry and blood gas are taken. Does he have any acid-base disturbances?

Na^+ 130, K^+ 4, Cl^- 100, total CO_2 24, urea 10, creatinine 1, albumin 1, lactate 6, pH 7.42, P_{CO_2} 40, HCO_3^- 24, BE +1

Using the Fencl-Gilfix approach,[45,49] correcting the BDE for acidifying and alkalinizing processes reveals a complex situation.

Acidifying Process	Magnitude	BDC	Alkalinizing Process	Magnitude	BEC
Hyponatremia	130 mEq/L	–3	Hypoalbuminemia	1 g/dL	+11.9
Hyperchloremia	100 mEq/L	–3			
Lactacidemia	5 mEq/L	–5			
Total		–11	Total		+11.9

BDC – BEC = 0.9

(BDC = base deficit corrected, BEC = base excess corrected)

In this example, the patient has three significant acidifying processes going on. The presence of lactic acidosis is sinister. However, using traditional approaches to this example would not reveal the abnormalities.

volumes of free water (5% dextrose). Lorazepam is diluted in propylene glycol, large volumes of which cause metabolic acidosis similar to that seen with ethylene glycol.[62]

Continuous renal replacement therapy is used to provide hemofiltration and hemodialysis to critically ill patients who are hemodynamically unstable. Rocktaschel and others[63,64] have shown that continuous renal replacement therapy resolves the acidosis of acute renal failure by removing strong ions and phosphate. This correction unmasked metabolic alkalosis owing to hypoalbuminemia, however.

Other seemingly innocuous therapies may cause significant disturbances to acid-base balance. Loop diuretics are often administered to critically ill patients in the mistaken view that they will liberate sequestered fluids. These agents cause hypochloremic and contraction alkalosis. Carbonic anhydrase inhibitors, such as acetazolamide, cause excretion of sodium and bicarbonate and retention of chloride. This results in hyperchloremic acidosis.

Contraction alkalosis is treated by correcting the free water deficit using the following formula:

$$\text{Free water deficit} = 0.6 \times \text{patient's weight in kg} \times \left(\text{patient's sodium}/140 - 1\right)$$

Hypochloremic alkalosis should be treated by correcting the chloride deficit, using normal saline.

Neurosurgical patients are vulnerable to various acid-base disturbances relating to osmotherapy and brain injury.[65] Mannitol administered to reduce intracranial pressure initially causes a mild dilutional acidosis. These patients are routinely treated with normal saline solution and frequently with hypertonic saline. Both can cause acidosis.[66] Diabetes insipidus frequently occurs as a complication of severe head injury. It is caused by disruption of the hypothalamic-pituitary axis. In the absence of antidiuretic hormone, the kidney is unable to concentrate the urine. This results in a massive diuresis. The disorder is characterized by an increase in plasma osmolality in the presence of a low urinary osmolality; this typically manifests as a contraction alkalosis. The treatment is hormonal replacement with either vasopressin or desmopressin.

Conclusion

Much of the confusion regarding acid-base chemistry relates to attempts to apply observational approaches, such as that of Henderson-Hasselbalch or Schwartz and Brackett, to the entire spectrum of pathophysiologic processes. The use of physical chemistry principles permits a better explanation of acid-base balance and provides tools to apply to a wide variety of clinical situations. This does not suggest that the "traditional" approach is incorrect, merely that it looks at a mirror image of that proposed by Stewart, Fencl, and others. All acid-base disorders can be explained in terms of SID, A_{TOT}, and P_{CO_2}. Anesthesiologists may have a significant impact on acid-base balance with choice of fluids and mechanical ventilation strategy.

John Henderson

50 Airway Management in the Adult

Key Points

1. Three basic decisions needed before induction of anesthesia in every patient are whether to use awake intubation, use a percutaneous technique, or maintain spontaneous ventilation.
2. Conditions requiring particular caution include lesions at the base of the tongue, recent onset of hoarseness, upper airway obstruction, and obstructive sleep apnea.
3. The combination of mouth opening, jaw protrusion, and head extension is the core of airway assessment. The examination described by El-Ganzouri (mouth opening, prognathic ability, head extension, thyromental distance, and the Mallampati test) has been used with minor modification by others. It can be performed rapidly and is the most quantifiable (recording of actual values is recommended) of the tests included in the guidelines of the American Society of Anesthesiologists (ASA).
4. Radiology studies have shown that head extension is the most important single maneuver in maintaining space between the pharyngeal soft tissues. Head extension stretches the anterior neck structures and moves the hyoid bone and attached structures anteriorly.
5. Four principles are central to prevention of complications during tracheal intubation:
   - Maintenance of oxygenation must take priority over all other issues. Preoxygenation should be performed before induction of anesthesia. Mask ventilation should be used between attempts at tracheal intubation.
   - Trauma must be prevented. The first attempt at tracheal intubation should be performed under optimal conditions, including patient position, preoxygenation, and equipment preparation. The number of attempts with blind techniques should ideally be zero and certainly not more than four.
   - Anesthesiologists should have a sequence of backup plans in place before starting the primary technique. They should have the skills and the equipment needed to execute these plans. When unanticipated difficulty occurs in non-lifesaving surgery, the safest plan is to terminate attempts at tracheal intubation, awaken the patient, and postpone surgery.
   - Anesthesiologist should seek the best help available ("call for help") as soon as difficulty with tracheal intubation is experienced.
6. Immediate confirmation of correct tracheal tube placement is an essential and integral part of tracheal intubation. Several tests should be used because no single test is completely reliable. The most important safeguard is clinical suspicion. Visual confirmation of passage of the tracheal tube between the vocal cords is reliable, but not always possible, and experienced anesthesiologists are occasionally misled.
7. All anesthesiologists should be skilled in at least one alternative technique of tracheal intubation under vision. Strategies that include algorithms for the management of unanticipated difficult intubation have been devised by several organizations, including the ASA and the Difficult Airway Society, a U.K. organization. The ASA algorithm is the standard guide.
8. If noninvasive techniques do not restore oxygenation, cricothyrotomy is the percutaneous airway of choice because tracheotomy may take too long. It is not possible to define the Spo_2 at which cricothyrotomy should be performed—it depends on the degree of hypoxemia and how rapidly it is deteriorating.

Anesthesia was developed to enable the performance of therapeutic and diagnostic procedures that could not be performed in conscious or sedated patients. The reduction in consciousness produced by general anesthesia (or trauma or disease) is necessarily associated with depression of other physiologic systems. The depressant effects on airway, respiratory, and cardiovascular function can cause immediate threats to the patient. Airway management differs from management of other depressed function in that it requires a range of manual skills, as well as knowledge and judgment.

Some components of anesthesia respiratory care have become safer in the last 3 decades. American Society of Anesthesiologists (ASA) Closed Claims analyses show that nonspecific adverse respiratory system events decreased from about 37% of respiratory claims in the 1970s to 14% of claims in the 1990s. However, the proportions of claims attributable to difficult tracheal intubation has more than doubled.[1] The probable explanation is that monitoring has reduced the number of adverse outcomes from nonspecific events but prevention of adverse tracheal intubation outcomes is more difficult. Evidence of the limitations of "traditional" techniques has accrued and effective new techniques have been developed. However, many anesthesiologists continue to rely on multiple attempts with ineffective techniques.

Anatomy

The nose warms, filters, and humidifies incoming air and is the organ of smell. It consists of the external nose and the internal nasal cavity. The nasal cavities are divided by the nasal septum, which is frequently deviated with the consequence that the nasal cavities are narrowed or obstructed. The roof of the nasal cavity is the cribriform plate, a thin bone that is easily fractured, thereby resulting in communication between the nasal and intracranial cavities. The bony lateral wall of the nasal cavity is the origin of the three bony turbinates that project into the nasal cavity. They are easily damaged by force during the passage of nasotracheal tubes. Openings in the lateral wall communicate with the paranasal sinuses. Prolonged nasotracheal intubation impairs drainage through these openings, causing sinusitis. The lining of the nasal cavity is very vascular, and application of nasal vasoconstrictors to shrink the mucosa and dilate the airway reduces the risk of hemorrhage during the insertion of airway devices or tracheal tubes.

The roof of the mouth is bounded by the alveolar arch and teeth and consists of the hard palate anteriorly and the soft palate posteriorly. The tongue makes up most of the floor of the mouth, which is bounded by the mandible and teeth. Nonencapsulated lymphoid tissue on the posterior surface of the tongue (lingual tonsil) is part of the ring of Waldeyer. This tissue is important in that hypertrophy can cause serious difficulty in airway management.[2,3] The ability to achieve good mouth opening is important for many airway procedures. Initial mouth opening is achieved by rotation within the temporomandibular joint (TMJ) and subsequent opening by sliding (also known as protrusion, translocation, or subluxation) of the condyles of the mandible within the TMJ. The jaw-thrust maneuver uses the sliding component of the TMJ to move the mandible and attached structures anteriorly. The scissors maneuver (Fig. 50-1) achieves maximum mouth opening by the application of internal pressure on the teeth to achieve both TMJ movements. It can facilitate the insertion of oropharyngeal airways, supraglottic airway devices (SADs), and laryngoscopes. All movements of the TMJ should be firm but gentle to minimize the risk of joint damage.

The pharynx is a fibromuscular tube that extends from the base of the skull to the lower border of the cricoid cartilage. It joins the nasal and oral cavities above with the larynx and esophagus below. Both the pharynx and esophagus can be perforated by blind attempts at tracheal intubation. The nasopharynx is the part of the pharynx that lies posterior to the nose. Nasotracheal tubes

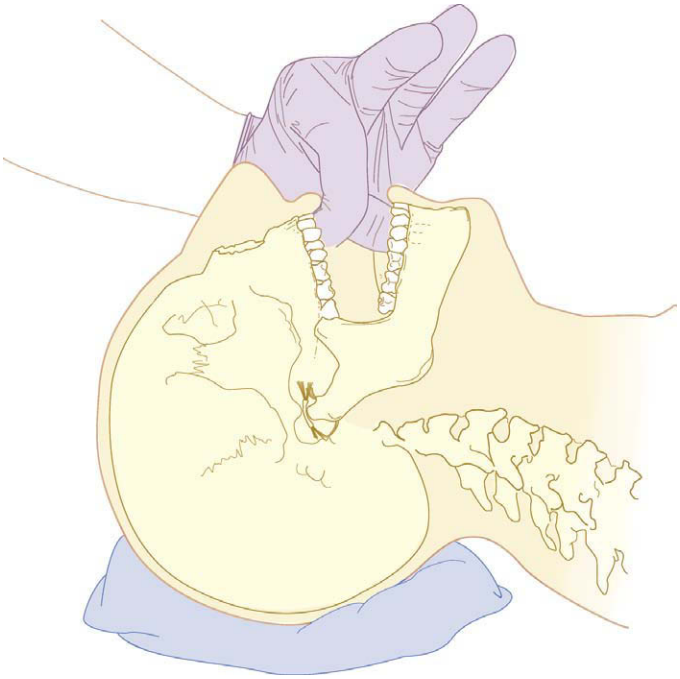

Figure 50-1 Scissors maneuver. The rotation and sliding components of the temporomandibular joint are used to achieve maximal mouth opening.

can impinge on the posterior wall of the nasopharynx, and application of increasing force when resistance is met can cause submucosal passage of the tube.

The larynx is situated at the upper end of the respiratory tract, where it extends from the epiglottis to the lower end of the cricoid cartilage. It evolved as a valve to protect the lower respiratory tract from alimentary contents and later developed into an organ of speech. The larynx bulges posteriorly into the laryngopharynx, with the piriform fossa lying on each side. The larynx consists of a framework of articulating cartilage connected by fascia, muscles, and ligaments. It is suspended from the hyoid bone by the thyrohyoid membrane. The principal cartilages are the thyroid, cricoid, and posterior (arytenoid, corniculate, and cuneiform) cartilage and the epiglottis. The cricoid cartilage is a complete ring that articulates with the thyroid and arytenoid cartilage. The arytenoid cartilage sits on the posterolateral border of the cricoid, from where it can be dislocated[4] during airway management. The laryngeal inlet is bounded by the epiglottis, aryepiglottic folds, posterior cartilage, and interarytenoid notch. The vocal cords run between the vocal processes of the arytenoid cartilage and the posterior surface of the thyroid cartilage. The lower end of the leaf-shaped epiglottis is attached to the middle of the posterior surface of the thyroid cartilage. The anterior surface is connected to the hyoid bone by the hyoepiglottic ligament and to the tongue by the median glossoepiglottic fold. The valleculae (often called vallecula) are depressions between the median and lateral glossoepiglottic folds that connect the lateral edges of the epiglottis to the base of the tongue. The Macintosh technique of laryngoscopy involves insertion of the tip of the laryngoscope into the vallecula, where it tensions the hyoepiglottic ligament to achieve indirect elevation of the epiglottis.

During swallowing the larynx is protected by several mechanisms. The larynx is tucked up behind the tongue, and the epiglottis diverts food away from the laryngeal inlet. The laryngeal

muscles can be grouped according to their actions on the vocal cords: abductors, adductors, and regulators of tension. Motor innervation to these muscles and the sensory innervation of the larynx are supplied by two branches of the vagus nerve: the superior and recurrent laryngeal nerves. The superior laryngeal nerve can be anesthetized at the point where it passes through the thyrohyoid membrane. The recurrent laryngeal nerve can be damaged during surgery on the thyroid gland or by pressure from a cuff that lies just below the vocal cords.[5]

The cricothyroid membrane joins the thyroid with the adjacent cricoid cartilage. It is close to the skin, relatively avascular, and the widest gap between the cartilage of the larynx and trachea, so it provides the best access for percutaneous airway rescue techniques. It is normally easy to palpate, but identification may not be possible in obese patients. In patients with fixed neck flexion, the cricothyroid membrane may lie behind the sternum.

The trachea extends from the lower edge of the cricoid cartilage to the carina. It consists of U-shaped cartilage joined by fibroelastic tissue and is closed posteriorly by the longitudinal trachealis muscle. The tracheal rings and trachealis muscle are responsible for the characteristic endoscopic appearance of the trachea.

Airway Assessment

Three basic decisions (Fig. 50-2) needed before induction of anesthesia in every patient[6] are whether

- To use awake endotracheal intubation
- To use a percutaneous technique
- To maintain spontaneous ventilation

These three strategies are safer than the use of an intravenous anesthetic with neuromuscular blocking drugs (NMBDs) in patients with potential airway difficulty, but they require more time and effort, and the anesthesiologist needs evidence on which to base these decisions. The purpose of airway assessment is to identify possible difficulty with direct laryngoscopy (and hence tracheal intubation), mask ventilation, or creation of a surgical (percutaneous) airway. This traditional approach may change with the introduction of sugammadex, an antagonist to replace neostigmine, into routine clinical practice (see Chapter 29). Rocuronium could be used to facilitate endotracheal intubation. If spontaneous ventilation is urgently needed, sugammadex can reverse profound neuromuscular blockade (i.e., no response to peripheral nerve stimulation) within 1.5 to 3.0 minutes.

Potential difficulty may be obvious in patients with anatomic or pathologic abnormalities, and further tests are not needed. Conditions requiring particular caution include lesions at the base of the tongue, recent onset of hoarseness, upper airway obstruction, and obstructive sleep apnea. However, the challenge is to detect potential difficulty in apparently normal patients. Airway assessment includes taking a history and performing a physical examination. Imaging is valuable in assessing a pathologic airway but is not practicable for routine assessment.

The *history* includes review of available previous anesthesia records, direct questioning of the patient, and in those with reduced consciousness, a search for communication about previous airway difficulty. A history of previous airway difficulty has a higher positive predictive value and lower negative predictive value than any tests.[7] However, a history of previous easy laryngoscopy does not guarantee straightforward intubation inasmuch as increased age or pathology may result in increased difficulty.

Airway tests to detect difficulty with direct laryngoscopy are based on anatomic features, and values have been selected as probable indicators of difficulty. The combination of mouth opening, jaw protrusion, and head extension is the core of airway assessment.[8] There is little interobserver variation in the assessment of mouth opening and jaw protrusion.[9] Mouth opening is measured as the interincisor distance, and a value of 4 cm (2 fingerbreadths) has been proposed as an indicator of probable difficult intubation.[10] The prognathic ability of the mandible depends on the size and shape of the mandible in relation to the maxilla and on TMJ function. Prognathic inability of the mandible (the mandibular incisors cannot be brought in line with the maxillary incisors) is associated with difficult intubation. Limited head (more accurately described as occipito-atlanto-axial) extension[10] impairs direct laryngoscopy. It can be measured as the angle between the occlusal surface of the maxillary teeth and the horizontal, with angles of less than 20 degrees suggesting difficult laryngoscopy. However, it is difficult to prevent extension of the midcervical vertebrae, so true head extension is frequently overestimated. The Mallampati test (visibility of pharyngeal structures) is of limited value on its own[11] but can be combined with an assessment of dentition.[12] The thyromental distance is of limited value as a predictor of difficult laryngoscopy,[13] but examination ensures that the laryngeal cartilage is palpated and submandibular compliance assessed. Evaluation of dentition is important in that caries or periodontitis increases the risk for dental damage. Some dental patterns, such as protruding or single or missing maxillary incisors,[14] increase the difficulty of direct laryngoscopy. The examination described by El-Ganzouri and colleagues[7] (assessment of mouth opening, prognathic ability, head extension, thyromental distance, and Mallampati test) has been used with minor modification by others.[3] It can be performed rapidly and contains the most quantifiable (recording of actual values is recommended) of the tests included in the ASA guidelines.[6]

Ventilation via mask requires the ability to achieve a seal between the mask and face and to overcome upper airway obstruction. Limited mandibular protrusion, abnormal neck anatomy, sleep apnea, snoring, and obesity are independent predictors of moderate or severe *difficulty with mask ventilation*. Snoring and a thyromental distance of less than 6 cm are independent predictors of severe difficulty.[15] No test can accurately predict complete failure of mask ventilation because its prevalence is as low as 0.07%.[7] Some pathologic causes of difficult mask ventilation cannot be predicted.[2]

Creation of a surgical airway (necessary for the management of a "cannot intubate, cannot ventilate" situation) depends on percutaneous access to the cricothyroid membrane. In some patients the cricothyroid membrane cannot be identified or lies behind the sternum, and creation of a percutaneous airway will not be possible. In such patients who have indications that laryngoscopy or mask ventilation will be difficult, the safest strategy is to secure the airway while the patient is conscious.

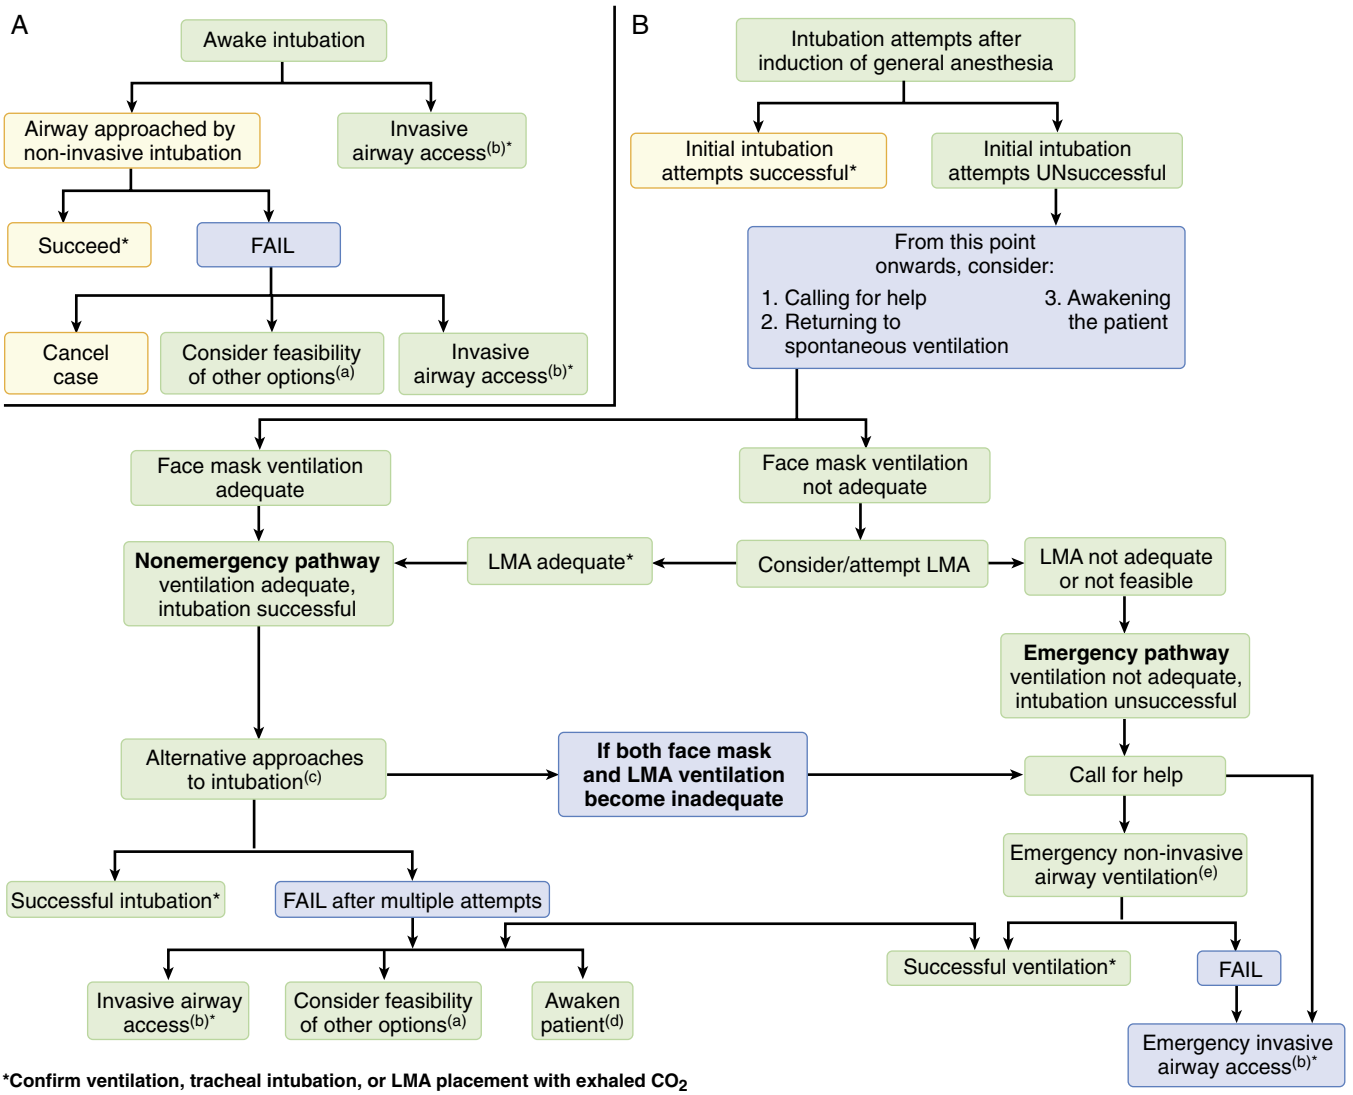
Integration of the evidence of difficulty with direct laryngoscopy, mask ventilation, and creation of a surgical airway has many limitations. The causes of difficult laryngoscopy are multifactorial, and single tests have limited value[11] as predictors. Prediction is improved by combining the results of different tests.[8]

Difficult Airway Algorithm

1. Assess the likelihood and clinical impact of basic management problems:
   - A. Difficult ventilation
   - B. Difficult intubation
   - C. Difficulty with patient cooperation or consent
   - D. Difficult tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management:
3. Consider the relative merits and feasibility of basic management choices:

A	Awake intubation	vs.	Intubation attempts after induction of general anesthesia
B	Noninvasive technique for initial approach to intubation	vs.	Invasive technique for initial approach to intubation
C	Preservation of spontaneous ventilation	vs.	Ablation of spontaneous ventilation

4. Develop primary and alternative strategies:



***Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO_2**

a. Other options include (but are not limited to) surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration, and regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has beed reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.

c. Alternative noninvasive approaches to difficult intubation include (but are not limited to) use of different larynoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or canceling surgery.

e. Options for emergency noninvasive airway ventilation include (but are not limited to): rigid bronchoscope, esophageal-tracheal Combitube ventilation, or transtracheal jet vantilation.

Figure 50-2 American Society of Anesthesiologists Difficult Airway Algorithm. *(From American Society of Anesthesiologists Task Force on Management of the Difficult Airway. Practice guidelines for management of the difficult airway. An updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. Anesthesiology 98:1269-1277, 2003.)*

Scores[7,8] are formulas that combine the results of tests. These scores have been developed to improve prediction of difficulty but many omit at least one test of some value, and the indicators are not usually weighted for importance. It is more meaningful to describe the result of individual tests. Airway assessment cannot detect some serious problems, including asymptomatic lesions[2,3] in the vicinity of the larynx, skeletal factors, and some varieties of TMJ dysfunction.

The problem with airway assessment is that the risk of difficulty is overestimated and not all cases of difficult airway management can be predicted. However, serious airway morbidity, though infrequent, is a much worse outcome than performing an awake intubation that might not have been necessary. Airway evaluation gives some indication of potential difficulty and should always be performed.[6] The anesthesiologist must then make a judgment of whether direct laryngoscopy, mask ventilation, and percutaneous rescue are likely to be successful. The limitations of airway assessment mean that preparation of an airway strategy for the management of unanticipated difficulty is the ultimate key to safe practice. Strategies are discussed later in the section "Challenging Airway Management Scenarios."

Physiology and Pathophysiology of the Upper Airway

Upper Airway Obstruction

In an awake patient, airway patency is maintained by muscle tone in the head and neck, particularly the pharynx and tongue. As consciousness is lost and muscle tone is reduced, tissues fall backward under the influence of gravity in a supine patient and can obstruct the upper airway. The order of importance of these obstructing tissues is the soft palate (velopharynx), epiglottis, and tongue. Head extension (as a consequence of tensioning the strap muscles) and jaw thrust move the hyoid bone and attached structures anteriorly and relieve airway obstruction to a variable extent. Jaw thrust is also effective in reducing obstruction at the velopharynx in slim but not in obese patients. The lateral position can be used alternatively or in addition to the aforementioned techniques to allow the obstructing tissues to move downward so that obstruction is reduced.[16]

There is now evidence of an additional dynamic component of upper airway obstruction when consciousness is reduced. In the conscious state the tone of the pharyngeal muscles is increased by neural discharge just before phrenic nerve discharge. Loss of pharyngeal tone and collapse of the narrow velopharynx play an important role in upper airway obstruction during spontaneous ventilation in an anesthetized patient.[17] The airway in the nose and nasopharynx is held open by bone and cartilage and in the larynx and trachea by cartilage. Dynamic collapse of the intervening pharynx can occur when muscle tone is reduced. The structure of a collapsible segment between two rigid tubes corresponds to the basic elements of a Starling resistor in that flow can depend on the intraluminal pressure gradient or on transmural pressure in the collapsible area.[17] Flow through the collapsible segment depends on how the intraluminal pressure upstream and downstream relate to the tissue pressure around the pharynx. Factors that narrow the pharynx, increase pressure around it, reduce pressure within it, or make its walls more compliant will increase upper airway obstruction. The therapeutic consequence of dynamic collapse is that nasal continuous positive airway pressure (CPAP) reduces dynamic upper airway obstruction. Nasopharyngeal airways might reduce this dynamic airway obstruction.

Laryngospasm

Laryngospasm (reflex closure of the true vocal cords alone or with the false cords because of stimulation of the intrinsic laryngeal muscles) can result from the combination of reflex hyperactivity at an intermediate depth of anesthesia and noxious distant surgical or local stimuli. Laryngospasm is usually maintained well beyond the duration of the stimulus. It is responsible for a significant proportion of postoperative critical events. Morbidity and mortality may result from the immediate (hypoxemia and hypercapnia) and delayed ("negative-pressure pulmonary edema") consequences of laryngospasm, and thus every effort should be made to rapidly relieve the airway obstruction caused by laryngospasm.[18] Management is discussed later.

Negative-pressure pulmonary edema[18] is a consequence of forceful inspiratory effort in the presence of a closed glottis or other cause of upper airway obstruction. The subatmospheric alveolar pressure generated promotes transudation of fluid from pulmonary capillaries into the interstitial space and alveoli. Small vessel damage may be responsible for frank hemorrhage into alveoli. Management consists of relief of the obstruction, oxygen therapy, and standard management of pulmonary edema. Most cases resolve rapidly, but reintubation and positive-pressure ventilation are sometimes required.

Oxygenation and Preoxygenation

Hypoxemia can occur in the time between induction of anesthesia and attainment of airway security and is particularly likely if airway management proves difficult. It makes sense to maximize oxygen stores before induction to prolong the period before the onset of hypoxemia in the event of serious difficulty with airway management. The principal oxygen stores are in the lungs. These stores can be increased by using a maneuver called "preoxygenation" (also know as denitrogenation), which is achieved by having the patient breath 100% oxygen from a close-fitting facemask before induction of anesthesia. Several techniques of preoxygenation have been described, and the most effective technique should be used. Deep breathing with a high fresh gas flow for 1.5 minutes and tidal breathing for 3 minutes are equally effective. It is particularly important to avoid leaks in the circuit, which are indicated by a flaccid reservoir bag and absence of a normal capnograph waveform. Wherever possible, the end-tidal oxygen concentration should be used as a guide to the adequacy of preoxygenation, with a value of 90% being well accepted. Preoxygenation in the semi-sitting position prolongs the time to development of hypoxemia by increasing functional residual capacity in relation to the supine position, particularly in an obese patient.[19] Use of positive end-expiratory pressure (PEEP) during induction may further improve oxygenation.[20]

Pharmacology of Airway Management

The choice of pharmacologic technique is part of the essential planning of airway management and will be influenced by both airway and surgical requirements, particularly for surgical access and neuromuscular blockade. Satisfactory conditions for tracheal intubation are particularly demanding and may be facilitated by several pharmacologic techniques, each of which has advantages and disadvantages. Direct laryngoscopy is facilitated by a reduction in tone of the head and neck muscles. A high success rate and low risk for laryngeal trauma are facilitated when the vocal cords are open and nonreactive, at the cost of reduced protection against pulmonary aspiration.

Inhaled Induction of Anesthesia

Induction plus maintenance of anesthesia by the inhalation of gaseous and volatile anesthetics was the original pharmacologic technique for anesthesia. It remains an important technique in situations such as lack of venous access and anticipated airway difficulty in a patient who refuses awake techniques. A major advantage of inhaled induction of anesthesia is that spontaneous ventilation is maintained while changes in the depth of anesthesia and associated respiratory and cardiovascular effects occur gradually. Good facemask technical skills are essential to prevent airway obstruction and leaks around the mask.

Deep anesthesia is necessary for direct laryngoscopy and tracheal intubation with inhaled anesthetics alone. It can be complicated by hypotension, hypoventilation, and airway obstruction. A depth of anesthesia that allows controlled ventilation has been recommended when sevoflurane is used. Prior administration of topical anesthesia (e.g., 4% lidocaine, 3 to 5 mL) can facilitate tracheal intubation under lighter inhaled anesthesia.

Sevoflurane has advantages over other volatile anesthetics for inhaled induction of anesthesia. It has a low blood-gas partition coefficient and causes minimal airway irritation, which facilitates rapid smooth attainment of a depth of anesthesia sufficient for airway procedures. A rapid technique ("single breath") in which the patient breathes 8% sevoflurane from a prefilled anesthesia circuit has been advocated rarely but causes apnea more frequently than the traditional technique does. Furthermore, seizure activity with sevoflurane is more likely with rapid induction of anesthesia.[21]

Inhaled induction of anesthesia is very useful in a wide variety of difficult airway conditions. Its use has been advocated in patients with stridor but can result in sudden airway obstruction, which prevents rapid reduction of the depth of anesthesia. Relief of obstruction may be difficult or impossible, even when CPAP is used with mask ventilation, so emergency cricothyrotomy may be required. Propofol infusion, with topical anesthesia before endotracheal intubation, has been used successfully for the management of patients with a difficult airway.[22] Caution is required because apnea can occur when propofol is infused in patients with normal airways.

Intravenous Anesthesia with Neuromuscular Blocking Drugs

The combination of an intravenous anesthetic with an NMDB is the pharmacologic technique most frequently used for tracheal intubation in routine practice (see Chapter 29). It provides good conditions rapidly in most patients inasmuch as neuromuscular blockade facilitates laryngoscopy, opens the vocal cords, and prevents coughing. The high quality of intubating conditions produced by NMBDs reduces the risk for postintubation laryngeal damage.[23] However, the apnea caused by this pharmacologic approach has disadvantages. If tracheal intubation of an apneic patient proves impossible, oxygenation requires effective ventilation with a facemask or SAD, neither of which is completely reliable. Pharmacologic techniques that produce apnea should not be used when difficulty with tracheal intubation or mask ventilation is predicted. As indicated previously, the use of sugammadex may alter the approaches to difficult intubation.

In routine practice, nondepolarizing NMBDs are often preferable to succinylcholine to prevent its side effects (as described in Chapter 29). Succinylcholine is chosen when rapid onset and offset are important. Use of rocuronium as an alternative to succinylcholine has been suggested to avoid the side effects unique to succinylcholine. Although the duration of paralysis produced by rocuronium is very much longer, the use of sugammadex as a reversal agent makes recovery from an NMBD as quick as that from succinylcholine and more predictable. It is now clear that a combination of rocuronium and sugammadex can restore spontaneous ventilation more rapidly than waiting for succinylcholine to wear off. Possibly the need for succinylcholine may disappear completely.

Intravenous Anesthesia with Narcotics

The use of short-acting narcotics instead of NMBDs to facilitate tracheal intubation has been advocated as a means of avoiding the side effects of succinylcholine. This technique is effective in many patients who have no risk factors for difficult intubation. However, it has serious disadvantages.[24] Conditions for direct laryngoscopy and tracheal intubation are worse than when NMBDs are used, so there is a higher frequency of failed intubation and airway trauma. Arterial hypotension is more likely when large doses of intravenous anesthetics and narcotics are given.[24] A higher incidence of laryngeal trauma when intubation is performed without NMBDs has been reported.[23] Use of a large dose of narcotics when ventilation with a facemask or SAD is intended has other significant disadvantages. It may produce apnea and delay the return of spontaneous ventilation. More importantly, it can make ventilation of the lungs with a mask or SAD difficult or impossible as a consequence of vocal cord closure, a problem sometimes attributed to "chest wall rigidity."[25] The combination of intravenous anesthesia with topical anesthesia of the larynx produces good conditions[26] and may be a better alternative to the use of NMBDs.

Local Anesthetic and "Awake" Techniques of Airway Management

Tracheal intubation of a conscious patient can allow uninterrupted respiration and airway protection while avoiding the risk to airway maintenance and protection inherent with general anesthesia. It is indicated when there is a possibility of difficulty with airway management. Tracheal intubation of a conscious patient is often called "awake" intubation. Good topical airway anesthesia, rapport, and gentleness are the keys to success. Sedation is often used but cannot compensate for inadequate topical anesthesia and is dangerous in patients with a critical airway.[27]

Topical anesthesia of the airway can be used to facilitate the performance of many airway procedures (Box 50-1) in a conscious patient in whom reduced consciousness is likely to cause difficulty in airway management. Direct laryngoscopy has long been used for awake intubation but is often difficult and can be distressing for all involved. Use of a flexible fiberoptic laryngoscope (FFL) for tracheal intubation under topical anesthesia was a milestone in safe airway management because intubation of a conscious patient could now be achieved with minimal discomfort. This technique has become the standard for management of an anticipated difficult airway. Options are preserved if awake flexible fiberoptic intubation is not successful: surgery can be postponed and the patient awakened, an unhurried surgical airway can be performed, or tracheal intubation can be attempted in a breathing patient (awake or inhaled induction) with other visual techniques.

Topical anesthesia reduces the caliber of a normal airway. Use of topical anesthesia in a patient with a compromised airway can lead to loss of the airway and should be performed only by experts who have a team prepared for immediate creation of a surgical airway.

Lidocaine has a better safety profile than other agents used for airway anesthesia. However, excessive doses can cause fatal toxicity. Administration should be titrated and the mental state of the patient monitored. Blood concentrations are influenced by the technique chosen, and aerosol delivery to the lower respiratory tract should be minimized.

Several techniques of airway anesthesia are shown in Box 50-2. Each has advantages and disadvantages. Nebulizers have been used to deliver topical anesthesia to the airway. The optimum particle size is larger than that required for the treatment of asthma. Simple aerosol techniques, such as injection into oxygen flowing in a narrow tube, appear to work satisfactorily. Most of the inhaled solution is exhaled, and up to 20 minutes may be required to achieve satisfactory topical anesthesia. Inhalation of an aerosol of local anesthetic is usually well tolerated and can anesthetize the entire respiratory tract. The quality of topical anesthesia achieved with nebulizers is not as good as that achieved with other techniques, but it is a useful option when other techniques cannot be used or coughing is particularly undesirable.

Box 50-1 Airway Techniques That Can Be Performed Under Topical Anesthesia in an Awake Patient

"Supraglotti airway device insertion
Direct laryngoscopy and intubation
Blind nasal intubation
Retrograde intubation
Flexible fiberoptic laryngoscopy and intubation
Rigid indirect optical devices and intubation
Tracheotomy/Cricothyrotomy"

Box 50-2 Techniques of Airway Anesthesia

Nebulizers—entire airway
Topical sprays and gels—upper airway
Transtracheal injection—larynx and trachea
"Spray as you go"—larynx and trachea
Nerve blocks—distribution of the nerve supply
Combinations of the above

Local anesthetic sprays and gels achieve rapid topical anesthesia of the nose, mouth, and pharynx. Pressurized aerosol sprays contain preservatives that may cause a sore throat postoperatively, and they are less effective than gels. Lidocaine 4% administered by a spray attachment for syringes is popular. The first spray is pungent and patients should be warned. Lidocaine gel (2%) is very effective and well tolerated, but subsequent optical images through the gel may be slightly impaired. Most of the lidocaine applied with sprays or gels is swallowed and the absorbed drug metabolized in first-pass hepatic metabolism.

Topical anesthesia of the larynx and trachea may be achieved by transtracheal injection or a "spray as you go" (SAYGO) technique. SAYGO is an intermittent application technique that causes coughing and requires time for recovery after each application. Use of an epidural catheter within the working channel of the fiberscope is an effective means of administering SAYGO. Transtracheal injection through the cricothyroid membrane is more invasive but quickly produces good topical anesthesia. Coughing spreads the local anesthetic. A bolus of narcotic is frequently given before transtracheal injection to prevent excessive coughing. Narcotics themselves can cause coughing, which can be suppressed by the inhalation of salbutamol or beclomethasone or by intravenous lidocaine.[28] The quality of transtracheal anesthesia is preferred by patients and endoscopists over that produced by nebulizers or SAYGO.

Nerve blocks produce more profound and longer-lasting anesthesia than topical anesthesia does. A superior laryngeal nerve block created by injection through the thyrohyoid membrane is the least invasive of the airway nerve blocks and provides good anesthesia of the area between the vocal cords and the epiglottis.[29]

Facemask Airway

Facemask techniques are a core skill that often requires considerable expertise. Use of a facemask with spontaneous ventilation throughout induction and maintenance of anesthesia with inhaled agents is the simplest and least invasive anesthesia technique. It

is very suitable for short operations in all patients except those with an increased risk of vomiting or regurgitation. Facemasks are also used for controlled ventilation before and after the use of tracheal tubes.

Facemasks are designed to form a seal around the mouth and nose and to connect to a resuscitator or anesthesia circuit. The two key elements of the technique are maintenance of a good seal between the mask and the patient's face and an unobstructed airway. Clinical signs of air leak and airway obstruction must be sought constantly. The quality of the seal during spontaneous ventilation is monitored by observing the fullness and movement of the reservoir bag. Leaks occur most frequently around the nose and cheeks, the latter particularly in edentulous patients with concave cheeks. It is possible to compensate for a leak by using a high fresh gas flow, but use of the oxygen flush facility on the anesthesia machine will dilute the concentration of any inhaled agents being administered.

The pathophysiology of upper airway obstruction has been considered. The clinical features of airway obstruction depend on the site and degree of obstruction and whether spontaneous breathing or positive-pressure ventilation is being used. Laryngospasm may be a component of airway obstruction and is considered separately. The most important signs of airway obstruction are clinical. Noisy respiration ("snoring" with supraglottic obstruction and inspiratory stridor with glottic obstruction) is a classic sign of airway obstruction during spontaneous ventilation. However, noise depends on airflow, which is determined by the degree of obstruction and the respiratory drive. Powerful inspiration in the presence of airway obstruction produces the combination of inward movement of the upper chest region and outward movement of the lower chest and upper abdominal regions, thereby creating the classic "seesaw" movement sign. Powerful descent of the diaphragm in the presence of severe obstruction results in tracheal tug. Movement of the reservoir bag is a guide to tidal volume, which can be supplemented by electronic measurement. Reliance on the capnograph alone is dangerous. Serious hypercapnia caused by airway obstruction can exist despite a satisfactory Spo_2.

Radiology studies have shown that head extension is the most important single maneuver for maintaining space between the pharyngeal soft tissues. Head extension stretches the anterior neck structures and moves the hyoid bone and attached structures anteriorly. In patients with an unstable cervical spine, head extension should be used only if all other airway maneuvers fail to overcome the airway obstruction. Jaw thrust, achieved by exerting anterior pressure behind the angles of the mandible, uses the sliding component of the TMJ to move the mandible, hyoid bone, and attached structures anteriorly. Considerable strength is sometimes required to overcome airway obstruction with head extension and jaw thrust. Use of the lateral position can dramatically reduce airway obstruction.[16]

If head extension and jaw thrust fail to maintain an unobstructed airway, options include insertion of an oropharyngeal airway, nasopharyngeal airway, or SAD and tracheal intubation. An oropharyngeal airway (Fig. 50-3) is normally the first choice, provided that sufficient mouth opening is possible. The airway should be inserted only when the pharyngeal and laryngeal reflexes are depressed to minimize the risk of provoking coughing and laryngospasm. The risk of damage to the teeth during the insertion of oropharyngeal airways is increased in the presence of caries and gingivitis.

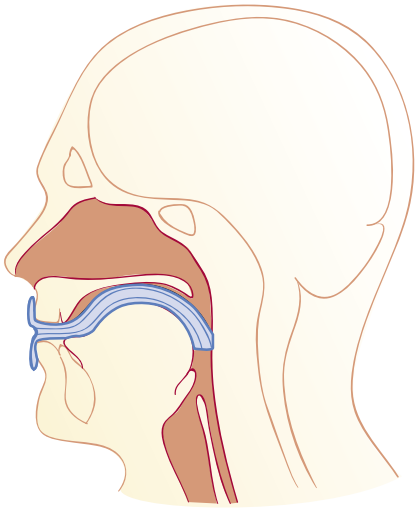


Figure 50-3 Oropharyngeal airway in place. The airway follows the curvature of the tongue. It pulls the tongue and the epiglottis away from the posterior pharyngeal wall and provides a channel for the passage of air. *(Adapted from Dorsch JA, Dorsch SE: Understanding Anesthesia Equipment, 4th ed. Baltimore, Williams & Wilkins, 1999.)*

If airway obstruction is not improved with the oropharyngeal airway, the next step has traditionally been insertion of a nasopharyngeal airway (Fig. 50-4), which often dramatically improves the airway. Nasopharyngeal airways may be preferable to oropharyngeal airways in the presence of limited mouth opening and dental caries or gingivitis. Once in place, a nasopharyngeal airway is less stimulating than an oral airway and better tolerated by lightly anesthetized patients. Insertion of a nasopharyngeal airway can cause epistaxis as a consequence of damage to the nasal mucosa, polyps, turbinates, or other tissues. This risk is minimized by gentle insertion of a well-lubricated small airway and termination if resistance is met. Unless other measures fail to maintain an adequate airway, nasopharyngeal airways should not

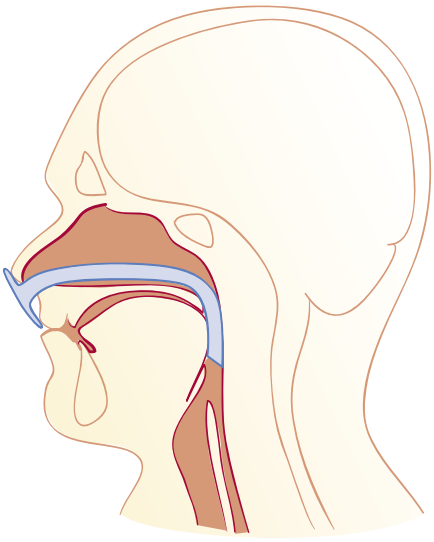

Figure 50-4 The nasopharyngeal airway in place. The airway passes through the nose and ends at a point just above the epiglottis. *(Adapted from Dorsch JA, Dorsch SE: Understanding Anesthesia Equipment, 4th ed. Baltimore, Williams & Wilkins, 1999.)*

be used in patients with basal skull fracture because of the risk of intracranial insertion. Ventilation through an SAD may be successful when facemask ventilation fails. A laryngeal mask airway (LMA) is now frequently inserted before trial of a nasopharyngeal airway if mouth opening is adequate and the depth of anesthesia is sufficient. Successful tracheal intubation will improve the airway when facemask ventilation is inadequate but may be hazardous because difficulty with facemask ventilation is associated with difficult tracheal intubation.

When airway obstruction makes facemask positive-pressure ventilation difficult, any of the aforementioned maneuvers may be used. Use of increased airway pressure has a good theoretical basis as a means of overcoming dynamic airway obstruction. Two-person techniques are of proven value. The more experienced person maintains head extension, bimanual jaw thrust, and mask seal while an assistant squeezes the reservoir bag under supervision. Excessive airway pressure should be avoided because it may insufflate gas into the stomach, thereby increasing the risk for regurgitation. Mask ventilation may be difficult or impossible,[2] particularly when cricoid pressure is applied.

Laryngospasm during Anesthesia

The pathophysiology of laryngospasm has been discussed. Laryngospasm during surgery can occur during use of a facemask or SAD. The clinical picture depends on the degree of obstruction and the respiratory drive. High-pitched inspiratory stridor is a classic sign, but complete airway obstruction is silent. Obstruction must be relieved rapidly to prevent hypoxemic damage and the development of negative-pressure pulmonary edema.[18] Mild laryngospasm should be managed initially with positive-pressure ventilation by facemask along with head extension and jaw thrust. The Larson maneuver of inward pressure in the "laryngospasm notch" (between the mandible and mastoid process) has no disadvantages and should be attempted.[30] When laryngospasm is severe with complete glottic closure, attempted facemask positive-pressure ventilation is ineffective because it distends the piriform fossae and presses the aryepiglottic folds more firmly against each other. The depth of anesthesia may be increased rapidly with intravenous anesthetics (preferably propofol). Stimulating surgery should be interrupted. If the obstruction or hypoxemia does not improve, a small dose (e.g., 0.1 mg/kg) of succinylcholine can relax the vocal cords for about 2 minutes and give time to increase the depth of anesthesia. This dose usually causes brief apnea, and laryngospasm may recur when neuromuscular transmission recovers. If the obstruction or hypoxemia is severe, an intubating dose of succinylcholine followed by tracheal intubation is indicated. If tracheal intubation fails, a percutaneous airway will be necessary.

Supraglottic Airway Devices

SADs have been used widely since the 1990s. They provide an airway intermediate between the facemask and tracheal tube in terms of anatomic position, invasiveness, and security. All are designed to form a seal in the pharynx between the respiratory and digestive tracts to protect the airway and facilitate gas exchange. All have a proximal tube that is connected to an anesthesia circuit or other device. All SADs are inserted blindly, and tests are then used to determine whether their function is satisfactory. Many classifications have been proposed; a simple differentiation is between esophageal obturator and periglottic devices.

Esophageal Obturator Devices

A tube with a closed distal end that is designed for passage into the esophagus is common to all esophageal obturator devices. A distal seal in the esophagus is provided by an inflatable cuff, and a proximal seal is achieved with a facemask or oropharyngeal cuff. Holes in the tube between the proximal seal and the distal cuff deliver gases to the laryngopharynx. The Combitube has been widely used in prehospital care. The proximal seal is provided by an oropharyngeal cuff. It has a second open-ended tube that can function as a tracheal tube if it is inadvertently inserted into the trachea. It gives protection against regurgitation similar to that provided by modern periglottic devices. The incidence of esophageal damage should be reduced when the SA (small adult) size is used. Its performance is inferior to that of the ProSeal LMA (PLMA) and the Laryngeal Tube Sonda (LT),[31] but it has been successful when other devices have failed. The LT is a single-lumen esophageal obturator device in which both cuffs are inflated from a single inflation line. Multiple- and single-use versions are available, and the size and number of holes between the two cuffs have been increased. Placement is rapid and the incidence of laryngospasm and coughing is low. The LT achieves a high leak pressure, thus facilitating higher airway pressure than with the LMA classic (LMAc) during positive-pressure ventilation. The LT has been used successfully in the "cannot intubate, cannot ventilate" situation and LMA failure. A gastric drainage tube was added in the "Sonda" models and perform well.[31] Other esophageal obturator devices are also available.

Periglottic Devices

Periglottic devices form a seal around the larynx, usually with an inflatable cuff. Most clinical experience has been with the LMA family of devices, and only these will be described in detail here. This does not imply that other devices are not of value.

The original LMA (now also known as the LMAc) was introduced into clinical practice in 1988 and has been used in more than 200 million patients. All LMAs have three main components: mask, airway tube, and inflation line. The mask has a bowl surrounded by an inflatable cuff, which is designed to form an airtight and fluid-tight seal round the larynx. The airway tube has a standard 15-mm connector.

Technique

Large LMAs may increase the risk for sore throat postoperatively but achieve a better seal.[32] An LMA is inserted blindly and thus gentleness is important.[33] Several insertion techniques will achieve an acceptable position and function in most patients. The technique developed over many years by Archie Brain (the inventor) (Fig. 50-5) is reliable but not always successful, and alternative techniques are sometimes needed. The "sniff" position is recommended for insertion of an LMA.

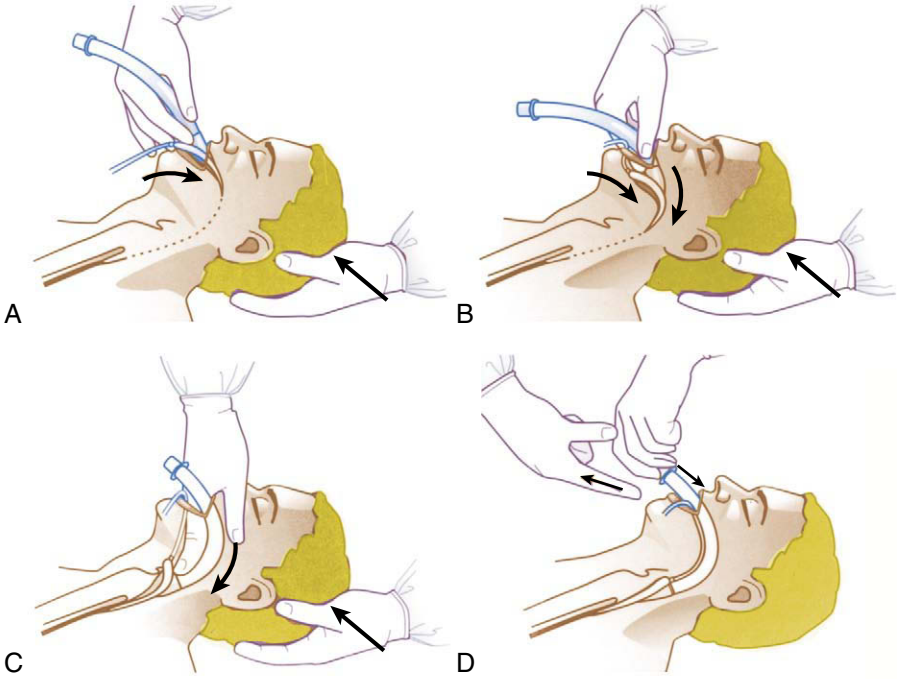

Figure 50-5 Insertion of a laryngeal mask airway (LMA). **A,** The tip of the cuff is pressed upward against the hard palate by the index finger while the middle finger opens the mouth. **B,** The LMA is pressed backward in a smooth movement. Notice that the nondominant hand is used to extend the head. **C,** The LMA is advanced until definite resistance is felt. **D,** Before the index finger is removed, the nondominant hand presses down on the LMA to prevent dislodgment during removal of the index finger. The cuff is subsequently inflated, and outward movement of the tube is often observed during this inflation. *(Courtesy of LMA North America, Inc., San Diego, CA.)*

Propofol or sevoflurane give good conditions for insertion of an LMA. The combination provides particularly good conditions with a low incidence of apnea and movement during insertion.[34] Short-acting narcotics improve the ease of insertion and airway patency.[35] Alfentanil (10 µg/kg) suppresses swallowing, coughing, gagging, and laryngospasm without unduly long apnea. Intravenous lidocaine facilitates LMA insertion and reduces the incidence of coughing and airway obstruction. Insertion should be performed only after an adequate depth of anesthesia has been achieved, best demonstrated by the ability to perform a "jaw thrust." The recommended technique involves passing the device along the palate and then the posterior pharyngeal wall until resistance increases, at which point the tip should be lie within the upper esophageal sphincter. This route should reduce the risk of posterior displacement of the epiglottis. Malposition of the LMA is less likely if jaw thrust or direct laryngoscopy is used to assist insertion. The laryngoscope-assisted technique has been successful when the standard technique has failed.

When resistance to insertion is detected, the tube is left free while air is inflated into the cuff. Inflation to the maximum recommended volume produces high cuff pressure and suboptimal function. Inflation to a cuff pressure not higher than 60 cm H_2O is recommended. The tube is connected to the anesthesia circuit and gentle manual ventilation begun. Initial checks of LMA function are now performed. Lung expansion is observed. Slow refill of the reservoir bag is a feature of airway obstruction. Auscultation over the neck may detect sounds of respiratory obstruction. When airway obstruction is detected, examination with an FFL is recommended because management of LMA impaction in the glottis is different from that of vocal cord closure.

LMA function is now assessed in more detail (Box 50-3). Two tests that correlate well with optimum position are the ability to generate an airway pressure of 20 cm H_2O and the ability to ventilate manually.[36] Gas exchange and the possibility of obstruction are assessed by capnography, expired tidal volume, and the flow-volume loop. Airway "leak" pressure may be used to quantify the efficacy of the seal between the mask and the larynx and indicates both the feasibility of positive-pressure ventilation and the degree of airway protection. The test is performed by determining the airway pressure at which gas escapes.

An effective seal depends on the size and position of the LMA, inflation of the cuff, low airway resistance, and high pulmonary compliance. Poor initial function may be caused by laryngospasm or bronchospasm. Withdrawal followed by readvancement (the up-down maneuver) may improve position and function of the LMA. The number of maneuvers should be limited because airway obstruction is occasionally caused by undiagnosed laryngeal lesions or laryngeal closure. If the airway remains unsatisfactory, the anesthesiologist may reinsert the same or a different size of LMA and accept some leakage, or use a facemask or tracheal intubation.

Box 50-3 Assessment of Function of the Laryngeal Mask Airway

- Observation of airway pressure and chest movement with a manual ventilation
- Reservoir bag refill during expiration
- Capnograph
- Auscultation over the neck
- Cuff leak pressure
- Expired tidal volume and flow-volume loop
- Examination with a flexible fiberoptic laryngoscope

The laryngeal mask is secured. A bite block should be inserted and remain in place until the LMA has been removed to reduce the possibility that biting will obstruct the airway or damage the tube.

Airway Obstruction

The final position of the LMA in relation to the vocal cords, epiglottis, and upper part of the esophagus varies greatly and has been investigated with the FFL. The average views obtained in 26 studies included an unobstructed view of the vocal cords in 40% and no view of the vocal cords in 6%.[37] Malposition occurs in 50% to 80% of patients, is usually associated with an undefined "clinically acceptable" airway,[37] but can adversely affect the quality of the airway.

There have been few scientific investigations of airway resistance as a measure of obstruction during the clinical use of SADs. An important study showed that although median airway resistance was similar in the LMA (plus larynx) and tracheal tube groups, airway resistance was greatly increased in 3 of 12 patients in the LMA group, indicative of significant airway obstruction.[38] Conversion to tracheal intubation has been required in 11.4% of patients in whom the LMA was used for tonsillectomy.[39] Head extension and jaw thrust have been required in 5% of patients. Failure to achieve a satisfactory airway occurred in 4.7% of LMA patients in one large study.[10] Variation in the incidence of "acceptable" or obstructed airways may be partly a consequence of differences in clinical criteria. Airway obstruction unresponsive to simple measures should be no more acceptable than with a facemask and should be relieved. Reversion to a facemask is often effective. Emergency intraoperative tracheal intubation is sometimes necessary and is likely to be more hazardous than elective intubation (Box 50-4).

Pulmonary Aspiration

The seal achieved by LMAs provides less protection against pulmonary aspiration than a properly inserted cuffed tracheal tube does. LMA malposition in which the upper end of the esophagus lies within the bowl of the LMA increases the risk that regurgitation or vomiting will result in pulmonary aspiration and has been reported in a third (or more) of patients. Massive pulmonary aspiration during LMA anesthesia is infrequent but can lead to death or serious morbidity.[40] The LMA should not be used in patients with an increased risk for regurgitation or vomiting.

Positive-pressure ventilation, with or without NMBDs, is frequently used with the LMA. Despite reports of safe use in large series, there is concern about the safety of this practice.[41] Positive-pressure ventilation increases the risk for gastric insufflation, which in turn increases the risk for regurgitation.

Removal of the Laryngeal Mask Airway

Laryngeal function is depressed after LMA use.[42] Monitoring and oxygen administration should be continued during emergence from anesthesia. Removal of the LMA should always be carried out at locations where personnel and equipment are available to perform tracheal intubation. Most keep the LMA in place until consciousness recovers, airway reflexes return, and patients can open their mouth on command. Removal with the cuff inflated is associated with a higher incidence of hoarseness but not overall airway complications, and many recommend this technique.

Comparison of the Laryngeal Mask Airway with the Facemask and Tracheal Tube

Basic skill is mastered more readily with an LMA than with a facemask. A reasonable success rate is achieved more rapidly with an LMA than with the Macintosh technique of tracheal intubation. A greater degree of skill is required for tracheal intubation. An LMA is inserted blindly, whereas a tracheal tube is normally inserted under vision. Difficulty in LMA insertion occurs in at least 4.5% of patients, a incidence comparable to that of difficulty with the Macintosh technique. LMA insertion causes less hemodynamic stimulation than laryngoscopy and tracheal intubation do. The LMA has advantages over tracheal intubation at the time of "extubation." The incidence of minor laryngopharyngeal morbidity is similar with both devices. However, coughing is less frequent at LMA than at tracheal tube removal, and adverse hemodynamic effects occur less frequently. The glottic aperture is narrowed after tracheal intubation but not with use of an LMA.[42]

Complications and Contraindications

There are few published reports of serious complications as a consequence of LMA use, but there have been unreported deaths and cases of brain damage.[43] Less serious complications include nerve damage.

Role of the Laryngeal Mask Airway

The LMA is extremely useful when used conservatively and has proved valuable as a rescue device. The LMA is a key device at several places in the ASA algorithm for difficult airways.[6] There are many reports of successful use of an LMA as a rescue airway when tracheal intubation had failed, including the "cannot intubate, cannot ventilate" situation, and lives have been saved. However, the LMA does not always provide a satisfactory airway in the failed tracheal intubation situation.[2] Cricoid pressure can interfere with the insertion and function of SADs and should be reduced to a level that allows successful insertion and adequate function. An LMA may be used to allow completion of surgery if the latter cannot be postponed, although there is a risk of airway obstruction and pulmonary aspiration. The most prudent course is to postpone surgery and awaken the patient or to convert to tracheal intubation with a visual technique such as the Aintree intubating catheter (AIT).

Elective use of an LMA in a patient with a known or anticipated difficult airway has serious disadvantages. The difficult airway remains and the development of airway obstruction could produce a critical situation that requires immediate percutaneous

airway rescue. Asai states, "It is inadvisable to rely on the LMA when tracheal intubation is predicted to be difficult."[43a] Although the LMA has been inserted under topical anesthesia, gagging, coughing and a high incidence of sore throat have been reported.[44] The LMA has failed to provide a satisfactory airway in patients with micrognathia, previous oral or cervical radiotherapy, and laryngeal abnormalities and disease. Insertion of an LMA is frequently difficult in patients in whom tracheal intubation is difficult. Use of an LMA when the patient's position is other than "sniff" will delay conversion to tracheal intubation when necessary. The development of airway obstruction with such positions places the patient at risk, requires rapid repositioning of the patient by staff, and jeopardizes the surgical outcome. The risks associated with intraoperative tracheal intubation (see Box 50-4) will be increased.

The LMA has been used safely for major surgery, but the user must be very experienced with both the LMA and tracheal intubation, and that is the paradox. If future generations of anesthesiologists were to have less skill in tracheal intubation, use of an LMA instead of tracheal intubation for major surgery would become more risky. Skill in tracheal intubation is essential, and it is generally the safer option. Insertion of an LMA is regarded as less stressful for the anesthesiologist than the use of direct laryngoscopy for tracheal intubation. However, a tracheal tube is a more reliable airway that provides better protection against pulmonary aspiration. Most comparisons with tracheal intubation have used the Macintosh laryngoscope, the limitations of which are now better understood.[45] It is probable that problems and complications with tracheal intubation will become less frequent as alternative intubation techniques are used more regularly.[46,47] Expediency and some minor advantages of SADs must be offset against lower airway security and reliability. Patient safety must always be the prime concern.

Newer Supraglottic Airway Devices

Flexible, intubating, and ProSeal LMAs have been introduced. Several changes have been made to improve the performance of newer models. The LMA Flexible has a wire-reinforced, flexible airway tube designed to resist kinking during oral or other head and neck surgery. Some SADs introduced by other manufacturers perform well. The i-gel and LMA Supreme seem very promising, but there are still limited data and other new devices will certainly appear.

ProSeal Laryngeal Mask Airway

The PLMA was designed to facilitate positive-pressure ventilation with higher airway pressure than possible with the LMAc. A second posterior cuff and deeper bowl were designed to improve the seal around the larynx. The PLMA has a drainage tube to provide access to the esophagus. Other features of the PLMA include a reinforced airway tube that is narrower than that of the LMAc and an integrated bite block. The tip of the PLMA lacks the semirigid back plate of the LMAc.

Insertion Technique

A greater depth of inhaled and intravenous anesthesia is required for insertion of a PLMA than an LMAc. The technique of PLMA insertion is more demanding than that for an LMAc, but a high success rate can be achieved.[48] This effort is rewarded by a superior quality of airway. Airway seal pressure is increased by 50% in relation to the LMAc, thus facilitating positive-pressure ventilation and probably providing better airway protection. The device may be introduced digitally or with a special introducer. An alternative laryngoscope introducer technique has been developed to prevent folding of the mask tip during insertion. A lubricated introducer is passed through the PLMA drainage tube so that it protrudes beyond the tip. A Macintosh laryngoscope is used to facilitate insertion of the introducer into the esophagus. The laryngoscope is then removed and the PLMA inserted by using the introducer as a guide. This technique may be the most reliable but is most invasive method of PLMA insertion. After insertion, the PLMA cuff is inflated to a pressure not greater than 60 cm H_2O.

An incorrectly placed PLMA will result in unreliable or obstructed ventilation. The diagnosis of correct and incorrect PLMA position is considered in detail because it may be relevant to a new generation of SADs that incorporate a drainage tube. Correct placement of the PLMA should produce a leak-free seal around the glottis with the mask tip and drainage tube lying inside the upper esophageal sphincter. There are three important malpositions of the PLMA: (1) The PLMA may not be inserted sufficiently far, with the consequence that the tip of the drainage tube lies in the pharynx. Positive-pressure ventilation is ineffective because delivered gas passes out the drainage tube. (2) The tip of the PLMA may lie within the glottis, thereby obstructing ventilation and impairing function of the drainage tube. (3) The tip may be folded over and obstruct ventilation and the drainage tube. Malposition should be corrected by repositioning the PLMA, using a different insertion technique, or replacing it with an alternative airway device.

Initial checks of function are identical to those used with the LMAc. In particular, chest expansion should be good with reasonable airway pressure, and there should be no signs of obstruction of expiration, particularly slow refill of the reservoir bag. The capnograph should be square and the flow-volume loop closed without expiratory scalloping or other signs of obstruction. Airway leak pressure should be greater than 20 cm H_2O. Additional checks unique to devices with a drainage tube may then be performed. A thin layer of water-soluble gel or nontoxic soapy film is used to cover the proximal end of the drainage tube. The effect of changes in pressure in the lungs (sternal compression or positive-pressure ventilation) or esophagus (pressure on the suprasternal notch) are noted. Normal results are as follows:

- The drainage tube gel does not move with positive-pressure ventilation or brief firm pressure applied to the sternum.
- The drainage tube gel does not move when airway pressure is raised to 20 cm H_2O.
- The drainage tube gel moves slightly when brief "bobbing" pressure is applied to the suprasternal notch (the mechanism is pressure on the esophagus).

Protection against Pulmonary Aspiration

The PLMA provides greater protection against pulmonary aspiration than the LMAc does. In clinical practice, the PLMA has prevented aspiration in the presence of massive regurgitation. However, pulmonary aspiration has occurred when malposition of the PLMA was not corrected and function checks had been satisfactory. The PLMA provides good but incomplete protection against pulmonary aspiration.

Airway Obstruction

Significant airway obstruction has been reported with the PLMA. Intraoperative tracheal intubation was required in 13% of obese patients undergoing laparoscopic cholecystectomy.[49] Obstruction may be caused by malposition or obstruction of the bowl by folds of the inflated cuff, by narrowing of the glottis via direct pressure, or by laryngospasm during use of a properly positioned PLMA.

Use of the PLMA during major surgery such as laparoscopic cholecystectomy has been advocated[49] but is controversial.[41] Use of the PLMA for such surgery should be considered only in patients who have no extra risk factors (including obesity, symptomatic gastroesophageal reflux disease, reduced compliance, increased airway resistance) for SAD use. The anesthesiologist must be ready to convert to tracheal intubation at any time.[49] Tracheal intubation provides a more secure airway and should be the norm for major surgery.

Single-Use Supraglottic Airway Devices

The original LMAs were designed for use up to 40 times. Protein contamination occurs after the first use and increases with each subsequent use despite proper cleaning and autoclaving. Single-use SADs have been developed to prevent cross-infection. Ease and quality-of-use results from different studies have been conflicting.

Tracheal Tubes

Tracheal tubes are designed to provide a secure channel through the upper airway. The distal end lies in the mid to lower part of the trachea, whereas the proximal end lies outside the mouth or nose, where it is connected to an anesthesia circuit or other device. Tracheal tubes used in adult patients have a cuff near the distal end that is inflated to provide a seal against the tracheal wall to protect the lungs from pulmonary aspiration and to ensure that the tidal volume delivered ventilates the lungs rather than escapes into the upper airway. Cuffs are normally inflated with air and have an inflation tube with a pilot balloon that indicates cuff inflation.

The size of the tracheal tube is normally described as the internal diameter (ID) in millimeters, but the relationship of the ID to the external diameter varies between different designs and manufacturers. Use of the largest possible tracheal tube was once considered good practice. Very small tracheal tubes may allow insufficient time for completion of exhalation and produce air trapping ("auto-PEEP") with the risk of barotrauma and circulatory compromise. Others have found no evidence of obstruction to expiration with tube sizes as small as 6-mm ID, and the increased workload created is usually of little clinical significance during anesthesia. Use of small tracheal tubes reduces the incidence of sore throat and hoarseness. Small tracheal tubes are easier to insert than larger tubes and may cause less tissue pressure at the larynx. It is easier to pass small tracheal tubes over introducers or FFLs.[50] Restriction of gas flow through a tracheal tube is markedly increased by the presence of an FFL or suction catheter within the lumen of the tracheal tube. Tracheal tube sizes of 8 mm (ID) for males and 7.5 mm (ID) for females are often used.

Specialized tracheal tubes produced for anesthesia include preformed, adjustable shape, and reinforced. Specialized tubes are also used for ear, nose, and throat (ENT) surgery (laser and microlaryngeal surgery) and for thoracic anesthesia and critical care. Tracheal tubes can become kinked and hence obstructed when they are angulated. Armored (reinforced) tubes have an embedded coil (usually stainless steel) that minimizes kinking of the tube when it is subjected to angulation. Armored tracheal tubes are the tubes of choice in many head and neck procedures and patient positions other than supine. However, an armored tube that has been compressed remains pinched, so it is particularly important to prevent biting on such a tube.

The material and bevel shape of the tip of the tracheal tube can affect the ease and probably the trauma of tube passage. The tip of the earliest Magill tracheal tubes had a soft, simple bevel. The Murphy eye, a hole in the wall of a firm tip opposite the bevel, was designed to provide a patent airway if the tracheal tube became occluded at the bevel. Air leakage through the Murphy eye may facilitate early diagnosis of tracheal tube displacement before complete accidental extubation has occurred.

Cuff inflation achieves a seal between the tracheal tube and the wall of the trachea. There should be no air leak at airway pressures required for positive-pressure ventilation, and the lungs should be protected from aspiration. The cuffs of early tracheal tubes produced a high pressure that could cause mucosal ischemia. High-volume, low-pressure cuffs were developed to conform to the D-shaped cross section of the trachea and provide a seal at a lower cuff pressure, thereby reducing the risk of tracheal damage.

Inflation of the cuff with a volume that just prevents an air leak ("just-seal volume") is often recommended. However, this cuff pressure varies greatly. Prevention of excessive cuff pressure may reduce the incidence of tracheal damage, vocal cord dysfunction from recurrent laryngeal nerve palsy, and sore throat after surgery. Because palpation is not a good guide to cuff pressure, use of a monitor to maintain cuff pressure in the range of 25 to 30 cm H_2O is recommended.[51]

Cuff pressure can change after initial inflation. Inhaled N_2O diffuses into tracheal tube cuffs that have been inflated with air and increases the volume and pressure within the cuff enough to cause tracheal lesions and an increased incidence of sore throat. A leak in the cuff or valve or a reduction in trachealis muscle tone can lower cuff pressure and increase the risk for pulmonary aspiration. Early detection of both low and high pressure is important.

A properly inflated cuff protects against massive pulmonary aspiration, but silent aspiration (micro-aspiration) of pharyngeal contents occurs along channels between folds in the cuff and is a major contributor to ventilator-associated pneumonia in intensive care. New materials and cuff designs attempt to eliminate cuff channels and may help prevent micro-aspiration.

Tracheal Intubation

Tracheal intubation (insertion of the tracheal tube) is an essential skill in anesthetic practice. Indications for tracheal intubation are shown in Box 50-5. There are no absolute contraindications to tracheal intubation.

Box 50-5 Indications for tracheal intubation

Surgical and Anesthetic Indications

Surgical requirement for neuromuscular blocking drugs, e.g., abdominal surgery

Airway access shared with the surgeon, including ear, nose, and throat surgery

Patient position in which access to the airway is restricted or precludes rapid tracheal intubation, e.g., lateral, prone

Predicted difficult airway

Risk of aspiration of gastric contents or blood, e.g., upper gastrointestinal obstruction or sepsis, facial trauma, bleeding into the respiratory tract from any cause

Surgery that impairs gas exchange

Prolonged surgery

Other airway techniques ineffective

Critical Illness

Inability to protect the airway, e.g., coma from any cause

Impaired respiratory function (hypoxemia or hypercapnia) unresponsive to noninvasive management

Prevention of hypercapnia, e.g., raised intracranial pressure

Principles of Clinical Practice of Tracheal Intubation

The incidence of complications should be minimized by using best practice.[6] Adequate personnel, drugs, and equipment must be available. Four principles are central to prevention of complications[52]:

1. Maintenance of oxygenation must take priority over all other issues. Preoxygenation should be performed before induction of anesthesia.[6] Mask ventilation should be used between attempts at tracheal intubation.
2. Trauma must be prevented. The first attempt at tracheal intubation should be performed under optimal conditions (including patient position, preoxygenation, and equipment preparation).[53] The number of attempts with blind techniques should ideally be zero and certainly not more than four.
3. The anesthesiologist should have backup plans before starting the primary technique[6] and the skills and equipment needed to execute these plans. When unanticipated difficulty occurs in non-lifesaving surgery, the safest plan is to terminate attempts at tracheal intubation, awaken the patient, and postpone surgery.
4. The anesthesiologist should seek the best help available ("call for help") as soon as difficulty with tracheal intubation is experienced.

Intravenous access is secured (occasionally achieved only during inhaled induction of anesthesia) and standard monitoring is established. The patient should be in the optimal position. Time spent adjusting the position after induction of anesthesia may delay successful tracheal intubation, prolong the time at risk for pulmonary aspiration, and increase the risk for hypoxemia or airway trauma.

Nasotracheal Intubation

Nasotracheal intubation (NTI) is necessary when the oral route is not possible (e.g., limited mouth opening) or would impede surgical access. NTI was formerly considered the technique of choice for resuscitation, but orotracheal intubation using the rapid-sequence technique is now usually the first choice. NTI has been used in critical care as an alternative to tracheotomy because it is better tolerated than oral intubation. However the tube used must be longer and narrower than oral tracheal or tracheotomy tubes so that airway resistance is greater and therapeutic aspiration of pulmonary secretions is more difficult. Problems associated with prolonged duration of NTI include nasal damage, local abscesses, otitis media, and sinusitis. The nasal route is contraindicated in patients with a history (old or new) of basal skull fracture or surgery. Nevertheless, if there is no alternative, this infrequent complication may be less likely when a catheter is used as a guide.

The technique of NTI is influenced by the need to minimize the incidence of complications peculiar to this route, including cuff tears, damage to the nasal cavity (epistaxis, fractured turbinates, avulsed nasal polyps, septal abscess) and nasopharynx (avulsed adenoids). It is beneficial to use vasoconstrictors to shrink the mucosa of both nasal cavities before passage of the tube. Another complication is a consequence of the right angle through which the tube must turn when it passes from the nasal cavity into the oropharynx. The tube may impact on and tear the mucosa of the posterior nasopharynx and pass submucosally. This complication is less likely if a soft catheter is first passed into the oropharynx and then used as a guide. Tube factors that reduce the risk of trauma include diameter not larger than 7.5-mm ID for men and 7.0-mm ID for women, warming before insertion, and use of a soft tip. The tube is passed directly backward along the floor of the nose. Resistance to nasal passage may be overcome by gentle rotation or use of a narrower tube or the other nasal cavity. It is important to be gentle and stop if abnormal resistance is met. The risk of damage may be reduced by passage through the nasal cavity under vision with an FFL.

Blind nasal intubation was first used in patients breathing spontaneously under deep inhaled anesthesia but can also be performed in awake patients under topical anesthesia. Tube advancement is guided by changes in breath sounds at the proximal end of the tube (amplification by a whistle can be very helpful) and by external palpation of the larynx. Cessation of breath sounds indicates that the tip of the tube has entered the esophagus, piriform fossa, or vallecula. The tube is withdrawn until breath sounds are heard, the head and neck position is adjusted, and the tracheal tube is then readvanced. Temporary inflation of the cuff when in the oropharynx may improve success rates.[54] If the tube is held up at the larynx, head flexion can help the tracheal tube enter the trachea by improving alignment with the trachea. Blind nasal intubation during spontaneous ventilation may still be useful when an FFL is not available. Attempted blind NTI in an apneic patient risks trauma and failure.

NTI is often performed after the administration of intravenous anesthetics and NMBDs. A direct laryngoscope is used to facilitate NTI under vision and is inserted once the tip of the tube has reached the oropharynx. Magill forceps are frequently used to grasp the tracheal tube (avoiding the cuff) and guide it into the trachea. An assistant then advances the tube. Rigid indirect laryn-

goscopes (RILs) can facilitate NTI under vision in patients in whom this is not possible with direct laryngoscopes.

Direct Laryngoscopy: Theoretical Basis

Direct laryngoscopy is used to facilitate tracheal intubation under vision. Successful direct laryngoscopy depends on achieving a line of sight from the maxillary teeth to the larynx. The tongue and epiglottis are the anatomic structures that intrude into the line of sight. Management of the tongue and epiglottis is therefore central to successful direct laryngoscopy. Before the laryngoscope is inserted, the patient is normally placed in the "sniff" position (see later). The direct laryngoscope is then used to displace the tongue and epiglottis out of the line of sight. The tongue is displaced horizontally (normally to the left) from the line of sight, the hyoid bone and attached tissues are moved anteriorly, and the epiglottis is elevated directly or indirectly to reveal the larynx. The force applied to the laryngoscope handle should lift the hyoid bone and attached tissues parallel to the line of sight. Adequate lifting force, which may cause considerable tissue distortion,[7,55,56] is a key factor in successful direct laryngoscopy.[7,56] It is important to achieve the best possible view of the larynx without causing tissue trauma. It is not always possible to achieve line of sight with direct laryngoscopy.

The theoretical basis of the head and neck position used for direct laryngoscopy was attributed to the need to align the axes of the oral cavity, pharynx, and larynx on the basis of a radiology study. Magnetic resonance imaging in awake patients has been used to challenge this hypothesis, but the conclusions have been controversial. Understanding of management of the tongue and the epiglottis is more likely than the axis alignment hypothesis to improve direct laryngoscopy technique.

The "sniff" position (Fig. 50-6) is usually the best starting position for direct laryngoscopy. In the sniff position, the cervical spine below C5 is relatively straight, there is increasing flexion from C4 to C2, and the head is fully extended (occipito-atlanto-axial complex).[57] Neck flexion between C2 and C4 is achieved by elevation of the head. No statistical advantage of the sniff position over simple head extension was found in one study, except in the presence of obesity or limited head extension.[26] However, the sniff position facilitated a view of the larynx in 4% of patients in whom this was not possible with simple head extension. The sniff position also improves pharyngeal airway patency in patients with obstructive sleep apnea. Head extension facilitates insertion of the laryngoscope, reduces contact between the laryngoscope and the maxillary teeth, improves the view of the larynx, and facilitates full mouth opening. Head extension should be used unless there is a contraindication.

Figure 50-6 "Sniff" position. A volunteer positioned on the Popitz pillow (DermaCare, Louisville, KY) demonstrates cervical flexion and a small degree of atlanto-occipital extension. The flexion aligns the laryngeal and pharyngeal axes. Further extension of the head results in the true sniffing position.

Macintosh Laryngoscope and Technique of Orotracheal Intubation

The Macintosh curved laryngoscope is radically different from the preexisting straight laryngoscopes. In particular, the long axis of the blade is curved, the cross section is a right-angled "Z" section, the web and flange are bulky, the tip is atraumatic, and the light bulb is shielded by the web. However, Macintosh's key innovation was his novel technique of indirect elevation of the epiglottis, achieved by tensioning the hyoepiglottic ligament after the tip of the laryngoscope was positioned in the vallecula. This technique is the key to success of the Macintosh laryngoscope—and its fundamental flaw. When it works well, the epiglottis is elevated completely and lies behind and along the posterior surface of the laryngoscope blade. However, it is not possible to position the Macintosh laryngoscope correctly in some patients. Minor difficulty results in partial elevation of the epiglottis, erroneously described as a "floppy epiglottis," and major difficulty leads to complete failure to elevate the epiglottis with the consequence that the vocal cords cannot be seen.

Tracheal intubation is normally achieved with a rapid sequence of maneuvers in which all components of a complex technique merge into one another. The best technique will develop if all components are optimized. The three component steps of direct laryngoscopy are insertion of the laryngoscope, adjustment of its position and lifting force, and use of other maneuvers to optimize the view of the glottis.

The "sniff" position is used. Full mouth opening facilitates insertion of the laryngoscope. It is inserted from the right side of mouth and to the right of the tongue while taking care to not trap the lips between the laryngoscope blade and the teeth. The laryngoscope is advanced and simultaneously moved into the midline to displace the tongue to the left. Progressive visualization of anatomic structures minimizes the risk of trauma. The epiglottis is the first key anatomic landmark. The tip of the laryngoscope is advanced into the vallecula, and the epiglottis is elevated indirectly by applying a force that tensions the hyoepiglottic ligament. Elevation of the epiglottis is optimized and a further lifting force is applied to the laryngoscope to achieve the best view of the larynx (Fig. 50-7). It is very important not to lever on the maxillary teeth because this may cause dental damage[58] and reduce the view of the larynx. If visualization of the larynx cannot be achieved without pressure on the teeth, use of this laryngoscope should be abandoned and another technique of tracheal intubation used.

When a good view of the larynx is achieved, the vocal cords, aryepiglottic folds, posterior cartilage, and interarytenoid notch can be identified (Fig. 50-8). The view should be optimized

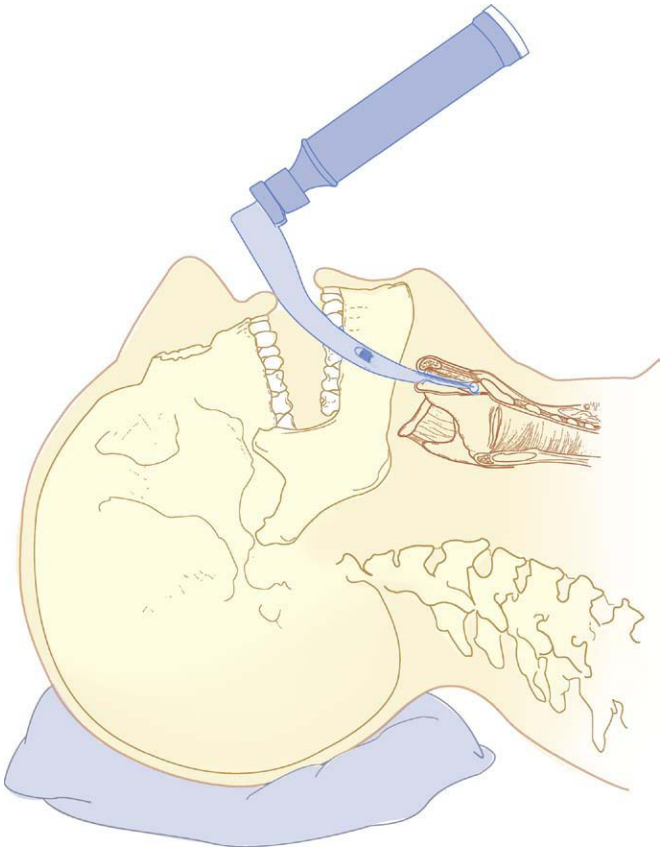

Figure 50-7 Macintosh laryngoscope in position. The laryngoscope tip is in the vallecula, the hyoepiglottic ligament is tensioned and the epiglottis has been elevated indirectly so that it lies along the posterior surface of the laryngoscope. *(From Key Topics in Airway Management, Cambridge University Press.)*

to facilitate passage of the tracheal tube. If the view of the larynx is poor, it is important to check that the basic technique has been performed optimally and other maneuvers used (Box 50-6). External laryngeal manipulation (better described as "bimanual laryngoscopy," which implies internal movement of the laryngoscope with external manipulation of the larynx), performed by the anesthesiologist who guides an assistant (Fig. 50-9), consistently improves the laryngeal view. It is a key maneuver.

Box 50-6 Maneuvers Used to Optimize the View at Direct Laryngoscopy

- Maximum head extension
- Tongue entirely to the left of the laryngoscope
- Optimal depth of insertion of the laryngoscope
- Strong lifting force applied in the correct direction to the laryngoscope
- External laryngeal manipulation—applied initially with the right hand of the anesthesiologist

Tracheal Tube Passage with Successful Macintosh Laryngoscopy

The view of the vocal cords is maintained while the anesthesiologist guides the tube under vision between the vocal cords. Passage of the tube from a position posterolateral to the larynx facilitates observation of progress of the tracheal tube toward and between the vocal cords. Steering of the tube and passage under vision are facilitated if the tube has the optimal "ice hockey stick" shape, normally created by the use of a stylet within the tube. The tracheal tube is advanced until the cuff is about 2 cm distal to the vocal cords. This position is important inasmuch as more proximal positions may cause cuff leaks and pressure on the recurrent laryngeal nerve.[5] The cuff is inflated to slightly higher than the "just-seal" pressure, and the correct position of the tube is confirmed. Cuff pressure is then adjusted to 25 to 30 cm H_2O.

If only the posterior portion of the vocal cords can be seen, including the interarytenoid notch, passage of the tracheal tube may be awkward but is not difficult. Either a styletted tracheal tube or passage of an introducer ("bougie") under vision, followed by passage of the tracheal tube over the introducer, may be used. Both are reliable visual techniques.

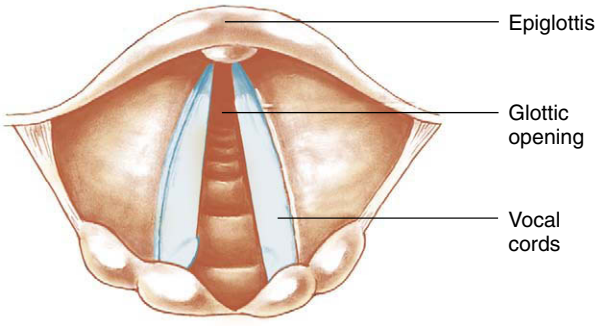

Figure 50-8 Schematic view of the glottic opening during direct laryngoscopy when the epiglottis is elevated with a curved or straight laryngoscope blade. The glottic opening is recognized by its triangular shape and the pale, white vocal cords. *(From Stoelting RK, Miller RD: Basics of Anesthesia, 3rd ed. New York, Churchill Livingstone, 1994.)*

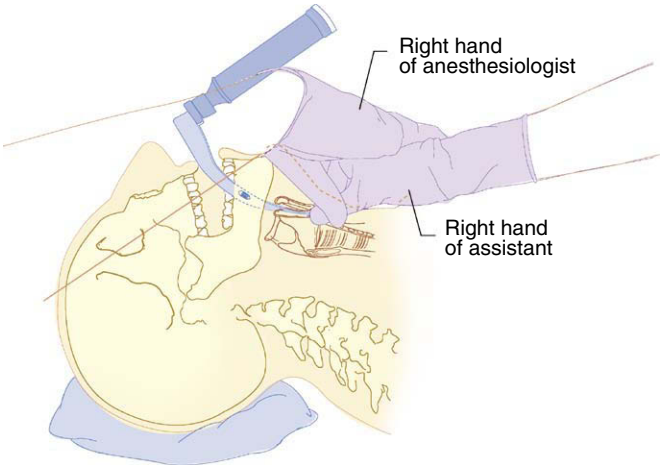

Figure 50-9 Bimanual laryngoscopy (external laryngeal manipulation). The anesthesiologist guides the position and pressure exerted by the assistant's hand on the larynx to maximize view of the vocal cords. The left hand of the anesthesiologist, which holds the laryngoscope handle, is omitted.

Difficulty with the Macintosh Technique

Difficulty with tracheal intubation is predominantly a consequence of failure to see the larynx.[53] The efficacy of direct laryngoscopy is measured in terms of the best view of the larynx achieved. The most widely used scale is that described by Cormack and Lehane (CL) (Fig. 50-10). The definitions used are grade 1, most of the glottis is visible; grade 2, only the posterior extremity of the glottis is visible; grade 3, no part of the glottis and only the epiglottis is visible; and grade 4, not even the epiglottis can be seen. The most useful modification is a subclassification of grade 3 into 3a when the epiglottis can be lifted from the posterior pharyngeal wall and 3b when it cannot be lifted.[59] This modification of grade 3 is important in clinical practice because the introducer technique does not work well in the grade 3b situation.[59] All the definitions apply to the best view that can be achieved, which implies the use of external laryngeal manipulation whenever the initial view is unsatisfactory.

The complexity of tracheal intubation may be recorded with the intubation difficulty scale (IDS),[60] a numerical score based on seven parameters—number of attempts, number of operators, number of alternative techniques, laryngeal view, lifting force required, application of laryngeal pressure, and vocal cord mobility—associated with difficult intubation. It does not include the duration of attempts. The IDS alone does not indicate the cause of the difficulty, and it is more important to communicate the scores for the individual elements of the IDS. A record of all these elements plus the duration of attempts is desirable after every tracheal intubation.

A 2% or lower incidence of CL grade 3 or 4 has been recorded. However, other large prospective studies, excluding patients with obvious[7] or anticipated[61] airway difficulty, have shown an incidence of CL grade 3 or 4 of 6.1%,[7] 10.1%,[61] or higher. External laryngeal manipulation was not used in most of these studies, so the clinically important incidence was probably half that reported. Difficulty with laryngoscopy has probably become more frequent as a consequence of patient factors such as increasing age, obesity, and modern dentistry. Anesthesiologists may also have become more reluctant to apply high lifting pressure to the laryngoscope as a result of awareness of airway trauma and the availability of alternative techniques.

Not all of the factors that contribute to difficulty with direct laryngoscopy have been identified. Factors that impair insertion of the laryngoscope, lateral displacement of the tongue, or elevation of the epiglottis will impair the efficacy of direct laryngoscopy. Anatomic causes include limited mouth opening, awkward dentition, hypoplastic mandible, impaired TMJ function, and limited head extension. A final common pathway of difficulty with the Macintosh laryngoscope was suggested by a soft tissue radiology study of laryngoscopy.[62] In patients with known difficult laryngoscopy the tongue could not be completely displaced and part was trapped between the tip of the laryngoscope and the hyoid bone. The tip of the laryngoscope could not enter the vallecula and advancement of the laryngoscope displaced the epiglottis further into the line of sight. Thus, indirect elevation of the epiglottis, the novel feature of the Macintosh technique, is also its fundamental flaw.

Blind Endotracheal Intubation with the Macintosh Laryngoscope

If the larynx cannot be seen, it is not possible to intubate the patient under vision with the Macintosh laryngoscope, and failure and soft tissue trauma are potential risks. The anesthesiologist must decide whether to use a blind technique with the Macintosh laryngoscope, abandon further attempts at tracheal intubation and awaken the patient, or use an alternative visual technique of laryngoscopy—provided that skills have been developed. Use of an SAD for elective surgery in these patients when tracheal intubation had been the first choice places them at risk if the airway becomes obstructed.

Blind techniques (styletted tracheal tube or introducer) have been the first alternative used when the larynx cannot be visualized with the Macintosh laryngoscope. Introducers, such as

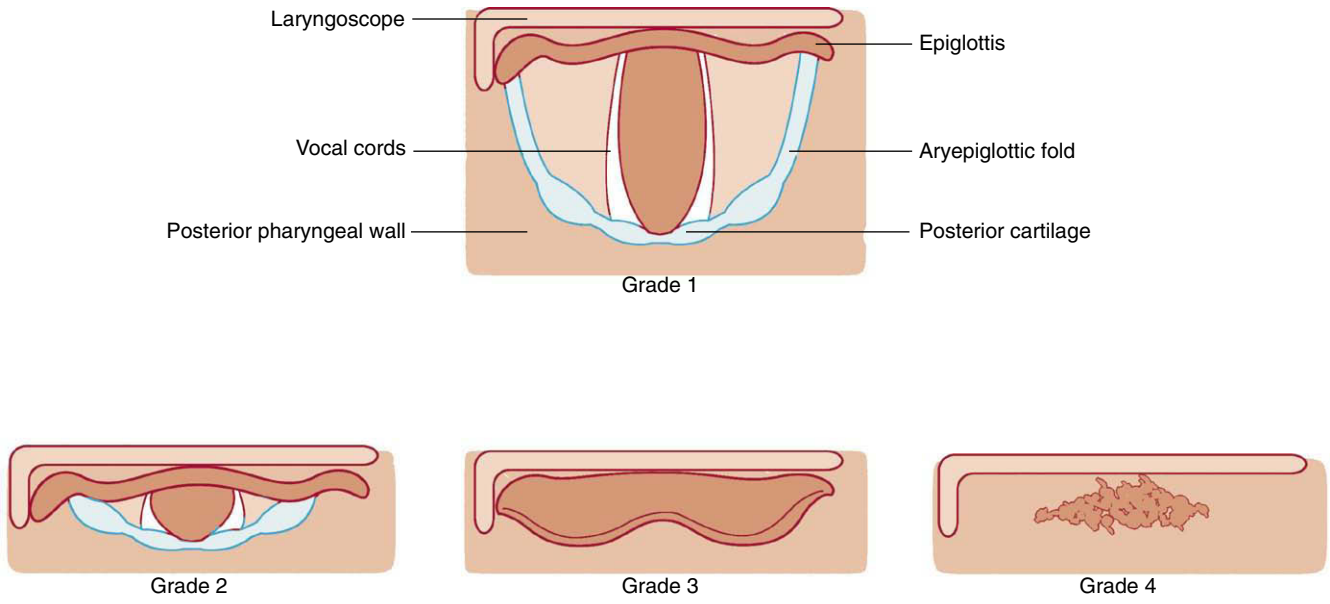

Figure 50-10 Laryngoscopy view grades.

"gum elastic bougies" with an angulated tip, are passed (introduced) into the trachea and then used as a guide for passage of the tube. The introducer technique is relatively simple and incorporates verification of its blind passage down the trachea.[52] It can be divided into three parts: passage of the introducer, confirmation of tracheal position, and passage of the tube over the introducer into the trachea. The laryngoscope is kept in the midline, and the anesthesiologist estimates the probable location of the larynx and attempts to pass the tip of the introducer behind the epiglottis and blindly between the vocal cords and into the trachea. Gentle technique should minimize trauma and facilitate verification of passage into the trachea. A sensation of clicks and distal holdup have been detected in at least 90% of correct intratracheal placements. Successful positioning of the introducer in the trachea is followed by passage of the tracheal tube over the introducer and into the trachea. This sometimes proves difficult.[52] The laryngoscope should be kept in place during passage of the tracheal tube, and 90-degree anticlockwise rotation of the tube is often effective. The use of small tracheal tubes facilitates passage of the tracheal tube. Other tracheal tube factors affecting the success of passage are considered in the section on use of the FFL. When the tube has been passed and the introducer removed, tracheal position must be confirmed. The blind introducer technique has a high success rate, such as 90% in a prospective study that permitted a maximum of two attempts.[63] However, there are many case reports of failure, and the technique does not work well when the epiglottis cannot be elevated from the posterior pharyngeal wall.[59]

The introducer technique was developed to overcome problems with the Macintosh technique before there was evidence of the efficacy of alternative techniques. There is now evidence of high success rates of tracheal intubation under vision with the straight laryngoscope,[45] FFL,[46] and RIL[47] when the Macintosh technique fails. Multiple blind attempts at tracheal intubation were often made in the past but are associated with morbidity and mortality.[43,64,65] Eventual tracheal intubation after several attempts with blind techniques should be regarded not as success but as a "near miss."

The role of blind techniques in modern practice should be questioned. The anesthesiologist should be aware that airway difficulty can be a consequence of friable lesions such as lingual tonsil hypertrophy.[3] Use of blind techniques in such unpredictable situations can cause airway obstruction. Some centers do not use blind techniques,[46,47] others limit the number of attempts to two,[63] and all should seek to emulate this enlightened practice. If a few attempts with alternative techniques are not successful, elective surgery should be postponed, the patient awakened, and subsequent awake flexible fiberoptic laryngoscopy scheduled.

Modifications of the Macintosh laryngoscope

Many variations have been described, most without data about their efficacy. A Macintosh-type laryngoscope with a hinged tip that flexes when a lever on the handle is depressed was introduced by McCoy. It works well in *simulated* difficult laryngoscopy, and there have been many clinical reports of success when the glottis could not be visualized with the Macintosh laryngoscope. However, an angulated straight laryngoscope performed much better than the McCoy in *clinical* unanticipated difficult intubation, and there have been many reports of failure of the McCoy laryngoscope to achieve a view of the glottis.

Straight Laryngoscope

Laryngoscopy for tracheal intubation was first performed with the straight laryngoscope, which remains the diagnostic and therapeutic laryngoscope used by ENT surgeons. Many studies[45] have reported successful tracheal intubation under vision with the straight laryngoscope in patients in whom intubation proved impossible with the Macintosh laryngoscope. Corroborative evidence of the value of this technique comes from many reports of successful use of the ENT straight laryngoscope and the rigid bronchoscope in such patients.

The mechanism of the greater efficacy of the straight laryngoscope is probably both improved control of the tongue and more reliable elevation of the epiglottis and is consistent with the reduced force and head extension needed with the straight laryngoscope.[55] The straight laryngoscope is of particular value with laryngeal lesions (including lingual tonsil hypertrophy) and in patients with a hypoplastic mandible. It is useful in some patients with awkward dentition, particularly the presence of a gap in the right upper dentition. Mastery of the straight laryngoscope is an asset to any anesthesiologist.

The technique described here, the paraglossal technique, affords optimum control of the tongue. Initial preparation for tracheal intubation is identical to that used with the Macintosh laryngoscope. Head extension is as important as in the Macintosh technique. It is essential to displace the entire tongue to the left of the laryngoscope. The laryngoscope is inserted lateral to the tongue and advanced carefully along the paraglossal gutter between the tongue and tonsil. Application of continued moderate lifting force to the laryngoscope handle helps maintain lateral displacement of the tongue and reduces contact with the maxillary teeth. As the laryngoscope is advanced, the epiglottis comes into view and the tip of the laryngoscope is passed posterior to it. The optimal position of the tip of the straight laryngoscope is in the midline of the posterior surface of the epiglottis, close to the anterior commissure of the vocal cords (Fig. 50-11). This position achieves good control of the epiglottis and facilitates passage of the tracheal tube. The direction of force applied to the handle of the straight laryngoscope is at right angles to the straight laryngoscope blade (and in line of sight of the larynx). Under no circumstances should levering action be applied to the teeth. Not only does this risk dental damage, but it also degrades the view. If a good view cannot be achieved, a different technique of laryngoscope or tracheal intubation should be used.

If the larynx is not visible, it is probable that the tip of the laryngoscope is located in the vallecula, piriform fossa (usually the right), posterior pharyngeal wall, or the esophagus. The basic checks and maneuvers for direct laryngoscopy techniques (see Box 50-6) are performed. Bimanual laryngoscopy, including lateral movement of the larynx (regularly used by ENT surgeons), is particularly important. Direct tracheal tube passage with the Miller laryngoscope can be awkward. The visual introducer technique is useful whenever it proves difficult to guide the tube to the larynx.

The Miller laryngoscope is popular because its low profile facilitates insertion and positioning, but there are some problems. The tip has a small point of contact with the posterior surface of the epiglottis, so there is a risk of trauma and unstable elevation of the epiglottis. Precise positioning is difficult because the tip is

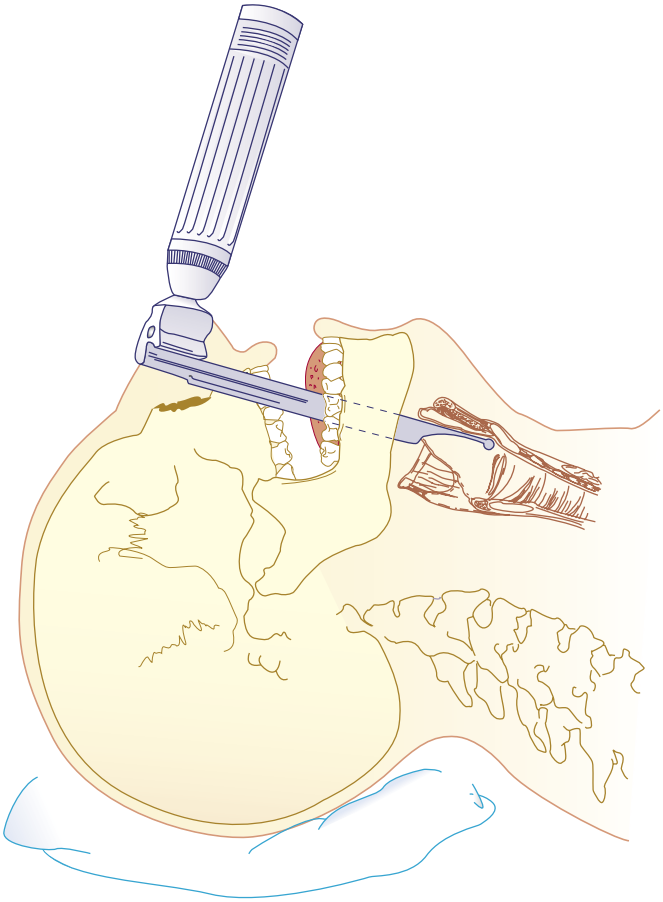

Figure 50-11 Straight laryngoscope in position. The laryngoscope tip is posterior to the epiglottis, which is elevated directly. The tip of the laryngoscope is close to the anterior commissure of the vocal cords. *(From Key Topics in Airway Management, Cambridge University Press.)*

not visible. The major problem with the Miller laryngoscope is that its cross section impedes passage of the tracheal tube. Straight laryngoscopes have been designed to overcome problems with the Miller laryngoscope. The Belscope is a narrow angulated straight laryngoscope with a low profile and an atraumatic tip that was designed to reduce contact with the maxillary teeth. The efficacy of the Belscope when the larynx cannot be seen with the Macintosh laryngoscope has been confirmed. The C-shaped cross section of the Henderson laryngoscope facilitates the passage of tracheal tubes.

Indirect Laryngoscopy: Theoretical Basis

In some patients, direct laryngoscopy cannot provide a view of the larynx. Optical devices have been developed to facilitate tracheal intubation under vision with technology that transmits the image from a distal lens to the proximal end of the device. Because the proximal end of the line of sight is transferred from above the maxillary teeth to the laryngopharynx, a view of the larynx is obtained from a position that cannot be achieved with direct laryngoscopy. Visualization of the larynx without the need to distort the tissues (displace the tongue to the left) or to use head extension becomes possible. Lower laryngoscope lifting force may be needed than is the case with direct laryngoscopy. Consequently, these techniques can be used readily with topical anesthesia in an awake patient. Indirect laryngoscopy allows tracheal intubation under vision in patients in whom this is not possible with direct laryngoscopy. Many devices have been designed, and features of the ideal technique are shown in Box 50-7. No single technique meets all these criteria.

Separation of anatomic structures beyond the distal lens is essential to provide adequate vision. Separation may be achieved by maneuvers such as jaw thrust (not normally necessary in an awake patient), displacement by the device itself (many RILs), or simultaneous use (frequently in the case of optical stylets [OSs]) of a laryngoscope. Problems with condensation, blood, and secretions are common to all these devices. Modern indirect laryngoscopes can be divided into flexible (FFLs) and rigid devices (RILs). Each group has advantages and disadvantages.

Flexible Fiberoptic Laryngoscope

The FFL uses flexible optical fibers to transmit images from a distal lens as it is steered under vision toward the larynx and into the trachea.[66] A typical FFL is shown in Figure 50-12. The insertion cord contains bundles of optical fibers that transmit the image, a different group of optical fibers that transmit light to the distal end, and cables from a control lever in the handpiece that flex and extend the distal section. The hollow channel can be used for aspiration of secretions or instillation of local anesthetic. The simplest FFLs have a proximal eyepiece. The image can be displayed on a monitor by attaching a camera to the eyepiece or by using an FFL with an integral camera. Some models have a distal video chip from which the image is transmitted electronically to a video display, so a more accurate term is "flexible video laryngoscope," but they function as FFLs and this term is used for simplicity. Use of video monitors incurs greater expense than

Box 50-7 Characteristics of the ideal laryngoscope technique for tracheal intubation

- Facilitates rapid tracheal intubation under vision
- Used with the patient in a neutral position
- Minimal tissue distortion required
- Tracheal tube passage integrated in design and technique
- Few steps involved in a technique that is intuitive
- Competence can be gained rapidly
- Equipment simple, robust, portable, and inexpensive
- High success rate in all clinical situations
- Preparation time should be minimal
- Sterilization easy and effective (or the device should be single-use type)
- Illumination good
- Optical device characteristics
  - Sufficient optical quality
  - Fogging of lens unlikely

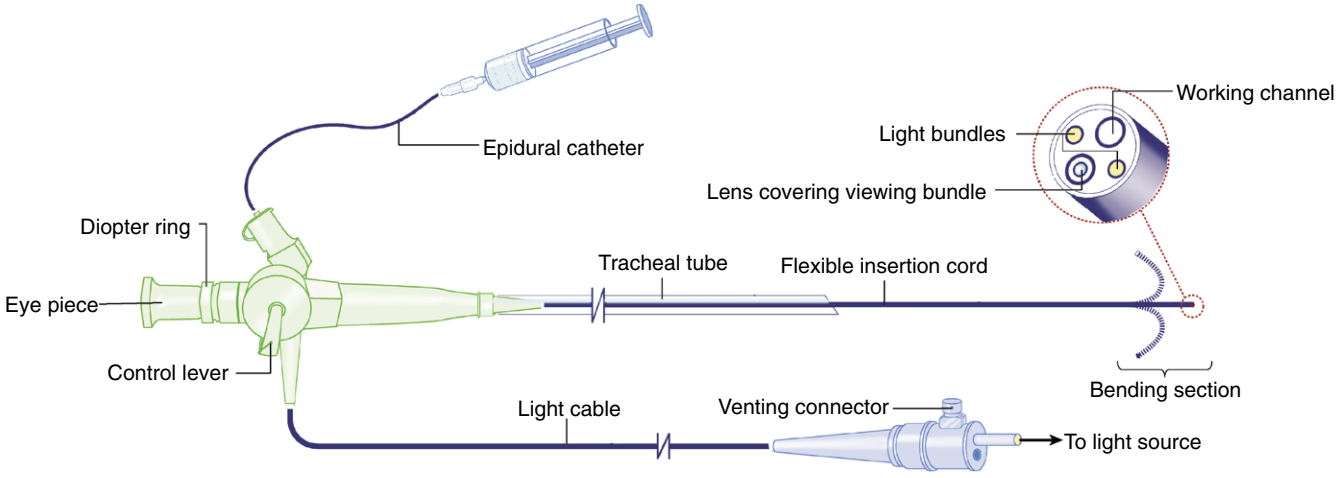

Figure 50-12 Flexible fiberoptic laryngoscope.

reliance on eyepieces, but they facilitate teaching and ease of use and may improve success rates.

The FFL is the most versatile laryngoscope (Box 50-8) for tracheal intubation and can facilitate intubation that could not be achieved with any other technique. Some advantages are shown in Box 50-9. A high success rate can be achieved.[67,68] Its use in patients with anticipated difficult intubation significantly reduces the number of complicated intubations and the incidence of intubation trauma and postoperative upper airway edema. The FFL in expert hands is well tolerated by an awake patient. Awake flexible fiberoptic laryngoscopy is the safest noninvasive means of securing a critical airway.[68] It is indicated in many situations, some of which are presented in Box 50-10. A low threshold for use of awake flexible fiberoptic intubation in emergency patients is particularly important inasmuch as the option of postponing surgery and awakening the patient is not available.

Neither deep sedation nor general anesthesia should be used when the airway is compromised.[27] When the patient is alert, ventilation, oxygenation, and airway protection are maintained. Normal pharyngeal tone is preserved, so there is sufficient space between structures to facilitate vision several centimeters beyond the distal lens. Phonation, which can help identify the larynx, is possible. Options are preserved. Because some patients will not tolerate awake flexible fiberoptic laryngoscopy, sedation or general anesthesia may be necessary, but there are risks of hypoventilation, upper airway obstruction, and hypoxemia. The ideal sedative would have little effect on spontaneous ventilation and allow patients to protect their airway. Dexmedetomidine may provide effective and safe sedation in apprehensive or combative patients. Remifentanil infusions have been used, but careful monitoring is essential to prevent hypoventilation and hypoxemia.

Box 50-8 Versatility of the Flexible Fiberoptic Laryngoscope

- Flexible and steerable
- Minimal tissue pressure and trauma
- Continuous visualization
- Oral or nasal route possible
- Other intubating devices may facilitate combination techniques
- Visual confirmation of the depth of intubation on withdrawal

Box 50-9 Advantages of Awake Patient State for Flexible Fiberoptic Laryngoscopy

- Spontaneous breathing continues
- Oxygenation and ventilation maintained
- Intubation easier
- Anatomy and muscle tone preserved
- Phonation as a guide
- Safety
- Airway protection preserved
- Options preserved

Technique

The technique is summarized in Box 50-11. The patient's position may be supine, semisupine, or sitting (Fig. 50-13), and the anesthesiologist may face or work from behind the patient. These choices are influenced by clinical requirements and personal preference. Use of the fully upright sitting position has been recommended when pulmonary aspiration is a consideration.

The FFL may be passed through the nose or mouth. The nasal cavity acts as a conduit that provides good alignment with the larynx as the FFL passes from the nasal cavity to the pharynx. Use of conduits such as tubular oropharyngeal airways[69] (e.g., Williams, Ovassapian, Bermann II), the intubating LMA (ILMA), or the AIT through other SADs may facilitate passage of the FFL through the mouth. These techniques keep the FFL in the midline and deliver its tip to the laryngopharynx. They also protect the FFL from biting. The gag reflex is more troublesome with the oral than with the nasal route. Experience in other fields of medicine and dentistry shows that gagging can be managed by hypnosis, control of hyperventilation, acupressure, or sedation with nitrous oxide or propofol.

Proper preparation contributes greatly to successful awake use of the FFL. Rapport with the patient and good topical anesthe-

Box 50-10 Indications for Flexible Fiberoptic Laryngoscopy

- Anticipated difficult tracheal *intubation*
- Anticipated difficult mask *ventilation*, including seep apnea
- Anticipated difficult *rescue* technique
- Confirmation of tracheal tube position
- Diagnosis of malfunction of a supraglottic airway device
- Cervical spine instability (the rigid indirect laryngoscope is an alternative)
- Positioning of a double-lumen tube and bronchial blocker
- Assessment of swelling or trauma after difficulty with airway management
- Tracheal tube change (between the nasal and oral routes)
- Intensive care use, including aspiration of secretions and confirmation of the dilatational tracheotomy site

Box 50-11 Flexible Fiberoptic Laryngoscopy Technique

- Drying agent
- Effective topical anesthetic
- Equipment check: lenses clean and focused, antifog agent applied
- Tracheal tube mounted
  - On the flexible fiberoptic laryngoscope for the nasal route
  - Within the oral airway for the oral route
- Patient position: supine, semisitting, or sitting
- Rapport: full explanation
- Flexible fiberoptic laryngoscope technique
  - Insertion cord kept straight and the scope maneuvered in three planes
  - Tip flexion-extension, rotation, and advance-withdrawal
  - Secretions aspirated
  - White-out, red-out, or loss of target—withdraw, indentify structures, readvance
  - Targets (epiglottis, vocal cords, tracheal cartilages, carina) kept in the center of view as the flexible fiberoptic laryngoscope is advanced
  - Advance to close to the carina
  - Tracheal tube passed over the flexible fiberoptic laryngoscope
  - Tube position confirmed and secured and anesthesia induced

sia of the airway are important. A drying agent (such as atropine or glycopyrrolate) may be given before the application of topical anesthesia to the airway to increase its efficacy and minimize problems with visualization caused by secretions. A vasoconstrictor is sprayed into the nose when the nasal route is planned. Equipment preparation includes checking the optics, cleaning and antifogging of the distal lens, passage of an epidural catheter through the working channel, and lubrication of the insertion cord. The tracheal tube is normally mounted on the FFL before NTI but may be positioned with the tip in the oropharynx before passage of the FFL.

General care of the patient during intubation is important, particularly maintenance of airway patency and oxygenation.[66] Insufflation of oxygen down the working channel of the FFL has been advocated to increase F_{IO_2} and keep the lens clear of secretions but has caused barotrauma and is not advisable. Oxygen should be administered nasally or via facemask, and the oximeter beep should be audible.

The principles of FFL manipulation are simple.[66] The basic maneuvers of flexion and extension of the tip combined with rotation of the insertion cord make it possible to steer the FFL under vision around tissues as it is moved toward the larynx and trachea. The external portion of the insertion cord must be kept

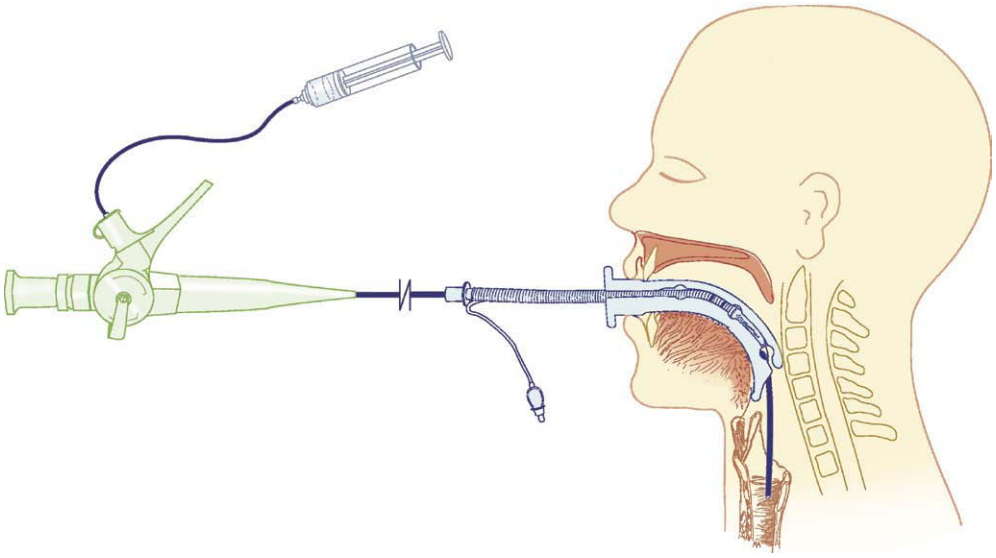

Figure 50-13 A flexible fiberoptic laryngoscope inserted through a Bermann airway in a patient in the sitting position. An epidural catheter attached to a syringe has been passed through the working channel. The tracheal tube has been placed within the airway and the fiberoptic laryngoscope is advanced under vision between the vocal cords and into the trachea.

straight during manipulation so that rotation of the handpiece is transmitted to the distal end. Movements should be gentle and fine. The FFL is advanced while keeping the target in the center of the image as the FFL moves toward the epiglottis, vocal cords, tracheal rings and muscle, and carina. The FFL is passed into the distal portion of the trachea and the tracheal tube then passed over it into the trachea as the patient is asked to inhale deeply. As soon as tracheal intubation is confirmed, the FFL should be withdrawn in an awake patient because respiration will be significantly obstructed while the FFL remains within the tracheal tube. However, premature removal of the FFL during passage of the tracheal tube can result in dislodgement of the tube and esophageal intubation. Tracheal intubation is confirmed by visualization of the carina close to the end of the tracheal tube, and this distance is adjusted to 3 to 4 cm. Additional confirmation of tracheal intubation with capnography is mandatory before anesthesia is induced.

The FFL technique is straightforward in most patients but may be difficult in those with distorted anatomy or very limited space. Jaw thrust may help in the latter situation. An opaque red view implies contact of mucosa or blood with the lens, and a white view is caused by secretions. If sight of the target is lost, the FFL should be withdrawn, the target identified, and the FFL advanced again.

In situations in which use of the FFL alone proves difficult, combination with other techniques may be successful. A retrograde guide can be threaded up the working channel of an FFL on which the tube had been mounted and the combined assembly then advanced to the cricothyroid membrane before the guide is removed. Alternatively, passing the FFL alongside a retrograde guide within a tracheal tube and then advancing the FFL to the carina to act as an introducer may be particularly reliable. Direct or indirect rigid laryngoscopy may be used with the FFL. Use of a capnograph as a guide has been described.[70] Use with SADs is described later.

Tracheal Tube Passage Issues

Difficulty passing tracheal tubes over a properly positioned FFL is common and can result in hypoxemia or airway trauma and be a threat to life.[50] The principal sites that obstruct passage of the tracheal tube are the interarytenoid notch and the right arytenoid cartilage and epiglottis, plus obstruction within the nasal cavity when that route is used.[50] A technique involving withdrawal of the tracheal tube 1 to 2 cm, 90-degree anticlockwise rotation, and readvancement often achieves tracheal intubation in these cases.[50] Jaw thrust may help steer the FFL into the trachea but can obstruct subsequent passage of the tracheal tube, so the thrust should be reduced after the tracheal tube has passed the larynx.[50] Force must not be used during attempts to pass the tracheal tube.

All measures should be taken to ensure that the first attempt at passage of the tracheal tube is likely to be successful.[50] Tracheal tube factors that can increase success of passage include a small gap between the tracheal tube and the FFL[50] and the type of tracheal tube.[50] Although use of a warmed standard tracheal tube has been recommended, it is not clear how long it retains increased softness, there is no evidence that it is better than an armored tracheal tube, and the risk of kinking may be increased. There is some disputed evidence that armored tubes pass more readily than standard tracheal tubes over the FFL into the trachea. Tracheal tubes with tips modified to facilitate passage into the trachea are of proven value and may be the current tracheal tubes of choice.

Limitations of the Flexible Fiberoptic Laryngoscope in Unanticipated Difficult Intubation

Use of the FFL in anesthetized patients immediately after failure of direct laryngoscopy can be difficult (Box 50-12). The flexibility that contributes to the versatility of the FFL in elective patients can be disadvantageous because rapid control of the tip's position is not possible. Use of the nasal route in an unprepared patient risks epistaxis, which is particularly hazardous in this situation. Oral fiberoptic intubation is preferable, but jaw thrust, tongue traction, or concomitant use of a direct laryngoscope may be required unless a conduit is used. Use of a tubular oral airway can be very successful when staff are well trained.[46] The airway must be kept in the midline and directed toward the larynx. Fiberoptic intubation through the ILMA or LMAc has been recommended in guidelines.[52] Use of the FFL through the ILMA is usually successful, but failures do occur.[71] Use of the Aintree or similar catheter with the LMAc is another good alternative.[72] Use of the FFL in a patient with an unanticipated difficult airway requires immediate availability of a sterile FFL.

Contraindications and Complications

There are no absolute contraindications to use of awake flexible fiberoptic laryngoscopy. It cannot be performed without patient cooperation. Awake intubation with the FFL is unlikely to work in the presence of massive airway bleeding, although the LMA can provide an effective conduit.

The arytenoid cartilage can be displaced, even when tube advancement seems atraumatic. Laryngeal damage is more likely when multiple efforts at passage of the tracheal tube are made, but such damage is less frequent and less serious than in patients managed with direct laryngoscopy. Morbidity and mortality associated with use of the FFL have been reported in closed claims.[43] Complete airway obstruction during "awake" fiberoptic intubation in patients with a critical airway has been reported, but heavy sedation and incomplete topicalization were blamed.[27] Awake flexible fiberoptic laryngoscopy is safe in a critical airway when expertly used.[68]

Box 50-12 Problems with the Flexible Fiberoptic Laryngoscope Technique in Unanticipated Difficult Intubation*

- High skill level needed for rapid control of the tip of the laryngoscope
- Two skilled practitioners needed
- Equipment often not ready (time)
- Secretions, edema, and hemorrhage
- Airway less open than when awake—jaw thrust and/or dedicated oral airway needed
- Cricoid pressure impeding entire procedure
- Tracheal tube passage difficult
- Patient risks: hypoxemia, hypoventilation, and pulmonary aspiration

*Patient anesthetized and paralyzed.

Rigid Indirect Optical Devices

The rigidity of rigid indirect optical devices allows rapid control of the position of the tip of the device at the expense of reduced versatility in comparison to flexible devices. They are also less expensive and more robust and portable than the FFL. They may be subdivided into RILs and OSs.

The blade of an RIL can retract tissues to achieve a line of sight from the distal lens, and this ability can be important when there is little space in the oropharynx and laryngopharynx. OSs are optical devices that fit inside the tracheal tube.

The term "video laryngoscope" has been used by manufacturers of devices that differ in many features. "Video laryngoscope" is not a good description for these devices because the display is not the key element in their success. However, video systems have advantages. They are of proven value for teaching flexible fiberoptic intubation and RIL technique[73] and may improve success rates. Ease of use is better because anesthesiologists do not need to follow the eyepiece with their head. Observation of structures throughout insertion and removal is facilitated. The video display facilitates help by assistants, who observe the effect of manipulations. Video tapes of the intubation can be reviewed later.

Rigid Indirect Laryngoscope

RILs vary greatly in features and technique. Most RILs have a distal curve that is designed to match the anatomic curve between the oral and pharyngeal portions of the tongue. Technologies used to transfer the image from the distal lens include lenses and prisms (e.g., Airtraq, TruView), fiberoptics (e.g., Bullard, Upsherscope, WuScope), and electronic transmission from a video chip to a monitor (e.g., Glidescope, McGrath, Pentax AWS). They may be used with the head and neck in a neutral or "sniff" position. The recommended technique of elevation of the epiglottis may be direct or indirect. Direct elevation is more likely to be successful in the presence of lingual tonsil hypertrophy or other laryngeal lesions. The technique of tracheal tube passage is integrated into the design of some RILs. NTI guided by RILs is a very useful technique that overcomes the problems of passage of the oral tracheal tube inherent in some RILs.

The Bullard laryngoscope, the first RIL, was introduced in the late 1980s. Very high success rates have been achieved in patients in whom the larynx cannot be seen with the Macintosh laryngoscope.[47] Techniques can be divided into different stages. The technique with the Bullard laryngoscope is illustrated in Figure 50-14. Most RILs are rotated over the dorsum of the tongue from the oropharynx into the laryngopharynx. Once the tip of the RIL is in the appropriate position in relation to the epiglottis, a lifting force is applied to elevate the epiglottis. Visualization of the larynx is optimized by adjustment of the lifting force and position of the RIL.

The technique of tracheal tube passage depends on the design of the RIL. Integrated tube passage may be accomplished with either a dedicated stylet attached to the RIL or a channel for the tube. Exit of the tube from such a stylet or channel is designed to converge with the line of sight a few centimeters distal to the lens. The tube is guided in a lateral or posterolateral direction to the RIL and is sometimes impeded by the right posterior cartilage or aryepiglottic fold. This problem can be overcome by manipulating the RIL so that the vocal cords are to the right of the center of the image and by leaving sufficient space between the tube and the aryepiglottic fold. An introducer with an angulated tip can be inserted within tubes passed through a dedicated channel to further facilitate passage into the trachea.

Some RILs do not have an integral tracheal tube passage system, so use of a detached stylet to create an optimal shape for delivery of the tracheal tube to the glottis is recommended. Both a "hockey stick" shape and a curvature that matches the RIL have been advocated, as have adjustable stylets. Passage of detached styletted tracheal tubes with RILs is likely to be inherently difficult, but performance improves with experience. The vector of advancement of oral tracheal tubes into the larynx is about 90 degrees from the direction of the force applied to the proximal end of the tube. Although good results have been reported, tracheal intubation can fail when the larynx is visible and multiple attempts at passage of the tracheal tube have been required.[74] Damage to the palatopharyngeal folds and palate by blind passage of detached styletted tracheal tubes through the mouth has been described. A technique that involves looking in the mouth when passing the Glidescope, at the monitor when optimizing its position, at the mouth again when passing the styletted tracheal tube into the pharynx, and then at the monitor when passing the tracheal tube into the trachea has been recommended[75] to reduce the risk of soft tissue damage.

There is good evidence of the efficacy of RILs in many situations. They should be accepted as a necessary alternative to direct laryngoscopy and should be included in plan A (initial tracheal intubation plan) for the management of unanticipated difficult intubation. They may also be useful in anticipated difficult direct laryngoscopy in an uncooperative patient, when an FFL is not available, and possibly when a minor degree of difficulty with direct laryngoscopy is anticipated. Their advantages of minimal neck movement and more reliable view of the larynx than with direct laryngoscopes are strong indications for use in patients with an unstable cervical spine if an FFL is not available.[57,76]

Optical Stylets

OSs are robust and portable stylets that incorporate a distal lens and optical system. They may be rigid or malleable or have a tip that can be flexed and extended. The tracheal tube is mounted on the stylet and advanced under vision for a variable distance into the larynx. The stylet is then held in place while the tracheal tube is advanced into the trachea. Midline or lateral routes may be used.[77] OSs cannot retract tissues, and failure to identify anatomic structures has been reported. Vision beyond the lens may be improved by separating the pharyngeal structure with the jaw-thrust maneuver,[76,77] displacing the tongue and opening the pharynx with a Macintosh or McCoy laryngoscope, or using anterior traction on the tongue.[77] Use of jaw thrust combined with a direct laryngoscope may be necessary in the most difficult patients. Recessed positioning of the tip within the tracheal tube may help keep secretions or blood off the tip. A high success rate in unanticipated difficult intubation has been reported,[78] but some find the technique difficult. It has been used successfully for passage of double-lumen tubes and in patients in whom use of the FFL proved difficult. In a patient with cervical spine injury, an OS may be better than the Macintosh but not as good as an RIL.[76] OSs have been used successfully in awake patients.

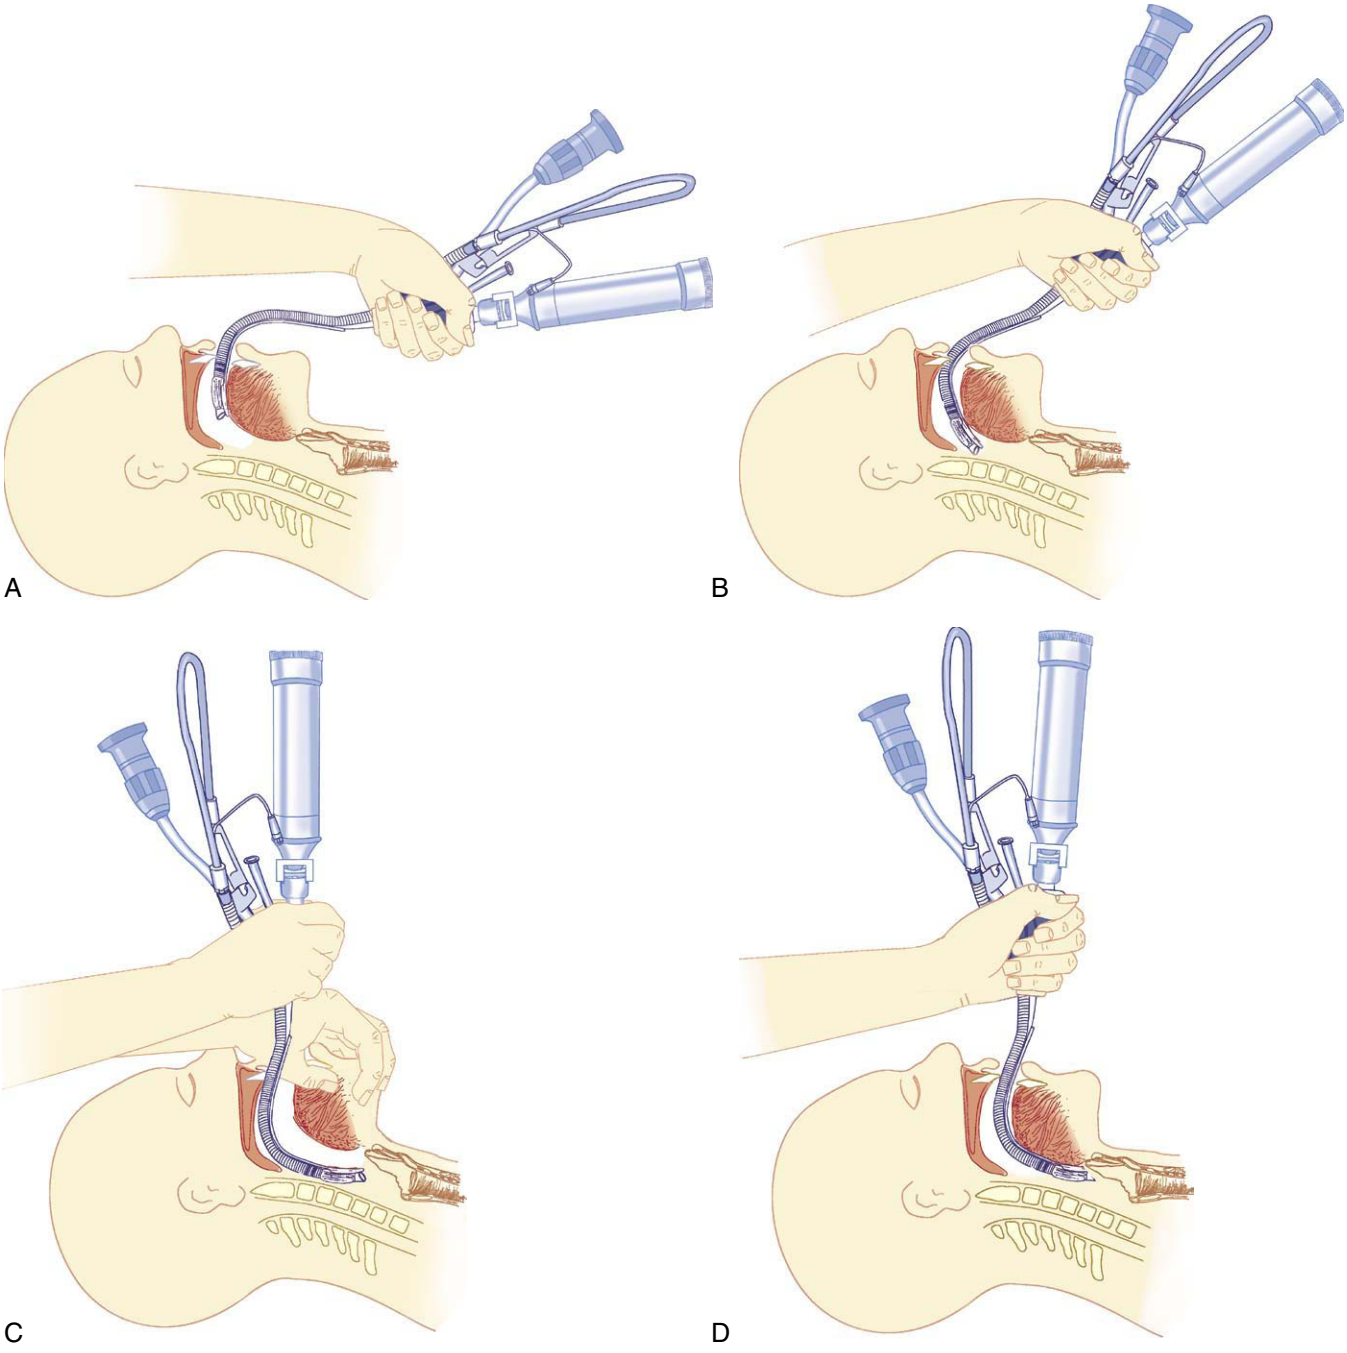

Figure 50-14 Insertion sequence for the Bullard laryngoscope. **A,** Start position with the Bullard handle close to the chest and the tip within the mouth. **B,** Midway through rotation of the Bullard laryngoscope. **C,** Rotation of the Bullard laryngoscope is complete, with the tip lying on the posterior pharyngeal wall and the handle vertical. The anesthesiologist has used a jaw thrust to increase space behind the tongue. **D,** The anesthesiologist seeks and optimizes the view of the larynx. The Bullard laryngoscope has been moved anteriorly so that the tip lies posterior to and elevates the epiglottis.

Tracheal Intubation through the Laryngeal Mask Airway

The LMAc has been used to facilitate tracheal intubation in both elective and rescue situations. Blind techniques have a low success rate and a significant risk of causing airway trauma. However, passage of a tracheal tube mounted on an FFL through the LMA can achieve a high tracheal intubation success rate with minimal risk of trauma,[79] but the widest tracheal tube that will pass down a size 3 or 4 LMA is 6 mm (ID). The tracheal tube must also be long enough for the cuff to lie 2 cm beyond the vocal cords when the proximal end is level with the LMA connector. A 6-mm (ID) microlaryngeal tube is particularly satisfactory because it is sufficiently long and the cuff diameter is suitable for adult patients. However positive-pressure ventilation during fiberoptic intubation through a size 3 or 4 LMA with a 6-mm tracheal tube is unsatisfactory because of the restricted air channel between the

tube and the LMA.[80] Techniques for subsequent LMA removal have been described, but they may fail and expose the patient to the danger of accidental extubation. The AIC (Fig. 50-15) is used in a two-stage fiberoptic technique that facilitates insertion of a wider tracheal tube and safe removal of the LMA.[72] This hollow guide is 56 cm long and fits snugly over a standard (narrower is recommended) FFL, apart from its controllable tip. The AIC is mounted on the FFL, and the combined unit is steered under vision through the LMA and into the trachea. When the tip of the AIC reaches the lower portion of the trachea, the LMA and FFL are withdrawn and a tracheal tube (7 mm or larger) is then passed over the AIC. The technique is mastered rapidly. The AIC has been used successfully with other SADs.

Intubating Laryngeal Mask Airway

The ILMA (Fastrach) was designed as a conduit for tracheal intubation to facilitate ventilation between attempts at tracheal intubation.[71] The rigid handle and airway tube enable rapid and precise control of mask position. The 13-mm ID allows passage of a tracheal tube as wide as 8 mm (ID). An epiglottic elevating bar is designed to elevate the epiglottis as the tube is advanced into the bowl. Single- and the original multiple-use versions of the ILMA are available. Dedicated reusable or single-use tracheal tubes are designed to facilitate atraumatic blind intubation through the ILMA. The tubes are straight, reinforced with wire, and have a soft molded tip with the leading edge close to the midline. The reusable tube has a low-volume, high-pressure cuff, whereas the single-use tube has a high-volume, low-pressure cuff. Standard polyvinyl chloride tracheal tubes should not be used for blind intubation through the ILMA because they exert much higher tissue pressure as they exit from the ILMA and repeated attempts at passage may cause serious damage to the esophagus.

The technique of insertion of the ILMA differs in many respects from insertion of the LMAc, and there is a significant learning curve. A "neutral" head position (nonextended head on a support) is recommended. The ILMA handle is used to rotate the mask into the pharynx. Oxygenation, ventilation, and anesthesia are stabilized after insertion. If resistance to ventilation is encountered, the position of the ILMA is adjusted. The "up-down maneuver" is recommended for management of a down-folded epiglottis, but prior jaw thrust may be needed. The "Chandy maneuver" consists of two separate maneuvers: The ILMA is rotated in the sagittal plane until resistance to bag ventilation is minimal. The ILMA is then lifted gently from the posterior pharyngeal wall just before passage of the tracheal tube. The value of the Chandy maneuver is disputed. Passage of the tracheal tube should be performed gently. The ILMA should be removed soon after tracheal intubation has been verified because its rigidity results in high pressure on adjacent tissues.

A high success rate can be achieved. However, the technique of tracheal tube passage is blind, several attempts may be required, and esophageal intubation can occur. Laryngeal and esophageal damage has been reported. The risk of failure is increased in the presence of laryngeal lesions and previous cervical radiotherapy. Intubation under vision with the FFL through the ILMA achieves higher first-attempt and overall success rates than blind techniques do.

The ILMA is the SAD of choice for blind tracheal intubation and is of proven value as a rescue device in cases of unanticipated difficult intubation. However visualization of the larynx through the ILMA is not as good as that achieved with the LMAc.[81] Use of the ILMA may be difficult if mouth opening is restricted or the glottis is displaced. Use of the ILMA in an "awake" patient when difficulty with tracheal intubation is anticipated has been reported. Awake intubation through the ILMA has few advantages and some disadvantages in comparison to awake FFL intubation through a tubular oropharyngeal airway.[69]

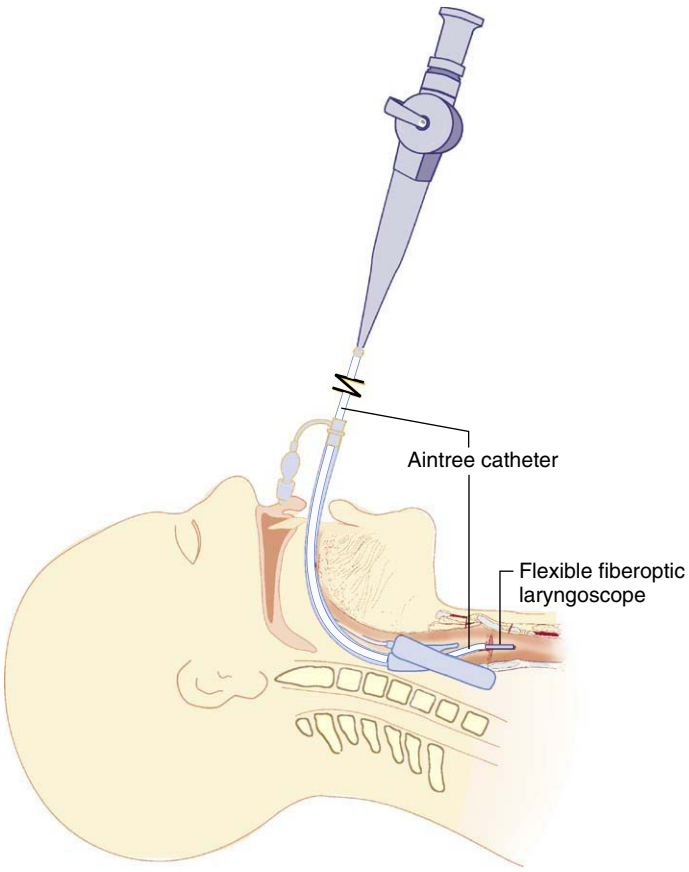

Figure 50-15 Aintree intubating catheter within a flexible fiberoptic laryngoscope, inserted through a laryngeal mask airway and advanced into the trachea.

C-Trach

The C-Trach is a variation of the ILMA that uses fiberoptic bundles to transmit an image from within the bowl of the mask and provides illumination through a light bundle. A separate unit that contains a camera, video display, and source of illumination is attached after insertion of the C-Trach. The display facilitates optimum positioning of the device, but the view remains poor in some patients.[82] Tracheal intubation under vision has been achieved with the C-Trach after failed intubation attempts with the FFL or ILMA,[82] including a case of undiagnosed lingual tonsil hypertrophy. The image is not as good as that produced by a conventional FFL,[82] with problems including secretions, inadequate light intensity, and obstruction of the view by the epiglottis.[83] However, the C-Trach is a relatively portable, inexpensive system that can be prepared rapidly and facilitates ventilation between attempts at passage of the tracheal tube.

Retrograde Intubation

The retrograde technique of intubation consists of percutaneously passing a narrow flexible guide into the trachea from a site below the vocal cords and advancing this guide through the larynx and out the mouth or nose. In the basic technique, the tracheal tube is then passed over the guide into the upper part of the trachea, the guide is removed, and the tube is advanced into the trachea (Fig. 50-16). Guides may emerge from the mouth or nose. If nasal intubation is planned and the guide comes out of the mouth, a soft catheter can be passed through the nose, retrieved from the mouth, and then used to bring the guide out through the nose. Guides used have included plastic introducers, epidural catheters, steel guidewires, and sutures. These guide materials have different properties, but their clinical efficacy has not been compared. Passage of an epidural catheter through the larynx has been successful after failure with a guidewire, and it is easier to retrieve a plastic guide than a steel guidewire from the mouth. Guidewires are a better choice for use with the FFL. The technique can be performed under topical anesthesia in a sedated patient.

Details of the technique are important. Neck extension facilitates access to the cricothyroid membrane. The guides are inserted through a needle or cannula that is inserted horizontally (so that the vocal cords are not damaged) with the bevel directed cephalad. The intratracheal position of the initial needle should be confirmed by aspiration of air. Jaw thrust and tongue traction can facilitate passage of the guide behind the tongue.

A number of problems with the retrograde technique have been reported and variations have been developed (Fig. 50-17) to improve reliability. The most frequent problem is that the tracheal tube springs into the esophagus after the guide is removed, which is a consequence of the location of the cricothyroid membrane (Fig. 50-18) only 1 cm below the vocal cords. Passage of a wider, stiffer plastic sheath over the guide to act as an introducer for the tracheal tube improves reliability. Excessive tension on the guide may pull the tracheal tube anteriorly, thereby causing misalignment and increasing the risk that the tube will be impeded by the epiglottis or other laryngeal structures. Retrograde intubation through the nose has succeeded when the oral route failed, probably because impingement on the anterior glottis is less likely. Use of the subcricoid (cricotracheal) instead of the cricothyroid space may improve reliability at the possible cost of a greater risk of bleeding. The guide may be threaded through the Murphy eye and then passed up through the proximal lumen of the tracheal tube. Pulling the tube after tying a knot inside the Murphy eye has succeeded when other techniques have failed.[84]

The retrograde technique has some disadvantages. It is invasive and advancement of the tracheal tube is blind. It involves several steps and can take some time. The most frequent complications are minor bleeding, subcutaneous emphysema, pneumomediastinum, and infection. Contraindications include coagulopathy, inability to identify landmarks, laryngeal disease, and local infection. Some have achieved high success rates with the retrograde technique,[84] but others have recorded low success and significant complication rates.[85]

The great merit of the technique is its simplicity. It has little place in elective practice in advanced hospitals. It may be the technique of choice when the patient has pharyngeal bleeding and intubation is anticipated to be impossible. It is useful when awake intubation is indicated but sophisticated equipment is not available.

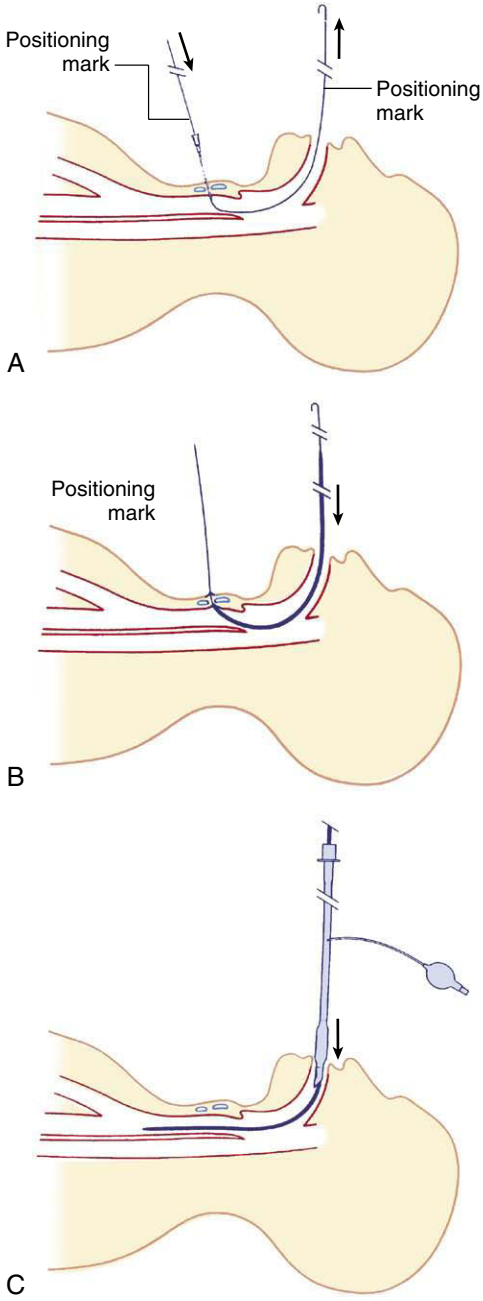

Figure 50-16 Retrograde intubation with the Cook Retrograde Intubation Set. **A,** After placement of an 18-gauge sheath needle into the larynx, the J end of the guidewire is inserted in a cephalad direction until it exits the mouth or nose. **B,** An 11.0 Fr Teflon catheter is threaded down over the guidewire until it contacts the laryngeal access site. The guidewire is removed from above. **C,** After advancing the Teflon catheter 2 to 3 cm, the endotracheal tube is advanced into the trachea while maintaining constant control of the catheter. *(Courtesy of Cook Critical Care, Bloomington, IN.)*

Lighted Stylet (Light-Guided Intubation)

The term "lighted stylet" may be used to describe any device that uses a bright light within the tip of a tracheal tube as a guide to

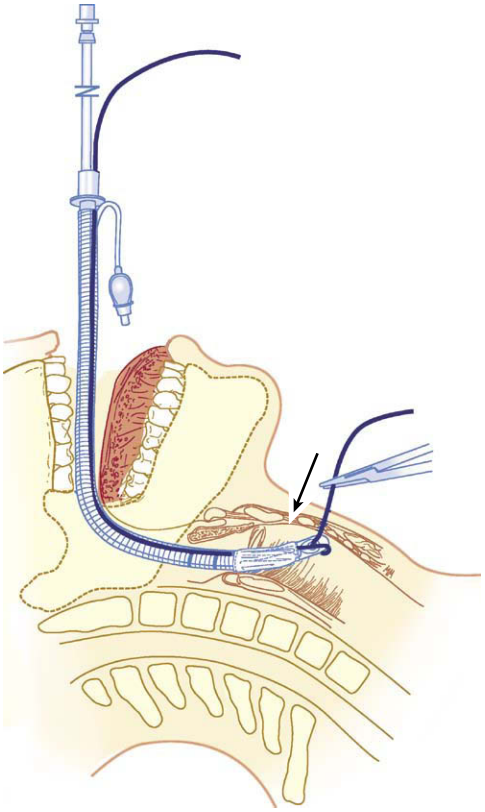

Figure 50-17 Variations on the retrograde technique. The cricothyroid membrane is indicated with an *arrow*. The guide has been inserted through the cricotracheal space, passed in a loop through the Murphy eye of the tracheal tube, and used to pull it toward the cricotracheal membrane. A hollow catheter has been passed through the tracheal tube for passage into the trachea to act as an introducer. These variations may not be used simultaneously in clinical practice.

facilitate tracheal intubation.[86] The technique depends on interpretation of the light transmitted through the skin of the neck to indicate the position of the tip of the tracheal tube. When the tip is at the larynx, the light should be in the midline, and its position in the longitudinal plane indicates its position in relation to the laryngeal cartilage. As the light passes more distally, a localized glow indicates a tracheal position and a diffuse glow indicates an esophageal position.

There is a significant learning curve, but high success rates with few complications can be achieved by those who use the technique regularly in routine practice.[87] It can be used with oral or nasal intubation, with double-lumen tubes, or in conjunction with other devices such as the LMA or ILMA. Successful use in many difficult airway conditions has been described,[87] including cervical spine disorders and intubation in the lateral position. Good success rates achieved after the use of NMBDs could not be repeated in nonparalyzed patients, in whom the incidence of adverse effects was not considered acceptable.[88] Causes of failure include poor illumination as a consequence of obesity[88] or skin pigmentation, resistance to advancement of the tracheal tube, and events such as coughing, hypoxemia, and esophageal intubation.[88] The technique is particularly difficult in the presence of cricoid pressure. It is a blind technique that can damage the larynx. Contraindications include airway tumors, infection, trauma, and foreign bodies.

Physiologic Response to Tracheal Intubation

Direct laryngoscopy and passage of a tracheal tube are noxious stimuli that can provoke adverse responses in the cardiovascular, respiratory, and other physiologic systems.

Significant hypertension and tachycardia are associated with tracheal intubation under light anesthesia. The magnitude of the response is greater with increasing force and duration[10] of laryngoscopy. The elevation in arterial pressure typically starts within 5 seconds of laryngoscopy, peaks in 1 to 2 minutes, and returns to control levels within 5 minutes. Such hemodynamic changes can result in myocardial ischemia but seem to cause little harm to most patients. However they are undesirable in patients with cardiac disease.

It is possible to separate the factors that contribute to the hemodynamic response. Hemodynamic changes start within seconds of direct laryngoscopy, and there is a further increase in heart rate and blood pressure with passage of the tracheal tube. Tracheal intubation through the ILMA causes a hemodynamic effect similar to that caused by direct laryngoscopy.[89] When orotracheal intubation or NTI is performed with the FFL under general anesthesia without topical anesthesia of the airway, hemodynamic changes are similar to those seen with the direct laryngoscope.

Many techniques have been tried in an effort to attenuate adverse hemodynamic responses to intubation, but none is ideal. Prevention by use of an increased depth of anesthesia is attractive in theory. However, changes in the concentration of anesthetic agents in blood and at effector sites occur slowly in relation to the onset and offset of airway stimuli and hemodynamic responses. Use of N_2O with a volatile agent may be beneficial. Large doses of narcotics (other than morphine), such as fentanyl, 6 µg/kg, suppress the hemodynamic response but risk prolonged respiratory depression. Aerosol or other application of topical anesthetics may be beneficial with a low risk of adverse effects. Application of such topical anesthesia may cause minor adverse hemody-

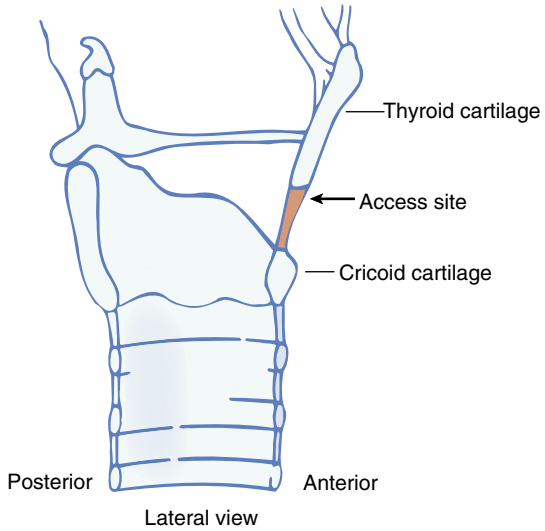

Figure 50-18 Anatomy of the cricothyroid membrane. *(Courtesy of Cook Critical Care, Bloomington, IN.)*

namic effects, much less[90] than those caused by tracheal intubation. Combinations of topical anesthetics with other drugs such as opioids may be useful.

Drugs that act primarily on the cardiovascular system have been studied. Many can reduce either the blood pressure or the heart rate response, but not both, and can cause hypotension or bradycardia. Labetalol and esmolol have been recommended, particularly in combination with narcotics. Use of such drugs is rarely indicated, however.

Another approach to reducing the cardiovascular response to tracheal intubation is to modify the technique of tracheal intubation. Awake flexible fiberoptic intubation with effective topical anesthesia almost eliminates the hemodynamic response to tracheal intubation.

Direct arterial pressure monitoring throughout induction of anesthesia is desirable in a high-risk patient so that the anesthesiologist can respond to accurate, continuous hemodynamic information. Moderate depression of arterial pressure and heart rate before laryngoscopy might limit the rise in arterial pressure at the expense of initial cardiorespiratory depression. Prolonged attempts at laryngoscopy should be avoided. Careful cardiovascular monitoring and willingness to interrupt direct laryngoscopy while anesthesia is deepened are keys to maintenance of reasonable homeostasis.

Respiratory System

Protection of the lungs from pulmonary aspiration is a core function of the upper airway. Laryngospasm is discussed elsewhere. It must be treated vigorously. Bronchospasm accounted for 2% of claims in the ASA Closed Claims Study, half in patients without a previous history of asthma.[64] An increase in airway resistance frequently occurs after tracheal intubation and can be reduced by prophylactic bronchodilator therapy. In patients with asthma, prophylactic steroids and bronchodilators[91] reduce the bronchoconstriction associated with tracheal intubation, as does topical lidocaine with flexible fiberoptic intubation.[92]

Confirmation of Tracheal Intubation

Misplacement of the tracheal tube in the esophagus or right main bronchus is still a major cause of avoidable anesthetic morbidity and mortality.[43] Immediate confirmation of correct tracheal tube placement is an essential and integral part of tracheal intubation. Several tests should be used because no single test is completely reliable.[93] The most important safeguard is clinical suspicion. Visual confirmation of passage of the tracheal tube between the vocal cords is reliable, but not always possible, and experienced anesthesiologists are occasionally misled. The esophageal detector (negative-pressure) test is simple and inexpensive and may be performed before initial ventilation. Air can readily be aspirated from the trachea, but attempted aspiration from the esophagus causes apposition of its walls around the tube so that aspiration of air is not possible. A syringe or self-inflating bulb may be used. It is particularly valuable in cardiac arrest and other emergency intubation situations, but misleading results occur, particularly after gastric insufflation and in the presence of pulmonary disease, obesity, and pregnancy. Airway obstruction has been caused by aspiration of mucus into the tracheal tube. It should be regarded as a device to augment other techniques, particularly when capnography is not available.

A gurgling sound with the first inflation suggests esophageal intubation. Auscultation over the epigastrium and axillae is usually reliable, but there are many sources of error[93] and other confirmation must be sought. Identification of CO_2 in the expired gas is the standard for verification of proper tracheal tube placement, and a characteristic waveform over several breaths is sought. However, there are many possible causes of false-negative and false-positive results.[93] Carbon dioxide concentrations are low or zero despite tracheal intubation in very low cardiac output states, severe respiratory disease, and capnograph or other equipment malfunction. A CO_2 waveform may be detected from the esophagus after gastric insufflation during facemask ventilation or ingestion of carbonated beverages, but these CO_2 concentrations decline rapidly with successive breaths. A glottic or pharyngeal position of the tracheal tube tip can give a normal capnograph and acceptable breath sounds but leave the patient exposed to the risk of accidental extubation and inadequate airway protection. Colorimetric devices sensitive to low concentrations of CO_2 may be misinterpreted as tracheal intubation when the tube is in the esophagus. Identification of the tracheal rings and carina through a standard or simplified[94] FFL passed down the tracheal tube provides reliable confirmation of proper position.

Early hypoxemia after tracheal intubation should be regarded as esophageal intubation until proved otherwise. If there is any suspicion of esophageal intubation, the traditional maxim is "*if in doubt, take it out*," but this strategy is not without risk in that a correctly placed tube may be removed from a hypoxemic patient.

Accidental bronchial intubation can occur during intubation or subsequently, especially if head flexion is increased after initial tracheal tube fixation, the diaphragm is elevated by increased intra-abdominal pressure, or a head-down position is used. It can cause serious morbidity. The most important sign is hypoxemia, usually combined with increased airway pressure. Bronchial intubation is suggested by asymmetric chest expansion. Auscultation over both axillae is usually, but not always diagnostic. Absence of breath sounds over one lung, generally the left, strongly suggests bronchial intubation, but pneumothorax and any causes of atelectasis can also produce this picture. The diagnosis can still be difficult in patients with lung disease, and use of the standard or simplified[95] FFL or chest radiography may be necessary.

Unplanned tracheal extubation is a significant cause of morbidity and mortality. The risk is high in patients with facial burns, in whom the tracheal tube should be left long to allow for facial swelling. The tracheal tube is secured after confirmation of satisfactory position so that it will neither come out nor advance into the right main bronchus. Adhesive or tie tape, or both, may be used. Venous congestion caused by tape tied around the neck should be prevented. Proprietary devices are available, and sutures have also been used.

Care During Surgery

When the airway has been secured, any immediate complications of intubation should be treated. TMJ function should be checked immediately after any procedure that involves maximum mouth opening to prevent undiagnosed dislocation.

Careful intraoperative monitoring of the airway is essential because problems during surgery are a cause of morbidity and mortality.[43] Intraoperative tracheal tube obstruction can be caused by biting, kinking, external compression, and secretions or other intraluminal material. The clinical picture of increased airway pressure and hypoxemia may also be caused by bronchospasm, pneumothorax, surgical manipulation, lung collapse, and raised intra-abdominal pressure. Resistance to passage of a gastric tube or suction catheter down the tracheal tube indicates obstruction but not the cause. Examination with the FFL may be needed to make a complete diagnosis.

Leaks in the anesthesia circuit may be caused by disconnection of the circuit, cuff leaks, or supraglottic position of the tube. Disconnection of anesthesia circuit components should be detected rapidly with the capnograph and respiratory volume monitoring. Leakage of air when the tracheal tube cuff is intact may be caused by insufficient depth of insertion of the tracheal tube so that the cuff lies between or proximal to the vocal cords. Cuff pressure is likely to be elevated, and the tube markings will indicate insufficient depth of insertion. The diagnosis can be confirmed by chest radiography or fiberoptic endoscopy. Low-pressure leaks may be due to damage to the cuff, inflation tube, or valve. Valve incompetence can often be managed by insertion of a three-way stopcock. If major leakage from the cuff cannot be managed by cuff inflation, the tracheal tube will need to be changed (preferably over an introducer or airway exchange catheter [AEC]) to prevent hypoventilation or pulmonary aspiration. If intraoperative tube replacement is judged too dangerous, pharyngeal packing may reduce the leak, but airway protection is limited and there is a risk of gastric insufflation. Inadvertent insertion of a nasogastric tube into the trachea is a rare cause of leakage.

Extubation

The tracheal tube (extubation) is removed when it is no longer needed for airway protection. Timing and technique are influenced by the balance between the residual effect of anesthetic drugs and recovery of airway and other reflexes. A significant number of complications (Box 50-13), including death, occur around the time of extubation.[43] The ASA recommends that the anesthesiologist have a preformulated strategy for extubation and management of postextubation problems.[6] Essential components of the strategy include continued administration of oxygen, continued ventilation, and a strategy to facilitate reintubation.

Box 50-13 Complications at Extubation

- Hypoventilation (residual effect of anesthetic drugs and neuromuscular blockade)
- Upper airway obstruction
- Laryngospasm and bronchospasm
- Coughing (wound disruption)
- Impaired laryngeal competence and pulmonary aspiration
- Hypertension, tachycardia, dysrhythmias, myocardial ischemia

Extubation may be performed at different depths of anesthesia, with the terms "awake," "light," and "deep" often being used. "Light" implies recovery of protective respiratory reflexes and "deep" implies their absence. "Awake" implies appropriate response to verbal stimuli. "Deep" extubation is performed to avoid adverse reflexes caused by the presence of the tracheal tube and its removal, at the price of a higher risk of hypoventilation and upper airway obstruction. Straining, which could disrupt the surgical repair, is less likely with "deep" extubation. Upper airway obstruction and hypoventilation are less likely during "light" extubation, at the price of adverse hemodynamic and respiratory reflexes. An alternative strategy of replacing a tracheal tube with an LMA during "deep" anesthesia has been described. However, there are risks of hypoventilation and malposition of the LMA.

Pathophysiology and Pharmacology of Extubation

Restart of respiration after positive-pressure ventilation can be erratic, with apnea occurring in the presence of hypercapnia. Respiratory complications at extubation include pulmonary aspiration, upper airway obstruction, or hypoventilation leading to hypoxemia and laryngospasm. Laryngeal function is impaired, even after use of an LMA,[42] and may be particularly severe after neck and thyroid surgery. The risk of impaired laryngeal function is increased in patients with neurologic or neuromuscular disease. Coughing may be particularly troublesome during "light anesthesia" extubation and cannot be entirely prevented. The frequency of cough may be reduced when the volatile used is sevoflurane. Intravenous alfentanil and lidocaine can also reduce the risk of coughing, as can local anesthetic in the tracheal tube cuff or applied to the airway.

Cardiovascular complications include arterial hypertension (with an associated increase in intracranial and ocular pressure), tachycardia, and dysrhythmias. Pulmonary edema may be caused by myocardial ischemia or by negative intrapulmonary pressure created by respiratory effort during airway obstruction. Marked increases in arterial blood pressure and heart rate occur frequently at the time of "light" extubation. These effects are alarming but normally transient, and there is little evidence of adverse consequences. However, they may cause detrimental increases in intracranial and intraocular pressure after neurologic and ophthalmic surgery. Many techniques can reduce the incidence of these adverse effects. Narcotics, β-adrenergic drugs, and calcium channel blocking drugs have been studied most extensively. The results are conflicting and there is a risk of adverse effects. On the rare occasions when these drugs are indicated, short-acting agents should be used and direct arterial pressure monitoring continued.

Rapid recovery of consciousness shortens the at-risk time during extubation and may reduce morbidity, particularly in obese patients. Avoidance of sedative premedication facilitates rapid recovery. Nitrous oxide, sevoflurane, and desflurane all contribute to rapid recovery, particularly after prolonged procedures. Remifentanil also facilitates rapid recovery, early extubation, and high Spo_2 values on admission to the postanesthesia care unit.

Position

The "sniff position" is the standard position for extubation. Its major advantage is that airway management, including reintubation, is optimized. The "recovery" (lateral) position may be a safer option when there is an increased risk for pulmonary aspiration.

Gravity causes soft tissues and any foreign material in the pharynx to move downward and away from the larynx and fluid to drain out of the mouth, so the risk of upper airway obstruction and pulmonary aspiration is reduced. Preemptive turning of at-risk patients into the recovery position is wise because emergency turning of a vomiting or regurgitating patient creates increased risk for the patient and staff. The combination of the recovery position with awake extubation is recommended for patients at high risk for pulmonary aspiration. If the recovery position cannot be used in such patients, awake extubation is mandatory. Use of the recovery position with minimal stimulation reduces the incidence of laryngospasm, coughing, and desaturation.[96]

Extubation after Uncomplicated Airway Management

Preparations for extubation are shown in Box 50-14. Recovery of neuromuscular function is essential, but confirmation can be difficult. Respiration should be well established and confirmed by capnography and measurement of ventilation. "Preoxygenation" before extubation delays the onset of hypoxemia if upper airway obstruction develops and is recommended. Throat packs must be removed before extubation. Complete airway obstruction caused by biting a tracheal tube as anesthesia lightens can lead to the rapid development of hypoxemia and may be followed by negative-pressure pulmonary edema. Bite blocks reduce but do not eliminate the risk of tracheal tube compression. Insertion of a bite block, if not in place, should be considered as the anesthesia lightens.

Suction of pharyngeal secretions or other material before extubation should reduce the risk of pulmonary aspiration or laryngospasm. Positive-pressure extubation may expel secretions lying above the cuff but should be performed carefully to prevent complications caused by raised airway pressure.

Inability to deflate the cuff may be due to occlusion of the pilot tube. Surgical fixation by sutures or other devices may cause resistance to withdrawal of the tube. Force should not be used. Fiberoptic examination may confirm the diagnosis, and surgical re-exploration may be necessary.

Laryngospasm at Extubation

Management of laryngospasm at extubation differs from intraoperative management of laryngospasm in that use of intravenous anesthetics will delay recovery. The Larson maneuver, pressure on the "laryngospasm notch" (between the angle of the mandible and the mastoid process), is noninvasive, safe, and often effective.[30] It is also a useful stimulant whenever there is respiratory depression after extubation. Helium is of proven value in the management of postextubation stridor. It does not resolve the underlying process but can increase tidal volume, improve oxygenation, and reduce anxiety. The ratio of oxygen to helium should be adjusted according to the clinical response.[97] If hypoxemia is severe or the laryngospasm does not respond to these noninvasive measures, succinylcholine should be given and the patient reintubated. The best help available should be sought whenever reintubation is performed in suboptimal conditions.

Extubation of Patients with a Difficult Airway

Many surgical and anesthetic factors (including airway disease, surgery, and trauma; cervical spine and other head and neck surgery; and difficult tracheal intubation, especially multiple intubation attempts) can cause swelling of tissues in the upper airway and increase the risk for airway obstruction after extubation. Other risk factors include obesity and a history of obstructive sleep apnea.[43] Such patients have died at extubation as a consequence of airway obstruction and failure to reintubate.[98] Important management issues for extubation of these patients include airway risk assessment and location, time, and technique of extubation.

The principal extubation risk assessments tests are the leak test and visual inspection and imaging of airway swelling. Leak tests are used to determine whether gas can pass between the tracheal tube and wall of the trachea after cuff deflation. The hypothesis is that this information indicates the absence of swelling and predicts airway patency after removal of the tracheal tube. Leak tests have been performed in different ways. There is a risk that negative-pressure pulmonary edema will develop when the leak test is performed during spontaneous ventilation. Results are conflicting, and a leak does not guarantee airway patency after extubation. However, low leak volumes are associated with an increased risk for upper airway obstruction.[99] Whenever there is any doubt about risks, a flexible fiberoptic endoscope should be used to assess swelling and other causes of upper airway obstruction.

An extubation-risk patient should remain intubated in the intensive therapy unit until there is evidence that airway swelling has resolved. Other factors such as altered neurologic status may affect the time of extubation, and tracheotomy may be needed in such patients. Extubation should not be performed when there is an increased risk for vomiting or regurgitation. The intensive therapy unit and the operating room are the safest places for extubation. A full range of equipment and personnel should be available, and all preparations, including surgical, should be made for airway management. Extubation should be performed in an awake patient after breathing 100% oxygen to maximize oxygen stores. Helium, noninvasive ventilation, and CPAP may reduce the need for reintubation.

Airway Exchange Catheters

Solid introducers have been used as guides for reintubation. They are passed through the tracheal tube before extubation and kept in situ until the possible need for reintubation has passed. AECs have been introduced as hollow reintubation guides that have the additional potential capability of maintaining oxygenation or monitoring tracheal gas. They are normally supplied with 15-mm

and Luer connectors. The ideal depth of insertion of the tip of the AEC is midtracheal. AECs are generally well tolerated by awake patients, who can breath around them. Insufflation of oxygen at low pressure or positive-pressure ventilation by the intermittent application of high pressure is possible. If positive-pressure ventilation is used, it should be started with great caution. The lowest pressure that produces an acceptable tidal volume, judged by movement of the chest and upper part of the abdomen, should be used. The next inspiration should not start until the chest returns to its preinspiration position. Expiratory resistance should be minimized by jaw thrust and head extension, augmented by an oropharyngeal airway or LMA, if required. The concern about oxygenation through AECs is the significant risk for barotrauma.[100] Although insufflation through AECs without barotrauma has been reported, insufflation through the FFL and AEC has caused serious barotrauma. Insufflation through an AEC is of doubtful value when oxygen can be administered by facemask.[101] The need for AEC ventilation should be weighed against the risks. It should be considered only by users who have practiced the AEC technique in workshops.

Percutaneous Airway

A percutaneous (transcutaneous) airway connects the trachea and lower airway to the atmosphere, anesthesia circuit, or other device through a surgically created opening in the front of the neck that bypasses the larynx and upper airway. Rapid emergency creation of such an airway is necessary when noninvasive techniques fail to relieve the "cannot intubate, cannot ventilate" situation and severe increasing hypoxemia develops. Creation of a percutaneous airway involves significant hazards.

Tracheotomy

Tracheotomy requires incision of the skin and subcutaneous tissues, separation of the strap muscles, division of the isthmus of the thyroid gland, incision of the anterior wall of the trachea, and insertion of a cuffed tracheotomy tube. Access is improved by neck extension achieved by placing a bolster under the shoulders. Emergency tracheotomy can be very difficult and give rise serious complications.[102] A few surgeons may succeed in 3 minutes, but most take longer. Delay in completion of tracheostomy in this situation is likely to result in death of the patient. Elective tracheotomy for airway management is indicated when the risk of loss of the airway during attempted tracheal intubation is high, such as when respiration is compromised by laryngeal tumors or deep neck abscesses. Wherever possible, tracheotomy is performed in a patient who is already intubated because operating conditions are better for the surgeon. The anesthesiologist coordinates withdrawal of the tracheal tube with the surgical incision in the trachea. Sensible precautions include preoxygenation before incision of the trachea and insertion of an introducer or AEC as the tracheal tube is withdrawn so that reintubation is facilitated, if necessary. Tracheotomy is performed under local anesthesia in an awake patient if the risk of airway loss during tracheal intubation is high.

Tracheotomy is also used as a replacement for orotracheal intubation in a critically ill patient who requires prolonged airway support. Dilatational tracheotomy is used frequently. Discussion of the technique is beyond the scope of this chapter.

Cricothyrotomy

Cricothyrotomy creates a percutaneous airway through the cricothyroid membrane. Its advantages over tracheotomy are that the membrane is superficial and relatively avascular and cartilage incision is not necessary because the height of the membrane is greater than the distance between the tracheal rings. Cricothyrotomy can be performed with a surgical or cannula (needle) technique, and appropriate use can prevent anesthetic-related deaths. It is a core skill for the anesthesiologist.

Surgical Cricothyrotomy

Surgical cricothyrotomy uses surgical techniques to insert a cuffed tube in the trachea (successful low-pressure ventilation with an uncuffed tube is not guaranteed[103]). It facilitates rapid restoration of ventilation and oxygenation in the "cannot intubate, cannot ventilate" situation.[2] Emergency cricothyrotomy can cause serious complications,[102] although they are infrequent when staff is well trained.[104] The four-step simplified cricothyrotomy technique (Box 50-15) can be performed in 30 seconds.[105] A No. 20 scalpel is preferred because its width is sufficient for insertion of a narrow tube without the need for extension of the incision, and its length is such that damage to the posterior wall of the trachea is unlikely. In an obese patient in whom the laryngeal cartilage cannot be identified, step 1 is modified to include an initial vertical incision so that the cartilage can be identified. Insertion of the tube in an obese patient may be facilitated by passage of an introducer into the trachea. When oxygenation has been restored, hemostasis can be secured.

Seldinger Cricothyrotomy

Anesthesiologists are reluctant to perform emergency surgical techniques, and thus Seldinger guidewire cricothyrotomy techniques have been developed.[103] These techniques are preferred by

Box 50-15 Surgical Cricothyrotomy

Equipment

No. 20 scalpel

Cuffed tracheal or tracheostomy tube with a 6- or 7-mm internal diameter

Technique

Step 1: Extend the head and neck and identify and immobilize the cricothyroid membrane (initial vertical incision if identification is not possible)

Step 2: Horizontal stab incision through the skin and cricothyroid membrane. Leave the blade in place until the tracheal hook is in position (step 3)

Step 3: Caudal and outward traction on the cricoid cartilage with the tracheal hook; remove the scalpel

Step 4: Insert the tube and inflate the cuff

Step 5: Ventilate with a low-pressure source

Step 6: Confirm pulmonary ventilation

many anesthesiologists because they do not involve unfamiliar surgical techniques. Seldinger cricothyrotomy has taken longer than the surgical technique to restore the airway in most studies. Kinking of the guidewire can be a serious problem.

Cannula (Needle) Cricothyrotomy

Cannula cricothyrotomy requires the *combination* of a cannula through the cricothyroid membrane *with* high-pressure ventilation. It can provide effective ventilation,[46] although low success rates have been reported. Kink-resistant cannulas must be used because standard intravenous cannulas are easily kinked. The technique is summarized in Box 50-16 and described in detail elsewhere. Verification of correct cannula placement by aspiration of air into a large syringe before the use of high-pressure ventilation is essential. Subsequent dislodgement of the cannula must be prevented.

Effective ventilation through a cannula is possible only when a high-pressure (e.g., hospital pipeline) source is used, and an adjustable device with a Luer-Lok connection is recommended. Barotrauma is a serious complication. It is less likely if an initial inflation pressure of less than 4 kPa (55 psi) is used. Ventilation should be started cautiously. It is important to keep the upper airway as open as possible and to verify deflation of the lungs and exhalation through the upper airway. Cannula cricothyrotomy can be safe only if meticulous technique is practiced regularly and safety rules are observed. Elective cannula cricothyrotomy may have a role in ENT surgery and when a difficult airway is anticipated.[106]

Complications of Airway Management

Many complications are associated with airway management and some are considered elsewhere in this chapter. The most serious complications are hypoxemia and soft tissue damage to the pharynx and esophagus. Hypoxemia should be preventable when anesthesiologists avoid high-risk strategies and have a sufficient range of skills to manage a wide variety of scenarios. Soft tissue damage is responsible for 6% of closed claims.[65] Mediastinitis should be prevented by gentleness and avoiding repeated use of techniques, particularly blind ones, when they prove ineffective. Unfamiliar techniques should not be used for the first time in an emergency situation. The effects of any trauma should be mitigated by arranging good follow-up care.[65] Damage to the glossopharyngeal, hypoglossal, lingual, superior laryngeal, recurrent laryngeal, mental, and branches of the trigeminal nerve has been reported after airway management. This damage has been attributed to direct trauma or cuff pressure.

Less serious complications occur more frequently. Dental damage is the most frequent cause of complaints against anesthesiologists,[12] with an incidence of 1 in 4500 reported from one department.[58] Serious injuries include subluxation, fracture, and avulsion of teeth.[58] Diseased teeth are at particularly high risk, but healthy teeth can also be injured. Only the most serious injuries are likely to lead to complaint, so the incidence of minor dental injury is probably higher than realized. Use of dental guards during direct laryngoscopy has been advocated, but prevention of injury is not guaranteed, the efficacy of direct laryngoscopy may be reduced, and the risk of injury may be increased. Injury to healthy teeth in patients undergoing elective surgery should be prevented by using alternative airway techniques if pressure on teeth cannot be avoided with the first laryngoscopy technique chosen. Dental damage can also be caused by insertion and removal of or biting on several airway devices. An urgent dental consultation should be arranged after any dental damage. Any dislodged teeth or fragments should be located and, if in the respiratory tract, removed.

Laryngeal damage has been found in 84% of patients, 69% of whom were symptomatic, when computed tomography was performed 6 months or longer after tracheal intubation for elective surgery. Patients with hoarseness or other signs of laryngeal damage after airway management should be referred to an ENT surgeon. Laryngeal and tracheal damage after long-term intubation is beyond the scope of this chapter.

Although the number of claims for airway management complications remains substantial, results from single hospitals show that airway management can be accomplished with a very low incidence of serious complications.[10,46,47,63]

Box 50-16 Cannula Cricothyrotomy

Equipment

Kink-resistant cannula

High-pressure ventilation system

Technique

Insert the cannula through the cricothyroid membrane

Confirm tracheal position by aspiration of air with a 20-mL syringe

Maintain position of the cannula with a dedicated hand

Attach the ventilation system to the cannula

Ensure an open upper airway (including jaw thrust, head extension, and possibly a laryngeal mask airway)

Commence cautious ventilation

Confirm inflation and deflation of the lungs and exhalation through the upper airway

Convert to a surgical cricothyroidotomy if ventilation fails or any complications develop

Follow-up After Difficulty with Airway Management

The anesthesiologist has continuing responsibility for issues that may influence future safety of the patient. The ASA guidelines[6] recommend that the anesthesiologist document the presence and nature of any airway difficulty, inform the patient, and evaluate and arrange appropriate management of complications. Documentation is summarized in the ASA guidelines and should include a description of the airway difficulties, the management used, and the number and duration of attempts.[6] Possible notification systems include a written report or letter to the patient, a written report in the medical chart, and communication with the

patient's surgeon or primary caregiver. Because only a warning bracelet (e.g., www.medicalert.com) may be effective if the patient is admitted unconscious to hospital, additional use of this system is recommended.

Patients in whom laryngoscopy proves unexpectedly difficult are entitled to a diagnosis and appropriate management. Fiberoptic nasendoscopy[3,6] and appropriate imaging should be considered. Domino and coworkers stated that "patients in whom tracheal intubation has been difficult should be observed for and told to watch for the development of symptoms and signs of retropharyngeal abscess, mediastinitis, or both."[65] Death is less likely if the diagnosis is made and treatment started promptly.

Cleaning and Disinfection of Airway Equipment

Equipment used for invasive procedures, including airway management, should be sterile to prevent cross-infection. The risk of spreading prion disease with the use of contaminated medical equipment[107] is a particular problem because conventional cleaning and sterilization do not remove protein deposits from equipment. Furthermore, sterilization can cause deterioration in equipment performance, such as the effect of repeated autoclaving on the fiberoptic bundles of direct laryngoscopes.

Transfer of infected material can be prevented by using single-use equipment. However, single-use equipment (direct laryngoscopes, introducers, SADs) has frequently been introduced without evidence of efficacy. In the case of direct laryngoscopes, there has been great variation in rigidity in the longitudinal and torsional axes. The blades are often thicker and thus the view of the larynx is impaired, and there is less room for maneuvering the tracheal tube. The illumination provided by single-use blades varies in intensity, width of the beam, and direction. Plastic single-use blades perform less well than standard metal reusable blades, may result in a longer duration of laryngoscopy, and are not recommended for rapid-sequence induction (RSI).

Challenging Airway Management Scenarios

Risk of Pulmonary Aspiration

Foreign material may be aspirated into the lungs when the normal laryngeal protective mechanisms fail. Pulmonary aspiration was confirmed in 1 in 8600 anesthetic procedures in a recent review.[108] The clinical consequences depend on the quantity, nature, and distribution of the material aspirated; the relative impact of the acid, bacterial, and particle content; and patient factors. The range of effects varies from cough and laryngospasm caused by aspiration of a small volume of pharyngeal contents to drowning secondary to aspiration of liters of gastrointestinal contents. Pulmonary aspiration accounted for 4% of claims in the ASA Closed Claims Study.[1] Most cases occur during induction of anesthesia or, less frequently, at extubation and recovery.[108]

When the lower and upper esophageal sphincters are working optimally, they prevent passive regurgitation from the stomach to the esophagus and from the esophagus to the pharynx, respectively. Their tone is reduced as consciousness is lost. Tone may be increased or decreased as a secondary effect of a variety of procedures and drugs used by anesthesiologists.

Major risk factors for regurgitation and vomiting include pregnancy after the first trimester and acute gastrointestinal disease, particularly esophageal or gastric disease, small bowel obstruction, and ileus. Other risk factors for gastrointestinal stasis include trauma, diabetes, obesity, and the administration of drugs (such as narcotics) that inhibit gastrointestinal function. The head-down and lithotomy positions increase the risk for regurgitation. Parkinson's disease, bulbar palsy, myotonia dystrophica, and other neurologic diseases impair protective reflexes and increase the risk for pulmonary aspiration. Recent ingestion of food is a risk factor, but fasting from the midnight before surgery to any time in the following day is thought to be excessive.[109] Fasting for 6 hours after a light meal and 2 hours after clear fluids is widely accepted as safe practice for patients without risk factors[109]; however, regurgitation can occur in patients without risk factors and anesthesiologists should always be prepared.

Awake tracheal intubation is the technique of choice when there is a risk of pulmonary aspiration and difficulty with airway management is predicted. Concern that an increased risk for pulmonary aspiration may be produced by topical anesthesia of the larynx has proved unfounded in a large series of high-risk patients. Consciousness contributes significantly to airway protection.

RSI is used to reduce the risk of pulmonary aspiration in at-risk patients. The principle of RSI is that tracheal intubation is achieved as rapidly as possible to reduce the time at risk for pulmonary aspiration and the development of hypoxemia. Preoxygenation, intravenous anesthesia, rapid-onset neuromuscular blockade, and use of cricoid pressure (controversy discussed later) are the essential components of RSI.

Cricoid pressure has been used to prevent pulmonary aspiration since its description by Sellick. The hypothetical basis is that pressure on the front of the cricoid cartilage is transmitted to its posterior lamina, which occludes the esophagus by compression against the vertebral bodies. Radiology and cadaver studies have demonstrated occlusion of the esophagus with cricoid pressure. However, lateral displacement of the esophagus has been found in 91% of patients when cricoid pressure was applied.[110] Many recommendations about the technique of cricoid pressure have been made. It should be applied in such a way that it does not interfere with insertion of the laryngoscope. Cricoid pressure may be applied with an initial force of 10 N (a weight of about 1 kg, which is tolerable) when the patient is awake and then increasing to 30 N (about 3 kg), which minimizes the risk of airway obstruction, as consciousness is lost.[52] The force should be reduced, with suction at hand, if it impedes laryngoscopy or passage of the tracheal tube.

Cricoid pressure has disadvantages. It reduces the tone of the lower esophageal sphincter, so the risk of regurgitation from the stomach to the esophagus is increased. It can impair insertion of the laryngoscope, degrade the view of the larynx, impede passage of an introducer or tracheal tube, and cause airway obstruction.[111] Application of cricoid pressure by an assistant impedes external laryngeal manipulation by the anesthesiologist. Fracture of the cricoid cartilage has been attributed to cricoid pressure. Vomiting in the presence of cricoid pressure may gener-

ate enough pressure to rupture the esophagus, although low levels of cricoid pressure might be safe in the presence of vomiting.

The role of cricoid pressure has become controversial.[112] The lack of prospective studies has been criticized, but ethical issues make such studies impossible. Difficult laryngoscopy caused by cricoid pressure may have caused deaths. Pulmonary aspiration has occurred despite the use of cricoid pressure, possibly partly as a consequence of iatrogenic difficulty with tracheal intubation.[108] However, occasional complications do not mean that the technique is of no value. Pulmonary aspiration has occurred when cricoid pressure was not applied, and case reports of massive regurgitation after release of cricoid pressure provide evidence of its value. However, there must be a low threshold for reducing cricoid pressure when there are problems with mask ventilation, laryngoscopy, or passage of the tracheal tube.

Use of wide-bore gastric tubes to empty the stomach before RSI has been recommended even though pulmonary aspiration can occur despite the presence of a nasogastric tube. Suction on a nasogastric tube can reduce the volume of gastric contents, but there is no guarantee that the stomach will be emptied. The stomach regularly fills from below in patients with intestinal obstruction. The presence of a nasogastric tube may increase the risk associated with regurgitation, and removal of the tube while suctioning has been advised before the implementation of RSI. The opposite view is that gastric tubes may limit rises in gastric pressure. Insertion of a nasogastric tube before induction of anesthesia is rarely indicated except in patients with gastrointestinal obstruction or ileus.[113]

Drugs (antacids, histamine H_2 receptor antagonists, proton pump inhibitors) may be used to reduce the acidity or volume (or both) of gastric fluid. These drugs should be given on the day of surgery to patients for whom they are already prescribed. Their use for premedication of patients with symptoms of gastroesophageal reflux disease is prudent. Neutralization of gastric contents with nonparticulate antacid in obstetric or other patients at high risk for aspiration of acid is recommended.

Anticipated Difficult Intubation

The basic management decisions for all patients are described in the ASA guidelines (see Fig. 50-2),[6] specifically, awake versus anesthetized, noninvasive versus invasive, and preservation of spontaneous ventilation versus apnea. Although creation of a surgical airway in an awake patient is occasionally necessary, the safest plan for most cases of anticipated airway difficulty is to perform awake tracheal intubation under topical anesthesia.[67] The most versatile instrument for this technique is the FFL. The threshold for using awake flexible fiberoptic intubation should be particularly low if surgery is urgent (cancellation of surgery is not an option) or examination suggests that rescue techniques will be difficult or impossible.

Lack of patient cooperation precludes awake techniques. In these patients and if minor difficulty is anticipated before elective surgery, general anesthesia may be induced by experienced anesthesiologists, but muscle relaxants must be given until the airway has been secured. RILs may have a significant role in such patients.

Use of alternatives to tracheal intubation for patients with anticipated airway difficulty may be considered. Inhaled induction and maintenance of facemask anesthesia for minor surgery of short duration in a fasted patient is a good technique for a skilled user. The hazards of using SADs in such patients have been considered. Use of regional anesthesia in patients with an anticipated difficult airway does not remove the airway problem and carries the risk that failure of the regional technique (including increased duration or extension of surgery) could result in the need for difficult intraoperative tracheal intubation under suboptimal conditions (see Box 50-4).

Unanticipated Difficult Intubation

Unanticipated difficulty with direct laryngoscopy cannot be prevented, and a management strategy based on a sufficient range of skills should be in place. All anesthesiologists should be skilled in at least one alternative technique of tracheal intubation under vision.[47,114] Strategies that include algorithms for the management of unanticipated difficult intubation have been produced by several organizations, including the ASA and the Difficult Airway Society (DAS), a U.K. organization. The ASA algorithm is the standard guide (see Fig. 50-2). A great merit of the DAS algorithm[52] (Fig. 50-19) is its simplicity and emphasis on progression through a series of defined plans. Plan C, awakening the patient and postponing elective surgery, is an important means of maintaining oxygenation and preventing trauma. The choice of techniques within the plans is less important than the underling principles and strategy. Organizations and individuals should use evidence to select appropriate techniques within the strategy. However, guidelines cannot achieve their aims without good training. Some departments have produced their own guidelines, accompanied by a training program, and report excellent results.[46,63]

The most difficult situation is management of unanticipated airway difficulty in a patient requiring emergency surgery. The risks of delaying surgery must be balanced against the risk of proceeding with a suboptimal airway. If it is essential to proceed with surgery, a traditional technique has been to continue with a facemask and oral airway while maintaining cricoid pressure. Continuation of anesthesia with an LMAc is now an established technique, though not always effective. Insertion of SADs is impeded by cricoid pressure,[115,116] which should be reduced as necessary during insertion and then reapplied at a level that allows satisfactory function. The PLMA forms a better seal than the LMAc does and provides improved protection against aspiration. It may be preferred by users who have proven competence with the device. Early conversion to tracheal intubation with devices such as the AIC is desirable.

"Cannot Intubate, Cannot Ventilate" Situation

This situation may be defined as one in which ventilation with noninvasive techniques fails to maintain oxygenation and tracheal intubation proves impossible. This scenario may develop rapidly but often occurs after repeated unsuccessful attempts at intubation.[64]

Before resorting to invasive percutaneous airway techniques, maximum effort must be made to achieve ventilation and oxygenation with noninvasive techniques, such as optimum mask ventilation and use of SADs. Facemask ventilation may require

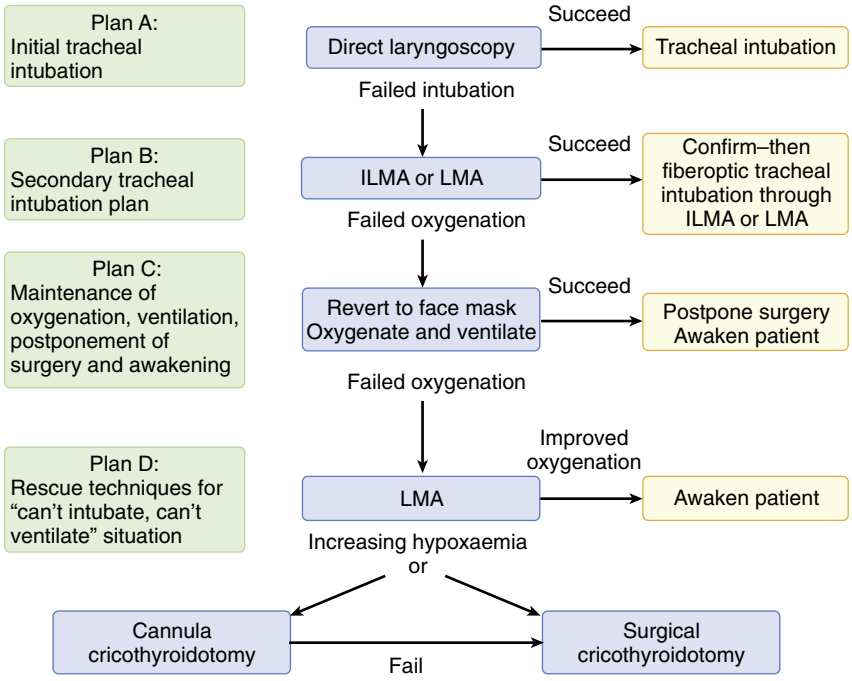

Figure 50-19 Basic algorithm of the Difficult Airway Society (DAS) guidelines for the management of unanticipated difficult tracheal intubation. *(From Henderson JJ, Popat MT, Latto IP, et al: Difficult Airway Society guidelines for management of the unanticipated difficult intubation. Anaesthesia 59:675-694, 2004.)*

the two-person technique and the use of an oral or nasal airway. It may be necessary to reduce cricoid pressure to achieve satisfactory ventilation. If satisfactory oxygenation cannot be achieved with a facemask, an SAD should be used instead. Insertion of an LMA in the "cannot intubate, cannot ventilate" situation has a significant failure rate.[43]

The risks associated with an invasive rescue technique must be constantly weighed against the risk of hypoxic brain damage or death. Rapid development of severe hypoxemia, particularly when associated with bradycardia, is an indication for imminent insertion of a percutaneous airway that can reliably deliver a large minute volume with an F_{IO_2} of 1.0. Many cricothyrotomy techniques have been criticized because they are not capable of providing effective ventilation.[117,118]

If noninvasive techniques do not restore oxygenation, cricothyrotomy is the percutaneous airway of choice[2] because tracheotomy may take too long. It is not possible to define the S_{PO_2} at which cricothyrotomy should be performed—it depends on the degree of hypoxemia and how rapidly it is deteriorating.[52] Cannula and surgical cricothyrotomy each have advantages and disadvantages. Cannula cricothyrotomy carries a lower risk of significant bleeding. It may be considered when dedicated equipment is immediately available and staff are fully trained in its use. However, it may fail or cause barotrauma.[2] If it cannot be performed rapidly, is ineffective,[2] or causes complications,[2] surgical cricothyrotomy should be performed immediately.[2] Surgical cricothyrotomy with insertion of a cuffed tube is more invasive but can be performed very rapidly and allows effective ventilation with low-pressure sources.

Emergency invasive airway access is a temporary measure to restore oxygenation and will be followed by definitive airway management. This may be a formal tracheotomy, but tracheal intubation is possible in some patients.

Summary

Airway management is at the core of care of anesthetized and unconscious patients. Though straightforward much of the time, it can be very difficult. Many new devices and techniques have become available, and their strengths and weaknesses have become apparent. Editorials have emphasized the need for skills in an increased range of techniques of tracheal intubation.[67,114] The range of equipment available, development and maintenance of skills, and organizational factors such as appropriate allocation of personnel are important safety issues.

Concern has been expressed about the airway skills of trainees, but experienced anesthesiologists have also been slow to develop and maintain airway skills in new techniques of proven value.[119] Popat stated that "most anaesthetists continue to use high-risk strategies as a consequence of a limited range of skills. Skills with the combination of the Macintosh laryngoscope, LMA and introducer are not sufficient core skills to allow safe airway management of all patients."[67] Crosby stated that "there is a population of patients for whom exclusive reliance on direct laryngoscopy is a high-risk strategy resulting in morbidity and occasional mortality … We should emphasise practitioners developing experience and a high comfort level with a limited number of alternatives."[114] However, there is hope. Departments that give sufficient time and resources to the development of airway skills have reported excellent results.[46,47,63] We should seek to emulate the safety culture of the airline industry, wherein regular practice is used to train staff to deal with infrequent emergencies—"There is no excuse for poorly designed procedures when human life is at risk."[120]

Caveats

Many airway devices have been introduced over the last few decades. Every effort has been made to include the most important devices, but it is possible that some have been omitted inadvertently. Omission of any such device does not imply that it might not be useful in clinical management. New devices are produced regularly and readers must research the market.

Statement of Interest

The author has received royalties from sales of the Henderson laryngoscope.

Acknowledgments

I am grateful to many colleagues who have provided useful criticism. Michelle McNicol worked to a very high standard to create new drawings.

51 Spinal, Epidural, and Caudal Anesthesia*

Key Points

1. Low neuraxial anesthesia (i.e., T10 or lower sensory level) carries a physiologic impact different from that of a block performed to produce high (T5) neuraxial anesthesia.
2. Neuraxial anesthesia carries more risk with the perioperative introduction of low-molecular-weight heparin and potent (glycoprotein) platelet inhibitors.
3. Many spinal and epidural anesthetics fail because of inadequate intravenous sedation and anxiolysis rather than technically flawed blocks.
4. Bupivacaine, levobupivacaine, and ropivacaine provide excellent quality of anesthesia for neuraxial techniques.
5. It is estimated that cerebrospinal fluid volume accounts for 80% of the variability in peak block height and regression of sensory and motor block. Except for body weight, the volume of cerebrospinal fluid does not correlate with other anthropomorphic measurements available clinically.
6. The epidural space is more segmented and less uniform than previously believed, and the ligamentum flavum is not uniform from skull to sacrum or even within an intervertebral space.
7. During neuraxial anesthesia, venous and arterial vasodilation occurs, but because of the large amount of blood in the venous system (approximately 75% of the total blood volume), the venodilation effect predominates.
8. It has long been taught that the decrease in blood pressure after a neuraxial block can be minimized by the administration of crystalloids intravenously before the block; however, this logic needs rethinking.
9. Nausea and vomiting may be associated with neuraxial block in up to 20% of patients, and atropine is almost universally effective in treating the nausea associated with high (T5) neuraxial anesthesia.
10. As facility with spinal anesthesia increases, the use of smaller, similarly tipped needles will decrease the incidence of headache if the number of spinal punctures does not increase.
11. Transient neurologic symptoms after spinal anesthesia develop most frequently after ambulatory procedures, especially in patients placed in the lithotomy or knee arthroscopy positions.
12. The lower frequency of headache with cone-shaped needle tips may be the result of exposure of more inflammatory mediators around the opening rather than the often-quoted more gentle spreading of the meninges at the site of puncture.
13. Epidural blood patches are more than 90% effective in relieving post–spinal puncture headache.
14. One method of increasing the likelihood of correct caudal needle placement is to inject 5 mL of saline rapidly through the caudal needle while palpating the skin overlying the sacrum. If no midline bulge is detected, the needle is probably positioned correctly. If a midline bulge is detected during saline injection, the needle is positioned incorrectly.
15. Local anesthetic–induced systemic toxicity occurs primarily through unintentional administration of the drug into an epidural vein.

Spinal, epidural, and caudal neuraxial blocks result in sympathetic blockade, sensory analgesia, or anesthesia and motor blockade, depending on the dose, concentration, or volume of local anesthetic, after insertion of a needle in the plane of the neuraxis. Despite these similarities, there are significant physiologic and pharmacologic differences. Spinal anesthesia requires a small mass (i.e., volume) of drug, virtually devoid of systemic pharmacologic effect, to produce profound, reproducible sensory analgesia; in contrast, epidural anesthesia necessitates the use of a large mass of local anesthetic that produces pharmacologi-

*See American Society of Anesthesiologists Practice Guidelines for Acute Pain Management in the Perioperative Setting, Practice Guidelines for Chronic Pain Management, and Practice Guidelines for Obstetric Anesthesia.

cally active systemic blood levels, which may be associated with side effects and complications unknown with spinal anesthesia. The introduction of combined spinal and epidural techniques blurs some of these differences but also adds flexibility to clinical care.

The blurring of differences between spinal and epidural anesthesia began early, when Corning[1] reported on spinal anesthesia and local medications of the cord (see Chapter 1). Whether his injection of cocaine "between spinous processes" produced spinal or epidural anesthesia is not clear. Bier understood that he was producing spinal anesthesia in 1898, and through self-investigation of spinal anesthesia, he had personal knowledge of the symptoms of post–spinal puncture headache. These early years were principally involved with the advancement of spinal rather than epidural anesthesia for at least three reasons. First, the only practical local anesthetic available until 1904 (when procaine was synthesized) was cocaine, which was more suited to spinal than epidural anesthesia because of systemic side effects at doses required for each. Second, the equipment available for neuraxial blocks favored spinal anesthesia because the end point of cerebrospinal fluid (CSF) return was well defined and did not demand the sophisticated glass syringes and needles required for epidural anesthesia. Third, muscle relaxants had not been introduced, and spinal anesthesia produced superb skeletal muscle relaxation that facilitated surgical exposure.

These advantages of spinal anesthesia historically created many enthusiastic clinicians. Morton[2] promoted high spinal anesthesia for surgical procedures carried out on the head and neck, whereas Koster[3] used total spinal blockade for thoracic and intracranial procedures. Spinal anesthesia was not limited to surgical conditions but was also touted for the treatment of medical conditions (e.g., pulmonary edema) by taking advantage of its venodilatory effect. However, a number of impediments prevented more widespread use of spinal and epidural blocks.

Despite the many advantages and the safety of spinal anesthesia, Kennedy and colleagues[4] described "grave spinal cord paralysis" accompanying the use of spinal anesthesia in 1950; this report was followed by one in 1954 detailing the well-publicized Woolley and Roe trial in England.[5] In the latter instance, two patients, Woolley and Roe, suffered neurologic injury after receiving spinal anesthesia, which was administered in the same hospital, on the same day, and by the same anesthetist in 1947. The exact cause of their neurologic dysfunction remains cloudy. Was it contaminated ampules or a toxic substance administered into the subarachnoid space by mistake?[6]

Anesthesiologists continue to face confusion about balancing the risks and benefits of spinal anesthesia, specifically those involving continuous spinal anesthesia or the use of 5% lidocaine. The U.S. Food and Drug Administration (FDA) withdrew approval for some spinal catheters in 1992 because of concern about a perceived association between the small-bore catheters and the development of cauda equina syndrome.[7] This decision appears to have been made with as many political implications as scientific ones. Since that time, attention turned to questions about the appropriate use of intrathecal 5% lidocaine[8] and how to minimize the risks associated with neuraxial anesthesia and concomitant use of low-molecular-weight heparin (LMWH).[9] Small-bore spinal catheters are being used effectively in Europe and are beginning to reappear in the United States, although it has taken nearly a decade and a half to emerge from the regulatory cloud of the early 1990s.[10]

Other impediments to the effective use of neuraxial blocks are the predictable decreases in arterial blood pressure and heart rate through the accompanying sympathectomy with its attendant vasodilation and blockade of cardioaccelerator fibers. Maintaining arterial blood pressure and heart rate at normal values during these blocks often requires the administration of vasoactive drugs and intravenous fluids. The extent to which these steps are necessary is discussed later.

Another clinically important impediment to successful use of these blocks is the idea that the "blocks should do it all." It seems unreasonable to expect a single injection of local anesthetic into the subarachnoid or epidural space to provide ideal conditions for all patients undergoing various surgical procedures, even in the face of an adequate block. It seems likely that far more spinal and epidural anesthetics have failed because of inadequate intravenous sedation and anxiolysis rather than technically flawed blocks.

Evidence is accumulating that the use of neuraxial blocks, principally continuous epidural techniques to provide postoperative analgesia, may be able to decrease perioperative morbidity. These techniques may also decrease the length of hospital stay and allow more efficient use of our increasingly stretched health care money.[11,12] To gain maximum benefit and minimize complications from these blocks, attention to technique and anatomy is essential, and the blocks should be used when the risk-benefit equation for the block is favorable.[13-17]

Indications and Contraindications

At the most basic level, neuraxial blockade is indicated when the surgical procedure can be accomplished with a sensory level of anesthesia that does not produce adverse patient outcomes. The surgical procedure must include the amount and type of supplemental medications and even the capacity for administering "light general anesthesia" to ensure effective sedation and anxiolysis. The level of sensory analgesia required is of prime importance. It is clear that low spinal anesthesia (i.e., T10 or lower sensory level) carries a different physiologic impact than a block performed to produce high (T5) spinal anesthesia does.[18]

There are few strong contraindications to neuraxial blockade. Some of the most important include patient refusal; a patient's inability to maintain stillness during the needle puncture, which can expose the neural structures to an unacceptable risk of injury; and raised intracranial pressure, which may theoretically predispose to brainstem herniation. Relative contraindications that must be weighed against the potential benefits include intrinsic and idiopathic coagulopathy, such as that occurring with administration of warfarin (Coumadin) or heparin; skin or soft tissue infection at the proposed site of needle insertion; severe hypovolemia; and lack of anesthesiologist experience. The often-cited relative contraindication of preexisting neurologic disease (e.g., lower extremity peripheral neuropathy) is not usually based on medical criteria but rather on legal considerations.

When deciding between epidural and spinal anesthesia, a number of variables should be considered. Is the procedure (or surgeon's typical time) of predictable length, thus minimizing the need to consider a continuous catheter technique? Conversely, is the surgeon's estimate so unpredictable that a combined spinal

and epidural technique should be recommended? Is the surgical procedure so short that waiting for the epidural to take effect makes spinal anesthesia more practical? Is the patient a candidate for prolonged postoperative analgesia, thus making a continuous epidural technique preferred? Can the procedure be equally well handled with spinal or epidural anesthesia, thereby allowing consideration of patient variables affecting the incidence of headache (e.g., age and gender)? Are there concurrent patient diseases, such as hypertrophic cardiomyopathy, that may be of concern with either technique? Will the patient be traveling a significant distance immediately after the procedure, thus making epidural blood patch therapy for a post–spinal puncture headache problematic? These are some of the questions that should be considered when contemplating the risk and benefit of neuraxial blocks.

Anatomy

After a decision is made to use one of these blocks, the key feature of performing the block is combining appropriate technique with a three-dimensional understanding and tactile appreciation of anatomy.

Subarachnoid local anesthetics effect their sensory block at the spinal cord, which is continuous cephalad with the brainstem through the foramen magnum and terminates distally in the conus medullaris. This distal termination, because of differential growth rates between the bony vertebral canal and the central nervous system (CNS), varies from L3 in infants to the lower border of L1 in adults. Most of us develop the impression that the spinal nerve roots are uniform in size and structure, but Hogan and Toth[19] have shown that there is large interindividual variability in nerve root size. These differences may help explain the interpatient differences in neuraxial block quality when equivalent techniques are used on seemingly similar patients. Another anatomic relationship may affect neuraxial blocks; although the dorsal (sensory) roots are generally larger than the anterior (motor) roots, the dorsal roots are often blocked more easily. This seeming paradox is explained by organization of the dorsal roots into component bundles, which creates a much larger surface area on which the local anesthetics act, thus perhaps explaining why larger sensory nerves are blocked more easily than smaller motor nerves.[20] Lumbosacral CSF volume varies from patient to patient, in part because of differences in body habitus and weight.[21] It is estimated that CSF volume accounts for 80% of the variability in peak block height and regression of sensory and motor blockade. Nevertheless, except for body weight, the volume of CSF does not correlate with other anthropomorphic measurements available clinically.[22]

Surrounding the spinal cord in the bony vertebral column are three membranes (from within to the periphery): the pia mater, arachnoid mater, and dura mater (Fig. 51-1). The pia mater is a highly vascular membrane that closely invests the spinal cord and brain. The arachnoid mater is a delicate, nonvascular membrane closely attached to the outermost layer, the dura. Of these two membranes, it is thought that the arachnoid functions as the principal barrier to drugs crossing in and out of the CSF and is estimated to account for 90% of the resistance to drug migration.[23] As Lui and McDonald[20] and Bernards[24] emphasize, the functional proof of the arachnoid's role as the primary barrier to flow is the observation that spinal CSF resides in the subarachnoid and not the subdural space.

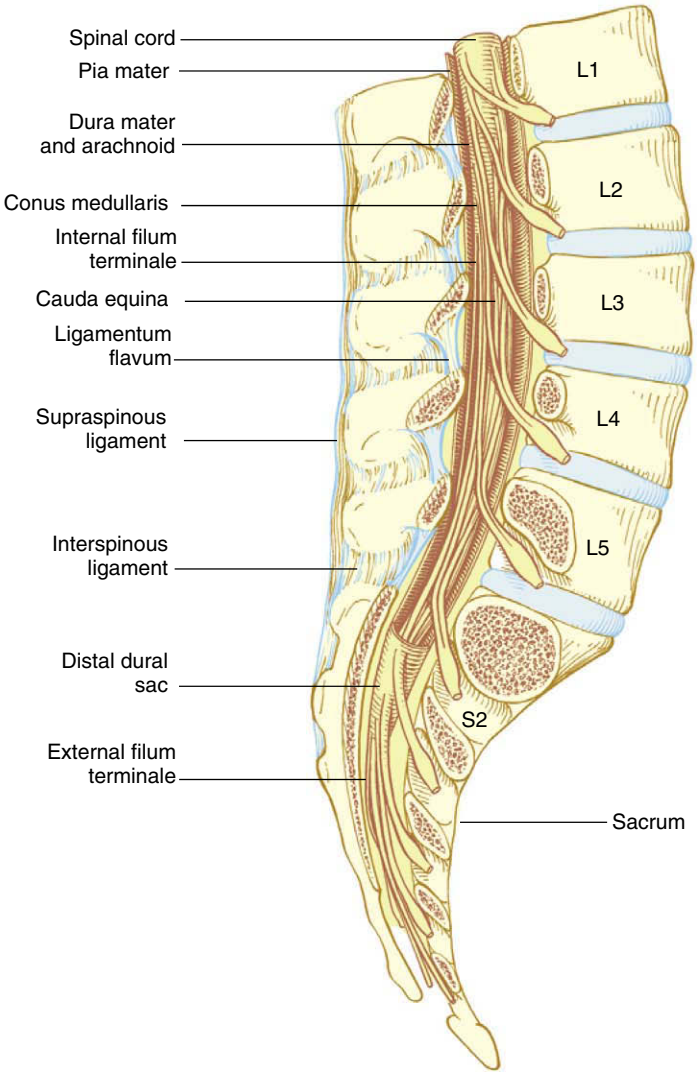

Figure 51-1 Spinal cord anatomy. Notice the termination of the spinal cord (i.e., conus medullaris) at L1-2 and termination of the dural sac at S2.

In the subarachnoid space are the CSF, spinal nerves, a trabecular network between the two membranes, and blood vessels that supply the spinal cord and lateral extensions of the pia mater and dentate ligaments, which provide lateral support from the spinal cord to the dura mater (Fig. 51-2).[25] Although the spinal cord ends at the lower border of L1 in adults, the subarachnoid space continues to S2.

The third and outermost membrane in the spinal canal is a randomly organized fibroelastic membrane, the dura mater (or theca).[26] This layer is a direct extension of the cranial dura mater and extends as the spinal dura mater from the foramen magnum to S2, where the filum terminale (an extension of the pia mater beginning at the conus medullaris) blends with the periosteum on the coccyx (see Fig. 51-1). There is a potential space between the dura mater and the arachnoid, the subdural space, that contains only small amounts of serous fluid and thus allows the dura and arachnoid to move over each other. This space is not

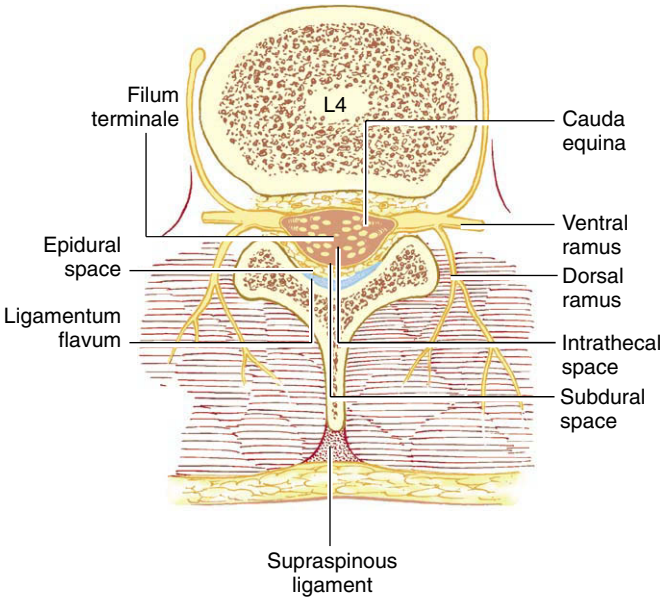

Figure 51-2 Contents of the dural sac at the level of L4. The cauda equina is contained within a dural sac filled with cerebrospinal fluid.

intentionally used by anesthesiologists, although injection into it during spinal anesthesia may explain the occasional failed spinal anesthetic and the rare "total spinal" after epidural anesthesia when there is no indication of errant injection of local anesthetic into CSF.

Surrounding the dura mater is another space that is often used by anesthesiologists, the epidural space. The spinal epidural space extends from the foramen magnum to the sacral hiatus and surrounds the dura mater anteriorly, laterally, and more usefully, posteriorly. The epidural space is bounded anteriorly by the posterior longitudinal ligaments, laterally by the pedicles and intervertebral foramina, and posteriorly by the ligamentum flavum. Contents of the epidural space include the nerve roots that traverse it from foramina to peripheral locations, as well as fat, areolar tissue, lymphatics, and blood vessels, including the well-organized Batson venous plexus. Hogan[27] suggests from his study of frozen cryomicrotome cadaver sections that the epidural space is more segmented and less uniform than previously believed from indirect anatomic analysis (Fig. 51-3). This lack of epidural space uniformity also extends to age-related differences. There is evidence that adipose tissue in the epidural space diminishes with age.[28] Another anatomic change in epidural space anatomy that has long been promoted is that the intervertebral foramina decrease in size with increasing age. This decrease has been linked conceptually to higher block levels for similar epidural doses of local anesthetic. Saitoh and coworkers[29] showed that this concept is probably wrong because they could find no correlation between leakage of radiocontrast material through the intervertebral foramina and age. When the data of Igarashi and associates[28] and Saitoh and colleagues[29] are considered together, it may be that the decrease in epidural space adipose tissue with age may dominate the age-related changes in epidural dose requirements. Unique insights into the epidural space are covered eloquently by Bernards.[24]

Posterior to the epidural space is the ligamentum flavum (the so-called yellow ligament), which also extends from the foramen magnum to the sacral hiatus. Although classically portrayed as a single ligament, it is really composed of two ligamenta flava, the right and the left, which join in the middle and form an acute angle with a ventral opening (Fig. 51-4).[27,30] The ligamentum flavum is not uniform from skull to sacrum, nor even within

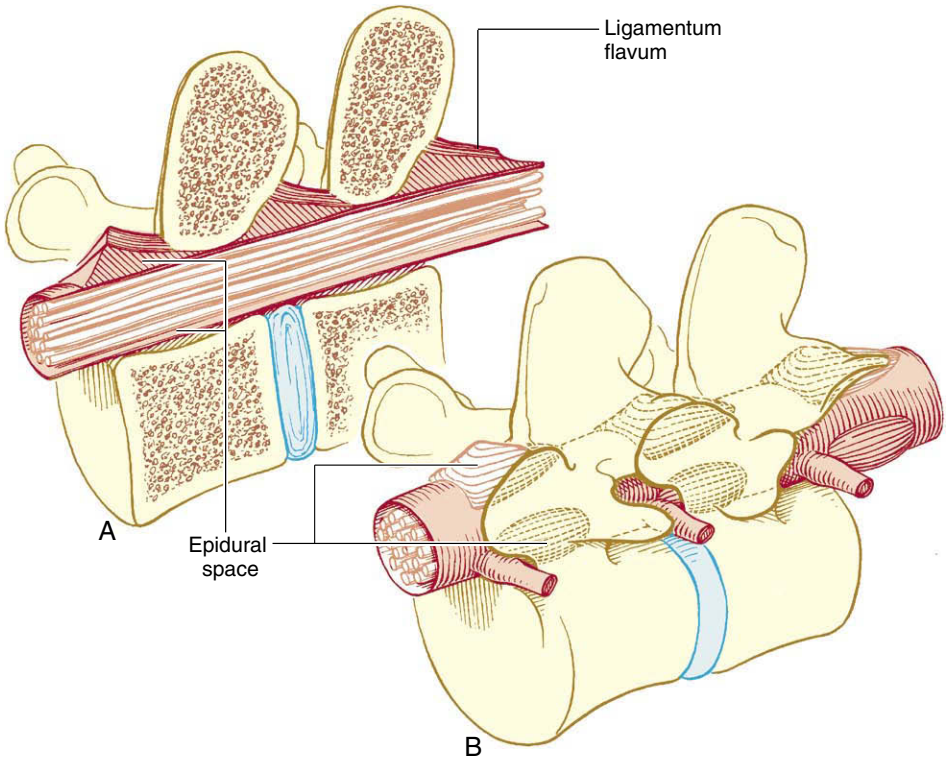

Figure 51-3 **A,** Sagittal section demonstrating that the contents of the epidural space depend on the level of the section. **B,** Three-dimensional drawing of the epidural space showing discontinuity of the epidural contents, but this potential space can be dilated by injection of fluid into the epidural space.

an intervertebral space. Ligament thickness, distance to the dura, and skin-to-dura distance vary with the area of the vertebral canal (Table 51-1). The two ligamenta flava are variably joined (fused) in the midline, and this fusion or lack of fusion of the ligamenta flava even occurs at different vertebral levels in individual patients.[27] Immediately posterior to the ligamentum flavum are the lamina and spinous processes of vertebral bodies or the interspinous ligaments. Extending from the external occipital protuberance to the coccyx posterior to these structures is the supraspinous ligament, which joins the vertebral spines (see Fig. 51-4).

Occasionally, clinically unilateral anesthesia may follow an apparently adequate epidural technique.[31,32] Hogan[33] has also shown in cadavers that spread of solution after epidural injection into tissues of the epidural space is nonuniform, and he postulated that this accounts for the clinical unpredictability of epidural drug spread.

Table 51-1 Characteristics of the Ligamentum Flavum at Different Vertebral Levels

Site	Distance from Skin to Ligament (cm)	Thickness of Ligament (mm)
Cervical	—	1.5-3.0
Thoracic	—	3.0-5.0
Lumbar	3.0-8.0*	5.0-6.0†
Caudal	Variable	2.0-6.0

*The distance is 4 cm for 50% of patients and 4 to 6 cm for 80% of patients.
†Within each interlaminar space, the ligamentum flavum varies in thickness from cephalad to caudad: near the rostral lamina, it is 1.3 to 1.6 mm, and near the caudad lamina, it is 6.9 to 9.1 mm.

Blomberg used a fiberoptic technique to demonstrate that the subdural extra-arachnoid space is easily entered in 66% of autopsy attempts in humans.[34] Despite this being an infrequent clinical problem with epidural anesthesia, it does allow a visual understanding of the subdural complications of epidural anesthesia.[35] Blomberg continued his endoscopic approach to understanding neuraxial anatomy with a subarachnoid study.[36] He identified in autopsy subjects that a distinct posterior midline structure was present in the lower thoracic and upper lumbar regions. He also found that fibrous attachments were present between nerve roots and other subarachnoid structures in many subjects. He postulated that these fibrous structures and attachments might help explain some variations in spinal anesthesia.

Performance of caudal anesthesia calls for an expanded understanding of epidural anatomy and especially the frequent variations in sacral anatomy.[37] The sacrum results from fusion of the five sacral vertebrae. The sacral hiatus, which is failure of the laminae of S5 and usually part of S4 to fuse in the midline, is the detail of interest. It results in a variably shaped and sized inverted V–shaped bony defect covered by the posterior sacrococcygeal ligament, a functional counterpart to the ligamenta flava. The sacral hiatus is identified by locating the sacral cornua, remnants of the S5 articular processes (Fig. 51-5). This bony defect allows access to the sacral canal, although needle insertion through this defect may be difficult because of the frequency of anatomic variation. For example, the shape of the space may vary from slitlike to a wide-based, inverted V, and in 1 in 20 patients, the bony defect may be absent, thereby precluding the caudal approach (Fig. 51-6).[38,39]

The sacral canal contains the terminal portion of the dural sac, which typically ends cephalad to a line joining the posterior superior iliac spines, or S2. Variation is found in this feature as well, with the termination of the dural sac being lower in children, although the ease of palpating the sacral hiatus in children may make the pediatric caudal technique easier overall. In addition to

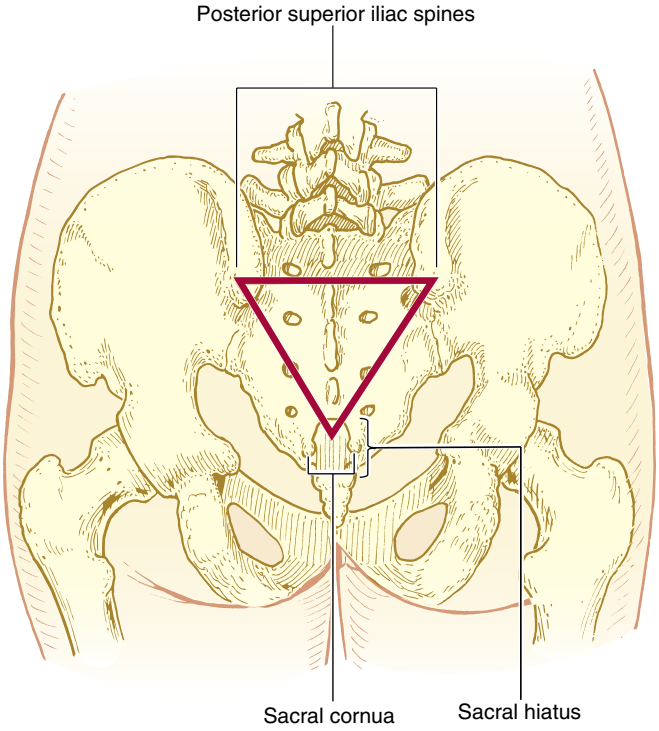

Figure 51-5 Sacral surface anatomy. An equilateral triangle can be drawn to connect the posterior superior iliac spines and the sacral hiatus. It can be useful in confirming palpation of the sacral hiatus.

the dural sac, the sacral canal contains a venous plexus, which is part of the valveless internal vertebral venous plexus. It is estimated from magnetic resonance imaging (MRI) studies that the volume of the caudal canal in adults, excluding the foramina and dural sac, is about 10 to 27 mL. Perhaps this wide variability in volume accounts for some of the variation in block height with caudal anesthesia.[37]

After the anatomy pertinent to neuraxial blocks is understood, it is tempting to administer the blocks immediately. Nevertheless, safe conduct of spinal, epidural, and caudal anesthesia requires an appreciation of the physiologic effects of these blocks if they are to be used appropriately.

Physiologic Effects

The physiologic effects of neuraxial blocks are often misinterpreted as complications, which is highlighted by observers listing hypotension under complications of the techniques. Clear distinction should be made between the physiologic effects of an anesthetic technique and complications, which imply some harm to the patient.[40] This distinction is important to determine the risk-benefit equation of the technique in question.

Cardiovascular Effects

The cardiovascular effects of neuraxial blocks are similar in some ways to the combined use of intravenous α_1- and β-adrenergic blockers: decreased heart rate and arterial blood pressure (see Chapter 16). The sympathectomy that accompanies the techniques depends on the height of the block, with the sympathectomy typically described as extending for two to six dermatomes above the sensory level with spinal anesthesia and at the same level with epidural anesthesia.[41] This sympathectomy causes venous and arterial vasodilation, but because of the large amount of blood in the venous system (approximately 75% of the total volume of blood), the venodilation effect predominates as a result of the limited amount of smooth muscle in venules; in contrast, the vascular smooth muscle on the arterial side of the circulation retains a considerable degree of autonomous tone. After neuraxial block–induced sympathectomy, if normal cardiac output is maintained, total peripheral resistance should decrease only 15% to 18% in normovolemic healthy patients, even with nearly total sympathectomy. In elderly patients with cardiac disease, systemic vascular resistance may decrease almost 25% after spinal anesthesia, whereas cardiac output decreases only 10%.[42] The heart rate during a high neuraxial block typically decreases as a result of blockade of the cardioaccelerator fibers arising from T1 to T4. The heart rate may decrease because of a fall in right atrial filling, which decreases outflow from intrinsic chronotropic stretch receptors located in the right atrium and great veins.[41]

The clinical question of what level of decrease in arterial blood pressure after a neuraxial block is acceptable remains to be answered. It will probably remain speculative because conducting ethical human investigations designed to define a dose-response curve of decreased arterial blood pressure accompanying neuraxial blockade would be difficult. That dilemma notwithstanding, it appears that total-body oxygen consumption in patients undergoing spinal anesthesia correlates with the extent of spinal anesthesia, thus providing a margin of safety for organ perfusion unavailable with non-neuraxial techniques.[43]

Some data are available to help determine the extent to which arterial blood pressure should be allowed to decrease. Despite methodologic problems with the study,* Kety and colleagues[44] demonstrated that producing spinal anesthesia to the midthoracic levels with procaine, even in patients with essential hypertension, results in a decrease in mean arterial pressure of 26% (155 to 115 mm Hg) accompanied by only a 12% (52 to 46 mL/100 g/min) decrease in CBF. When the level of spinal anesthesia was purposely increased to produce higher levels of block (T4) in normotensive and hypertensive patients, mean arterial pressure decreased by 32% (93 to 63 mm Hg) and 50% (158 to 79 mm Hg), respectively. Although CBF was unchanged in the normotensive group (45 to 46 mL/100 g/min), a 19% decrease occurred in the apparently untreated hypertensive patients (46.5 to 37.5 mL/100 g/min).[45] When coronary artery blood flow and myocardial metabolism were determined in humans during spinal anesthesia to T4 in hypertensive and normotensive patients, decreases in coronary blood flow (153 to 74 mL/100 g/min) paralleled the decrease in mean arterial blood pressure (119 to 62 mm Hg), and the percent extraction of myocardial oxygen was unchanged (75% to 72%). Extraction of oxygen was unchanged because myocardial work, as expressed by myocardial use of oxygen, paralleled the decrease in mean arterial pressure and coronary blood flow (16 to 7.5 mL/100 g/min).[46] These data

*Cerebral blood flow (CBF) was studied with nitrous oxide. Only global CBF was measured, and the patients studied were severely hypertensive (i.e., average mean arterial blood pressure of 155 mm Hg).

support the observations by Stanley and coworkers[43] but still do not provide a patient-by-patient indication of the organ most at risk for flow-related ischemia, suggesting that further research in this area is required.

Human investigations are limited by cerebral and myocardial blood flow methodologies that were not limiting factors when Sivarajan and associates[47] investigated organ blood flow by means of microspheres in rhesus monkeys during spinal anesthesia at the T10 and T1 levels. During the T10 block, there was no significant change in organ blood flow; during the T1 block, with a 22% decrease in mean arterial pressure, cerebral and myocardial blood flow was insignificantly altered. Prevention of decreases in mean arterial pressure of greater than 30% has some basis, but it is important to remember that these data were derived from severely hypertensive, presumably untreated patients. For normotensive and treated hypertensive patients, a wider undocumented margin of safety probably exists.

After arterial blood pressure decreases to a level at which treatment is believed to be necessary, ephedrine, a mixed adrenergic agonist, provides more appropriate therapy for the noncardiac circulatory sequelae of neuraxial block than a pure α-adrenergic agonist does (see Chapter 16), unless the patient has a specific and defined blood pressure requirement.[48] That the decrease in arterial blood pressure after neuraxial block can be minimized by the administration of crystalloids intravenously is probably not a valid concept. Specifically, 250- to 2000-mL preblock hydration regimens appear to temporarily increase preload and cardiac output without consistently increasing arterial blood pressure or preventing hypotension.[20]

Is there any indication that epidural and spinal anesthesia differ in their effect on arterial blood pressure? A common concept is that the decrease in arterial blood pressure is more gradual and of less magnitude with epidural than with spinal anesthesia of comparable levels. Despite this belief, it was shown that when tetracaine (10 mg) spinal anesthesia was compared with lidocaine (20 to 25 mL of a 1.5% solution) epidural anesthesia, there was a larger decrease in arterial blood pressure, approximately 10%, with the epidural technique than with the spinal

one.[49] The proposed advantage of a slower onset of epidural blockade is often mitigated by anesthesiologists administering a decreased volume of local anesthetic with the initial epidural therapeutic dose; when the block height does not rise as rapidly as desired, additional epidural local anesthetic is administered, and a higher block than necessary may result. The extent to which arterial blood pressure decreases with either technique depends on multiple factors, including patient age and intravascular volume status.

Respiratory Effects

Alterations in pulmonary variables in healthy patients during neuraxial block are usually of little clinical consequence. Tidal volume remains unchanged during high spinal anesthesia, and vital capacity decreases a small amount from 4.05 to 3.73 L.[50] This decrease in vital capacity is a result of a decrease in expiratory reserve volume related to paralysis of the abdominal muscles necessary for forced exhalation rather than a decrease in phrenic or diaphragmatic function.[18] This minimal impact on pulmonary function also holds for elderly patients undergoing lumbar and thoracic epidural anesthesia.[51] Pulmonary function testing in cesarean section patients undergoing epidural anesthesia shows that using lidocaine provides larger decrements in peak expiratory pressure (abdominal musculature–dependent maneuver) than using bupivacaine does.[52]

The rare respiratory arrest associated with spinal anesthesia is also unrelated to phrenic or inspiratory dysfunction but rather to hypoperfusion of the respiratory centers in the brainstem. Supportive evidence for this concept is observed after resuscitation, when apnea almost always disappears as soon as pharmacologic and fluid therapies have restored cardiac output and blood pressure. This would not be the case if phrenic paralysis induced by high levels of local anesthetic was the cause of the apnea.[18] There is experimental evidence from rabbits during epidural anesthesia that their response to hypoxia results in apnea, which is different from the response without neuraxial anesthesia.[53] This finding may have implications for understanding some episodes of cardiovascular depression during neuraxial blockade in humans, although confirmation is needed. Conversely, in a canine model of hypoxia, epidural anesthesia and hypoxic challenge result in the same outcome but with more normal acid-base function than in animals receiving general anesthesia alone.[54]

Neuraxial block should be used cautiously in respiratory cripples because of paralysis of the respiratory muscles. Except for severely compromised patients with respiratory failure, inspiratory muscle function during neuraxial blocks should be adequate to maintain ventilatory function. The physiologic consideration related to muscle paralysis with neuraxial block should focus on the expiratory muscles in these severely compromised patients because these muscles are important for effective coughing and clearing of intrapulmonary secretions.[42,50]

Gastrointestinal Function

Another organ system affected during neuraxial blockade is the gastrointestinal tract. Nausea and vomiting may be associated with neuraxial block in up to 20% of patients and are primarily related to gastrointestinal hyperperistalsis caused by unopposed parasympathetic (vagal) activity.[55] Atropine is effective in treating nausea associated with high (T5) subarachnoid anesthesia.[56,57] This gastrointestinal hyperperistalsis has the advantage of providing excellent surgical conditions because of a contracted gut. An often-cited advantage of regional anesthesia in patients with compromised gastrointestinal function (e.g., hepatic dysfunction) is that less physiologic impairment is possible than with general anesthesia. Nevertheless, it appears that if intra-abdominal surgery is performed, the magnitude of the decrease in hepatic blood flow parallels the site of surgery rather than the anesthetic technique chosen. The decrease in hepatic blood flow during spinal anesthesia parallels the decrease in mean arterial blood pressure.[58] When epidural analgesia is continued into the postoperative period, there may be a protective effect on the gastric mucosa because intramucosal pH is higher during postoperative epidural analgesia than during systemic analgesia.[59]

Renal Function

Renal function has a wide physiologic reserve. Despite predictable decreases in renal blood flow accompanying neuraxial blockade, the decrease is of little physiologic importance.[60] One aspect of genitourinary function that is of clinical importance is the belief that neuraxial blocks are a frequent cause of urinary retention, which delays discharge of outpatients and necessitates bladder catheterization in inpatients. Lower concentrations of local anesthetic are necessary for paralysis of bladder function than for paralysis of motor nerves to the lower extremities. However, some studies do not support this belief. For example, in orthopedic patients undergoing hip replacement, it was demonstrated that bladder catheterization was no more frequent after neuraxial (spinal or epidural) block than after general anesthesia and narcotic analgesics.[61] In any case, it is prudent to avoid administration of excessive volumes of crystalloid solutions intravenously to patients undergoing spinal anesthesia and to individualize the requirement for voiding before discharge in low-risk ambulatory surgery patients after short-acting spinal or epidural anesthetics are used.[62]

Effects Specific to Epidural Anesthesia

The physiologic effects of epidural anesthesia are similar to those of spinal anesthesia, with the exception that local anesthetic blood levels reach concentrations sufficient enough to produce systemic effects on their own. Even intravenously administered lidocaine (resulting in blood levels similar to those after continuous epidural analgesia) can decrease postoperative narcotic requirements (Fig. 51-7).[63] When blood levels are excessive, adverse CNS and cardiovascular effects occur (see Chapter 30).

Spinal Anesthesia

Technique

To perform spinal anesthesia, the pertinent anatomy must be constantly kept in mind while inserting the spinal needle. It is

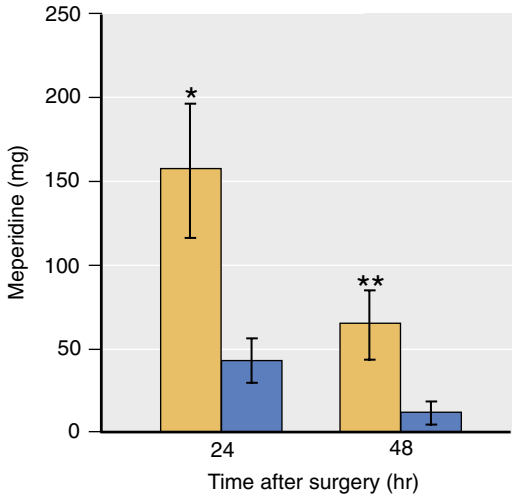

Figure 51-7 Meperidine requirements during the first and second postoperative days in patients receiving intravenous lidocaine (*blue bars*) and in control patients (*yellow bars*). Data are expressed as means ± SEM. **P* < .02; ***P* < .01 versus control data. *(Adapted from Cassuto J, Wallin G, Högström S, et al: Inhibition of postoperative pain by continuous low-dose intravenous infusion of lidocaine. Anesth Analg 64:971, 1985.)*

often helpful for the technique to be broken down into a series of steps (i.e., the four P's): preparation, position, projection, and puncture.

Preparation

Preparation of the equipment and drugs is essential for subarachnoid injection. When choosing a drug for subarachnoid injection, the duration of block should be matched to the surgical procedure and to patient variables (Table 51-2). It may be more time efficient to use a hypobaric solution in a patient in the prone jackknife position rather than turning the patient after a hyperbaric solution has been allowed time to take effect. Is the patient planning to go home after an outpatient procedure, thus dictating use of a shorter-acting drug? Will a prolonged period of lower extremity analgesia, such as that achieved by adding an opioid to the spinal drugs, be advantageous to a patient undergoing knee reconstruction and immediate postoperative use of a range-of-motion machine? These are only a few of the many clinical permutations that dictate familiarity with the combinations of drugs available for subarachnoid use.

When choosing equipment for spinal anesthesia, the initial choice involves reusable or disposable equipment. Most anesthesiologists are forced to accept disposable spinal trays, which may seem limiting, but suppliers are willing to customize trays to meet professional preferences. Despite the emphasis on disposable trays, there is no indication that these trays shift the spinal anesthesia risk-benefit equation in the patient's favor.[64]

Spinal needles fall into two main categories: those that cut the dura and those with a conical tip. The former include the Quincke-Babcock needle, the traditional disposable spinal needle, and the latter contain the Whitacre and Sprotte needles (Fig. 51-8). If a continuous spinal technique is chosen, use of a Tuohy or other thin-walled needle can facilitate passage of the catheter. The use of small needles reduces the incidence of post–spinal puncture headache, whereas the use of larger needles improves the tactile sense of needle placement. Multiple punctures probably increase the incidence of headaches. If use of a smaller needle increases the number of punctures, the difference between small and large needles in producing headaches may be reduced. There is also a decrease in the incidence of post–spinal puncture headache when a conical-tipped needle is used, even when needle sizes are comparable.[65] Nevertheless, as facility with spinal anesthesia increases, the use of a smaller, similarly tipped needle can decrease the incidence of headache if the number of dural punctures does not increase.

Position

Positioning (see Chapter 36) is frequently the most poorly managed part of the spinal technique for at least two reasons. First, the assistant often does not understand the rationale for positioning a patient, and second, patients are often inadequately or excessively sedated, thus making cooperation poor. The three

Table 51-2 Drug Selection for Hyperbaric Spinal Anesthesia

Local Anesthetic Mixture	Dose (mg)*		Duration (min)	
	To T10	To T4	Plain	Epinephrine, 0.2 mg

Figure 51-9 Lateral decubitus positioning for a neuraxial block. The assistant can help the patient assume the ideal position of "forehead to knees."

primary patient positions include the lateral decubitus, sitting, and prone positions, each with advantages in specific situations.

The lateral decubitus position is the most commonly used because it allows easier administration of more sedation and is less dependent on a well-trained assistant than the sitting position is. Patients are placed with their back parallel to the edge of the operating table nearest the anesthesiologist, their thighs flexed on their abdomen, and their neck flexed to allow the forehead to be as close as possible to the knees. The assistant may be invaluable during this positioning by encouraging and assisting a patient in assuming the ideal lateral decubitus position (Fig. 51-9). The patient should be positioned so that spread of hypobaric, isobaric, or hyperbaric solution to the operative site is optimized.

The sitting position should be chosen when low lumbar and sacral levels of sensory anesthesia are adequate for the surgical procedure, such as perineal and urologic operations, or when obesity or scoliosis makes identification of midline anatomy difficult in the lateral position. When placing patients in this position, a stool can be provided as a footrest and a pillow placed in the lap. The assistant then maintains the patient in a vertical plane while flexing the patient's neck and arms over the pillow to open up the lumbar vertebral space (Fig. 51-10). If the reason for choosing the sitting position is to keep the sensory level low, the patient should be maintained sitting for 5 minutes; if the choice was made because of obesity or scoliosis and a higher sensory level is needed, the patient should be placed supine immediately after subarachnoid injection, with the table manipulated appropriately. The most common error made in placing patients in this position is allowing the patient to slump, which loses the advantage of improved midline identification.

The prone position should be chosen when the patient is to be maintained in that position (often with the jackknife modification) during the surgical procedure. This position is often appropriate for rectal, perineal, or lumbar procedures. An advantage of the hypobaric technique is that patients can help position themselves, thus minimizing the opportunity for positioning injuries. After the patient is in position, lumbar lordosis should be minimized, and most often, the paramedian approach should be used. The anesthesiologist may have to aspirate for CSF because CSF pressure is minimized when insertion of the lumbar needle is carried out in this position.

Projection and Puncture

After the equipment, local anesthetics and additives, and the patient have been properly prepared, the midline or paramedian spinal puncture can be performed. The midline approach relies on the ability of patients and assistants to minimize lumbar lordosis and allow access to the subarachnoid space between adjacent spinous processes, usually at the L2-3, L3-4, or sometimes the L4-5 space. The palpating fingers (usually the index and third fingers) should identify the interspinous area by locating the caudad extent of the more cephalad spine and the midline by rolling the fingers in a medial-to-lateral direction (Fig. 51-11). A subcutaneous skin wheal is developed over this space, and the introducer is inserted into the substance of the interspinous ligament. The introducer is grasped with the palpating fingers and steadied while the other hand is used to hold the spinal needle like a dart, and the fifth finger is used as a tripod against the patient's back to prevent patient movement and unintentional insertion to a level deeper than intended. The needle, with its bevel parallel to the midline, is advanced slowly to heighten the sense of tissue planes traversed and to prevent skewing of nerve roots until the characteristic change in resistance is noted as the needle passes through ligamentum flavum and dura. The stylet is then removed, and CSF should appear at the needle hub. If it does not, the needle is rotated in 90-degree increments until CSF appears. If CSF does not appear in any quadrant, the needle should be advanced a few millimeters and rechecked in all four quadrants. If CSF still has not appeared and the needle is at a depth appropriate for the patient, the needle and introducer should be withdrawn and the insertion steps should be repeated

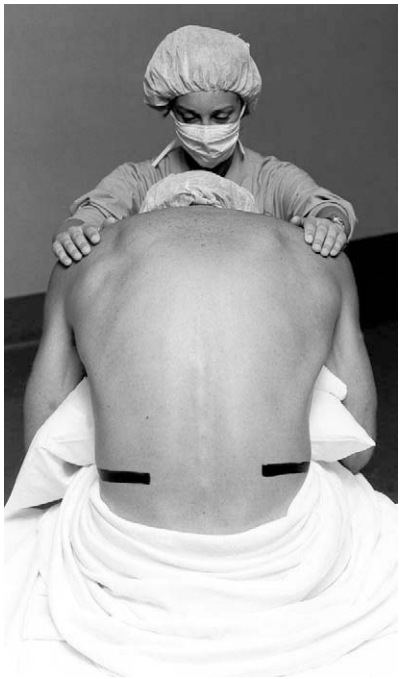

Figure 51-10 Sitting position for a neuraxial block. The assistant provides the patient with a foot rest (stool) and a pillow and prevents the patient from slumping to either side.

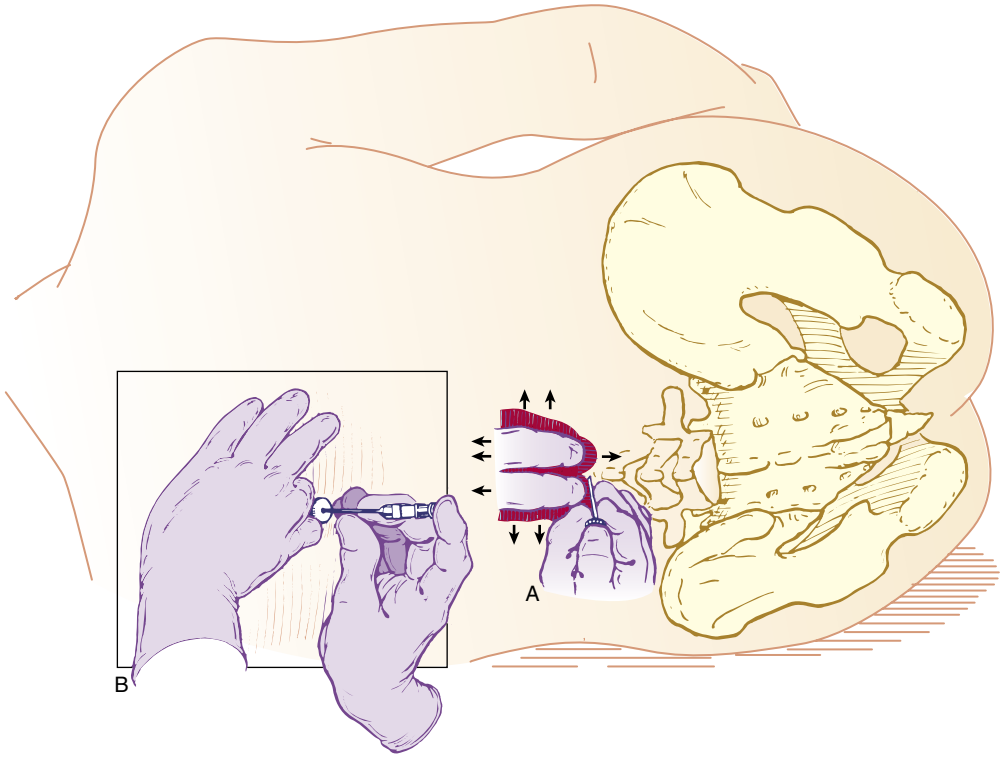

Figure 51-11 Insertion of the spinal needle. **A,** The palpating fingers are "rolled" in a side-to-side and a cephalad-to-caudad direction to identify the interspinous space. **B,** During needle insertion, the needle should be stabilized in a tripod fashion while placed in the hand, similar to a dart being thrown.

because the most common reason for lack of CSF return is that the needle is being inserted off the midline. Another common error preventing subarachnoid placement is excessive cephalad angulation on initial insertion of the needle.

After CSF is freely obtained, the dorsum of the anesthesiologist's nondominant hand steadies the spinal needle against the patient's back while the syringe containing the therapeutic dose is attached to the needle. CSF is again freely aspirated into the syringe, and the anesthetic dose is injected at a rate of approximately 0.2 mL/sec. After completion of the injection, 0.2 mL of CSF is aspirated into the syringe and reinjected into the subarachnoid space to reconfirm location and clear the needle of the remaining local anesthetic. The patient and operating table should then be placed in the position appropriate for the surgical procedure and drugs chosen.

The midline approach is the technique of first choice because it requires anatomic projection in only two planes (Fig. 51-12) and provides a relatively avascular plane. When difficulty in needle insertion is encountered with the midline approach, one option is to use the paramedian route, which does not require the same level of patient cooperation and reversal of lumbar lordosis for success.

The paramedian approach exploits the larger "subarachnoid target" that exists if a needle is inserted slightly lateral to the midline (see Fig. 51-12). The most common error when using the paramedian technique is that the needle entry site is placed too far off midline, which makes the vertebral lamina barriers to insertion of the needle. In the paramedian approach, the palpating fingers again identify the caudad edge of the cephalad spinous process, and a skin wheal is raised 1 cm lateral and 1 cm caudad to this point. A longer needle (e.g., 1.5 to 2 inches) is then used to infiltrate deeper tissues in a cephalomedial plane. The spinal introducer and needle are next inserted 10 to 15 degrees off the sagittal plane in a cephalomedial plane (see Fig. 51-12). Similar to the midline approach, the most common error is to angle the needle too far cephalad on initial insertion. Nevertheless, if the needle contacts bone, it is redirected slightly in a cephalad direction. If bone is again contacted, but at a deeper level, the slight cephalad angulation is continued because it is likely that the needle is being walked up the lamina. As in the midline approach, the characteristic feel of the ligaments and dura is possible, although needle angulation requires more of the needle to be inserted. After CSF is obtained, the block is carried out in a manner similar to that described for the midline approach.

A variation on the paramedian approach is the lumbosacral approach described by Taylor.[66] This technique is carried out at the L5-S1 interspace, the largest interlaminar interspace of the vertebral column. A 5-inch spinal needle is inserted in a cephalomedial direction through a skin wheal raised 1 cm medial and 1 cm caudad to the lowermost prominence of the posterior superior iliac spine. If bone is encountered on initial needle insertion, the needle is walked off the sacrum into the subarachnoid space. After CSF is obtained, the steps are similar to those outlined previously (Fig. 51-13).

If a continuous spinal anesthetic is prescribed, a needle with a laterally facing opening is typically used to perform the lumbar puncture (Fig. 51-14). A midline or paramedian approach may be used, with some authorities suggesting that use of the paramedian approach facilitates insertion of the catheter.[67] The catheter should be threaded 2 to 3 cm into the subarachnoid space and the needle withdrawn over the catheter. Care must be taken to ensure that the catheter is not inserted more deeply into

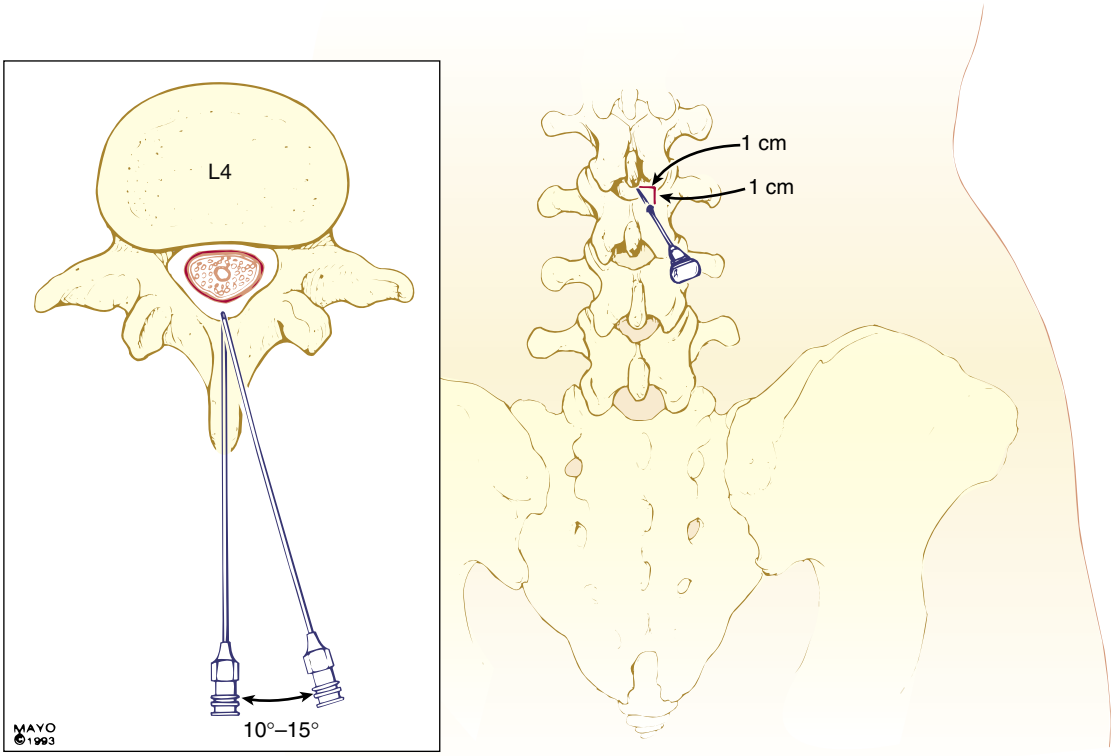

Figure 51-12 Vertebral anatomy of the midline and paramedian approaches to centroneuraxis blocks. The midline approach highlighted in the *inset* requires anatomic projection in only two planes: sagittal and horizontal. The paramedian approach shown in the *inset* and in the posterior view requires an additional oblique plane to be considered, although the technique may be easier in patients who are unable to cooperate in minimizing their lumbar lordosis. The paramedian needle is inserted 1 cm lateral and 1 cm caudad to the caudad edge of the more superior vertebral spinous process. The paramedian needle is inserted approximately 15 degrees off the sagittal plane, as shown in the *inset*. *(Courtesy of the Mayo Foundation, Rochester, MN.)*

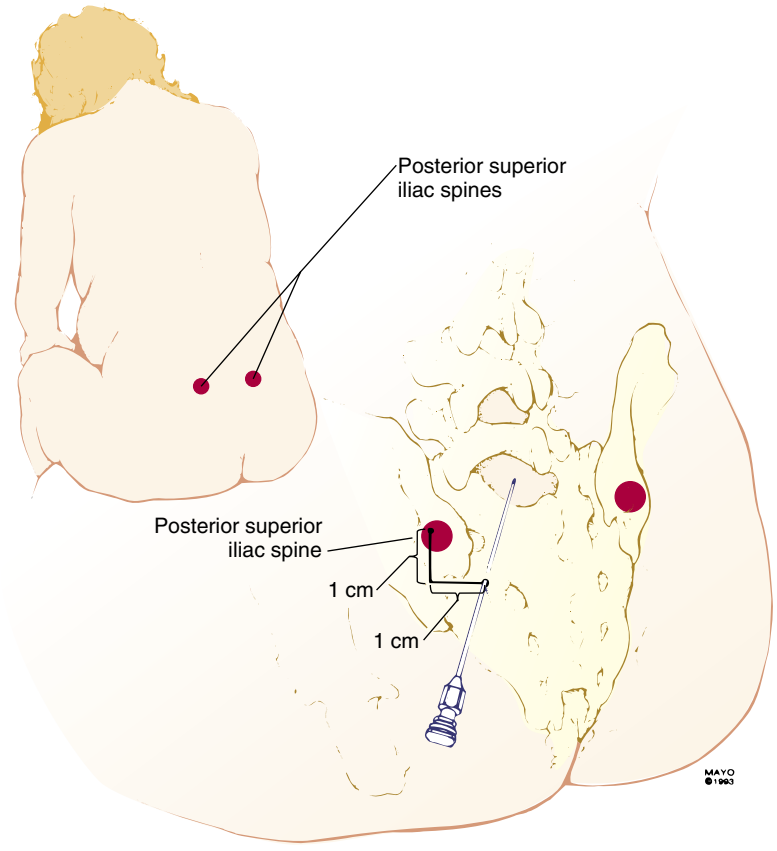

Figure 51-13 Neuraxial anatomy of the Taylor approach to spinal anesthesia. This is really a paramedian approach at the L5-S1 vertebral level. A skin mark is made 1 cm caudad and 1 cm medial to one of the posterior superior iliac spines. Through this skin mark, the needle is inserted in a cephalad and medial direction. The needle is walked off the sacrum and into the largest interspinous space, the L5-S1 intervertebral space. The posterior superior iliac spines are located immediately anterior to the "skin dimples" often found overlying the superior aspect of the sacrum. *(Courtesy of the Mayo Foundation, Rochester, MN.)*

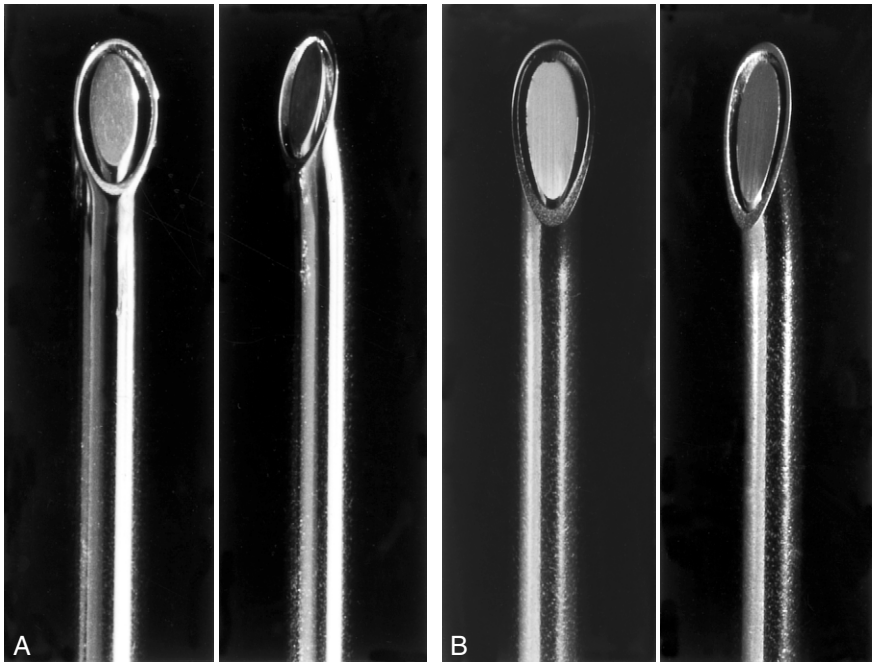

Figure 51-14 Examples of continuous spinal needles, including a disposable, 18-gauge Hustead (**A**) and a 17-gauge Tuohy (**B**) needle. Both have distal tips designed to direct the catheters inserted through the needles along the course of the bevel opening; 20-gauge epidural catheters are used with these particular needle sizes.

the subarachnoid space when the needle is withdrawn over the catheter. Catheter-over-the-needle devices are also available for use with continuous spinal anesthesia. They are promoted as minimizing leakage of CSF around the catheter.[68]

Pharmacology

Useful Drugs

There are many choices of drugs (see Chapter 30) in the United States to produce spinal anesthesia: procaine (Novocain), lidocaine (Xylocaine), mepivacaine (Carbocaine), tetracaine (Pontocaine), ropivacaine (Naropin), (*S*)-(−)-levobupivacaine (Chirocaine), and bupivacaine (Marcaine or Sensorcaine). These drugs provide a duration of spinal anesthesia ranging from 45 to 400 minutes and offer two clinical lengths of action: shorter (<90 minutes) and longer (>90 minutes).

Procaine is one of the oldest spinal anesthetics and originally replaced cocaine as the drug of choice for spinal anesthesia early in the 20th century. It is used for brief spinal anesthesia (<1 hour) but appears to be used less frequently than lidocaine for shorter spinal anesthesia because of three primary clinical differences. It is associated with a higher frequency of nausea (unexplained cause), a relatively high anesthetic failure rate, and a slower time to recovery.[69] It is often used as a hyperbaric drug in a dose ranging between 50 and 150 to 200 mg in a 10% concentration. The reason that some anesthesiologists continue in their use of procaine is the lower frequency of back and leg pain after its use than with lidocaine.[69]

Lidocaine is also often chosen for shorter procedures that can be completed in 1.5 hours or less. It has measurable effect in less than 5 minutes and is most commonly used as the 5% solution in 7.5% dextrose; however, many continue exploring reducing the concentration of the drug during spinal anesthesia.[70,71] It is not clear that reducing the concentration of lidocaine affects the incidence of the back and leg pain (called transient neurologic symptoms and formerly called transient radicular irritation) that follows its use for spinal anesthesia.[72] Transient neurologic symptoms develop most frequently after ambulatory procedures, especially in patients placed in the lithotomy or knee arthroscopy positions. Although many continue attempts to link these symptoms with subclinical neurologic injury, the evidence for such an association remains elusive.[73,74] A Cochrane review of transient neurologic symptoms strongly encourages discontinuation of the term to avoid linking the clinical symptoms of back pain and leg pain to neurologic change after the use of lidocaine, which remains unproven.[75] I further caution against abandoning the use of a useful, short-acting spinal anesthetic until the back pain associated with lidocaine spinal anesthesia is better defined. My use of lidocaine for spinal anesthesia is directed by the following suggestions. Limit the dose to 60 to 70 mg, inject the dose at a rate exceeding 0.2 mL/sec, keep the needle aperture directed cephalad, and limit use of the drug for continuous spinal techniques as much as practical.

Mepivacaine is another drug useful for spinal anesthesia and is being applied in settings in which lidocaine was used in the past. The drug-mass ratio for mepivacaine and lidocaine is approximately 1.3 : 1, suggesting that mepivacaine can be used for spinal anesthesia in a 30- to 60-mg dose and typically in the 2% concentration. In many aspects, mepivacaine is slightly longer-acting lidocaine, with variable reports of lower or equivalent rates of transient neurologic symptoms.[76-78]

When longer-acting agents for spinal anesthesia are desired, four drugs are available: tetracaine, bupivacaine, ropivacaine, and levobupivacaine. Tetracaine has been used in spinal anesthesia for years and is packaged as niphanoid crystals (20 mg) and as a 1% solution (20 mg). This drug has an onset of 5 to 10 minutes and is selected for procedures lasting up to 2 to 3 hours when epinephrine is added and up to 5 hours for lower extremity procedures when phenylephrine (0.5 mg) is added as a vasoconstrictor.[79,80] When niphanoid crystals are used, a 1% solution is obtained by adding 2 mL of sterile water (without preservatives) to the crys-

Table 51-3 Effect of Adding Epinephrine or Phenylephrine to Tetracaine Spinal Anesthesia

	Duration of Blockade*	
Group	**T10 (min)**	**L1 (min)**
I: Tetracaine (plain)	159 ± 41	230 ± 55
II: Tetracaine + epinephrine	234 ± 59†	327 ± 72† (0.5 mg)
III: Tetracaine + phenylephrine	273 ± 90†	406 ± 63†‡ (5 mg)

*The duration of blockade is defined as the time between administration of the spinal anesthetic and regression of the blockade to T10 or L1.
†Significant difference from group I ($P < .01$).
‡Significant difference from group II ($P < .025$).

tals. The appropriate milligram dose of the 1% solution is then mixed in equal volumes of 10% dextrose to produce a 0.5% tetracaine solution weighted with 5% dextrose. Subsequently, a vasoconstrictor may be added. Epinephrine and phenylephrine prolong spinal anesthesia with tetracaine (Table 51-3).[81,82]

Bupivacaine spinal anesthesia is commonly carried out with 0.75% and 0.5% solutions in dextrose, as well as with isobaric forms of the drug, the 0.5% and the 0.75% plain solutions. The clinical difference between 0.5% tetracaine and 0.75% bupivacaine as hyperbaric solutions is minimal, although more bupivacaine is used than tetracaine. It appears that when "isobaric" 0.5% and 0.75% bupivacaine are compared, the mass of drug (milligram dose) injected is more important in determining the eventual block height than the volume of isobaric drug administered.[83,84] Bupivacaine is appropriate for procedures lasting up to 2 to 2.5 hours.[85]

Ropivacaine is an amide local anesthetic that is frequently used for epidural anesthesia because of experimental evidence of less effect on the cardiac conduction system than occurs with bupivacaine. With spinal anesthesia, this difference is minimal because small doses are administered. When compared with bupivacaine, it is estimated to require 1.8 to 2 times the dose to produce a similar clinical effect.[86,87] Many believe that it is clinically indistinguishable from bupivacaine when the dose of drug administered is of a mass to produce an equal effect.[20]

Levobupivacaine is the isolated (*S*)-enantiomer of bupivacaine and is available for use as a spinal anesthetic. Clinical data suggest that this drug is converted to bupivacaine when used for spinal anesthesia, and for doses ranging from 4 to 12 mg, a volunteer study suggests little clinical difference between levobupivacaine and racemic bupivacaine.[88] In 80 patients undergoing elective hip replacement and receiving isobaric levobupivacaine (3.5 mL of a 0.5% solution) or isobaric bupivacaine (3.5 mL of a 0.5% solution), their clinical efficacy was judged equivalent.[89] In a clinical situation in which systemic toxicity is a minimal issue (or the typical spinal anesthetic), the advantage of levobupivacaine over bupivacaine appears to be more theoretical than real.

Spinal Anesthetic Additives

Some physicians are concerned that the use of additives, particularly vasoconstrictors, may be risky. The concept is that epinephrine and phenylephrine have such potent vasoconstrictive action that they place the blood supply of the spinal cord at risk. There are no human data supporting this theory. Kozody and colleagues[82,90,91] have shown that administering subarachnoid epinephrine (0.2 mg) or phenylephrine (5 mg) does not decrease spinal cord blood flow in dogs. These traditional vasoconstrictors are not the only adrenergomimetic agents being studied. Clonidine, an α_2-agonist, prolongs the motor block associated with tetracaine spinal anesthesia in dogs as much as epinephrine does while prolonging sensory blockade for an even longer interval.[92] The mechanism for this prolongation may involve vasoconstriction and antinociception from α-adrenergic stimulation.[93] Another drug investigated for spinal use as an additive is neostigmine.[94] This acetylcholinesterase inhibitor inhibits the breakdown of acetylcholine and thereby induces analgesia. It also prolongs and intensifies the analgesia through release of nitric oxide in the spinal cord. Despite the side effect of nausea and prolongation of motor block when combining it with local anesthetics, it is slowly gaining acceptance clinically.[95]

The interaction of various vasoconstrictors and local anesthetics is better understood. Traditionally, epinephrine was thought to prolong tetracaine spinal anesthesia but not bupivacaine or lidocaine spinal anesthesia.[96] This theory was postulated because of differences in the vasodilatory action of the local anesthetic drugs; plain lidocaine and bupivacaine cause vasodilation, whereas plain tetracaine does not. The original investigations of spinal anesthetic duration used two-dermatome regression in the thoracic dermatomes to establish duration.[97] Since that time it has become clearer that two-dermatome regression in the middle to high thoracic dermatomes may be misleading when measuring spinal anesthetic duration in the lower thoracic and lumbar dermatomes. Some data indicate that lidocaine spinal anesthesia is prolonged by epinephrine when measured by two-dermatome regression in the lower thoracic dermatomes and by occurrence of pain at the operative site for procedures carried out at the level of the lumbosacral dermatomes.[78,98]

When epinephrine has been compared with phenylephrine as a means of prolonging spinal anesthesia, conflicting information has resulted. Concepcion and coworkers[99] compared epinephrine (0.2 and 0.3 mg) and phenylephrine (1 and 2 mg) added to tetracaine and did not find a difference in increased duration with the two vasoconstrictors. Caldwell and associates[81] used larger doses of vasoconstrictors, epinephrine at 0.5 mg and phenylephrine at 5 mg, and showed that phenylephrine prolonged tetracaine spinal anesthesia significantly more than epinephrine did (see Table 51-3). Phenylephrine has been shown to prolong lidocaine spinal anesthesia, but it appears that the length of prolongation is more similar to that produced with epinephrine rather than significantly longer.[98,100] The duration of bupivacaine spinal anesthesia does not appear to be prolonged by phenylephrine.[97,101] Whichever local anesthetic solution and additives are selected for subarachnoid injection, special care should be taken to ensure that the clinician knows what substance is being injected and that all procedures have been carried out aseptically.

Hypobaric and Isobaric Spinal Anesthesia

The density of any solution is the weight in grams of 1 mL of the solution at a standard temperature. Specific gravity is the ratio of the density of a solution to the density of water. Baricity is a ratio comparing the density of one solution to another. If the other solution happens to be water, the baricity will be the same as the specific gravity. To make a drug hypobaric to CSF, it must be less dense than CSF, with a baricity appreciably less than 1.0000 or a

specific gravity appreciably less than 1.0069 (the mean value of the specific gravity of CSF).

In the United States, a common method of formulating a hypobaric solution is to mix tetracaine in a 0.1% to 0.33% solution with sterile water. This makes the baricity of the solution less than 0.9977 and allows clinically useful anesthesia to be induced. In the prone position for anorectal procedures or in the lateral position for hip repairs, 4 to 6 mg of a selected hypobaric dilution is often adequate. There is evidence that the rate of injection (0.02 versus 0.5 mL/sec) of hypobaric (0.2%) tetracaine influences spread of the drug.[102]

Another method of formulating a hypobaric-like solution is to use warmed 0.5% bupivacaine.[103] Data show that 0.5% bupivacaine warmed to 37°C as opposed to 4°C demonstrates hypobaric characteristics when the block is administered to sitting patients. The investigators suggest that warmed bupivacaine provides more predictable cephalad spread of the sensory level than a cold or room-temperature drug does. Another drug that has been investigated as a "clinically" hypobaric spinal drug is 2% lidocaine. Its physiochemical characteristics make it more similar to an isobaric than a hypobaric drug; however, some clinicians have found it useful in situations generally reserved for hypobaric techniques.[104]

When isobaric spinal anesthesia is planned, the drugs most often chosen across the globe are bupivacaine, ropivacaine, and levobupivacaine (in 0.5% or 0.75% concentrations). Another drug that can be used is tetracaine. It is formulated into an isobaric solution by diluting the niphanoid tetracaine crystals (20 mg) with CSF and then injecting the selected mass of drug in an isobaric fashion.

Box 51-1 Factors Postulated to Be Related to Spinal Anesthetic Block Height

  - Density
- Characteristics of the anesthetic solution
  - Density
  - Amount (mass)
  - Concentration
  - Temperature
  - Volume
- Vasoconstrictors

Factors Affecting Block Height

More than 20 factors have been postulated to alter spinal anesthetic block height (Box 51-1).[105,106] Box 51-2 lists the most important documented factors known to influence block height. Age has a statistically significant effect on block height, but when examined, the difference in block height with isobaric bupivacaine in patients in the third to ninth decades is small (i.e., T9 for those 20 to 28 years old and T6 for those older than 80 years).[107,108] Unlike epidural dose requirements, weight is not related to block height during spinal anesthesia. Patient height is related, although the contribution is minor when compared with more important factors. Similarly, the injection rate and barbotage of isobaric and hyperbaric solutions have not been shown to affect block height, although injection rates in these studies have been greater than 0.1 to 0.2 mL/sec.[109] It is becoming clear that the direction of the laterally facing openings of spinal needles affects block height levels, even with isobaric spinal solutions.[110,111] Other maneuvers that do not appear to affect block height are coughing and straining after local anesthetic injection. This is related to the physics of injecting drugs into a closed column of CSF, which instantaneously transmits pressure changes throughout the CSF column, such as those that occur with coughing or straining (Box 51-3).[105]

When more global factors affecting block quality are examined, at least in some teaching programs, the spinal failure rate may be as high as one in six blocks.[112] To understand the failure rate fully, the definition must be examined. Investigators[113] considered the need to supplement the block with any inhaled anesthetic as failure. This is a key point because to provide comprehensive regional anesthesia, supplementation of the block must be considered appropriate rather than a de facto failure.[113] These data emphasize an important contributor to failed blocks, the lack of free flow of CSF after needle placement. Obviously, some level of experience is needed to carry out spinal anesthesia successfully, but even in a teaching program, this should not prohibit the successful use of spinal anesthesia because the failure rate can be as low as 1%.[55,85]

Box 51-2 Factors Influencing Block Height

Controllable Factors

- Dose (volume × concentration)
- Site of injection along the neuraxis
- Baricity of the local anesthetic solution
- Posture of the patient

Factors Not Controllable

- Volume of cerebrospinal fluid
- Density of cerebrospinal fluid

Complications

Complications include neurologic changes; headache after spinal puncture; backache, which accompanies 25% of procedures performed with spinal anesthesia; and unexpected cardiac arrest.[114]

Neurologic injury after spinal anesthesia has received considerable media attention through the years, including the Wooley and Roe case in England, the investigation published by Kennedy and colleagues[4] in 1950 in the United States, and cases of cauda equina syndrome associated with small-bore continuous spinal anesthesia.[115] Overlooked by many is information from Marinacci,[116] whose investigation was performed after Kennedy and colleagues' publication. Marinacci, a neurologist, evaluated 542 patients who were thought to have neurologic complications related to previous spinal anesthesia. After neurologic evaluation, in only 4 of the 542 patients was there any indication that the prior spinal anesthetic was the cause of the postoperative neurologic change. The total number of patients undergoing spinal anesthesia that resulted in the four cases of neurologic symptoms related to spinal anesthesia is unknown.

Some reports outline the numerator and denominator of neurologic change after spinal anesthesia. Vandam and Dripps[117] documented 10,098 patients who underwent spinal anesthesia and reported no severe neurologic sequelae related to spinal anesthesia. A review of neurologic complications associated with neuraxial blocks, prompted by the chloroprocaine epidural controversy in the early 1980s, tabulated 304 patients undergoing spinal anesthesia with only one permanent lesion, a lumbar plexus injury, potentially related to spinal anesthesia.[118] Rigler and coworkers[115] reported cauda equina syndrome developing in four patients after continuous spinal anesthesia. The pool of patients from which the four patients were drawn is unknown. This research team has continued to highlight perceived difficulties with the spinal use of lidocaine and has added significant data to the question. Auroy and associates[119] reported on the regional anesthesia practice of more than 700 French anesthesiologists during a 5-month interval in the 1990s. These investigators highlighted that lidocaine appeared to be over-represented in their series of neurologic deficits after spinal anesthesia. The ultimate decision about using lidocaine for spinal anesthesia still requires consideration of the alternatives and suggestions outlined in the earlier section of this chapter on the pharmacology of spinal drugs.

The large series and case reports documenting infrequent neurologic lesions after spinal anesthesia should not provide a false sense of security.[120] Neurologic changes can occur; Reynolds has documented this in a group of predominately obstetric patients.[121] Fettes and Wildsmith addressed the findings of Reynolds in a thoughtful editorial and emphasized that we must always appreciate that another's nervous system is on the far end of the spinal needle.[122] The important point is that severe neurologic change can also occur after general anesthesia. The risk-benefit equation of anesthesia and neurologic injury must include the cases of neurologic injury (e.g., hypoxic CNS lesions) that are possible during general anesthesia if a logical and well-informed decision based on neurologic outcome is to be made.

A more common complication of spinal anesthesia is postoperative headache. This post–spinal puncture headache* is not exclusively related to spinal anesthesia; it also occurs after myelography and diagnostic lumbar puncture. Lybecker and coworkers[123] popularized a post–spinal puncture headache rating scale that may make comparison between future studies of postoperative headache more meaningful. Factors increasing the incidence of post–spinal puncture headache or unrelated to its development are listed in Table 51-4.[124]

Mihic's investigation of bevel direction during insertion of a spinal needle suggested that orienting a needle bevel parallel with the length of the neuraxis results in a lower incidence of post–spinal puncture headache.[125] Although needle type was unspecified in Mihic's report, it is likely that a Quincke-type needle was used. This clinical observation has been supported by a laboratory investigation by Ready and associates[65] showing that simulated spinal puncture with cone-shaped spinal needle tips produces slower transdural loss of fluid than a similar puncture

Table 51-4 Relationships Among Variables and Post–spinal Puncture Headache

Factors That May Increase the Incidence of Post–spinal Puncture Headache	
Age	Younger more frequent
Gender	Females > males
Needle size	Larger > smaller
Needle bevel	Less when the needle bevel is placed in the long axis of the neuraxis
Pregnancy	More when pregnant
Dural punctures (no.)	More with multiple punctures
Factors Not Increasing the Incidence of Post–spinal Puncture Headache	
Continuous spinals	
Timing of ambulation	

*Post–spinal puncture headache is used throughout chapter rather than post–dural puncture headache because it appears that arachnoid puncture is more linked to the resulting headache than the dural rent.[24]

with cutting-tipped needles does. Perhaps more important, a meta-analysis has shown that noncutting needle tip designs have a lower frequency of post–spinal puncture headache than cutting needle tip designs do.[126] Data from Reina and colleagues[26] have shown that the lower frequency of headache with cone-shaped needle tips may be the result of exposing more inflammatory mediators around the opening rather than the often-quoted more gentle spreading of the dura at the site of puncture. An arbitrary period of recumbency after spinal anesthesia has not been found to decrease the incidence of post–spinal puncture headache,[127] and some data indicate that early ambulation may actually decrease its incidence.[128,129]

Possibly more important than knowing all the variables resulting in an increased incidence of post–spinal puncture headache is understanding how and when to carry out the definitive therapy—epidural blood patch—for this complication.[130] Successful application of spinal anesthesia necessitates the early use of epidural blood patching when indicated. This therapy was introduced by Gormley[131]; its safety and efficacy (>90% effective in relieving headache per epidural patch) have been well documented, and contemporary practice has validated that epidural blood patch continues to have a greater than 90% improvement rate.[132]

A question that has been debated since its introduction concerns the volume of blood that is most effective in balancing blood patch efficacy and risks. By injecting radionucleotide-labeled red blood cells epidurally, Szeinfeld and coworkers[133] have shown that approximately 15 mL of blood provides efficacy and allows spread over a mean distance of nine spinal segments, thus providing some latitude for blood patch needle placement. They demonstrated that the blood was spread over more segments in the cephalad direction than in the caudad direction. As a result, they recommend inserting the blood patch needle in a more caudad site if it is impossible to insert the needle at the same level as that of the previous dural puncture. MRI of epidural blood patch spread has validated their data about primarily cephalad spread of an epidural blood patch.[134]

Data from Brown and Elman[135] demonstrate that approximately 25% of all surgical patients undergoing anesthesia, regardless of anesthetic technique, experience backache. Backache after neuraxial block should not immediately be attributed to "needling" of the back or to the use of 5% lidocaine.

When properly conducted, spinal anesthesia has proved to be extremely safe. Caplan and associates[114] identified 14 cases of sudden cardiac arrest in healthy patients receiving spinal anesthesia. Because these cases seemed to appear suddenly after stable hemodynamic status, they concluded that a poorly understood potential exists for sudden cardiac arrest in healthy patients. It can be debated whether this represented lack of vigilant monitoring and treatment as opposed to some mysterious physiologic explanation.[136] It is clear that hypoxemia and oversedation are not required for severe bradycardia and asystole to develop during well-conducted spinal anesthesia.[53,137] Likewise, it is clear that the development of severe bradycardia after spinal anesthesia is not a new phenomenon but has been recognized for many years.[138,139] In any case, it should be emphasized that cardiovascular changes can occur rather suddenly after spinal anesthesia, and as Auroy and colleagues[119] highlight, these events continue to occur.

Clinical Pearls

Frequently, the little things necessary to carry out effective spinal anesthesia are unstated because they somehow seem less important than the broader issues, such as the incidence of neurologic complications after spinal anesthesia. Nevertheless, the little things often spell the difference between successful use of the technique and failure.

Successful integration of neuraxial blocks into an anesthesia practice requires that anesthesiologists be willing to supplement their blocks with CNS depressants.[113] A concept has developed that a regional anesthetic should need no supplementation and that if it does, it should be considered a failed block. This reasoning needs rethinking. For example, an anesthesiologist would not be expected to pick an arbitrary concentration of an inhaled agent before general anesthesia and, on discovering that the concentration needs to be altered during the anesthesia, consider the technique a failure! Likewise, supplementation of a spinal or epidural anesthetic contributes to its comprehensive use and should not be a marker of failed blocks. After this concept is accepted, neuraxial blocks can be adapted to many more situations, thereby allowing an anesthesiologist's experience and confidence with the techniques to grow.

To prevent prolongation of a patient's recovery room stay and therefore unnecessarily introduce institutional inefficiency, inpatients should be allowed to leave the recovery room after spinal anesthesia as soon as it can be demonstrated that their block is receding appropriately (at least four dermatomes' regression or a spinal level of less than T10), they are hemodynamically stable, and they are comfortable. After spinal anesthesia, outpatients should be able to ambulate without orthostatic changes and void before discharge if they are in a high-risk group for urinary retention[62] (see Chapter 78).

Intraoperatively during high spinal anesthesia, patients occasionally complain excessively about dyspnea. This is not a result of significantly decreased inspiratory capacity but most often seems to be related to loss of chest wall sensation, which does not allow patients to experience the reassurance of a deep breath. This impediment to patient acceptance can often be overcome by instructing the patient to raise a hand near the mouth and exhale forcefully. The tactile appreciation of the deep breath seems to provide reassurance.

If a neurologic complication is identified after an operation performed with spinal anesthesia, it is useful to obtain neurologic consultation early so that an unbiased consultant can examine the patient and determine whether the "new" neurologic finding was preexistent, related to a peripheral neuropathy, or more rarely, potentially related to the spinal anesthetic. The latency in electromyographic alterations associated with denervation secondary to neurologic injury takes time (14 to 21 days) to develop in the lower extremities. The physician should obtain electromyographic studies early and serially after a potential spinal anesthetic–related lesion. In this manner, it is possible to document whether the lesion was preexisting or provide evidence that it is a peripheral rather than a central lesion.

Probably more important than any single factor for the success of spinal anesthesia in the day-to-day use of anesthesia is that it must be time efficient. It cannot add measurably to the surgical day if nurses and surgeons are to be coadvocates of the

technique. The physician should plan ahead to maximize time efficiency. Often overlooked is that patient preparation for surgery can begin almost as soon as the block is administered if sedation is at an appropriate level.

Epidural and Caudal Anesthesia

Epidural Technique

The technique of epidural anesthesia relies on the same four P's as spinal anesthesia, with minor modifications.

Preparation

In addition to patient preparation, selection of epidural equipment is essential. The physician must decide on a continuous or single-shot technique. This is the principal determinant of needle selection. If a single-shot epidural technique is chosen, a Crawford needle is appropriate; if a continuous catheter technique is indicated, a Tuohy or another needle with a laterally facing opening is chosen (Fig. 51-15). A method of identifying the epidural space must also be selected, with most using a loss-of-resistance technique. If a loss-of-resistance technique is used, an additional decision about the type of syringe (i.e., glass versus plastic and Luer-Lok versus friction hub) is required. The theoretical ideal is a Luer-Lok, finely ground glass syringe because it minimizes the chance of misidentification of the epidural space. Most disposable equipment can be customized to an individual's needs if the advantages of reusable equipment are not available.

Position

The patient positions necessary for epidural puncture are the same as those for spinal anesthesia, with the exception of the prone position for the caudal approach. Inadequate positioning

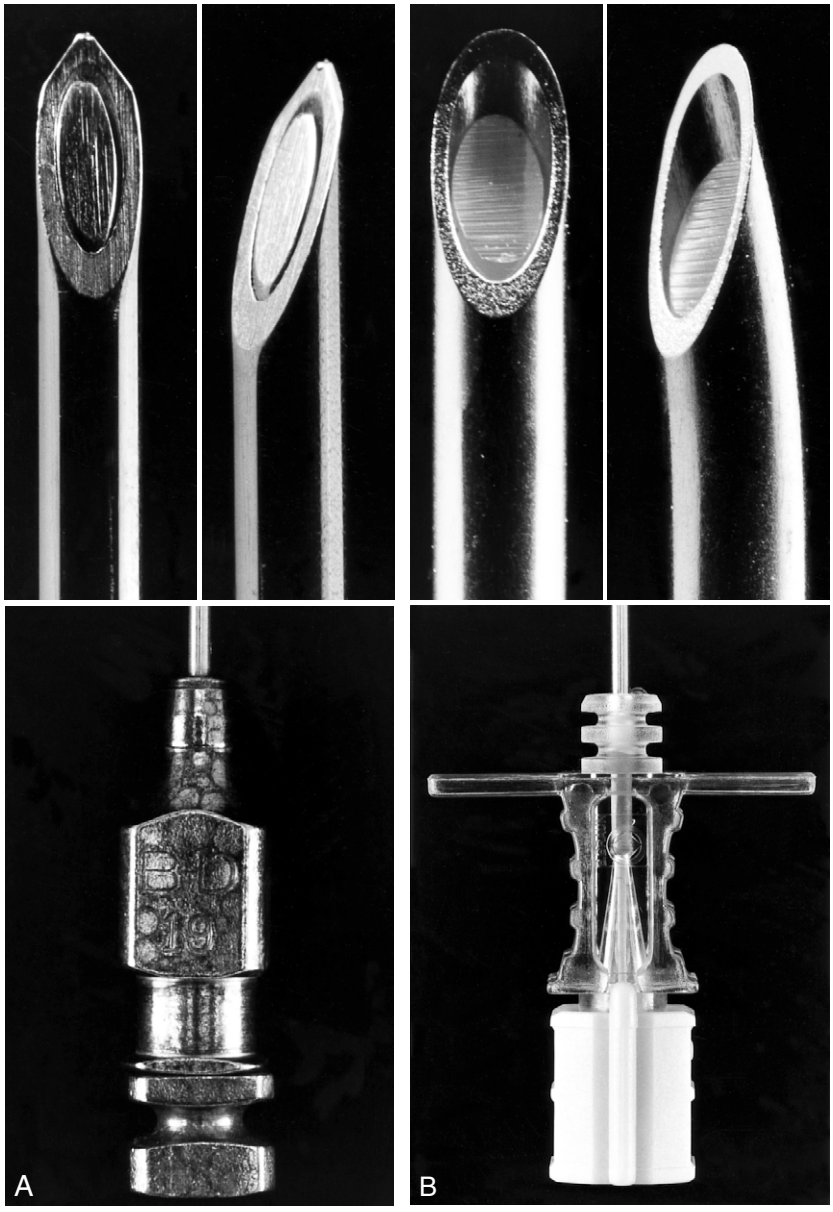

Figure 51-15 Epidural needles with catheter assortment. **A,** A 19-gauge, reusable Crawford epidural needle. **B,** A 19-gauge, disposable Tuohy needle.

of the patient can negate otherwise meticulous technique and should be prevented. Limitation of block spread (i.e., height) is not clinically predictable with alterations in position during epidural anesthesia because gravity and solution baricity are not intimately related to block spread. Despite these facts, Seow and coworkers[140] have demonstrated slightly faster block onset times in patients' dependent body regions when the lateral decubitus position is used for epidural block.

Three positions are available for caudal anesthesia, with the prone position most often chosen in adults, the lateral decubitus position in children, and the knee-chest position infrequently used. The lateral decubitus position is used in children because it is easier to maintain a patent airway in this position than in the prone position, and the landmarks are more easily palpable than in adults (see Chapter 81). This consideration is valuable because caudal anesthesia is often combined with general anesthesia in pediatric patients to decrease the amount of volatile agent used intraoperatively or to provide postoperative analgesia. In contrast, a caudal block is often administered during preoperative sedation in adults and when the prone position is applicable. When placing a patient in the prone position, a pillow should be inserted beneath the iliac crests to rotate the pelvis and make cannulation of the caudal canal easier. An additional help is to spread the lower extremities about 20 degrees with the heels rotated laterally, which minimizes gluteal muscle contraction and eases needle insertion (Fig. 51-16).

Projection and Puncture

Epidural technique requires placement of the needle tip into the ligamentum flavum for the loss-of-resistance and hanging-drop methods. Placing the needle (with stylet) into the ligamentum flavum before attaching the syringe or placing solution into the needle hub allows an improved appreciation of epidural anatomy for the operator. If the needle is merely inserted into the supraspinous ligament and then loss-of-resistance or hanging-drop

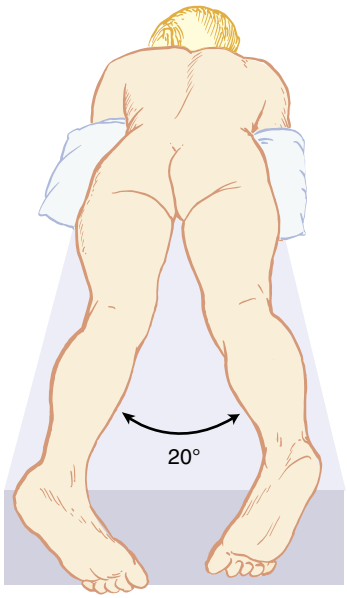

Figure 51-16 Prone position for the caudal technique. A pillow is used under the anterior iliac crests to rotate the pelvis, the legs are spread 20 degrees to ease identification of the sacral hiatus, and the heels are rotated laterally to relax the gluteal musculature.

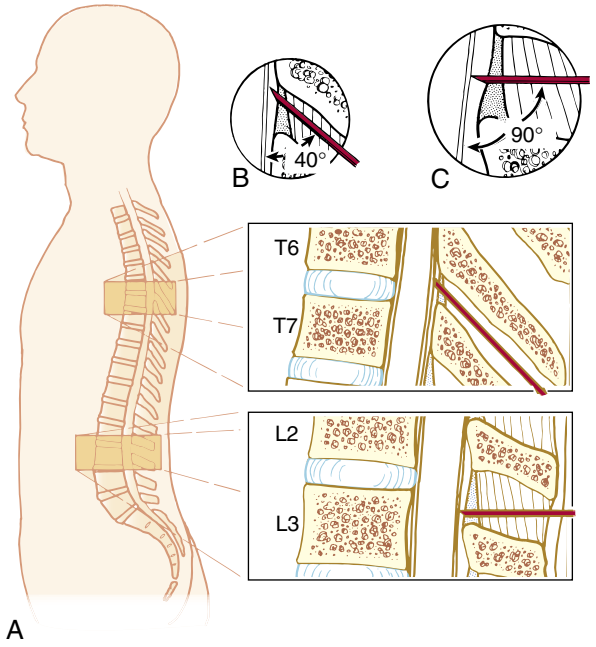

Figure 51-17 A, Lumbar and thoracic epidural technique. The increased angle of needle insertion during thoracic epidural cannulation may provide a slightly longer distance of "needle travel" before entering the subarachnoid space. In contrast to lumbar epidural cannulation (**B**), the distance traveled is modified by a more perpendicular angle of needle insertion (**C**).

insertion is begun, an increased chance of false release seems likely.

When a lumbar approach is used, the depth from skin to the ligamentum flavum commonly approaches 4 cm, with the depth in most (80%) patients being between 3.5 and 6 cm. In this region, the ligamentum flavum is 5 to 6 mm thick in the midline, which requires needle control if unintentional dural puncture is to be prevented. Some investigators are exploring the use of ultrasound to help minimize dural puncture by more accurately defining the distance between the skin and the epidural space.[141] When a thoracic approach is chosen, control is of equal or greater importance because injury to the spinal cord is possible if the needle is advanced too far. Theoretically, the increased angle of needle insertion in the thoracic region may provide an element of safety in that the more acute angle necessary to gain epidural cannulation provides some margin of safety (Fig. 51-17). Clinically, thoracic epidural anesthetics do not appear to be associated with an increased incidence of neurologic injury because those choosing to use the technique are most often anesthesiologists with considerable experience in lumbar epidural anesthesia.[142] In any event, significant caution about performing thoracic epidural techniques in adult patients receiving general anesthesia is warranted because these patients are unable to provide feedback to the operator about neural stimulation during needle insertion.

The preferred method of carrying out the loss-of-resistance technique involves inserting the needle to the ligamentum flavum and then attaching a 3- to 5-mL glass syringe filled with 2 mL of saline and a small (0.25-mL) air bubble. The needle is grasped with the nondominant hand and pulled toward the epidural space while the dominant hand (thumb) applies constant steady pressure on the syringe plunger to compress the air bubble. When the epidural space is entered, the pressure applied to the syringe plunger allows the solution to flow without resistance into the epidural space.

An alternative, although with a less precise end point, is the technique of hanging-drop identification of entry into the epidural space. After the needle is placed into the ligamentum flavum, a drop of solution is placed within the hub of the needle. When the needle is advanced into the epidural space, the solution should be "sucked in." The theory behind this maneuver has been attributed to subatmospheric pressure in the epidural space. The subatmospheric pressure has been related to expansion of the epidural space as the needle pushes the dura away from the ligamentum flavum.[143] The negative intrathoracic pressure may influence the pressure in the epidural space in the thoracic region.

Regardless of the method selected for needle insertion, when the anesthesiologist chooses to cannulate the epidural space with a catheter, success may be increased by advancing the needle 1 to 2 mm after the space is identified. The incidence of unintentional intravenous cannulation with an epidural catheter may be lessened by injecting air or solution before threading the catheter.[144,145] Unless radiographic guidance is used for some special reason, epidural catheters should be inserted only 2 to 3 cm into the epidural space for surgical or obstetric patients needing rapid onset of analgesia.[146] Threading more catheter may increase the likelihood of catheter malposition. If malposition does occur, data suggest that one of the more common sites of malposition is entry of the catheter into the anterior epidural space.[147] In obstetric patients, it appears that the catheter should be inserted between 4 and 6 cm to optimize efficacy and prevent unintentional movement of the catheter during prolonged labor analgesia.[148,149] Multiport (three lateral ports) or single–end-hole (uniport or distal port) catheters are available. The choice is up to individual clinicians, although it has been shown in laboring patients that the incidence of inadequate analgesia is less with multiport catheters than with uniport catheters.[150]

Despite an adequately positioned catheter during first use of a local anesthetic, each subsequent injection should be preceded by aspiration and an epidural test dose because catheter migration into vessels and the subarachnoid or subdural space does occur. In the past, many considered the catheter unusable in the event that the epidural catheter hub becomes disconnected from the epidural catheter. It appears that the catheter can be reused if strict reconnection criteria are followed.[151]

Caudal Technique

Caudal anesthesia requires identification of the sacral hiatus. The sacrococcygeal ligament (i.e., extension of ligamentum flavum) overlying the sacral hiatus lies between the sacral cornua. To facilitate locating the cornua, the posterior superior iliac spines should be located and, by using the line between them as one side of an equilateral triangle, the location of the sacral hiatus should be approximated (Fig. 51-18). After the sacral hiatus is identified, the index and middle fingers of the palpating hand are placed on the sacral cornua, and the caudal needle is inserted at an angle of approximately 45 degrees to the sacrum. While advancing the needle, a decrease in resistance to needle insertion should be appreciated as the needle enters the caudal canal. The needle is advanced until bone (i.e., dorsal aspect of the ventral plate of the sacrum) is contacted and then slightly withdrawn, and the needle

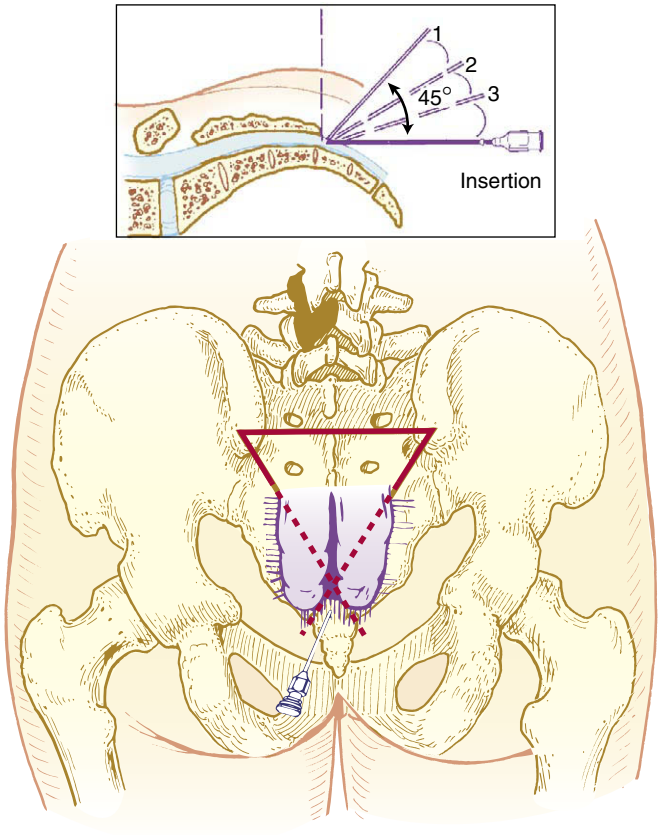

Figure 51-18 Caudal technique. Palpating fingers locate the sacral cornua by using the equilateral triangle (shown in Fig. 51-5). Needle insertion is carried out by insertion and withdrawal in stepwise fashion (*inset*; so-called 1-2-3 insertion) until the needle can be advanced into the caudal canal and the solution can be injected easily (without creation of a subcutaneous "lump" of fluid).

is redirected so that the angle of insertion relative to the skin surface is decreased. In male patients, this angle is almost parallel to the coronal plane; in female patients, a slightly steeper angle (15 degrees) is necessary. During redirection of the needle and after loss of resistance is again encountered, the needle is advanced approximately 1 to 2 cm into the caudal canal. Further advance is not attempted because dural puncture and unintentional intravascular cannulation become more likely. One method of increasing the likelihood of correct caudal needle placement is to inject 5 mL of saline rapidly through the caudal needle while palpating the skin overlying the sacrum. If no midline bulge is detected, the needle is probably positioned correctly. In contrast, if a midline bulge is detected during saline injection, the needle is positioned incorrectly.

After ensuring correct needle position and before injection of the therapeutic dose of caudal anesthetic, aspiration should be performed and a test dose administered because as in lumbar epidural anesthesia, a vein or the subarachnoid space can be entered unintentionally.

Pharmacology

Useful Drugs

Successful selection of drug for epidural anesthesia (see Chapter 30) requires an understanding of the local anesthetic's potency and duration, as well as estimation of the surgical requirements and duration and postoperative analgesia requirements. As with any regional anesthetic, the surgeon, anesthesiologist, procedure, and anesthetic technique must all be included in the drug choice equation.

Drugs available for epidural use can be categorized as short-, intermediate-, and long-acting local anesthetics, and with the addition of epinephrine to these agents, surgical anesthesia ranging from 45 to 240 minutes is possible (Table 51-5). Chloroprocaine, an ester local anesthetic, is a short-acting agent that was associated with neurotoxicity (i.e., adhesive arachnoiditis) when unintentionally injected in large volumes into the subarachnoid space before a change in formulation.[151,152] Since 1985, reduced bisulfate concentrations of the drug formulation have been available; since 1987, bisulfate-free 2-chloroprocaine has been available; and since 1996, preservative-free 2-chloroprocaine has been available. Since these formulation changes, there have been no reports of neurotoxicity attributable to 2-chloroprocaine until recently. Winnie and Nader[153] have highlighted that in this era of increasing drug costs, some hospitals are substituting generic formulations of anesthetic drugs, and in one situation, metabisulfite-containing 2-chloroprocaine was returned to anesthesia stock without knowledge of the physicians. We must all be aware of the solutions that we are using because this type of substitution is likely to increase.

In the era of ever-increasing numbers of surgical outpatients, combining 2-chloroprocaine and a catheter technique allows efficient matching of the surgical procedure and duration of epidural analgesia and enables patients to spend minimal recovery time in the facility. It is available in 2% and 3% concentrations, with the latter preferable for surgical anesthesia and the former for techniques not requiring muscle relaxation.

There is evidence that the back pain developing after larger volumes (>25 mL) of 2-chloroprocaine was related to the ethylenediaminetetraacetic acid used as a preservative in the chloroprocaine.[154] It appears that preservative-free chloroprocaine is not associated with back pain in larger doses at the same frequency.

Lidocaine is the prototypical amide local anesthetic and is used epidurally in 1.5% to 2% concentrations. Mepivacaine is

Table 51-5 Comparative Onset Times and Analgesic Durations of Local Anesthetics Administered Epidurally in 20- to 30-mL Volumes

			Duration (min)	
Drug	**Conc. (%)**	**Onset (min)**	**Plain**	**1:200,000 Epinephrine**
2-Chloroprocaine	3	10-15	45-60	60-90
Lidocaine	2	15	80-120	120-180
Mepivacaine	2	15	90-140	140-200
Bupivacaine	0.5-0.75	20	165-225	180-240
Etidocaine	1	15	120-200	150-225
Ropivacaine	0.75-1.0	15-20	140-180	150-200
Levobupivacaine	0.5-0.75	15-20	150-225	150-240

similar to lidocaine in the concentrations necessary for epidural anesthesia and lasts 15 to 30 minutes longer. Epinephrine prolongs the duration of surgical anesthesia by approximately 50% with lidocaine and mepivacaine.[116] Another additive to these drugs that may influence clinical use is fentanyl, an intermediate-acting amide drug for epidural use. When fentanyl was added to mepivacaine, it accelerated the onset of analgesia and enhanced the analgesic effect during epidural anesthesia.[155] One technique receiving more attention to minimize the length of an epidural motor block after surgery is completed is the use of saline in 15- to 30-mL volumes through the epidural catheter before it is removed.[156]

Bupivacaine remains the most widely used long-acting local anesthetic; it is used in 0.5% and 0.75% concentrations for surgical anesthesia. Analgesic techniques can be performed with concentrations from 0.125% to 0.25%. Its duration of action is less consistently prolonged by the addition of epinephrine, although up to 240 minutes of surgical anesthesia can be obtained when epinephrine is added. In 1983, the FDA stated that 0.75% bupivacaine was no longer recommended in obstetric anesthesia as a result of a perception that systemic toxicity at that concentration resulted in more difficult resuscitation than occurred with the lower concentrations. The evidence for this action remains controversial, although it does appear that bupivacaine and etidocaine are more likely than other local anesthetics to impair myocardial performance and conduction when systemic toxicity occurs.[157,158]

Ropivacaine is increasing in use as an epidural agent. It is used in 0.5% to 1.0% concentrations for surgical anesthesia and 0.1% to 0.3% concentrations for analgesia. Animal evidence supports the concept that ropivacaine has less impact on cardiac conduction and the frequency of arrhythmias than local anesthetics do at blood levels producing systemic toxicity.[159] In an individual patient, the clinical effect of ropivacaine is difficult to separate from a similar effect from bupivacaine, although it appears to produce less motor block and has a slightly shorter duration of action than bupivacaine does.[160] However, it is the only local anesthetic still in use that has a vasoconstrictive property at clinically used concentrations.

Levobupivacaine is also used as an epidural local anesthetic in 0.5% to 0.75% concentrations for surgical anesthesia, and analgesic techniques can be performed with concentrations of 0.125% to 0.25%. In an individual patient, the clinical anesthetic effect from the drug is indistinguishable from that of racemic bupivacaine.[161] Similar to ropivacaine, animal evidence supports the concept that levobupivacaine has less impact on cardiac conduction and the frequency of arrhythmias than local anesthetics do at blood levels producing systemic toxicity.

Etidocaine is an infrequently used epidural anesthetic, principally because of the perception and some data supporting that motor block is more profound than sensory block with the drug.[162] The reason may be that etidocaine is less effective than bupivacaine in producing small-fiber blockade.[163]

Additives

Some investigators advocate combining agents with local anesthetics to make epidural anesthesia last longer, to improve the quality of blockade, or to accelerate the onset of blockade. Epinephrine increases the duration of useful anesthesia with all the agents, although the proportional effect is greatest with lidocaine, mepivacaine, and 2-chloroprocaine; it shows a lesser effect with bupivacaine, levobupivacaine, and etidocaine and has a limited effect with ropivacaine (see Table 51-5). Phenylephrine has been used in epidural anesthesia less widely than in spinal anesthesia, perhaps because it does not reduce peak blood levels of local anesthetic as effectively as epinephrine does during epidural use.[164]

Carbonation of the local anesthetic solution has been suggested as a means of increasing the speed of onset and quality of the block by producing more rapid intraneural diffusion and more rapid penetration of connective tissue surrounding the nerve trunk.[165,166] Some data suggest that there are no clinical advantages for carbonated solutions,[167] and some disadvantages may occur more rapidly because peak blood levels of the drug are higher after carbonation of the local anesthetic and blood pressure decreases (see Chapter 30).[168,169]

The addition of bicarbonate has also been suggested as a means of increasing the pH of the local anesthetic solution and increasing the concentration of nonionized free base, which theoretically increases the rate of diffusion of the drug and the speed of onset of the block. Clinically, the addition of 1 mEq of sodium bicarbonate to each 10 mL of commercially prepared 1.5% lidocaine solution produces a significantly faster onset of anesthesia and more rapid spread of sensory block.[170] In addition to speeding onset of the block, there is evidence that a more complete block may be produced.[171] The clinical applicability of this modification should be considered individually on its merits by each institution's anesthesia group.

Another alteration of drugs for epidural use involves combining long- and short-acting drugs, theoretically to gain the benefits of each. This practice does not seem necessary or prudent because familiarity with the local anesthetics and additives available allows a spectrum of block lengths to be produced. Moreover, the purported advantage of faster onset with combinations of local anesthetics seems clinically inconsequential.

Complications

Intravascular Injection

Epidural anesthesia has the potential to produce local anesthetic–induced systemic toxicity (see Chapter 30), primarily through the unintentional administration of drug into an epidural vein. Considerable research has been undertaken to define the ideal test dose for continuous epidural catheter use. The use of test doses should minimize unintentional intravascular injections, although there are concepts in treating a local anesthetic–induced systemic toxicity reaction that all anesthesiologists should understand.

The toxic effects of local anesthetics primarily involve the CNS and cardiovascular system, with the CNS affected at lower blood levels. For example, four to seven times the dose of local anesthetic necessary to produce convulsions in dogs is required to produce cardiovascular collapse.[172] The CNS stimulation is a result of selective inhibition of inhibitory neurons in the cerebral cortex, which allows facilitatory neurons to discharge in unopposed fashion, producing CNS excitation.[173] After blood levels are high enough, inhibitory and facilitatory pathways are inhibited, thereby leading to CNS depression.

Initially, the potential for local anesthetic–induced toxicity (CNS and cardiovascular system) was thought to parallel anesthetic potency.[174,175] Information suggests that bupivacaine and

etidocaine may be proportionally more cardiotoxic than their anesthetic potency predicts.[176,177] This relative increase in cardiotoxicity appears to result from more potent electrophysiologic effects of the long-acting amides because of their fast-in–slow-out sodium channel blockade. Ropivacaine and (*S*)-(−)-levobupivacaine, other long-acting amide local anesthetics, have a CNS-to-cardiovascular toxicity ratio intermediate between that of lidocaine and bupivacaine.[178,179] The clinical importance of these observations about toxicity must be balanced against clinical studies showing limited cardiovascular depression in patients experiencing bupivacaine-induced seizures during regional anesthesia.[180]

If signs of CNS toxicity or frank convulsions occur, several steps must be followed if adverse outcomes are to be minimized (see Chapter 30). Early in local anesthetic–induced seizures, hypoxemia, hypercapnia, and acidosis develop rapidly, and symptomatic treatment of the toxicity must involve treatment of these factors. Oxygen should be given by bag and mask, and tracheal intubation is not mandated unless ventilation is ineffective.[181] The next step in therapy remains controversial, with administration of succinylcholine or an anticonvulsant. Succinylcholine is often recommended because the local anesthetic–induced seizures are usually short-lived and the muscle relaxation obtained facilitates ventilation and decreases the magnitude of the metabolic acidosis. Nevertheless, it does not decrease cerebral metabolism; CNS oxygen requirements remain increased. Others suggest that diazepam is effective in controlling local anesthetic–induced seizures, although 2 to 3 minutes is required to control seizures after administration.[182,183]

The most effective method of treating toxic reactions is prevention. Administration of excessive doses of local anesthetics should be prevented, and test doses of local anesthetics should be used before the injection of therapeutic doses. If a toxic reaction does occur, it is imperative that oxygen, a method of administering it, succinylcholine, and anticonvulsant drugs are immediately available.

Subarachnoid Injection

The adverse effects of unintentionally administering an epidural dose of local anesthetic into spinal fluid are highlighted by the neurologic changes that follow subarachnoid injection of 2-chloroprocaine. However, most subarachnoid injections of epidural local anesthetics are less dramatic; rather, the issue is how the physician should treat the cardiopulmonary effects resulting from such an injection. As in any neuraxial block that reaches high levels, arterial blood pressure and heart rate should be supported. The Trendelenburg position should be instituted to maximize venous return. Intravenous atropine and ephedrine are often effective and provide the time to administer a more potent catecholamine, if needed. Ventilation should be supported, and if the entire dose (20 to 25 mL) of local anesthetic has been administered into the CSF, tracheal intubation and mechanical ventilation are indicated because patients may require approximately 1 to 2 hours to maintain adequate spontaneous ventilation consistently. After a large dose of local anesthetic into the CSF, the pupils become dilated, which may seem to indicate CNS injury if this phenomenon is not recognized for what it is. The pupils return to the baseline state as the high block recedes. Fortunately, the necessity for sedation during the period of tracheal intubation and mechanical ventilation is minimal. These patients do not usually recall such events.[184]

When an epidural block is performed and a higher than expected block develops only after a delay of 15 to 30 minutes, subdural placement of local anesthetic must be considered. Treatment is symptomatic; the most difficult aspect is recognizing the possibility of a subdural injection.

Neurologic Injury

With the exception of the publicity surrounding 2-chloroprocaine–induced adhesive arachnoiditis, uncomplicated epidural anesthesia has not been linked to neurologic injury more frequently than with other anesthetics, regional or general.[117,120] No particular local anesthetic, needle versus catheter technique, addition or omission of epinephrine, or location of the epidural puncture seems to be associated with an increased incidence of neurologic injury. Despite this information, neurologic injury is often feared and epidural anesthesia is avoided in patients in whom antiplatelet drugs or other anticoagulants have been used preoperatively. Is this justified?

In patients taking the antiplatelet drug aspirin, there are no data showing an increased incidence of neurologic injury caused by epidural bleeding (hematoma) when epidural anesthesia is used.[185] It is doubtful that a perceived lack of data indicates that the problem has been overlooked because epidural anesthesia is frequently used in patients undergoing orthopedic procedures, in whom use of aspirin and nonsteroidal anti-inflammatory drugs is widespread. Nevertheless, there are isolated case reports of neurologic injury after epidural and spinal anesthesia in patients in whom antiplatelet drugs were used. It may be significant that in these case reports the initial neuraxial technique was abandoned after technical difficulties with needle placement.[186,187] The appropriate place of neuraxial techniques with the more potent antiplatelet drugs (e.g., abciximab, a glycoprotein IIb/IIIa receptor antagonist, and clopidogrel, a platelet aggregation inhibitor) remains undetermined, although significant caution is needed.

The use of epidural anesthesia for patients receiving anticoagulants is less clear because epidural anesthesia is often avoided in these patients. There are data from Odoom and Sih,[188] who used continuous epidural anesthesia without problem in 1000 vascular operations for patients receiving oral anticoagulants preoperatively. The acceptable magnitude of preoperative anticoagulation and the risk-benefit ratio of performing epidural anesthesia remain undetermined and should be focused on specific patients and their clinical setting. Despite lacking data, the use of epidural techniques in patients receiving subcutaneous heparin therapy is probably acceptable if the block can be performed atraumatically, although the risk-benefit ratio must be determined for each patient.[189] Some speculate that proof of minimal systemic effect from subcutaneous heparin (normal partial thromboplastin time) is necessary before neuraxial blockade.[188]

There is a consensus that when LMWH (e.g., enoxaparin) is used perioperatively, neuraxial block techniques need to be managed differently.[190] The risk of neuraxial bleeding is increased when LMWH and neuraxial techniques are combined if the following recommendations are not followed[9]:

1. Neuraxial block should be delayed for at least 10 to 12 hours after the last dose of LMWH in patients receiving the drug preoperatively.
2. Postoperative treatment with LMWH should be delayed at least 12 hours after completion of the surgical procedure.

3. Removal of the epidural and spinal catheters used for postoperative analgesia should take place 10 to 12 hours after the last dose, with subsequent dosing delayed for at least 2 hours.

It does seem that the issue of intraoperative anticoagulation after epidural catheter insertion is as settled as clinical data allow. Approximately 5000 patients have undergone epidural anesthesia for vascular surgery with intraoperative heparinization and without a neurologic injury attributable to epidural bleeding.[188,191,192] Despite minimal problems with epidural anesthesia and neurologic dysfunction related to anticoagulation, if a patient has neurologic symptoms consistent with a neuraxial mass after a regional block, immediate neurosurgical consultation is indicated because time is of the essence if permanent sequelae are to be prevented. If the patient appears to be at increased risk for neuraxial bleeding but the neuraxial technique remains indicated, it may be prudent to use a shorter-acting epidural local anesthetic, even if it means reinjecting more frequently, so that the block will resolve as rapidly as possible after the surgical procedure.

Clinical Pearls

"Success covers a multitude of blunders"* is an appropriate adage for the use of epidural anesthesia. To be successful, the anesthesiologist must perform the technique often enough to be technically facile. To increase use of the technique, several practical observations may be helpful.

If catheters can be avoided during epidural anesthesia (e.g., by selecting the appropriate local anesthetic), a potential source of difficulties with the technique can be avoided. It is important to allow the block enough "soak time" before the surgical procedure; this can be facilitated if the block is carried out in an induction room separate from the operating room. The anesthesiologist must recognize that there appears to be a plateau effect in dosing epidural local anesthetics. After some quantity of the local anesthetic has been injected, additional local anesthetic does not significantly increase block height but instead may make the block more dense (i.e., improve quality).[193] To be successful with the technique, the anesthesiologist should be prepared at all times to treat complications associated with epidural anesthesia; airway equipment, drugs, and especially oxygen and resuscitation must be immediately available.

Clinical Controversies and Neuraxial Blocks

Despite the many years that neuraxial blocks have been used, there remain controversies about the appropriate use of these blocks. Some continue to suggest that spinal anesthesia is inappropriate for outpatients because of the occurrence of post–spinal puncture headache, but there are data that the occasional headache can be successfully treated even in outpatients,[194] and considerable other data support use of the technique in outpatients (also see Chapter 78).[195] Similarly, spinal anesthesia seems to be well suited for use in patients undergoing cesarean section because of the short interval from injection to surgical anesthesia. If epidural blood patch therapy is used in timely fashion, the increased incidence of headache in this patient population should not necessarily limit use of the technique for cesarean section. An outgrowth of the management of post–spinal puncture headache was development of the "micro" or small-bore spinal catheter.[196] Appropriate reintroduction of this technique into anesthesia practice has not been established because there must be a point at which the risk-benefit ratio of a decreased incidence of spinal headache versus difficulties in technique with the microcatheter becomes unacceptable. These catheters (i.e., 27-gauge and smaller) are not available because the FDA withdrew the 510k approval in 1992 after concern over a possible association with the development of cauda equina syndrome.[7]

One reason that epidural anesthesia is not used as widely as may be indicated is that controversies surrounding its use create indecision. One of the most controversial adjuncts to epidural anesthesia has been the use of an epinephrine-containing test dose.[197] The original description used 15 μg of epinephrine in 3 mL of local anesthetic to indicate intravascular placement of an epidural catheter or needle. Most controversy surrounds the use of epinephrine in obstetric patients, in whom uterine blood flow may be decreased by the intravascular injection, thereby putting the fetus at risk. Some experimental data suggest that epinephrine may place the fetus at risk[198]; nevertheless, no clinical data suggest that any fetus has been harmed by use of a test dose, and many anesthesiologists believe that epinephrine-containing epidural test doses are useful in obstetric anesthesia.[199] Patients receiving β-adrenergic blockers also confound the use of a test dose. In these patients, heart rate may not change after the intravascular injection of 15 μg of epinephrine; rather, the heart rate may decrease as blood pressure increases.[200] The use of epidural anesthesia during general anesthesia may also confound interpretation of the epinephrine test dose.[201] Because there is no fail-safe method of guaranteeing an extravascular location of an epidural local anesthetic, prevention of systemic toxicity should also involve aspiration of the catheter and incremental dosing of the local anesthetic. It has been shown that onset of the block, quality of the block, and block height are unaffected by administration of the epidural drug in 5-mL fractions.[202]

Related to systemic toxicity with neuraxial blocks is information about benzodiazepines. Despite a widely held belief that benzodiazepines should be used with regional anesthesia to minimize systemic toxicity by elevating the seizure threshold, the data available indicate that this concept requires rethinking.[203] Resuscitation may be more difficult after cardiovascular collapse secondary to bupivacaine when diazepam is used as a premedication. It has also been demonstrated that animals premedicated with benzodiazepines may not show evidence of seizures before cardiovascular collapse.[204] The benzodiazepines may cover up one of the early signs of systemic toxicity, thereby potentially delaying definitive therapy.

The clinical arena has not been immune to controversy about epidural anesthesia. Yeager and colleagues[11] demonstrated a significant decrease in morbidity and mortality in high-risk patients undergoing epidural anesthesia and postoperative analgesia versus patients receiving high-dose narcotic anesthesia and parenteral narcotic analgesia. This information provided the impetus for many investigators to design studies to answer

*George Bernard Shaw (1856-1950).

whether the anesthetic technique, especially the postoperative analgesic technique, may be able to modify patient outcomes. In the case of Yeager and coworkers, it remains unclear whether their data support the benefits of the epidural techniques or condemn the use of high-dose narcotics and postoperative mechanical ventilation. Tuman and associates[12] addressed many of the criticisms directed at the work of Yeager and colleagues[11] and documented fewer complications in vascular surgery patients when epidural analgesia was used in an integrated perioperative regimen. Christopherson and coworkers[13] and Rosenfeld[14] and associates linked the analgesic regimens with possible mechanisms of improved patient outcomes. They found that continuing epidural anesthesia and analgesia into the postoperative period limited the adverse effects of surgery on the fibrinolytic system. Further investigations into the appropriate place of neuraxial blocks in anesthetic practice will have to be as concerned with the issue of cost in relation to outcome as with risk in relation to benefit to the patient.[16,17]

Another advance in neuraxial block technique that demands our attention is the development of effective methods of combining epidural and spinal anesthesia in a single-needle system.[204-207] These methods use epidural needle placement, followed by insertion of the spinal needle through a side lumen on the epidural needle or directly through the epidural needle lumen. The combined spinal-epidural technique allows flexibility in a number of clinical settings; some of the possible combinations and advantages are listed in Box 51-4. There is considerable evidence that combined spinal and epidural techniques can be used effectively in community practices and academic institutions.[208]

Box 51-4 Possible Clinical Advantages of Using Combined Spinal-Epidural Anesthesia

Initial epidural needle placement allows the spinal needle to be guided near the dura, thereby minimizing the number of times that the spinal needle tip touches bone and potentially becomes dulled.

Lower local anesthetic blood levels are possible when an initial spinal anesthetic is used for the operation and the epidural catheter is used for analgesia.

More rapid onset of spinal block allows the operative procedure to begin earlier, and the epidural catheter allows effective analgesia to be provided.

During labor, an opioid may be injected through a small spinal needle, and epidural analgesia can then be added if needed.

A lower initial mass of drug may be used during spinal anesthesia to minimize physiologic perturbations, whereas the epidural catheter is available to provide a higher level if needed.

The most common setting for combined spinal-epidural anesthesia is in obstetric anesthesia practice. When used for obstetric analgesia, typically a small amount of opioid is injected into the subarachnoid space via a spinal needle before insertion of the epidural catheter through the previously placed epidural needle. Infusion of a low-concentration combination of local anesthetic and opioid is then begun via the epidural catheter.

Simmons and colleagues completed a Cochrane database review focused on combined spinal and epidural anesthesia in labor. They found that overall there is little difference between combined spinal-epidural and other forms of low-dose epidural analgesia for relief of pain during labor.[209] This lack of difference is based on a similar effectiveness of labor analgesia with the techniques. There were limited differences in parturients' ability to ambulate or in obstetric and neonatal outcomes when comparing combined spinal-epidural and classic low-dose obstetric epidural analgesia. Despite these conclusions, many obstetric anesthesiologists continue to use a combined spinal-epidural technique for obstetric analgesia because of faster onset of analgesic action with the combined spinal-epidural technique and the ability to consistently and effectively use low-dose analgesic regimens with this method. Of interest, in the Cochrane database analysis, more mothers receiving the combined spinal-epidural technique itched than mothers administered the epidural-alone technique, probably because of the more rapid and profound analgesic action of the subarachnoid administered opioid. Overall, as a result of the significantly higher incidence of urinary retention and rescue interventions with the traditional standard-dose epidural-alone techniques, Simmons and colleagues suggested that the use of low-dose epidurals is preferred.[209] The most commonly used method for administering a low-dose epidural is as part of a combined spinal-epidural anesthesia technique.

52 Nerve Blocks

Key Points

1. In performing peripheral nerve blocks, elicitation of a paresthesia is equivalent to electrical stimulation. The success rate and time of onset are further improved if multiple stimulations are performed.
2. Direct visualization of spread of local anesthetic by ultrasound produces similar success as a multistimulation technique.
3. Diaphragmatic paresis occurs in 100% of patients undergoing an interscalene block, even with dilute local anesthetic solutions.
4. A complete lumbar plexus block may be accomplished through a proximal (psoas compartment) approach, but rarely with the femoral 3-in-1 or fascia iliaca techniques.
5. Continuous peripheral blockade improves outcome and rehabilitation after major orthopedic surgery, including knee, hip, and shoulder replacement surgery.
6. The sciatic nerve divides into its tibial and peroneal components 7 to 10 cm above the knee; a popliteal fossa block should be performed at this level.
7. Regardless of the level of blockade, a tibial motor response elicited by neurostimulation techniques is more efficacious than a peroneal response during performance of a sciatic nerve block.
8. The total local anesthetic dosage should be determined and kept within acceptable limits. Accumulation with time may occur with continuous techniques.
9. The frequency of neurologic complications after peripheral blockade is less than that associated with neuraxial techniques. Neurotoxicity and direct needle trauma are the major causes of neurologic complications.

The techniques of peripheral neural blockade were developed early in the history of anesthesia (see Chapter 1). The American surgeons Halsted and Hall[1,2] described the injection of cocaine into peripheral sites, including the ulnar, musculocutaneous, supratrochlear, and infraorbital nerves, for minor surgical procedures in the 1880s. James Leonard Corning[3] recommended the use of an Esmarch bandage in 1885 to arrest the local circulation, prolong the cocaine-induced block, and decrease uptake of that local anesthetic from tissues. This concept was furthered by Heinrich F. W. Braun,[4] who substituted epinephrine, a "chemical tourniquet," in 1903. Braun[5] also introduced the term *conduction anesthesia* in his 1914 textbook on local anesthesia, which described techniques for every region of the body. In 1920, the French surgeon Gaston Labat was invited by Charles Mayo to teach innovative methods of regional anesthesia at the Mayo Clinic. During his appointment there, Labat authored *Regional Anesthesia: Its Technic and Application*.[6] The book was considered to be the definitive text on regional anesthesia for at least 30 years after its publication. Labat's textbook focused on the intraoperative management of patients undergoing intra-abdominal, head and neck, and extremity procedures under infiltration, peripheral, plexus, and splanchnic blockade; neuraxial techniques were not widely applied at the time.

Peripheral blockade remains a well-accepted component of comprehensive anesthetic care. Its role has expanded from the operating suite into the arena of postoperative and chronic pain management (see Chapters 58 and 87). With appropriate selection and sedation, these techniques can be used in all age groups. Skillful application of peripheral neural blockade broadens the anesthesiologist's range of options in providing optimal anesthetic care.

Techniques for Localizing Neural Structures

Several methods of needle localization have been described, including fascial "pops," elicitation of one or more paresthesias, perivascular or transarterial injection, electrical stimulation, and field infiltration. More recently, direct imaging by ultrasonography,

fluoroscopy, computed tomography (CT), and magnetic resonance imaging (MRI) has been used. Although no definitive study has identified the best method for needle placement, generalities are possible. For example, elicitation of a paresthesia appears to be equivalent to electrical stimulation. Success rates and onset times of paresthesia and nerve stimulation techniques are further improved if multiple injections are performed. Transarterial injection is variably successful; a two-injection transarterial technique is comparable to single-injection paresthesia or nerve stimulator approaches. The success rate with a fascial pop or click is variable, and it may be more reliable in pediatric patients than in adults.[7]

In recent years, the number of prospective randomized studies comparing ultrasound-guided and electrical stimulation techniques has steadily increased. In general, onset times and the number of needle passes required to obtain a motor response are reduced with the use of ultrasound guidance.[8-10] Ultrasound guidance increases the success rate provided that (1) the needle is redirected (as necessary) to achieve uniform spread around the neural structure and (2) blocks in the control group are performed with a single injection. At this time, peripheral techniques are performed under ultrasound guidance with *or* without confirmation of needle placement by electrical stimulation. Both approaches involve visualization of local anesthetic spread during injection.[11]

Ultrasound images of the distribution of local anesthetic have provided clinicians with visualization of successful blocks[8-10] and have documented *why* single-injection techniques are less reliable. Although it has been theorized that visualization of needle advancement would decrease the frequency (or severity) of needle misadventures, the small number of patients reported precludes determination of either the absolute or relative frequency of neurologic complications. Both intraneural needle placement and injection have been reported during ultrasound guidance.[12] However, the risk of large-volume intravascular injection of local anesthetic may be reduced in experienced ultrasonographers' hands.

Upper Extremity Blocks

Successful regional anesthesia of the upper extremity requires knowledge of brachial plexus anatomy from its origin, where the nerves emerge from the intervertebral foramina, to its termination in the peripheral nerves. Detailed anatomic knowledge enables the anesthesiologist to choose the appropriate technique for the intended surgical procedure and to salvage inadequate blocks by supplementation with local anesthetic. Without mastery of the anatomy, luck rather than skill becomes the primary determinant of successful neural blockade. Also important is an understanding of the side effects and complications of upper extremity regional techniques, as well as the clinical application of available local anesthetics for these blocks. The role of appropriate sedation during placement of the block and during the surgical procedure should not be underestimated. Many a "perfect" regional anesthetic technique has been undone by inadequate management of sedation.

Anatomy

The brachial plexus is derived from the anterior primary rami of the fifth, sixth, seventh, and eighth cervical nerves and the first thoracic nerve, with variable contributions from the fourth cervical and second thoracic nerves. After leaving their intervertebral foramina, these nerves course anterolaterally and inferiorly to lie between the anterior and middle scalene muscles, which arise from the anterior and posterior tubercles of the cervical vertebra, respectively. The anterior scalene muscle passes caudad and laterally and inserts into the scalene tubercle of the first rib; the middle scalene muscle inserts on the first rib posterior to the subclavian artery, which passes between these two scalene muscles along the subclavian groove. The prevertebral fascia invests the anterior and middle scalene muscles and fuses laterally to enclose the brachial plexus in a fascial sheath.

Between the scalene muscles, these nerve roots unite to form three trunks that emerge from the interscalene space to lie cephaloposterior to the subclavian artery as it courses along the upper surface of the first rib. The superior (C5 and C6), middle (C7), and inferior (C8 and T1) trunks are arranged accordingly and are not in a strict horizontal formation, as is often depicted. At the lateral edge of the first rib, each trunk forms anterior and posterior divisions that pass posterior to the midportion of the clavicle to enter the axilla. Within the axilla, these divisions form the lateral, posterior, and medial cords, named for their relationship with the second part of the axillary artery. The superior divisions from the superior and middle trunks form the lateral cord, the inferior divisions from all three trunks form the posterior cord, and the anterior division of the inferior trunk continues as the medial cord.

At the lateral border of the pectoralis minor, the three cords divide into the peripheral nerves of the upper extremity. The lateral cord gives rise to the lateral head of the median nerve and the musculocutaneous nerve; the medial cord gives rise to the medial head of the median nerve, as well as the ulnar, the medial antebrachial, and the medial brachial cutaneous nerves; and the posterior cord divides into the axillary and radial nerves (Fig. 52-1).

Aside from branches from the cords that form the peripheral nerves as described, several branches arising from roots of the brachial plexus provide motor innervation to the rhomboid muscles (C5), the subclavian muscles (C5 and C6), and the serratus anterior muscle (C5, C6, and C7). The suprascapular nerve arises from C5 and C6; it supplies the muscles of the dorsal aspect of the scapula and makes a significant contribution to the sensory supply of the shoulder joint.

Branches arising from the cervical roots are usually blocked only with the interscalene approach to the brachial plexus. The sensory distributions of the cervical roots and peripheral nerves are shown in Figure 52-2.

Interscalene Block

Clinical Applications

The principal indication for an interscalene block is surgery on or manipulation of the shoulder. Blockade occurs at the level of the upper and middle trunks. Although this approach can also be used for forearm and hand surgery, blockade of the inferior trunk (C8 through T1) is often incomplete and requires supplementation at the ulnar nerve for adequate surgical anesthesia in that distribution.[13]

Technique

The brachial plexus shares a close physical relationship with several structures that serve as important landmarks for perform-

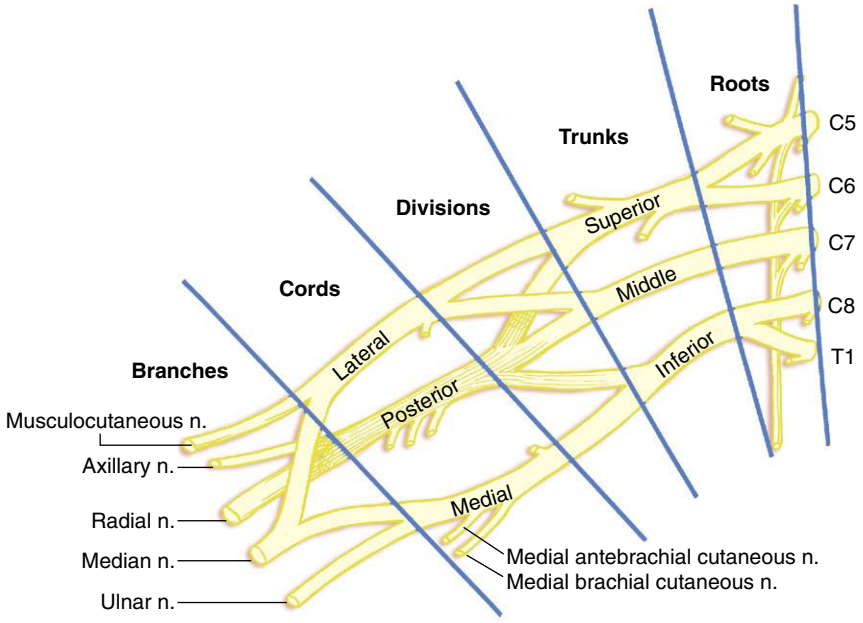

Figure 52-1 Roots, trunks, divisions, cords, and branches of the brachial plexus.

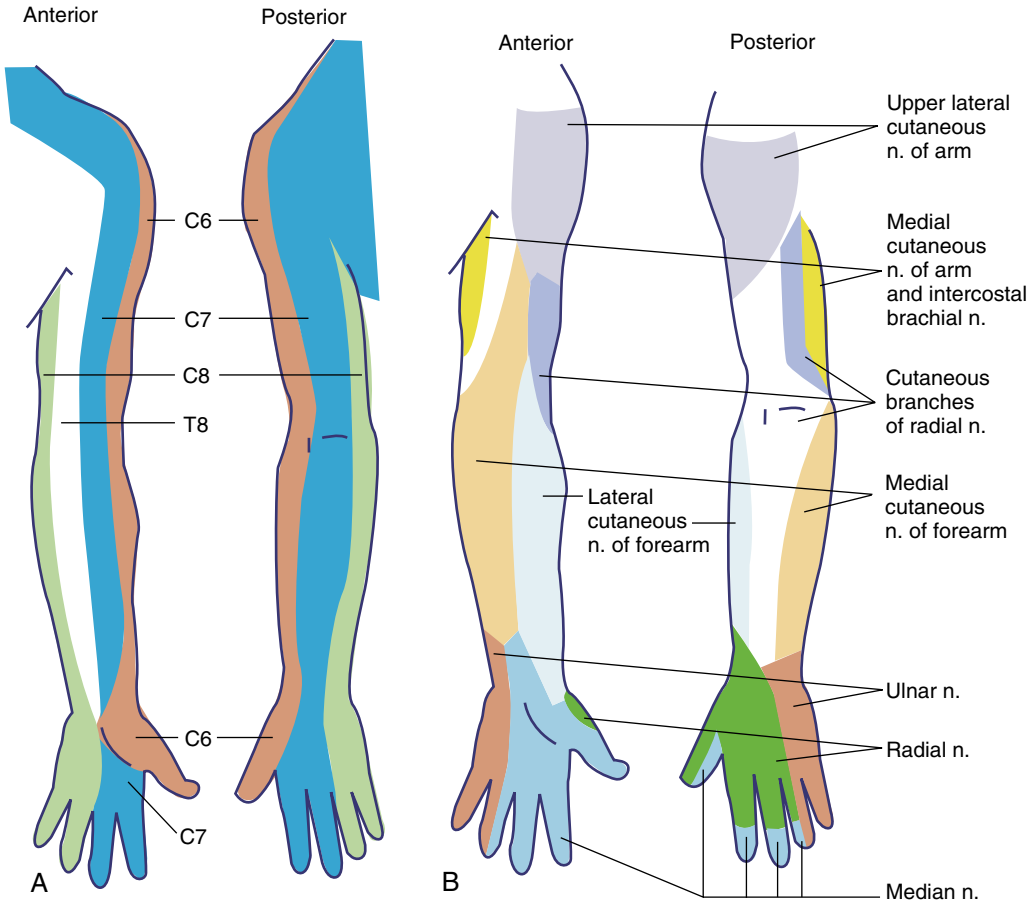

Figure 52-2 **A,** Cutaneous distribution of the cervical roots. **B,** Cutaneous distribution of the peripheral nerves.

ance of an interscalene block. In its course between the anterior and middle scalene muscles, the plexus is superior and posterior to the second and third parts of the subclavian artery. The dome of the pleura lies anteromedial to the inferior trunk.

This technique can be performed with the patient's arm in any position and is technically simple because of easy identification of the necessary landmarks.[14] The patient should be in the supine position with the head turned away from the side to be blocked. The posterior border of the sternocleidomastoid muscle is readily palpated by having the patient briefly lift the head. The interscalene groove may be palpated by rolling the fingers posterolaterally from this border over the belly of the anterior scalene muscle into the groove. A line extended laterally from the cricoid cartilage and intersecting the interscalene groove indicates the level of the transverse process of C6. Although the external jugular vein often overlies this point of intersection, it is not a constant or reliable landmark.

The use of a nerve stimulator or elicitation of paresthesias is recommended with this technique to accurately place the local anesthetic solution. After ordinary sterile precautions and development of a skin wheal, a 22- to 25-gauge, 4-cm needle is inserted perpendicular to the skin at a 45-degree caudad and slightly posterior angle (Fig. 52-3). The needle is then advanced until a paresthesia (usually the C5 and C6 dermatomes) or nerve stimulator response is elicited, which usually occurs at a very superficial level. Paresthesia and motor response of the arm or shoulder are equally efficacious.[15] If a blunt needle bevel is used, a "click" may be detected as the needle passes through the prevertebral fascia. If bone is encountered within 2 cm of the skin, it is likely to be a transverse process, and the needle may be "walked" across this structure to locate the nerve. Likewise, contraction of the diaphragm indicates phrenic nerve stimulation and anterior needle placement; the needle should be redirected posteriorly to locate the brachial plexus.

After the appropriate paresthesia or motor response is obtained, the needle is stabilized. The use of flexible extension tubing facilitates maintenance of the needle's position while aspiration and injection are taking place. After negative aspiration, 10 to 40 mL of solution is injected incrementally, depending on the desired extent of blockade. Radiographic studies suggest a volume-to-anesthesia relationship, with 40 mL of solution associated with complete cervical and brachial plexus blockade.[14] Clinical studies, however, indicate variable blockade of the lower trunk (i.e., ulnar nerve), even with large volumes of solution.[13] Digital pressure above the injection site and downward massage along with a 45-degree head-up position may facilitate caudad spread and blockade of the lower trunk.

Side Effects and Complications

Ipsilateral phrenic nerve block resulting in diaphragmatic paresis occurs in 100% of patients undergoing interscalene blockade,[16] even with dilute solutions of local anesthetics, and is associated with a 25% reduction in pulmonary function.[17,18] This effect probably results from anterior spread of solution over the anterior scalene muscle and may cause subjective symptoms of dyspnea. Although rare, respiratory compromise can occur in patients with severe respiratory disease. Involvement of the vagus, recurrent laryngeal, and cervical sympathetic nerves is rarely significant, but a patient experiencing symptoms related to these side effects may require reassurance. The incidence of pneumothorax is low when the needle is correctly placed at the C5 or C6 level because of the distance from the dome of the pleura.

Severe hypotension and bradycardia (i.e., the Bezold-Jarisch reflex) have been reported in awake, sitting patients undergoing shoulder surgery under an interscalene block. The cause is presumed to be stimulation of intracardiac mechanoreceptors by decreased venous return, which produces an abrupt withdrawal of sympathetic tone and enhanced parasympathetic output. This effect results in bradycardia, hypotension, and syncope. The frequency of this reflex is decreased when prophylactic β-blockers are administered.[19]

Nerve damage or neuritis can occur with any peripheral nerve block, but it is uncommon and is usually self-limited. Some surgical approaches to the shoulder, such as those for total-

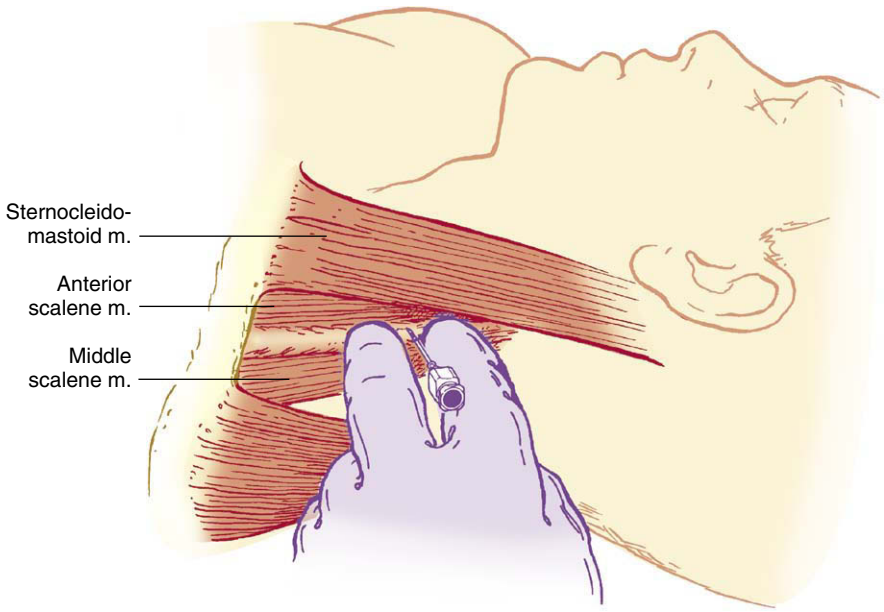

Figure 52-3 Interscalene block. The fingers palpate the interscalene groove, and the needle is inserted at a caudad and slightly posterior angle.

shoulder arthroplasty, are associated with neurologic risk to the brachial plexus.[20,21] In such cases an interscalene block may be placed postoperatively for pain relief after the surgical service has ascertained and documented that no neurologic damage has occurred. Epidural and intrathecal injections have been reported with this block, a finding emphasizing the importance of inserting the needle in a caudad direction.[22] The proximity of significant neurovascular structures may increase the risk for serious neurologic complications when an interscalene block is performed in heavily sedated or anesthetized patients.[23]

Several vascular structures are in proximity to a correctly placed needle. Local anesthetic toxicity as a result of intravascular injection should be guarded against by careful aspiration and incremental injection. Seizure activity from this complication is particularly undesirable after rotator cuff surgery because the repair can be compromised by the associated muscular activity.

Supraclavicular Block

Clinical Applications

Indications for a supraclavicular block are operations on the elbow, forearm, and hand. Blockade occurs at the distal trunk–proximal division level. At this point, the brachial plexus is compact and a small volume of solution produces rapid onset of reliable blockade of the brachial plexus. An additional advantage is that the block can also be performed with the patient's arm in any position.

Reliable supraclavicular blockade requires elicitation of a paresthesia or motor response. The classic block may be somewhat difficult to describe and to teach. A proposed modification of the technique, the so-called plumb-bob approach, may decrease complications and simplify the concept of this block.[24]

Technique

Several anatomic points are important in performance of the supraclavicular approach. The three trunks are clustered vertically over the first rib cephaloposterior to the subclavian artery, which can often be palpated in a slender, relaxed patient. The neurovascular bundle lies inferior to the clavicle at about its midpoint. The first rib acts as a medial barrier to the needle reaching the pleural dome and is short, broad, and flat, with an anteroposterior orientation at the site of the plexus.

The patient is placed in a supine position with the head turned away from the side to be blocked. The arm to be anesthetized should be adducted, and the hand should be extended along the side toward the ipsilateral knee as far as possible. In the classic technique, the midpoint of the clavicle should be identified and marked. The posterior border of the sternocleidomastoid can be palpated easily when the patient raises the head slightly. The palpating fingers can then roll over the belly of the anterior scalene muscle into the interscalene groove, where a mark should be made approximately 1.5 to 2.0 cm posterior to the midpoint of the clavicle. Palpation of the subclavian artery at this site confirms the landmark.

After appropriate preparation and development of a skin wheal, the anesthesiologist stands at the side of the patient facing the patient's head. A 22-gauge, 4-cm needle is directed in a caudad, slightly medial, and posterior direction until a paresthesia or motor response is elicited or the first rib is encountered. If a syringe is attached, this orientation causes the needle shaft and syringe to lie almost parallel to a line joining the skin entry site and the patient's ear. If the first rib is encountered without elicitation of a paresthesia, the needle can be systematically walked anteriorly and posteriorly along the rib until the plexus or the subclavian artery is located (Fig. 52-4). Location of the artery provides a useful landmark; the needle can be withdrawn and

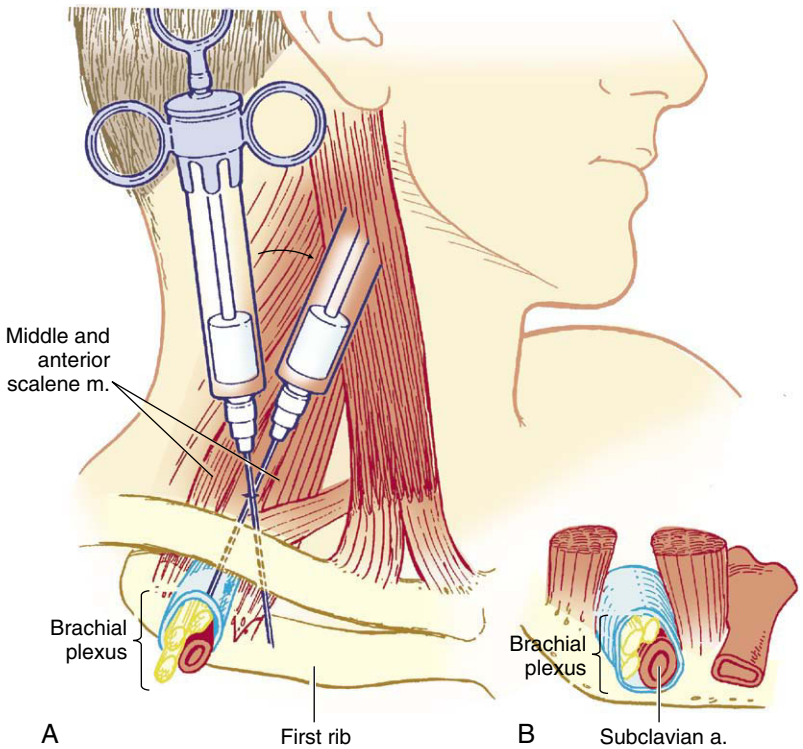

Figure 52-4 **A,** Supraclavicular block. The needle is systematically walked anteriorly and posteriorly along the rib until the plexus is located. **B,** The three trunks are compactly arranged at the level of the first rib.

reinserted in a more posterolateral direction, which generally results in a paresthesia or motor response. On localization of the brachial plexus, aspiration for blood should be performed before incremental injections of a total volume of 20 to 30 mL of solution.

The rib is usually contacted at a needle depth of 3 to 4 cm; however, in an obese patient or in the presence of tissue distortion from hematoma or injection of solution, the depth may exceed the length of the needle. Nonetheless, before the needle is advanced farther, gentle probing in the anterior and posterior directions should be done at the 2- to 3-cm depth if paresthesias are not obtained. Multiple injections may improve the quality or may shorten the onset of blockade.

The modified plumb-bob approach uses similar patient positioning, although the needle entry site is at the point where the lateral border of the sternocleidomastoid muscle inserts into the clavicle. After preparation and raising of a skin wheal, a 22-gauge, 4-cm needle is inserted while mimicking a plumb-bob suspended over the needle entry site (Fig. 52-5). Frequently, a paresthesia or motor response is elicited before contacting the first rib or artery. If no paresthesia or motor response is elicited, the needle is reinserted while angling the tip of the needle cephalad and then caudad in small steps until the first rib is contacted.

Side Effects and Complications

Although the block is more difficult in obese patients (also see Chapter 64), there does not appear to be an increased frequency of complications.[25] The prevalence of pneumothorax after a supraclavicular block is 0.5% to 6% and diminishes with experience. The onset of symptoms is usually delayed and may take up to 24 hours. Routine chest radiography after the block is not justified. The supraclavicular approach is best avoided when the patient is uncooperative or cannot tolerate any degree of respiratory compromise because of underlying disease. Other complications include frequent phrenic nerve block (40% to 60%), Horner's syndrome, and neuropathy. The presence of phrenic or cervical sympathetic nerve blockade normally requires only reassurance. Although nerve damage can occur, it is uncommon and usually self-limited.

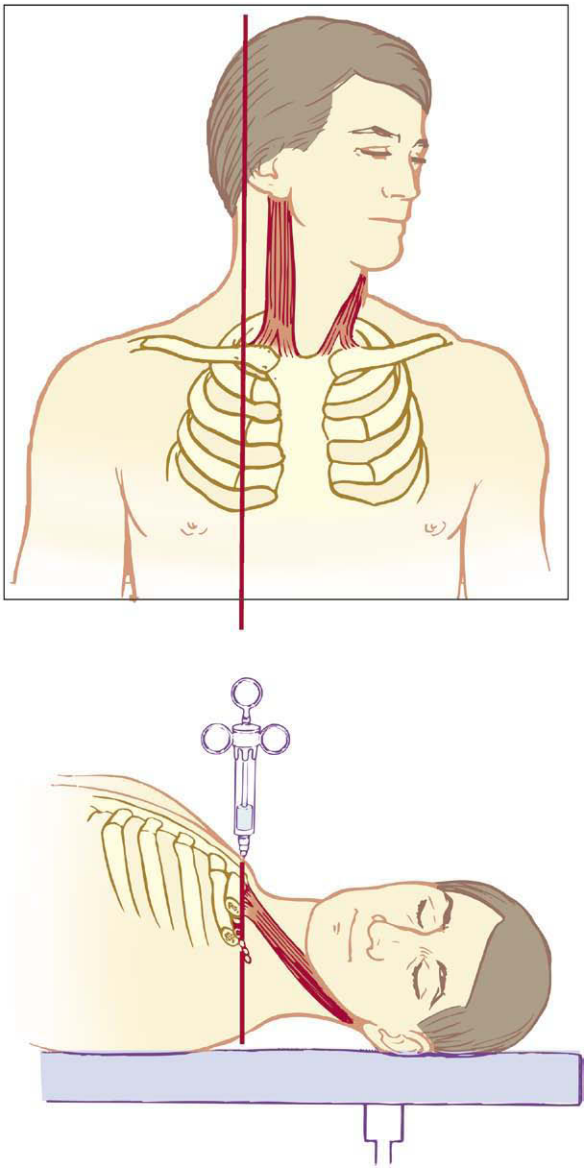

Figure 52-5 Supraclavicular block. The needle is inserted while mimicking a plumb-bob suspended over the needle entry site.

Infraclavicular Block

Clinical Applications

An infraclavicular block provides anesthesia to the arm and hand. Blockade occurs at the level of the cords and offers the theoretical advantages of avoiding pneumothorax while affording block of the musculocutaneous and axillary nerves. No special arm positioning is required. A nerve stimulator or ultrasound visualization is required because there are no palpable vascular landmarks to aid in directing the needle.

Technique

The needle is inserted 2 cm below the midpoint of the inferior clavicular border and advanced laterally, and a nerve stimulator is used to identify the plexus.[26] Marking a line between the C6 tubercle and the axillary artery with the arm abducted is helpful in visualizing the course of the plexus. Incremental injection of 20 to 30 mL of solution is sufficient after the needle is correctly placed. The success rate is improved with a distal motor response.[27] A coracoid technique consisting of insertion of the needle 2 cm medial and 2 cm caudal to the coracoid process has also been described.[28] However, the more lateral insertion site may result in the absence of blockade of the musculocutaneous nerve, thus removing the major advantage of this approach over the simpler axillary block.

Side Effects and Complications

Because of the necessarily blind approach to the plexus, the incidence of intravascular injection may be increased. Exaggerated medial needle direction may result in pneumothorax. Other rare complications such as infection and hematoma are theoretically possible.

Axillary Block

Clinical Applications

The axillary approach to the brachial plexus is the most popular because of its ease, reliability, and safety.[29] Blockade occurs at the level of the terminal nerves. Although blockade of the musculocutaneous nerve is not always produced with this approach, it can be supplemented at the level of the axilla or at the elbow. Indications for axillary block include surgery on the forearm and hand. Elbow procedures are also successfully performed with the axillary approach.[30] This block is ideally suited for outpatients and is easily adapted to the pediatric population.[31] However, an axillary block is unsuitable for surgical procedures on the upper part of the arm or the shoulder, and the patient must be able to abduct the arm to perform the block.

Technique

Anatomic concepts that should be considered before an axillary block include the following:

1. The neurovascular bundle is multicompartmental (Fig. 52-6).[32]
2. The axillary artery is the most important landmark; the nerves maintain a predictable orientation to the artery.
3. The median nerve is found superior to the artery, the ulnar nerve is inferior, and the radial nerve is posterior and somewhat lateral (Fig. 52-7).
4. At this level, the musculocutaneous nerve has already left the sheath and lies in the substance of the coracobrachialis muscle.
5. The intercostobrachial nerve, a branch of the T2 intercostal nerve, is usually blocked by the skin wheal overlying the artery; however, adequate anesthesia for the tourniquet can be ensured by extending the wheal 1 to 2 cm caudad and cephalad.

Figure 52-6 Computed tomogram after an axillary block with 0.5% bupivacaine combined with iodothalamate. Separate 10-mL injections of solution were performed after obtaining median and radial nerve paresthesias transarterially. The contrast medium appears to remain in three separate compartments.

The patient should be in the supine position with the arm to be blocked placed at a right angle to the body and the elbow flexed to 90 degrees. The dorsum of the hand rests on the bed or pillow; hyperabduction of the arm with placement of the hand beneath the patient's head is not recommended because this position frequently obliterates the pulse.

The axillary artery is palpated, and a line is drawn tracing its course from the lower axilla as far proximally as possible. The artery is then fixed against the patient's humerus by the index and middle fingers of the left hand, and a skin wheal is raised directly over the artery at a point in the axilla approximating the skin crease. Proximal needle placement and maintenance of distal pressure facilitate proximal spread of the solution.

Method of Needle Localization

Several methods of identifying the axillary sheath have been described, all with reportedly good results. Overall, paresthesias are unnecessary. However, multiple injections may shorten the onset and improve the reliability of blockade.

1. Paresthesias can be sought with a 25-gauge, 2-cm needle, beginning deeply (i.e., radial nerve) or with the nerves supplying the surgical site. Needles longer than 2 cm are rarely needed to reach the neurovascular bundle; smaller needles and a short needle bevel may be associated with a lower incidence of nerve damage.[33] Each paresthesia is injected with 10 mL of local anesthetic.
2. A nerve stimulator can also be used with an insulated needle to locate the nerves. This technique obviates the need for paresthesias.
3. A short-beveled needle can be advanced until the axillary sheath is entered, as evidenced by a fascial click, after which 40 to 50 mL of solution is injected after negative aspiration.
4. A transarterial technique can be used whereby the needle pierces the artery and 40 to 50 mL of solution is injected posterior to the artery; alternatively, half of the solution can be injected posterior and half injected anterior to the artery. Great care must be taken to avoid intravascular injection with this technique, particularly because the pressure of injection within the compartments of the axillary sheath may move anatomic structures in relation to the immobile needle. Some practitioners avoid intentional arterial puncture in the belief that it is unnecessarily traumatic.
5. Field block of the brachial plexus with a fanlike injection of 10 to 15 mL of local anesthetic solution on each side of the artery is a variation of the sheath technique. Paresthesias, though not sought, are often encountered with this technique and provide evidence of correct placement.
6. Ultrasound guidance with visualization of local anesthetic spread around the four nerves (with and without motor stimulation) decreases block onset time and may reduce the number of needle redirections. However, rates of

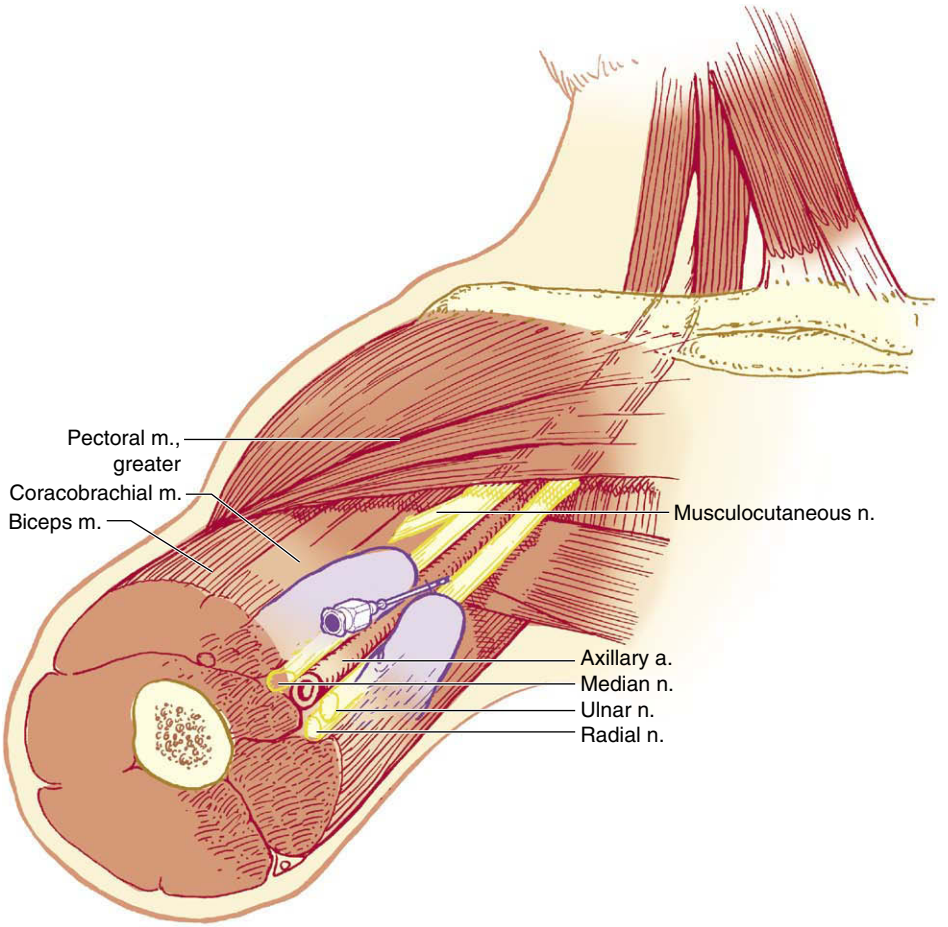

Figure 52-7 Axillary block. The arm is abducted at right angles to the body. Distal digital pressure is maintained during needle placement and injection of the local anesthetic.

success and complications are similar to those with other approaches.[34]

Classically, it was recommended that on completion of the injection, the arm should be adducted and returned to the patient's side to prevent the humeral head from obstructing proximal flow of the solution. However, a more recent study reported that maintaining the arm in abduction decreases onset time and prolongs both sensory and motor blockade.[35] If the musculocutaneous nerve is not blocked by the axillary approach, it can be blocked by injection within the body of the coracobrachialis muscle or at the elbow superficially at the lateral aspect of the antecubital fossa just above the interepicondylar line.

Success Rate with Axillary Block Techniques

The success rate of axillary blockade depends on the definition of a successful block (i.e., surgical anesthesia versus blockade of all four terminal nerves of the upper extremity), the technique used to localize the brachial plexus, and the number of injections. Success rates with single-injection techniques can vary.[36,37] Thompson and Rorie[32] concluded that the presence of multiple compartments limits diffusion of the solution (and the success of single-shot techniques). Although Partridge and coworkers[38] confirmed the presence of these compartments, they concluded that the "septa" dividing them were incomplete on the basis of injection of methylene blue and latex solutions into cadavers. The controversy surrounding single- versus multiple-injection techniques remains unresolved.

Eliciting a paresthesia is as efficacious as peripheral nerve stimulation (with a motor response of 0.5 to 0.8 mA). Most studies suggest that two-injection transarterial techniques are equivalent to single-paresthesia or single–nerve stimulation approaches. In general, the efficacy of paresthesia and peripheral nerve stimulator techniques increases when multiple injections are used. Conversely, success rates with the perivascular or fascial click approaches are variously reliable.[7] Familiarity with a variety of techniques for axillary block of the brachial plexus allows the anesthesiologist maximal flexibility in tailoring the anesthetic approach to the clinical situation.

Side Effects and Complications

Nerve injury and systemic toxicity are the most significant complications associated with the axillary approach. The assertion that neuropathies are more common with the paresthesia technique may be valid, but it is not supported by the data available. Even when paresthesias are not sought, they often occur unintentionally.[39] Injection of large volumes of local anesthetic, particularly via the transarterial approach, increases the risk for intravascular injection and systemic toxicity of local anesthetics. Hematoma and infection are rare complications. Central neural blockade and pneumothorax are not complications, as in other approaches to the brachial plexus.

Peripheral Blocks at the Midhumeral Level, Elbow, and Wrist

Clinical Applications

As techniques for brachial plexus blockade have gained popularity, indications for peripheral nerve blockade at the wrist and elbow have diminished. However, these techniques can be useful when limited anesthesia is required, when contraindications to a brachial plexus block (e.g., infection, bilateral surgery, coagulation abnormalities, bleeding diathesis, difficult anatomy) exist, or when brachial plexus blockade is incomplete. Only the midhumeral approach provides anesthesia for the use of a tourniquet. Most patients tolerate an inflated tourniquet for only a brief period.

Midhumeral Block

A midhumeral approach to the brachial plexus has been described. This novel approach involves blocking each of the four nerves of the brachial plexus separately in the humeral canal at the level of the proximal third and distal two thirds of the humerus. At this level, the median and ulnar nerves are located on the lateral and medial aspects of the brachial artery, respectively. The musculocutaneous nerve is identified within the body of the biceps muscle, and the radial nerve lies adjacent to the humerus. A volume of 8 to 10 mL of local anesthetic is injected after localization of each nerve with a nerve stimulator. Midhumeral block has been reported to have a higher success rate than traditional (defined as stimulation of two nerves) axillary brachial plexus block.[40] In this study, time to complete the block was not different between the two techniques; however, the onset of complete sensory block was shorter in the axillary approach, whereas the success rate of blockade of all four major nerves was higher in the midhumeral group. This technique may have applications when anatomic difficulties preclude a traditional approach or when the surgical procedure requires a dense block of all four major nerves. The safety and clinical practicality of the midhumeral approach remain to be proved.

Median Nerve Block

Blockade of the median nerve provides anesthesia of the palmar aspects of the thumb and index finger, the middle finger and radial half of the ring finger, and the nail beds of the same digits. Motor block includes the muscles of the thenar eminence, the lumbrical muscles of the first and second digits, and in the case of a block at the elbow, the median-innervated wrist flexor muscles of the forearm.

Technique at the Elbow

With the patient's arm placed in the anatomic position (i.e., palm up), a line is drawn connecting the medial and lateral epicondyles of the humerus. The major landmark for this technique is the brachial artery, which is found medial to the biceps tendon at the intercondylar line. The median nerve lies medial to the artery (Fig. 52-8) and can be blocked with 3 to 5 mL of solution after eliciting a paresthesia. If no paresthesia is obtained, the solution can be injected in a fanlike pattern medial to the palpated artery.

Technique at the Wrist

The median nerve is located between the flexor carpi radialis and palmaris longus tendons and can be blocked at a point 2 to 3 cm proximal to the wrist crease (Fig. 52-9). (The palmaris longus tendon is congenitally or postsurgically absent from some patients.) Loss of resistance is felt as the needle passes through the flexor retinaculum, at which point 2 to 4 mL of solution should be injected. A superficial palmar branch supplying the skin of the thenar eminence can be blocked by injecting 0.5 to 1 mL of solution subcutaneously above the retinaculum. Paresthesias should not be sought because of confinement of this nerve within the carpal tunnel.

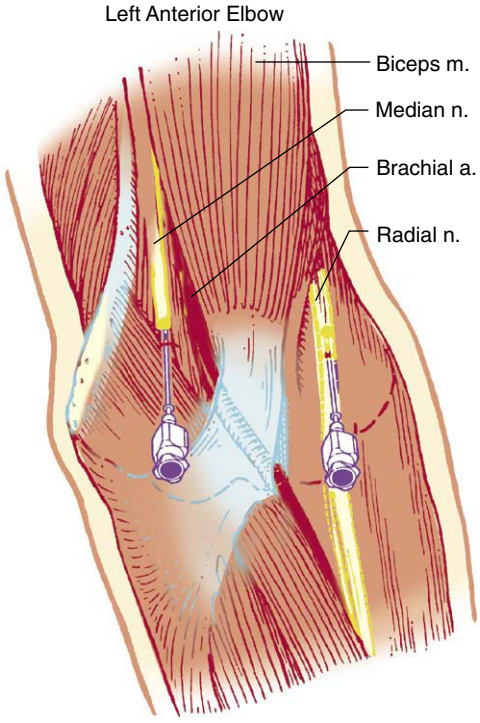

Figure 52-8 Anatomic landmarks for median and radial nerve blocks at the elbow.

Radial Nerve Block

Blockade of the radial nerve provides anesthesia to the lateral aspect of the dorsum of the hand (i.e., thumb side) and the proximal portion of the thumb, index, middle, and lateral half of the ring finger.

Technique at the Elbow

The radial nerve can be blocked at the elbow as it passes over the anterior aspect of the lateral epicondyle. The intercondylar line and lateral edge of the biceps tendon are marked. A 22-gauge, 3- to 4-cm needle is inserted at a point 2 cm lateral to the biceps tendon and advanced until bone is encountered (see Fig. 52-8). Three to 5 mL of solution is injected in a fanlike fashion.

Technique at the Wrist

The radial nerve block at the wrist is a field block of the multiple peripheral branches descending along the dorsum and radial side of the wrist. The extensor pollicis longus tendon can be identified when the patient extends the thumb. The needle insertion site is over this tendon at the base of the first metacarpal, and the solution is injected superficial to the tendon. A volume of 2 mL of local anesthetic is injected proximally along the tendon, and an

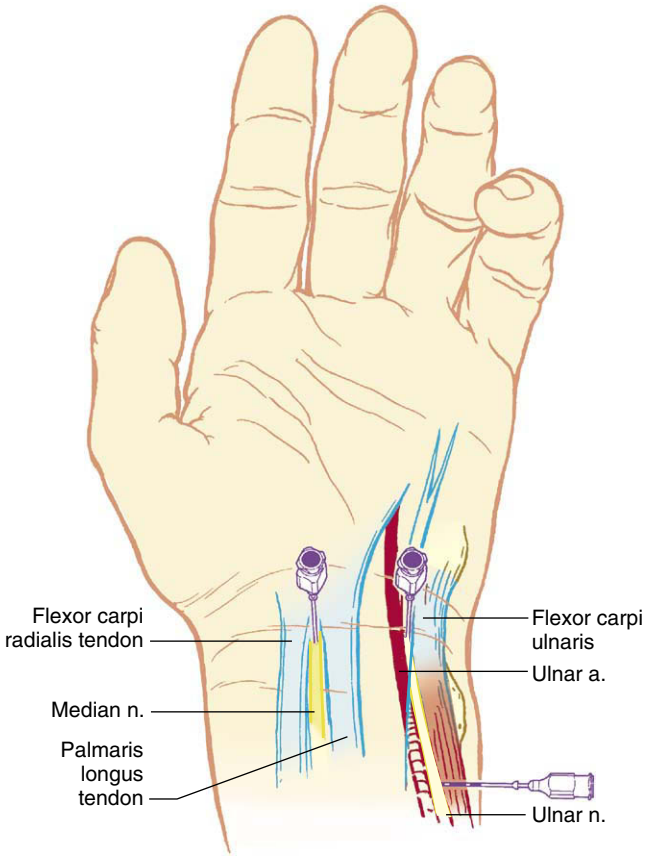

Figure 52-9 Anatomic landmarks for median and ulnar nerve blocks at the wrist. An alternative method for an ulnar nerve block, from the ulnar side of the wrist, is shown.

additional 1 mL is injected as the needle passes at a right angle across the anatomic snuffbox (Fig. 52-10).

Ulnar Nerve Block

Blockade of the ulnar nerve provides anesthesia to the ulnar side of the hand, the little finger, the ring finger, and all the small muscles of the hand, except those of the thenar eminence and the first and second lumbrical muscles.

Technique at the Elbow

Although the ulnar nerve is easily accessible at its subcutaneous position posterior to the medial epicondyle, blockade at this site is associated with a high incidence of neuritis. Because the nerve is surrounded by fibrous tissue at this point, intraneural injection is required for successful blockade. Use of a very fine needle along with a small volume of solution (1 mL) diminishes the risk; however, the nerve can be satisfactorily blocked with 5 to 10 mL of solution at a site 3 to 5 cm proximal to the elbow. The local anesthetic should be injected in a fanlike fashion without elicitation of a paresthesia.

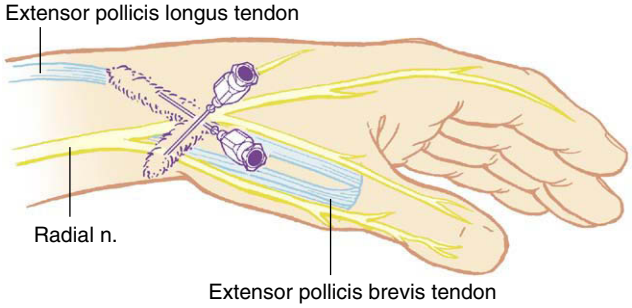

Figure 52-10 Anatomic landmarks and method of needle insertion for a radial nerve block at the wrist.

Technique at the Wrist

At the wrist, the ulnar nerve lies beneath the flexor carpi ulnaris tendon between the ulnar artery and the pisiform bone. At this point, it has already given off its palmar cutaneous and dorsal branches. The nerve can be approached by directing the needle medially from the radial side of the tendon or, alternatively, by directing the needle radially from the ulnar side of the tendon (see Fig. 52-9). After eliciting a paresthesia, 3 to 5 mL of anesthetic solution is injected or spread in a fanlike fashion.

Musculocutaneous Nerve Block

The musculocutaneous nerve terminates at the lateral cutaneous nerve of the forearm. This nerve provides sensory innervation to the skin on the radial side of the forearm up to the radiocarpal joint. This block is usually performed to supplement the axillary approach to brachial plexus anesthesia.

Technique at the Elbow

The lateral cutaneous nerve of the forearm can be blocked 1 cm proximal to the intercondylar line immediately lateral to the biceps tendon. Fanlike infiltration of 3 to 5 mL of solution subcutaneously at this site provides excellent anesthesia of this nerve.

Peripheral Blockade at the Elbow versus the Wrist

The forearm cutaneous nerves arise in the upper part of the arm and are not anesthetized by blockade of the peripheral nerves at the elbow. There is no relative advantage to blockade of the peripheral nerves of the upper extremity with either the elbow or the wrist technique; both provide sensory anesthesia of the hand.

Side Effects and Complications

In general, distal peripheral blocks are associated with a lower risk of complications. However, intravascular injection can occur, and the usual precautions of incremental injection after aspiration are recommended. The incidence of nerve injury is theorized to be greater when more distal peripheral blocks are performed, possibly because of superficial nerve placement between bony and ligamentous structures, which offers ready access to the probing needle point.

Intravenous Regional Blocks

Intravenous regional blocks were first described by a German surgeon, August Bier, in 1908.[41] Early methods involved two tourniquets and the first synthetic local anesthetic, procaine. The technique lost popularity as reliable methods of blocking the brachial plexus evolved.

Clinical Applications

The Bier block has multiple advantages, including ease of administration, rapidity of recovery, rapid onset, muscular relaxation, and controllable extent of anesthesia. It is an excellent technique for short (<90 minutes) open surgical procedures and for closed reduction of bony fractures.

Technique

An intravenous cannula is placed in the upper extremity to be blocked as far distally as possible; the patient should also have an intravenous cannula in the nonoperative upper extremity for administration of fluids and other drugs. Traditionally, a double tourniquet is placed on the operative side; both cuffs should have secure closure and reliable pressure gauges. After exsanguination of the arm, the proximal cuff is inflated to approximately 150 mm Hg more than systolic pressure, and absence of a radial pulse confirms adequate tourniquet pressure. The total dose of local anesthetic is based on the patient's weight, and it is injected slowly (3 mg/kg of 0.5% prilocaine or lidocaine, without epinephrine). The use of bupivacaine for intravenous regional anesthesia has been associated with local anesthetic toxicity and death[42] and therefore is not recommended. However, dilute solutions (0.125% levobupivacaine) of long-acting amides, as well as the addition of adjuvants (tramadol, ketorolac, clonidine), have been used to prolong sensory blockade and analgesia after deflation of the tourniquets.[43]

The onset of anesthesia usually occurs within 5 minutes. When the patient complains of tourniquet pain, the distal tourniquet, which overlies anesthetized skin, is inflated, and the proximal tourniquet is released. Use of a single wide cuff allows lower inflation pressures to be used during intravenous regional anesthesia. The postulated advantage is that the lower pressures will decrease the incidence of neurologic complications related to the high inflation pressures with the narrow double cuffs.[44] The tourniquet may be safely released after 25 minutes, but the patient should be closely observed for local anesthetic toxicity for several minutes after release of the tourniquet. Slow injection of local anesthetic solutions at a distal site has been shown to lower the risk for toxicity.[45]

Side Effects and Complications

Technical problems with this block include tourniquet discomfort, rapidity of recovery leading to postoperative pain, difficulty providing a bloodless field, and the necessity of exsanguination in the case of a painful injury. Accidental or early deflation of the tourniquet or use of excessive doses of local anesthetics can result in toxic reactions. Injection of the drug as far distally as possible at a slow rate has been shown to decrease blood levels and may theoretically increase safety.[45] Cyclic deflation of the tourniquet at 10-second intervals has been shown to increase the time to peak arterial lidocaine levels and may decrease any potential toxicity.[46] Other rare complications associated with this technique include phlebitis (with 2-chloroprocaine), the development of a compartment syndrome, and loss of a limb.

Lower Extremity Blocks

Knowledge of the anatomy of the lumbosacral plexus and peripheral nerves of the lower extremity enables anesthesiologists to provide more comprehensive anesthetic care. These blocks are safe and have certain advantages, such as postoperative pain relief and lack of complete sympathectomy, which make them ideal for selected patients.

Lower extremity blocks are less popular than those routinely used for surgical procedures on the upper extremity, in part because of the widespread acceptance and safety of spinal and epidural anesthesia. Unlike the brachial plexus, the nerves supplying the lower extremity are not anatomically clustered where they can easily be blocked with a relatively superficial injection of local anesthetic. Because of anatomic considerations, lower extremity blocks are technically more difficult and require more training and practice before expertise is acquired. Many of these blocks were classically performed with paresthesia, loss-of-resistance, or field block techniques, and success rates varied. Advances in needles, catheters, and nerve stimulator technology have facilitated localization of neural structures and improved success rates.[47] Recent applications have focused on prolonged postoperative analgesia to assist rehabilitation and hospital dismissal.

Anatomy

The nerve supply to the lower extremity is derived from the lumbar and sacral plexuses. The *lumbar plexus* is formed by the anterior rami of the first four lumbar nerves; it frequently includes a branch from T12 and occasionally from L5 (Fig. 52-11). The plexus lies between the psoas major and quadratus lumborum muscles in the so-called psoas compartment. The lower components of the plexus, L2, L3, and L4, primarily innervate the anterior and medial aspects of the thigh. The anterior divisions of L2, L3, and L4 form the obturator nerve; the posterior divisions of the same components form the femoral nerve; and the lateral femoral cutaneous nerve is formed from posterior divisions of L2 and L3.

The *sacral plexus* gives off two nerves important for lower extremity surgery: the posterior cutaneous nerve of the thigh and the sciatic nerve. The posterior cutaneous nerve of the thigh and the sciatic nerve are derived from the first, second, and third sacral nerves plus branches from the anterior rami of L4 and L5, respectively. These nerves pass together through the pelvis and the greater sciatic foramen and are blocked by the same technique. The sciatic nerve is a combination of two major nerve trunks, the tibial (i.e., ventral branches of the anterior rami of L4, L5, S1, S2, and S3) and the common peroneal (i.e., dorsal branches of the anterior rami of L4, L5, S1, S2, and S3). At or above the popliteal fossa, they separate, with the tibial nerve passing medially and the common peroneal passing laterally. Cutaneous distributions of the lumbosacral and peripheral nerves are shown in Figure 52-12.

Psoas Compartment Block (Posterior Approach to the Lumbar Plexus)

The psoas compartment block uses a technique in which a needle is placed into the space between the psoas major and quadratus lumborum muscles. It was initially performed with a loss-of-resistance technique and injection of a large volume of solution

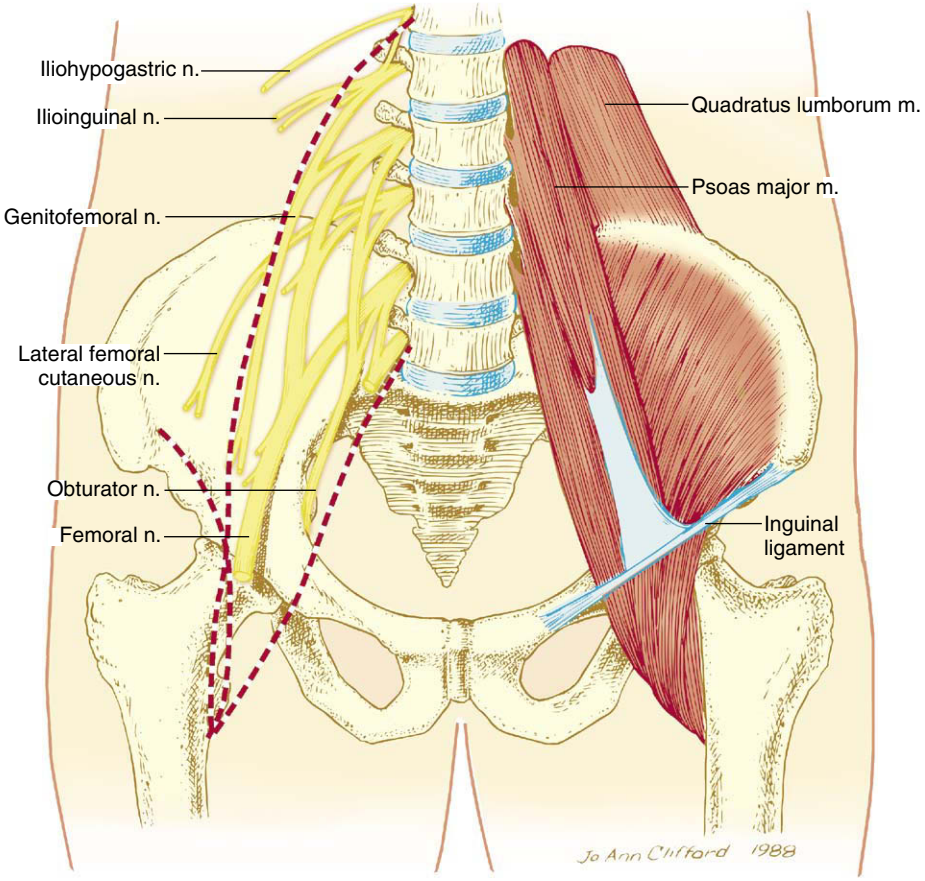

Figure 52-11 The lumbar plexus lies in the psoas compartment between the psoas major and quadratus lumborum muscles.

to provide anesthesia to the hip and anterolateral aspect of the thigh.[48]

Clinical Applications

A psoas compartment block offers a single injection rather than three separate needle insertions for anesthesia of the lumbar plexus.[49] The technique must be combined with a sciatic block for anesthesia of the entire lower extremity. A psoas compartment block is often used to provide postoperative analgesia for patients undergoing major knee and hip surgery.[50]

Technique

The patient is placed in the lateral position with the hips flexed and the operative extremity uppermost. A line is drawn to connect the iliac crests (i.e., intercristal line) and identify the fourth lumbar spine. After skin preparation, a skin wheal is raised 3 cm caudal and 5 cm lateral to the midline on the side to be blocked. A 21-gauge, 10-cm stimulating needle is then advanced perpendicular to the skin entry site until it contacts the fifth lumbar transverse process. The needle is redirected cephalad until it slides off the transverse process. The lumbar plexus is identified by elicitation of a quadriceps motor response. When the needle is in place, 30 mL of solution is injected.

Based on anatomic imaging studies, Capdevila and colleagues[51] modified the classic psoas technique (Fig. 52-13). The needle insertion site is the junction of the lateral third and medial two thirds of a line between the spinous process of L4 and a line parallel to the spinal column passing through the posterior superior iliac spine. (The spinous process of L4 was estimated to be approximately 1 cm cephalad to the upper edge of the iliac crests.) The needle is advanced perpendicular to the skin until it contacts the transverse process of L4 and is then advanced under the transverse process until quadriceps femoris muscle twitches are elicited. Despite a difference between men and women in the depth of the lumbar plexus (median values, 8.5 and 7.0 cm, respectively), the distance from the L4 transverse process to the lumbar plexus was comparable (median value, 2 cm) in both sexes (Fig. 51-14B). The investigators stressed the importance of achieving contact with the L4 transverse process to establish appropriate needle depth and position.

Side Effects and Complications

The deep needle placement with the posterior (psoas compartment) approach increases the risk for epidural, subarachnoid, or intravascular injection. Peripheral nerve damage is also a potential risk with this technique. A side effect of the paravertebral approach to the lumbar plexus is the development of a sympathetic block from extravasation of local anesthetic. This unilateral sympathectomy is usually of little consequence.

Epidural spread of local anesthetic is another common side effect of a psoas compartment block that occurs in 9% to 16% of adult patients.[47,49-51] This side effect is generally attributed to retrograde diffusion of the local anesthetic to the epidural space when large volumes of local anesthetic are used (>20 mL). In

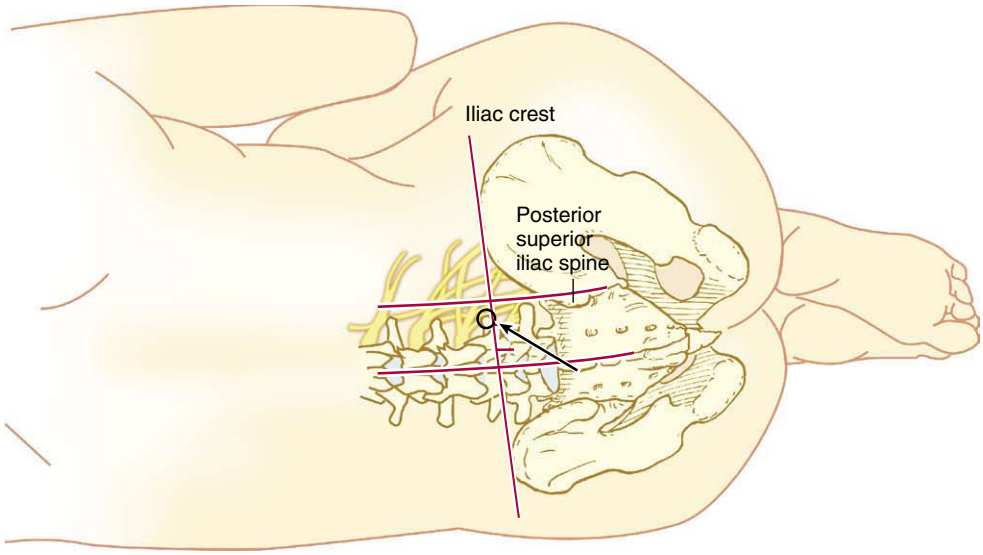

Figure 52-13 Psoas compartment block. The needle entry site is marked 1 cm cephalad to the intercristal line, two thirds of the distance from the midline to the posterior superior iliac spine line. The lumbar plexus is identified between the transverse processes of L4 and L5. Dural sleeves extend 3 to 5 cm laterally. The *circle* is the site of needle insertion. *(From Lennon RL, Horlocker TT: Mayo Clinic Analgesic Pathway, Peripheral Nerve Blockade for Major Orthopedic Surgery. Rochester, MN, Mayo Clinic Scientific Press, 2006.)*

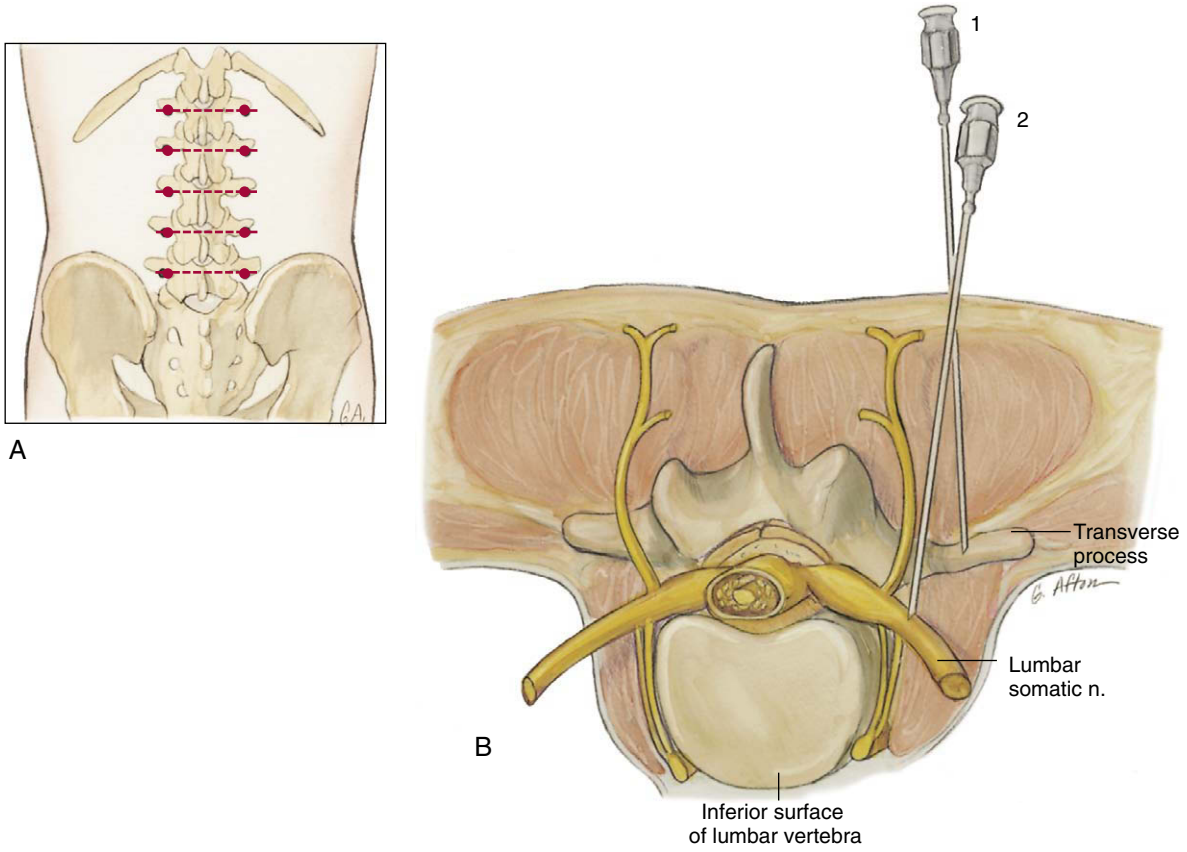

Figure 52-14 Paravertebral nerve block. **A,** Patient position and surface landmarks. **B,** The needle is advanced perpendicularly until it contacts the transverse process. It is redirected to walk off the caudad edge of the transverse process and advanced 1 to 2 cm.

most cases, residual lumbar plexus blockade is apparent after resolution of the contralateral block. However, because of case reports of total spinal anesthesia occurring during lumbar plexus blockade, vigilance must be maintained during management of this block.

Perivascular 3-in-1 (Femoral) Nerve Block

The femoral nerve is formed within the psoas major muscle by posterior divisions of the second, third, and fourth lumbar nerves. It emerges from the lateral border of the psoas muscle, descends in the groove between the psoas and iliacus muscles, and enters the thigh by passing beneath the inguinal ligament lateral to the femoral artery. At this point the nerve divides into multiple terminal branches, which have been classified as anterior and posterior. The anterior branches are primarily cutaneous, and the deep branches are chiefly motor. The femoral nerve supplies the anterior compartment muscles of the thigh (i.e., quadriceps, sartorius) and the skin of the anterior aspect of the thigh from the inguinal ligament to the knee. Its terminal branch is the *saphenous nerve*, which supplies an area of skin along the medial side of the leg from the knee to the big toe.

Clinical Applications

The perivascular approach (i.e., 3-in-1 block) to the lumbar plexus is based on the premise that injection of a large volume of local anesthetic within the femoral canal while maintaining distal pressure will result in proximal spread of solution into the psoas compartment and consequent lumbar plexus block.[52] However, recent imaging studies suggest that blockade occurs through lateral (lateral femoral cutaneous nerve) and medial (obturator nerve) spread of injected solution.[53]

Indications for femoral nerve block include anesthesia for knee arthroscopy in combination with intra-articular local anesthesia, as well as analgesia for femoral shaft fractures, anterior cruciate ligament reconstruction, and total-knee arthroplasty as a part of multimodal regimens. Their use in complex knee operations is associated with lower pain scores and fewer hospital admissions after same-day surgery.[47,50]

Technique

Femoral Block

The patient is placed in the supine position. A line is drawn between the anterior superior iliac spine and the pubic tubercle to identify the inguinal ligament. The femoral artery is marked. A 22-gauge, 4-cm needle is advanced lateral to this line (Fig. 52-15A). When the needle reaches the depth of the artery, a pulsation of the hub is visible. Elicitation of a paresthesia or motor response verifies correct needle position. Commonly, the anterior branch of the femoral nerve is identified first. Stimulation of this branch leads to contraction of the sartorius muscle on the medial aspect of the thigh and should not be accepted. The needle should be redirected slightly laterally and with a deeper direction to encounter the posterior branch of the femoral nerve. Stimulation of this branch is identified by patellar ascension as the quadriceps

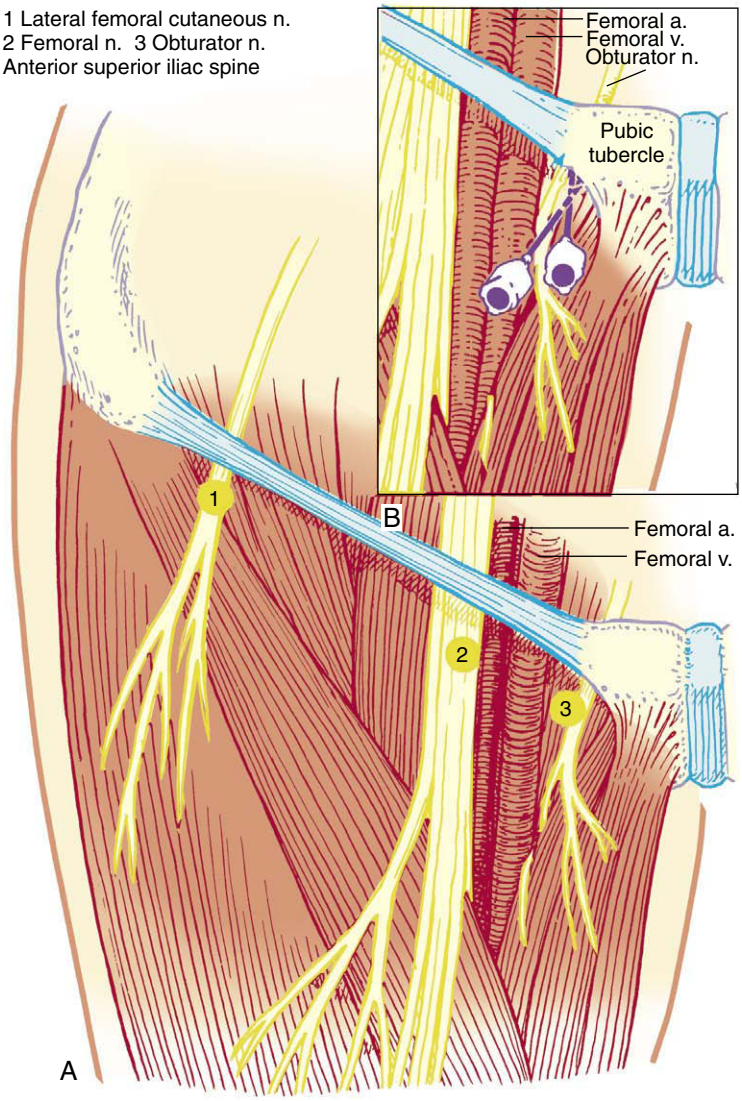

Figure 52-15 A, Anatomic landmarks for the lateral femoral cutaneous, femoral, and obturator nerve blocks. **B,** For an obturator nerve block, the needle is walked off the inferior pubic ramus in a medial and cephalad direction until it passes into the obturator canal.

contracts. A total of 20 to 40 mL of solution is injected incrementally after negative aspiration. Reliable anesthesia of the femoral and lateral femoral cutaneous nerves can be achieved with 20 mL. However, an obturator nerve block may not occur even with volumes greater than 30 mL.

Modified Femoral (Fascia Iliaca) Nerve Block

The fascia iliaca block was originally described in children. Clinical indications for its use are the same as those for a femoral nerve block.[50,54] Advocates believe that its utility lies in the double-pop technique for applying this block. The double pop refers to the sensation felt as the needle traverses the fascia lata and then the fascia iliaca. Penetration of both layers of fascia is important for successful fascia iliaca blockade (Fig. 52-16). To facilitate appreciation of the "clicks" or "pops," the use of a short-beveled or pencil-tipped needle has been advocated to provide more tactile feedback than can be obtained with cutting needles. This technique does not require a nerve stimulator; however, confirmatory motor responses may be sought. The needle entry site for the fascia iliaca block is determined by drawing a line between the pubic tubercle and the anterior superior iliac crest and dividing this line into thirds. The needle entry point is 1 cm caudal to the intersection of the medial two thirds and lateral third along this line. This site is well away from the femoral artery, thus making it useful for patients in whom femoral artery puncture is contraindicated.

Side Effects and Complications

Intravascular injection and hematoma are possible because of the proximity of the femoral artery. Anatomically, the nerve and artery are located in separate sheaths approximately 1 cm apart. In most patients with normal anatomy, the femoral artery can easily be palpated to allow correct, safe needle positioning lateral to the pulsation. The presence of femoral vascular grafts is a relative contraindication to these techniques. Nerve damage is rare.

Lateral Femoral Cutaneous Nerve Block

The lateral femoral cutaneous nerve (L2 and L3) emerges at the lateral border of the psoas muscle immediately caudad to the ilioinguinal nerve. It descends under the iliac fascia to enter the

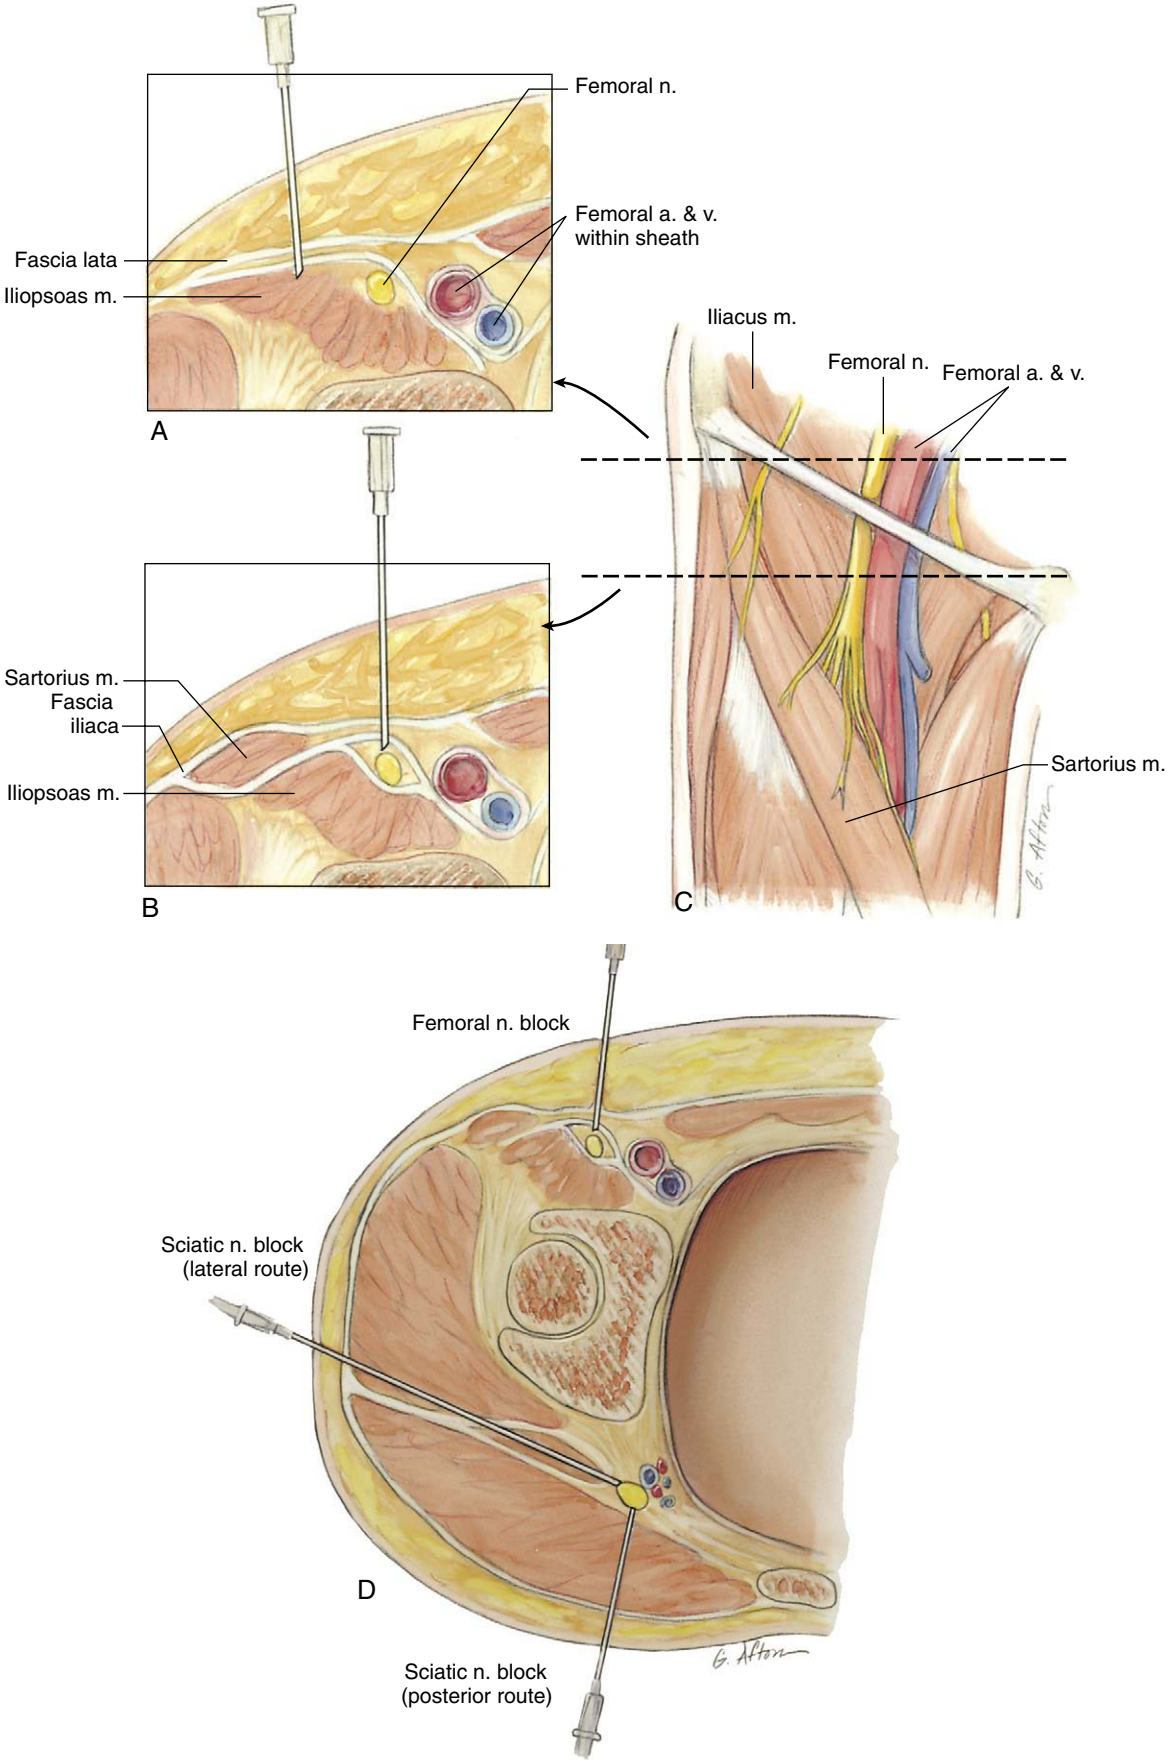

Figure 52-16 Proximal lower extremity blocks. **A,** Fascia iliaca compartment block. **B,** Classic femoral nerve block. **C,** Relationship of the femoral nerve in the groin. **D,** Insertion routes of the most common proximal blocks of the lower extremity (cross section of the thigh).

thigh deep to the inguinal ligament 1 to 2 cm medial to the anterior superior iliac spine. The nerve emerges from the fascia lata 7 to 10 cm below the spine and divides into anterior and posterior branches. The skin of the lateral portion of the thigh from the hip to the midthigh is supplied by the posterior branch; the anterior branch supplies the anterolateral aspect of the thigh to the knee.

Clinical Applications

This block is useful for skin graft harvesting and can be used in concert with other peripheral nerve blocks for complete anesthesia of the lower extremity.

Technique

A point is marked 2 cm medial and 2 cm caudad to the anterior superior iliac spine. A 22-gauge, 4-cm needle is advanced perpendicular to the skin entry site until sudden release indicates passage through the fascia lata. As the needle is moved in a fanlike pattern laterally and medially, 10 to 15 mL of solution is injected so that local anesthetic is deposited above and below the fascia (see Fig. 52-15A). Shannon and colleagues compared the traditional fan technique for lateral femoral cutaneous nerve block with the use of a nerve stimulator technique to seek tingling in the distribution of the nerve.[55]

Side Effects and Complications

The extent of anesthesia is quite limited with this block, but there is a low risk of associated complications. Neuritis of this nerve caused by needle trauma or drug toxicity is a potential but unlikely complication. There are no large blood vessels in the vicinity of this nerve, and the likelihood of rapid uptake or intravascular injection is very small.

Obturator Nerve Block

The obturator nerve is derived primarily from the third and fourth lumbar nerves with an occasional minor contribution from L2. The nerve lies deep in the obturator canal after having descended from the medial border of the psoas muscle. As the nerve leaves the obturator canal, it divides into anterior and posterior branches. The anterior branch supplies an articular branch to the hip and the anterior adductor muscles and a variable cutaneous branch to the lower medial portion of the thigh. The posterior branch innervates the deep adductor muscles and may send an articular branch to the knee.

Clinical Applications

The obturator nerve is usually blocked as part of regional anesthesia for knee surgery. Because it is primarily a motor nerve, it is rarely blocked on its own; however, an obturator nerve block can be useful in treating or diagnosing the extent of adductor spasm in patients with cerebral palsy and other muscle or neurologic diseases affecting the lower extremities before surgical intervention (e.g., adductor tenotomy).

Technique

The patient is placed in the supine position, and a mark is made 1 to 2 cm lateral and 1 to 2 cm caudad to the pubic tubercle. A skin wheal is raised, and a 22-gauge, 8- to 10-cm needle is advanced perpendicular to the skin entry site with a slight medial direction. The inferior pubic ramus is encountered at a depth of 2 to 4 cm, and the needle is walked in a lateral and caudad direction until it passes into the obturator canal. The obturator nerve is located 2 to 3 cm past the initial point of contact with the pubic ramus (see Fig. 52-15). After negative aspiration, 10 to 15 mL of local anesthetic is injected. A nerve stimulator is helpful in locating the obturator nerve, and correct needle position is evidenced by contraction of the adductor muscles of the medial aspect of the thigh.

The classic approach to an obturator nerve block involves painful periosteal contact and multiple needle redirections. An alternative interadductor approach was described by Wasseff.[44,56] In this technique, the needle is inserted behind the adductor tendon, near its pubic insertion, and directed laterally toward a mark on the skin 1 to 2 cm medial to the femoral artery and immediately below the inguinal ligament, which represents the obturator canal. The nerve is identified by a motor response to peripheral nerve stimulation in the adductor muscle. An inguinal approach consisting of insertion of the needle in the inguinal crease at the midpoint of a line drawn between the inner border of the adductor longus tendon and the femoral arterial pulse has been described recently.[57]

Side Effects and Complications

Complications are rare, but this block is technically more difficult than other lower extremity blocks. The obturator canal contains vascular and neural structures, and there is a theoretical risk of intravascular injection, hematoma, and nerve damage. Absence of anesthesia in the obturator nerve distribution can render an otherwise perfect lower extremity block inadequate for surgical procedures on the knee.

Parasacral Block

A parasacral block will consistently block both components of the sciatic nerve and the posterior cutaneous nerve of the thigh. Spread of local anesthetic may also anesthetize other branches of the sacral plexus, including the superior and inferior gluteal and pudendal nerves. The pelvic splanchnic nerves (S2-4), the terminal portion of the sympathetic trunk, the inferior hypogastric plexus, and the obturator nerve all lie in close proximity to elements of the sacral plexus and may be anesthetized with this approach.[58]

Clinical Applications

For procedures about the knee, a parasacral block may provide an advantage over more distal approaches to the sciatic nerve. For procedures below the knee, the adductor weakness from the obturator and superior gluteal nerve block may actually be disadvantageous for mobilization of the patient. This technique is also useful when immediate access to the individual nerves of the sacral plexus is not possible, for example, because of trauma or infection.

Technique

The parasacral approach is based on the bony relationship of the posterior superior iliac spine and the ischial tuberosity. The patient is positioned laterally with the side to be blocked uppermost. The most prominent aspects of the posterior superior iliac spine and the ischial tuberosity are identified, and a line is drawn joining these two points. Along the line a mark is made 6 cm

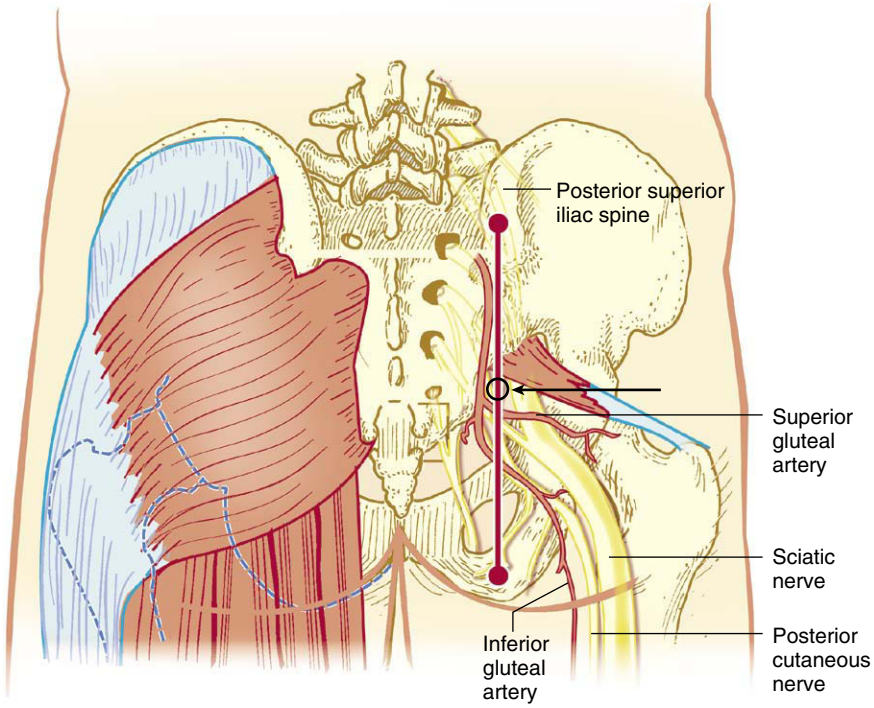

Figure 52-17 Parasacral block. This is the most proximal approach to the sciatic nerve and also results in block of the posterior femoral cutaneous nerve. The most prominent aspects of the posterior superior iliac spine and the ischial tuberosity are identified, and a line is drawn joining these two points. The needle insertion site is along the line, 6 cm inferior to the posterior superior iliac spine. *(From Lennon RL, Horlocker TT: Mayo Clinic Analgesic Pathway, Peripheral Nerve Blockade for Major Orthopedic Surgery. Rochester, MN, Mayo Clinic Scientific Press, 2006.)*

inferior to the posterior superior iliac spine to define the needle insertion site (Fig. 52-17). A 21-gauge, 10-cm insulated needle is advanced in a sagittal plane until an evoked motor response is elicited, typically at a depth of 5 to 7 cm from the skin. When the needle is properly placed, 20 to 30 mL of solution is slowly and incrementally injected. Plantar flexion of the foot (tibial nerve component) or dorsiflexion (common peroneal nerve) is an acceptable motor response. Because of the proximal nature of the block, a hamstring motor response is also acceptable.

Complications

Because the sacral nerves represent the parasympathetic portion of the autonomic nervous system, sympathetic blockade and its potential for hypotension are not seen with a transsacral block unless excessive volumes of solution spread proximally to the lumbar sympathetic fibers. Loss of parasympathetic innervation to the bowel, bladder, and sphincters may occur,[59] however. Injection of local anesthetic through misdirected needles into the subarachnoid or vascular compartments is a remote risk. Classically, the dural sac terminates at the lower border of S2; however, clinical reports of subarachnoid puncture with a 6- to 7-cm caudal needle suggest that there are individual variations below this "classic" location. Finally, an appreciation of the pelvic contents, especially the colon, rectum, and bladder, is important; should a deeply inserted needle enter the colon or rectum and not be noticed, it could result in seeding fecal material into the sacral canals.

Sciatic Nerve Block

The sciatic nerve (L4 and L5, S1 through S3) is the largest of the four peripheral nerves of the lower extremity, with a width of 2 cm as it leaves the pelvis along with the posterior cutaneous nerve of the thigh. The sciatic nerve is composed of two nerves bound by a common sheath of connective tissue; the tibial component is medial and anterior, and the common peroneal component is lateral and slightly posterior. After passing through the sacrosciatic foramen beneath the piriformis muscle, it lies between the greater trochanter of the femur and the ischial tuberosity. The nerve becomes superficial at the lower border of the gluteus maximus muscle, where it begins its descent down the posterior aspect of the thigh to the popliteal fossa. It supplies cutaneous innervation to the posterior of the thigh and all of the leg and foot below the knee, except for a thin medial strip supplied by the saphenous nerve.

Clinical Applications

Because of its wide sensory distribution, a sciatic nerve block can be used, together with a saphenous or femoral nerve block, for any surgical procedure below the knee that does not require a thigh tourniquet. It can also be combined with other peripheral nerve blocks to provide anesthesia for surgical procedures involving the thigh and knee. This form of anesthesia avoids the sympathectomy associated with neuraxial blocks and may therefore be advantageous when any shift in hemodynamics could be deleterious, such as in patients with significant aortic stenosis.

Technique

Classic (Posterior) Approach of Labat

For the classic (posterior) approach of Labat, the patient is positioned laterally, with the leg to be blocked rolled forward onto the flexed knee as the heel rests on the knee of the dependent (nonoperative) leg (Fig. 52-18).[6] A line is drawn to connect the posterior superior iliac spine to the greater trochanter of the femur. A perpendicular line bisecting this line is drawn and extended 5 cm caudad. A second line is drawn from the greater trochanter to the sacral hiatus. The intersection of this line with the perpendicular line indicates the point of needle entry, which falls 3 to 5 cm along

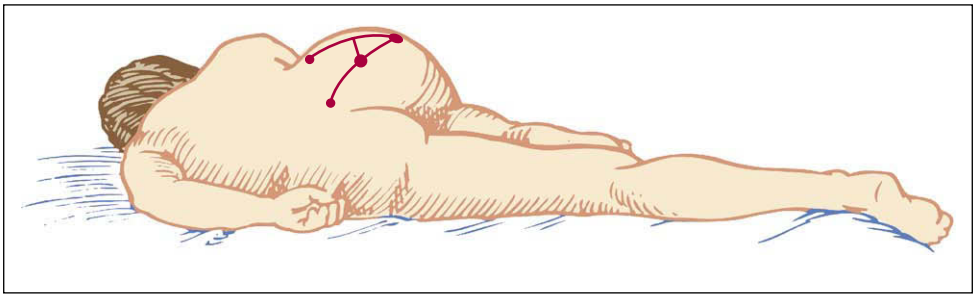

Figure 52-18 Patient positioning for the posterior approach to the sciatic nerve.

the line. A 22-gauge, 10- to 12-cm needle is advanced until a paresthesia or nerve stimulator response is elicited or bone is contacted (Fig. 52-19). If bone is encountered, the needle is redirected systematically in a lateral or medial direction. After the needle is properly placed, a total of 20 to 30 mL of solution is injected.

Subgluteal Approach

With this approach, the patient is positioned laterally in a modified Sims' position, and the leg to be blocked is rolled forward onto the flexed knee as the heel rests on the knee of the dependent (nonoperative) leg. This approach is based on the bony relationship to the greater trochanter and the ischial tuberosity. The most prominent aspects of the greater trochanter and the ischial tuberosity are identified by palpation, and a line is drawn joining these two points. A perpendicular line bisecting this line is drawn and extended 4 to 6 cm caudad. The second line approximates the location of the sciatic nerve. The site of needle insertion may be at the intersection of the two lines or as far as 6 cm distally along the second line. A 21-gauge, 10-cm insulated needle is inserted perpendicularly until a tibial or peroneal evoked motor response in the ankle or foot is elicited, and 20 to 30 mL of solution is injected incrementally (Fig. 52-20). The target response is an evoked response below the knee; stimulation of the tibial nerve component produces plantar flexion and inversion of the foot, and stimulation of the common peroneal nerve produces dorsiflexion and eversion. If no motor response is elicited, the needle may be redirected 1 to 2 cm medial or lateral to the original direction of the needle. It may be helpful to palpate or visualize the groove, which can be seen or palpated on the posterior aspect of the thigh. If bone contact is made, the needle is withdrawn and redirected medially.

Anterior Approach

The anterior approach is useful when the patient cannot be positioned for the classic posterior approach because of pain or lack

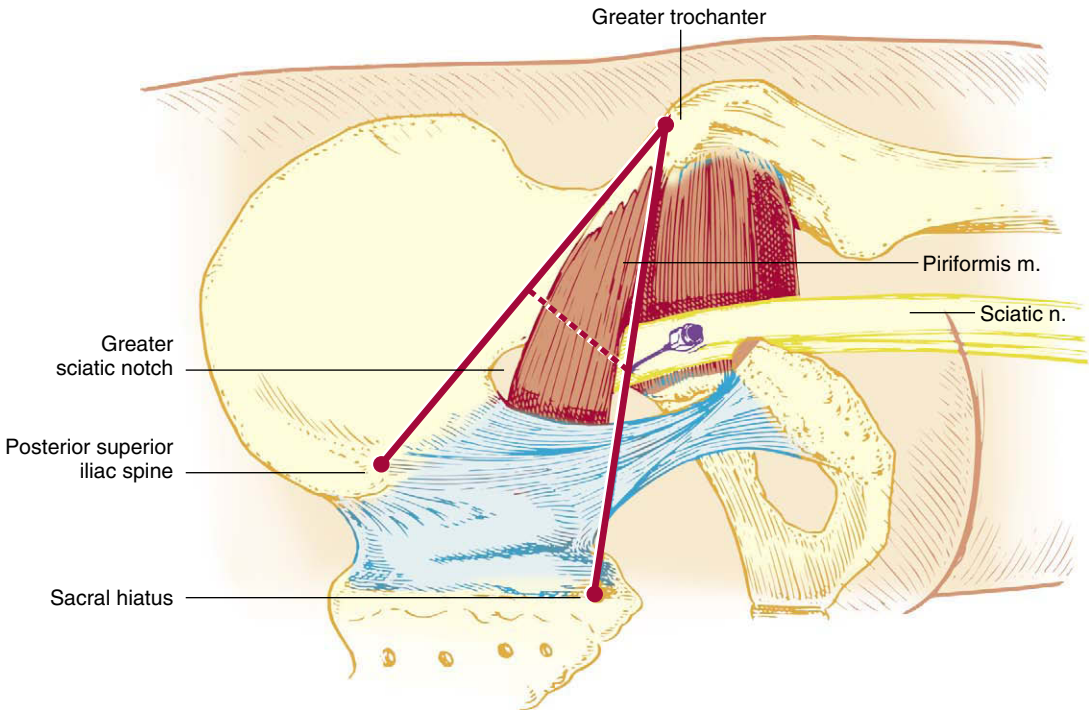

Figure 52-19 Anatomic landmarks for the posterior approach to a sciatic nerve block.

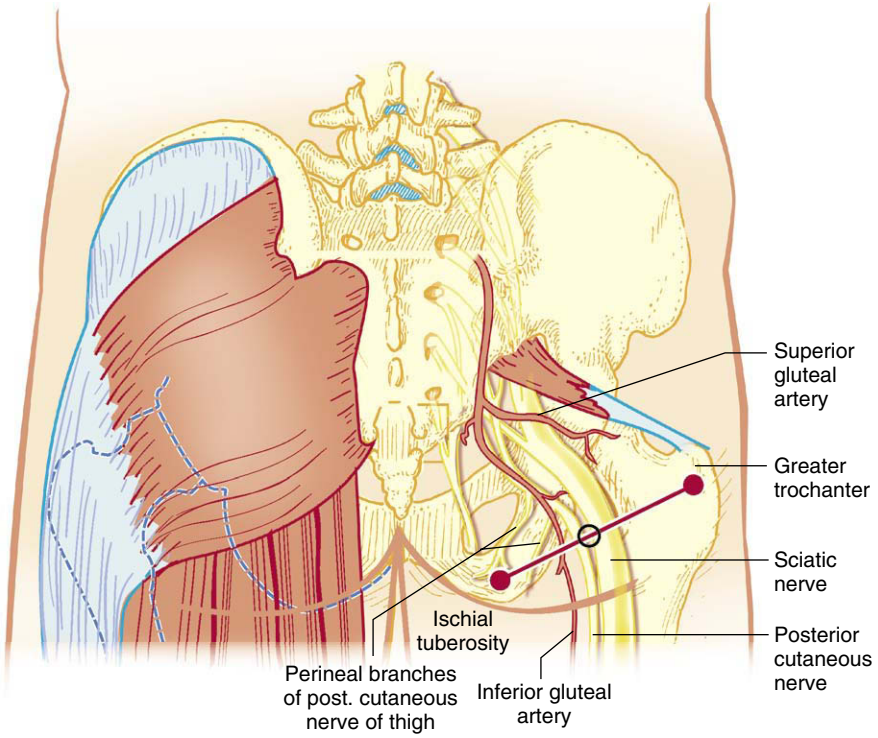

Figure 52-20 Sciatic nerve block (subgluteal approach). The sciatic nerve is relatively superficial at this level. Needle insertion is near the gluteal crease, between the hamstring muscles. *(From Lennon RL, Horlocker TT: Mayo Clinic Analgesic Pathway, Peripheral Nerve Blockade for Major Orthopedic Surgery. Rochester, MN, Mayo Clinic Scientific Press, 2006.)*

of cooperation.[60] Initial blockade of the femoral nerve decreases the pain associated with this approach.

With the patient in the supine position, a line drawn along the inguinal ligament from the anterior superior iliac crest to the pubic tubercle is trisected. A second line parallel to the inguinal ligament is drawn, beginning at the tuberosity of the greater trochanter. A 22-gauge, 10.5- to 12-cm needle is inserted perpendicularly with a slightly lateral angulation at the point where the line representing the juncture of the middle and medial thirds crosses the second line. The needle is advanced until it contacts bone, the lesser trochanter of the femur (Fig. 52-21). The needle is redirected medially past the femur, and a paresthesia or nerve stimulator response is sought at a depth of about 5 cm past the bone. A total of 20 to 25 mL of solution is injected incrementally after careful aspiration.

Other Approaches

The sciatic nerve can also be blocked with the patient in the lateral[61] and lithotomy positions,[62] although these are rarely used clinically.

Techniques to Improve Success Rates

Many methods have been tried in an attempt to improve success with sciatic nerve blockade. Attempts to place the needle in the middle of the sciatic nerve by identifying a specific motor end point (e.g., tibial response/foot inversion) may increase success rates.[63] Another method is the concept of multiple injections.[64] The two major components of the sciatic nerve are separately identified and blocked. Some experts recommend that sciatic nerve blocks be initiated well before the scheduled time of surgery to extend the dwell time and allow long latencies.

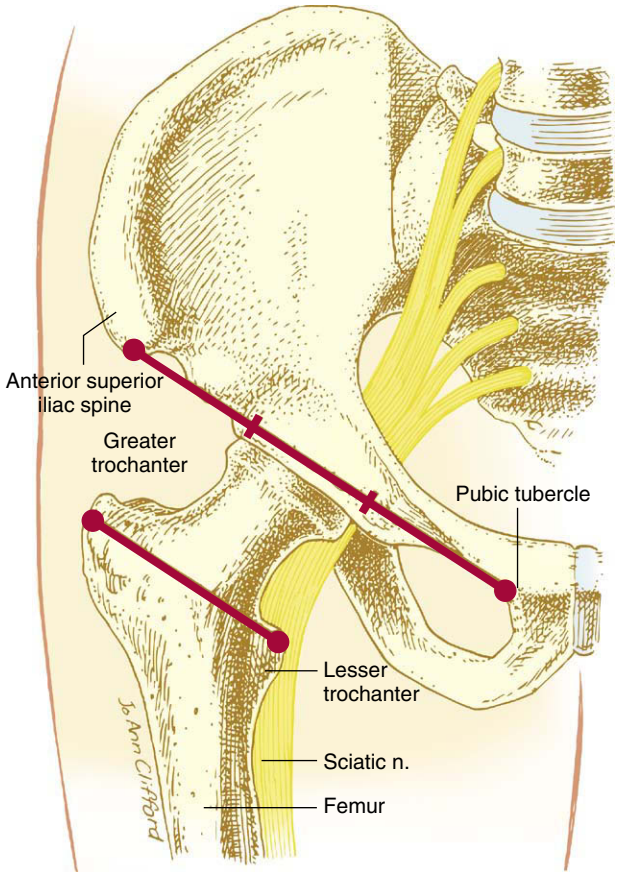

Figure 52-21 Anatomic landmarks for the anterior approach to a sciatic nerve block.

Side Effects and Complications

Serious complications of sciatic nerve block are rare. However, theoretical concerns regarding muscle trauma and puncture of a variety of vascular structures must be considered. A sciatic nerve block is primarily a somatic nerve block. It does carry some sympathetic fibers to the extremity, however, and may therefore allow pooling of small quantities of blood—usually insufficient to cause significant hypotension. In some situations, such as limb reimplantation and sympathetically mediated pain conditions, this sympathetic block may be advantageous. Residual dysesthesias for periods of 1 to 3 days are not uncommon but usually resolve within several months.[64,65] Importantly, many orthopedic surgical procedures (including total-hip and total-knee replacement) are associated with neurapraxia of one or both components of the sciatic nerve. Thus, thoughtful application of this technique is required to optimize neurologic outcome in patients considered to be at high risk for perioperative nerve injury from surgery or preexisting neurologic dysfunction.

Popliteal Fossa Block

The posterior muscles of the thigh are the biceps femoris, semimembranosus, semitendinosus, and posterior portion of the adductor magnus. As these muscles are traced distally from their origin on the ischial tuberosity, they separate into medial (semimembranosus, semitendinosus) and lateral (biceps) musculature, and they form the upper border of the popliteal fossa. The lower border of the popliteal fossa is defined by the two heads of the gastrocnemius. In the upper part of the popliteal fossa, the sciatic nerve lies posterolateral to the popliteal vessels. The popliteal vein is medial to the nerve, and the popliteal artery is most anterior, lying on the popliteal surface of the femur. Near the upper border of the popliteal fossa, the two components of the sciatic nerve separate. The peroneal nerve diverges laterally, and the larger tibial branch descends almost straight down through the fossa. The tibial nerve and popliteal vessels then disappear deep to the converging heads of the gastrocnemius muscle.

Clinical Applications

The popliteal fossa block is chiefly used for foot and ankle surgery. It has also been used in the pediatric population successfully. A popliteal fossa block is preferable to an ankle block for surgical procedures requiring the use of a calf tourniquet. The components of the sciatic nerve may be blocked at the level of the popliteal fossa through posterior or lateral approaches. Supplemental block of the saphenous nerve is required for surgical procedures on the medial aspect of the leg or when a calf tourniquet or Esmarch bandage is used.

Technique

Posterior Approach

The classic approach to the popliteal fossa is posterior with the patient positioned prone. However, access may also be achieved with the patient in the lateral position (i.e., operative side nondependent) or the supine position (i.e., with the leg flexed at the hip and knee).

The borders of the popliteal fossa are identified by flexing the knee joint. A triangle is constructed, with the base consisting of the skin crease behind the knee and the two sides composed of the semimembranosus (medially) and the biceps (laterally). A bisecting line is drawn from the apex to the base of the triangle, and a 5-cm needle is inserted at a site 5 to 10 cm above the skin fold and 0.5 to 1 cm lateral to the bisecting line (Fig. 52-22A). Classically, the 5-cm distance was described.[66] However, in an attempt to block the sciatic nerve before its division, a 7- to 10-cm distance has been recommended.[67] The needle is advanced at a 45-degree angle until a paresthesia or nerve stimulator response is elicited. With a nerve stimulator technique, inversion is the motor response that best predicts complete neural blockade of the foot.[68] Injection of approximately 30 mL of local anesthetic solution is sufficient.

The success rate is typically 90% to 95%.[66,68] No formal comparison between the paresthesia and nerve stimulator techniques has been made to assess efficacy and complications. It is believed that an incomplete block is the result of poor diffusion (because of the size of the sciatic nerve), the separate fascial coverings of the tibial and peroneal nerves, or blockade of only a single component of the sciatic nerve. Identification of the tibial and peroneal components decreases onset time and improves the success rate.[69]

Lateral Approach

A lateral approach to blockade of the sciatic nerve in the popliteal fossa has been described.[70] Although block time is somewhat longer, onset and quality of the block are similar to the posterior approach.[71] The lateral approach allows the patient to be positioned supine and eliminates the need for repositioning. The patient's leg is extended, with the long axis of the foot at a 90-degree angle to the table. The site of insertion is the intersection of a vertical line drawn from the upper edge of the patella and the groove between the lateral border of the biceps femoris and vastus lateralis. A 10-cm needle is advanced at a 30-degree angle posterior to the horizontal plane (see Fig. 52-22B). Because the common peroneal nerve is located lateral to the tibial nerve, the stimulating needle encounters the common peroneal nerve first with the lateral approach. As in the classic posterior approach, a tibial response is sought.[72] If a response associated with common peroneal nerve stimulation (e.g., eversion) is elicited, the needle is redirected more posteriorly.

Side Effects and Complications

As with other peripheral nerve blocks, neuropathy is the most common complication. Intravascular injection may occur as a result of the presence of vascular structures within the popliteal fossa. Performance of a popliteal fossa block in patients with previous total-knee arthroplasty or vascular bypass (femoral-popliteal) should be done with care. However, there have been no cases of graft disruption or joint infection related to needle placement in these patients.

Nerve Blocks at the Ankle

Four of the five individual nerves that can be blocked at the ankle to provide anesthesia of the foot are terminal branches of the sciatic nerve: the posterior tibial, sural, superficial peroneal, and deep peroneal branches. The sciatic nerve divides at or above the apex of the popliteal fossa to form the common peroneal and tibial nerves. The common peroneal nerve descends laterally around the head of the fibula, where it divides into the superficial and deep peroneal nerves.

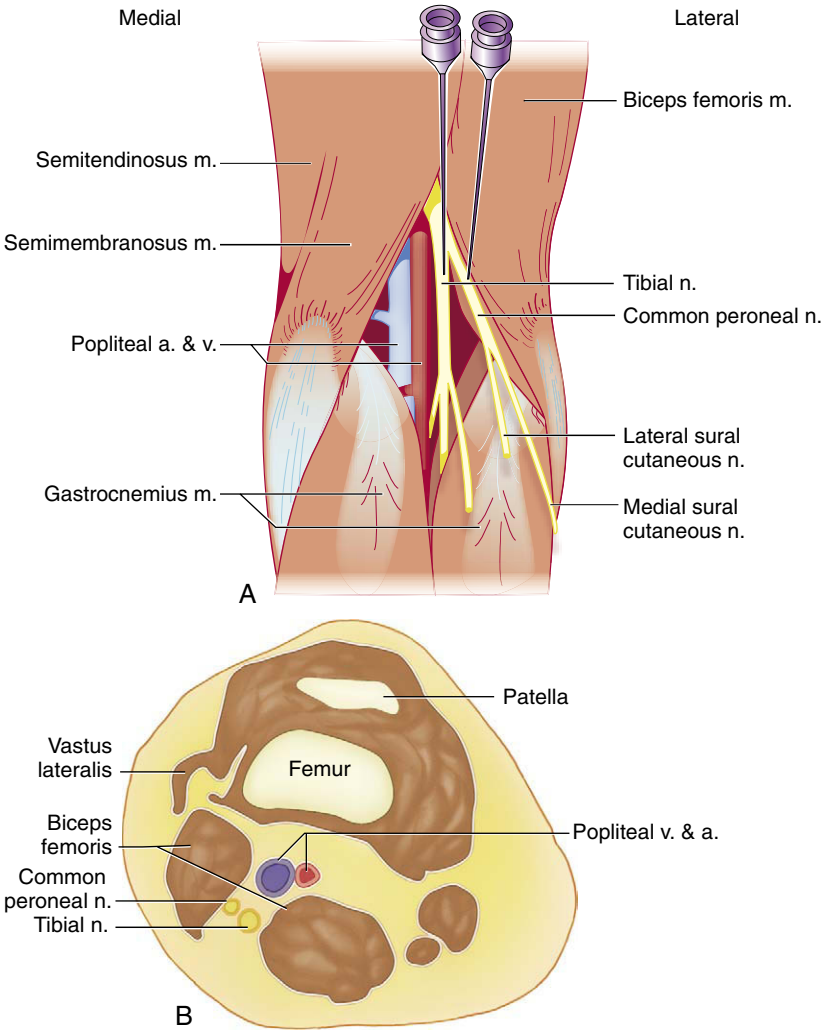

Figure 52-22 A, Anatomic landmarks for the posterior approach to the sciatic nerve in the popliteal fossa. **B,** Anatomic landmarks for the lateral approach to the sciatic nerve in the popliteal fossa.

The tibial nerve divides into the posterior tibial and sural nerves in the lower part of the leg. The posterior tibial nerve becomes superficial at the medial border of the Achilles tendon near the artery of the same name, and the sural nerve emerges lateral to the Achilles tendon.

Clinical Applications

Ankle blocks are simple to perform and offer adequate anesthesia for surgical procedures on the foot that do not require a tourniquet above the ankle.

Technique

Posterior Tibial Nerve

The posterior tibial nerve can be blocked with the patient in either the prone or the supine position. The posterior tibial artery is palpated, and a 25-gauge, 3-cm needle is inserted posterolateral to the artery at the level of the medial malleolus (Fig. 52-23A and B). A paresthesia is often elicited but is not necessary for a successful block. If a paresthesia occurs, 3 to 5 mL of local anesthetic should be injected. Otherwise, 7 to 10 mL of solution should be injected as the needle is slowly withdrawn from the posterior aspect of the tibia. Blockade of the posterior tibial nerve provides anesthesia to the heel, plantar portion of the toes, and the sole of the foot, as well as some motor branches in the same area.

Sural Nerve

The sural nerve is located superficially between the lateral malleolus and the Achilles tendon. A 25-gauge, 3-cm needle is inserted lateral to the tendon and directed toward the malleolus as 5 to 10 mL of solution is injected subcutaneously (see Fig. 52-23A and C). This block provides anesthesia to the lateral part of the foot and the lateral proximal aspect of the sole of the foot.

Deep Peroneal, Superficial Peroneal, and Saphenous Nerves

The deep peroneal, superficial peroneal, and saphenous nerves can be blocked through a single needle entry site (Fig. 52-24). A line is drawn across the dorsum of the foot connecting the malleoli. The extensor hallucis longus tendon is identified by having the patient dorsiflex the big toe. The anterior tibial artery lies between this structure and the tendon of the extensor digitorum longus muscle and is palpable at this level. A skin wheal is raised just lateral to the pulsation between the two tendons on the inter-

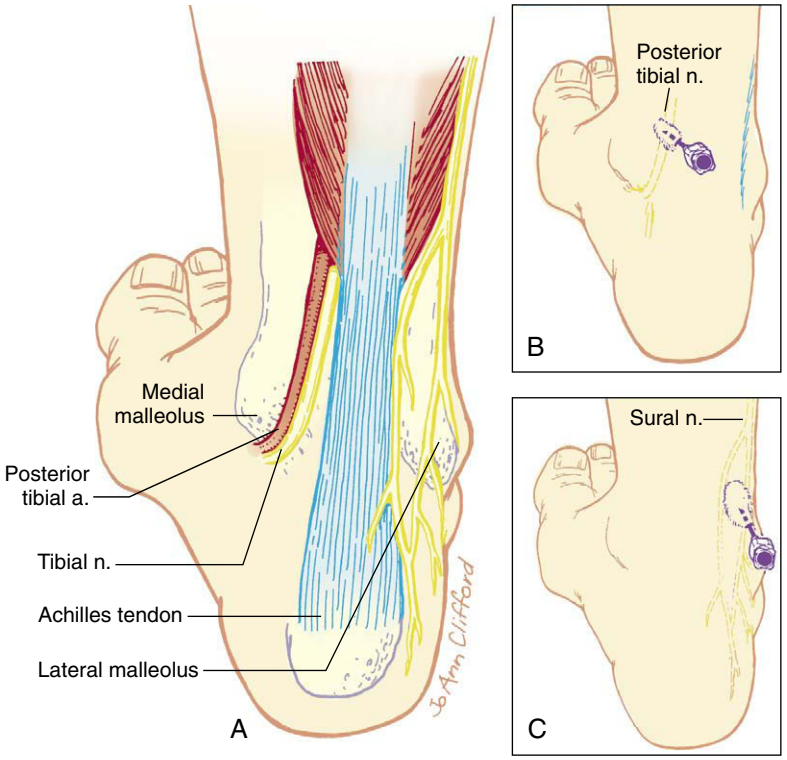

Figure 52-23 **A,** Anatomic landmarks for a block of the posterior tibial and sural nerves at the ankle. **B,** Posterior tibial nerve and method of needle placement for a block at the ankle. **C,** Sural nerve and method of needle placement for a block at the ankle.

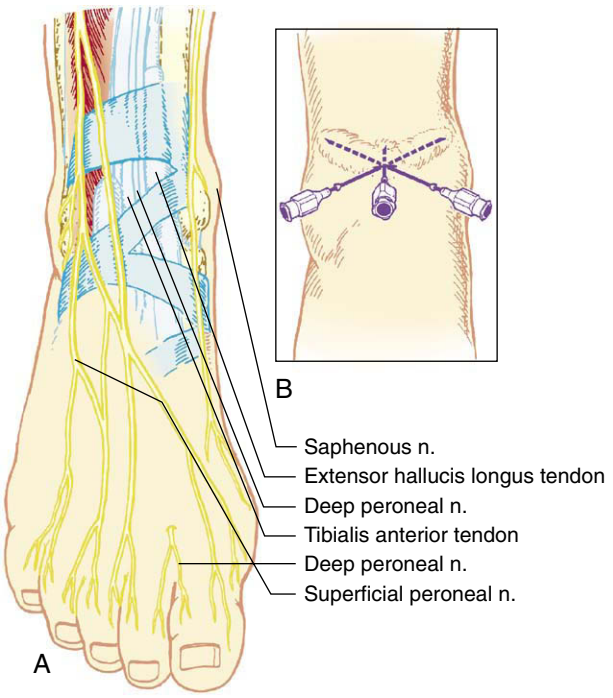

Figure 52-24 **A,** Anatomic landmarks for blockade of the deep peroneal, superficial peroneal, and saphenous nerves at the ankle. **B,** Method of needle placement for a block of the deep peroneal, superficial peroneal, and saphenous nerves through a single needle entry site.

malleolar line. A 25-gauge, 3-cm needle is advanced perpendicular to the skin entry site, and 3 to 5 mL of local anesthetic is injected deep to the extensor retinaculum to block the deep peroneal nerve. This technique anesthetizes the skin between the first and second toes and the short extensors of the toes.

The needle is directed laterally through the same skin wheal while injecting 3 to 5 mL of solution subcutaneously, which blocks the superficial peroneal nerve and results in anesthesia of the dorsum of the foot, excluding the first interdigital cleft. The same maneuver can be performed in the medial direction to anesthetize the saphenous nerve, a terminal branch of the femoral nerve that supplies a strip along the medial aspect of the foot.

Side Effects and Complications

The multiple injections required for some techniques result in discomfort for the patient. Persisting paresthesias may occur, but they are self-limited. The presence of edema or induration in the area of the ankle block can make palpation of landmarks difficult. Intravascular injection is possible but unlikely if aspiration for blood is negative. The volume of local anesthetic used is small, thereby decreasing the risk for local anesthetic toxicity.

Blocks of the Head and Neck

Regional anesthesia of the head and neck has become less popular as safer methods of general anesthesia have been developed. However, applications for these techniques still exist, especially in the postoperative and chronic pain settings. Airway anesthesia is often needed to facilitate endotracheal intubation.

The cutaneous innervation of the head and neck is provided by sensory fibers from the trigeminal nerve and the cervical plexus. Innervation of the airway is derived from the vagus and glossopharyngeal nerves. Sympathetic blockade of the face and upper extremity is achieved by anesthetizing the stellate ganglion.

Trigeminal Nerve Block

The trigeminal nerve divides into three main branches in the middle cranial fossa. These divisions—the ophthalmic, maxillary, and mandibular nerves—provide sensation to the eye and forehead, midface and upper jaw, and lower jaw, respectively (Fig. 52-25A). With the exception of motor fibers to the muscles of mastication, carried by the mandibular nerve, these nerves are wholly sensory.

A gasserian ganglion block, approached classically through the foramen ovale, is infrequently used for producing surgical anesthesia. In the past, it was primarily applied for the diagnosis and treatment of trigeminal neuralgia; however, the increasing popularity and safety of thermocoagulation for ablation of the ganglion have rendered neurolytic blocks obsolete.

Clinical Applications

Blockade of the second and third divisions of the trigeminal nerve, as well as blockade of the peripheral branches, is occasionally useful in the diagnosis and management of pain syndromes and for discrete surgical procedures in selected patients (see Fig. 52-25B).

Technique: Mandibular and Maxillary Nerves

The mandibular and maxillary nerves, two divisions of the trigeminal nerve, can be blocked through the same needle entry site (see Fig. 52-25B). The maxillary nerve (i.e., second division) is blocked as it exits the skull through the foramen rotundum and crosses the pterygopalatine or infratemporal fossa between the skull and the upper jaw. The nerve terminates as the infraorbital nerve as it exits through the infraorbital foramen, where it can also be anesthetized.

The coronoid notch of the mandible is located, and with the patient's mouth closed, a 22-gauge, 8-cm needle is inserted at the inferior edge of the coronoid notch perpendicular to the skin entry site. The needle contacts the lateral pterygoid plate at a depth of about 5 cm. It is then withdrawn and redirected anteriorly and superiorly to walk off the plate and is subsequently advanced approximately 0.5 cm into the pterygopalatine fossa (see Fig. 52-25C). Between 3 and 5 mL of local anesthetic solution produces anesthesia of the upper jaw and skin of the lower eyelid, cheek, and upper lip.

The mandibular nerve (i.e., third division) leaves the cranium through the foramen ovale and innervates the skin of the lower jaw and the skin anterior and superior to the ear by its posterior division. Peripheral sensory branches of cranial nerve V_3 include the buccal, auriculotemporal, lingual, and inferior alveolar (terminating in the mental nerve) nerves. The anterior division supplies motor innervation to the muscles of mastication.

The mandibular nerve is blocked through the same entry site as the maxillary nerve. The needle is advanced along the inferior margin of the coronoid notch until the bone of the lateral pterygoid plate is contacted (about 5 cm). The needle is withdrawn and redirected to walk off the posterior border of the pterygoid plate, and it is advanced in an attempt to elicit a paresthesia. The needle should not be inserted farther than 0.5 cm past the plate (see Fig. 52-25D). Injection of 3 to 5 mL of local anesthetic solution at this site is adequate.

Side Effects and Complications

Blockade of the maxillary nerve can be associated with hematoma formation and spread of the local anesthetic solution to the optic nerve, thereby causing temporary blindness. A mandibular nerve block is not associated with major complications. If the needle is advanced past the pterygoid plate more than the recommended 0.5 cm, the pharynx may be entered, which increases the risk of contaminating the infratemporal fossa. Rarely, subarachnoid spread of local anesthetic may occur and result in brainstem anesthesia.[73]

Terminal Sensory Branches of the Trigeminal Nerve

Clinical Applications

Blockade of the terminal branches of the three divisions of the trigeminal nerve is primarily used for the diagnosis of trigeminal neuralgia. Individual nerve blocks can also be used for minor surgical procedures.

Technique

Supraorbital and Supratrochlear Nerves

The supraorbital and supratrochlear nerves, branches of the ophthalmic nerve (i.e., cranial nerve V_1), are derived from the frontal nerve, which supplies the skin of the medial upper eyelid and forehead. The supraorbital notch can easily be palpated. This landmark lies on a vertical line with the pupil (when the eye is looking directly forward), the infraorbital foramen, and the mental foramen (Fig. 52-26).

A 25-gauge, 2-cm needle is inserted immediately superior to the supraorbital notch, and 2 to 4 mL of local anesthetic solution is injected. A paresthesia is sometimes elicited, but it is not essential. The supratrochlear nerve can be blocked by extending the supraorbital injection site medially with an additional 2 to 4 mL of solution.

Infraorbital Nerve

The infraorbital nerve can be blocked to provide anesthesia of the upper lip and skin of the cheek. The infraorbital notch lies on a line connecting the supraorbital and mental foramina and the pupil of the eye. The nerve can be blocked by advancing a 25-gauge, 3-cm needle laterally and cephalad toward the foramen from a point 1 cm inferior. A paresthesia is frequently elicited. When the needle tip is in the region of the foramen, 3 to 4 mL of solution is injected. It is not essential that the needle enter the foramen (see Fig. 52-26).

Mental Nerve

Blockade of the mental nerve as it exits the mental foramen provides anesthesia to the lower lip and chin. The mental foramen lies on a vertical line connecting the pupil of the eye with the

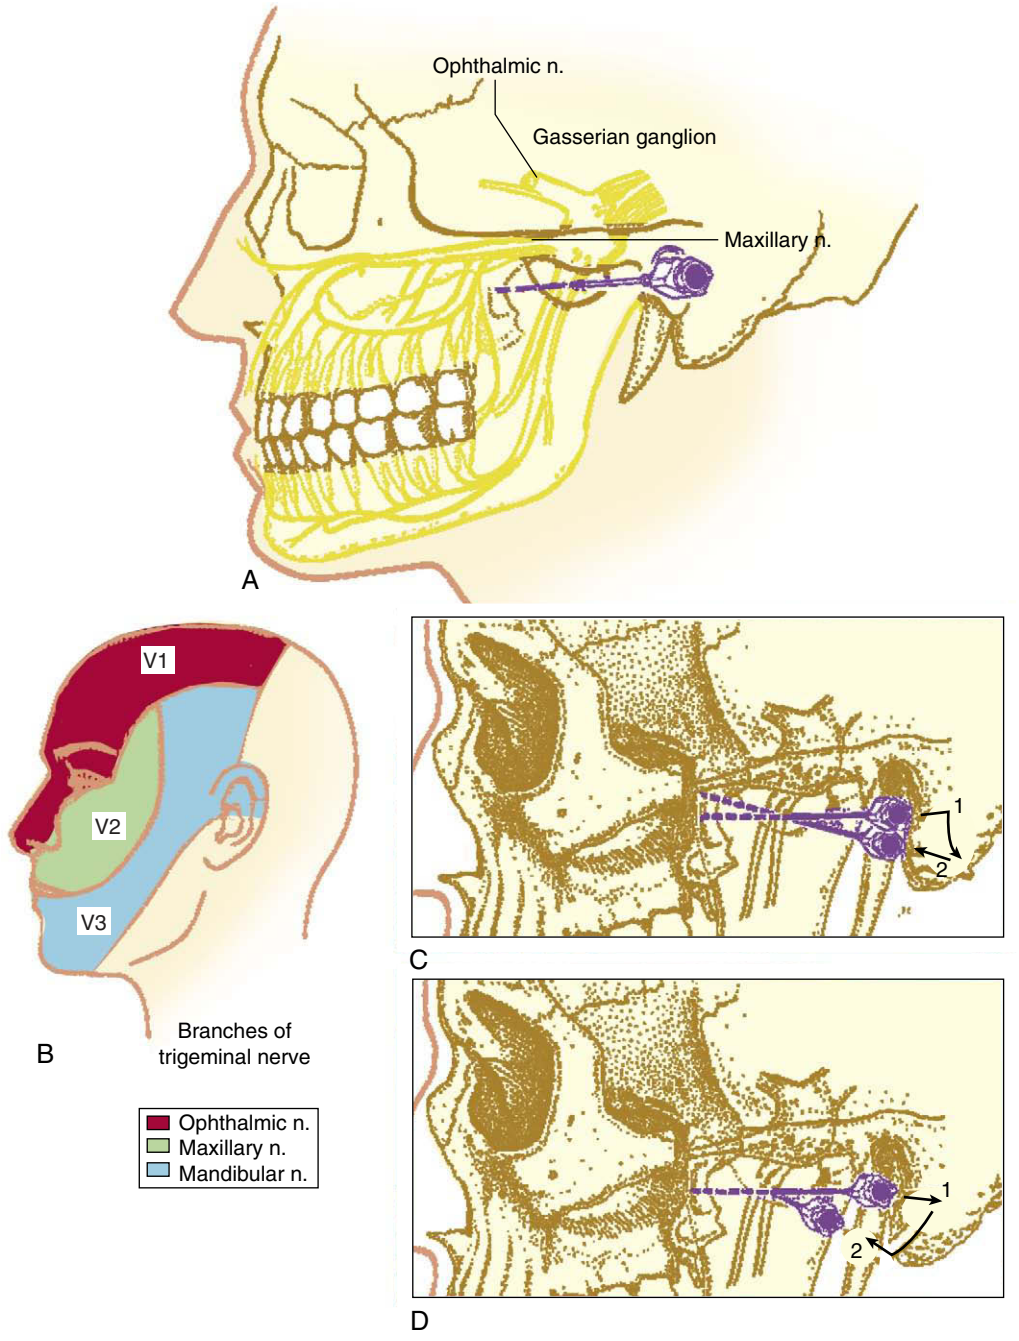

Figure 52-25 Anatomic landmarks and method of needle placement for maxillary and mandibular nerve blocks. **A,** The ophthalmic, maxillary, and mandibular nerves provide sensation to the eye and forehead, midface and upper jaw, and lower jaw, respectively. **B,** The mandibular and maxillary nerves can be blocked through the same needle entry site. **C,** A needle is inserted at the inferior edge of the coronoid notch perpendicular to the skin entry site, and after contacting the lateral pterygoid plate, it is withdrawn and redirected anteriorly and superiorly to walk off the plate (*arrows*). It is advanced approximately 0.5 cm into the pterygopalatine fossa. **D,** The mandibular nerve is blocked through the same entry site as the maxillary nerve and by the same method, except that the needle is withdrawn and redirected to walk off the posterior border of the pterygoid plate (*arrow*). When it is advanced to elicit paresthesia, the needle should not be inserted more than 0.5 cm past the plate.

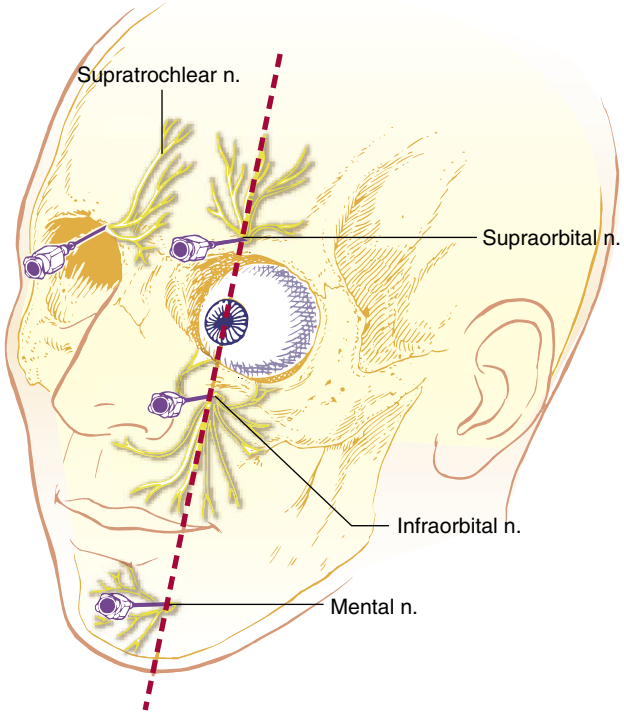

Figure 52-26 Blockade of the terminal sensory branches of the trigeminal nerve. A *vertical line* connects the supraorbital notch, infraorbital foramen, and mental foramen.

foramina of the peripheral nerves of V_1, V_2, and V_3. The foramen is palpated in the mandible, and a 25-gauge, 3-cm needle is inserted inferomedially. Infiltration of 2 to 4 mL of solution after elicitation of a paresthesia or in the region of the foramen results in anesthesia of the mental nerve (see Fig. 52-26).

Side Effects and Complications

Direct injection of the peripheral nerves within the bony foramina may result in nerve damage.

Cervical Plexus Blockade

The cervical plexus is derived from the C1, C2, C3, and C4 spinal nerves and supplies branches to the prevertebral muscles, strap muscles of the neck, and phrenic nerve. The deep cervical plexus supplies the musculature of the neck segmentally and the cutaneous sensation of the skin between the trigeminally innervated face and the T2 dermatome of the trunk. Blockade of the superficial cervical plexus results in anesthesia of only the cutaneous nerves.

Clinical Applications

Blockade of the cervical plexus is easy to perform and provides anesthesia for surgical procedures in the distribution of C2 to C4, including lymph node dissection, plastic repair, and carotid endarterectomy. The ability to monitor the awake patient's neurologic status continuously is an advantage of this anesthetic technique for the latter procedure and has resulted in an upsurge in popularity of this technique.[74] Bilateral blocks can be used for tracheostomy and thyroidectomy.

Technique

Superficial Cervical Plexus

The superficial cervical plexus is blocked at the midpoint of the posterior border of the sternocleidomastoid muscle. A skin wheal is raised at this point, and a 22-gauge, 4-cm needle is advanced while injecting 5 mL of solution along the posterior border and medial surface of the sternocleidomastoid muscle (Fig. 52-27). It is possible to block the accessory nerve with this injection, which results in temporary paralysis of the ipsilateral trapezius muscle.

Deep Cervical Plexus

The deep cervical plexus block is a paravertebral block of the C2 to C4 spinal nerves as they emerge from their foramina in the cervical vertebrae (Fig. 52-28). The traditional approach involves the use of three separate injections at C2, C3, and C4. The patient lies supine with the neck slightly extended and the head turned away from the side to be blocked. A line is drawn connecting the tip of the mastoid process and the Chassaignac tubercle (i.e., transverse process of C6); a second line is drawn 1 cm posterior to the first line. The C2 transverse process lies 1 to 2 cm caudad to the mastoid process, where it can usually be palpated. The C3 and C4 transverse processes lie at 1.5-cm intervals along the second line. After skin wheals are raised over the transverse processes of C2, C3, and C4, three 22-gauge, 5-cm needles are advanced perpendicular to the skin entry site at a slight caudad angulation. The transverse process is contacted at a depth of 1.5 to 3 cm. If a paresthesia is obtained, 3 to 4 mL of solution is injected after careful aspiration for blood and cerebrospinal fluid. If no paresthesia is elicited initially, the needle is walked along the transverse process in the anteroposterior plane until a paresthesia is obtained.

This block can also be performed with a single injection of 10 to 12 mL at the C4 transverse process.[75] Cephalad spread of the local anesthetic usually anesthetizes the C2 and C3 nerves. Cervical plexus anesthesia can also be observed after injection at the interscalene level for brachial plexus blockade. Maintenance

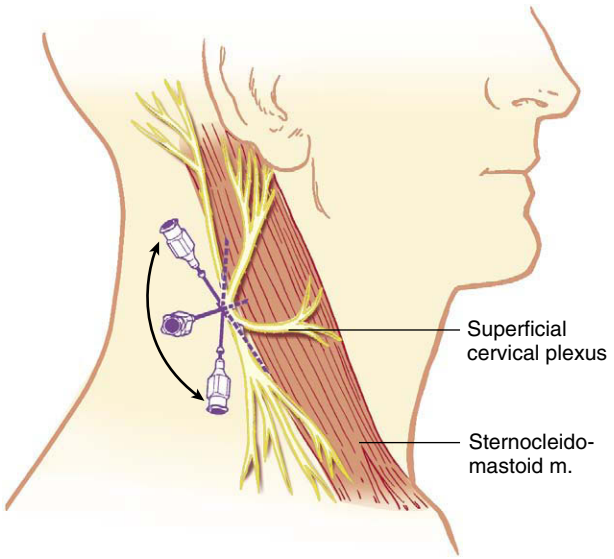

Figure 52-27 Anatomic landmarks and method of needle placement for a superficial cervical plexus block.

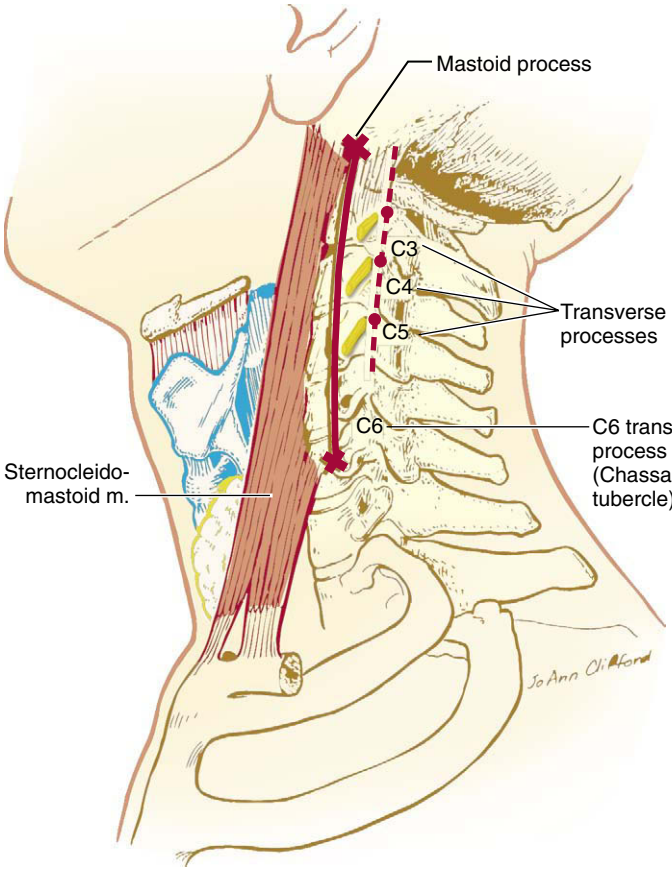

Figure 52-28 Anatomic landmarks and method of needle placement for deep cervical plexus blocks at C2, C3, and C4.

of distal pressure and a horizontal or slightly head-down position may facilitate the onset of cervical plexus blockade via the interscalene technique.

Side Effects and Complications

Although these blocks are technically straightforward, needle placement for a deep cervical block allows injection of local anesthetic in close proximity to a variety of neural and vascular structures. Reported complications and side effects include intravascular injection, blockade of the phrenic and superior laryngeal nerve, and spread of local anesthetic solution into the epidural and subarachnoid spaces.

Accessory Nerve Block

The accessory nerve (i.e., cranial nerve XI) is occasionally blocked to supplement the interscalene brachial plexus approach for shoulder procedures. Blockade of the accessory nerve results in motor paralysis of the trapezius muscle, thereby ensuring lack of patient movement during the surgical procedure. The nerve traverses the posterior triangle of the neck (bordered by the posterior border of the sternocleidomastoid muscle, middle third of the clavicle, and anterior border of the trapezius muscle) in a very superficial position after emerging from the substance of the sternocleidomastoid muscle at the junction of the superior and middle thirds of that muscle's posterior border. It can easily be blocked at that site by injecting 6 to 10 mL of local anesthetic. This nerve is often unintentionally anesthetized when a superficial cervical plexus block is performed.

Local Anesthesia of the Airway

Clinical Applications

Anesthesia of the airway can be used to facilitate diagnostic laryngoscopy and bronchoscopy and to allow comfortable placement of a tracheal tube in patients whose anatomy dictates an awake endotracheal intubation (also see Chapter 50). Block of the superior laryngeal nerves bilaterally, along with translaryngeal injection of local anesthetic, provides anesthesia of the airway from the infraglottic area to the epiglottis. Additional topical application of local anesthetic to the oral and nasal mucosa, along with appropriate sedation, provides satisfactory analgesia for endoscopic procedures.

Technique

Superior Laryngeal Nerve

The patient is placed supine with the neck extended. The hyoid bone is displaced laterally toward the side to be blocked, and a 25-gauge, 2.5-cm needle is walked off the greater cornu of the hyoid bone inferiorly and advanced 2 to 3 mm (Fig. 52-29). As the needle passes through the thyrohyoid membrane, a slight loss of resistance is felt, and 3 mL of local anesthetic solution is injected superficial and deep to this structure. The block is then repeated on the opposite side. This technique produces anesthesia from the inferior aspect of the epiglottis to the vocal cords.

Translaryngeal Block

A translaryngeal block is simple to perform and results in anesthesia of the trachea below the vocal cords. However, injection of local anesthetic usually stimulates the cough reflex, and this

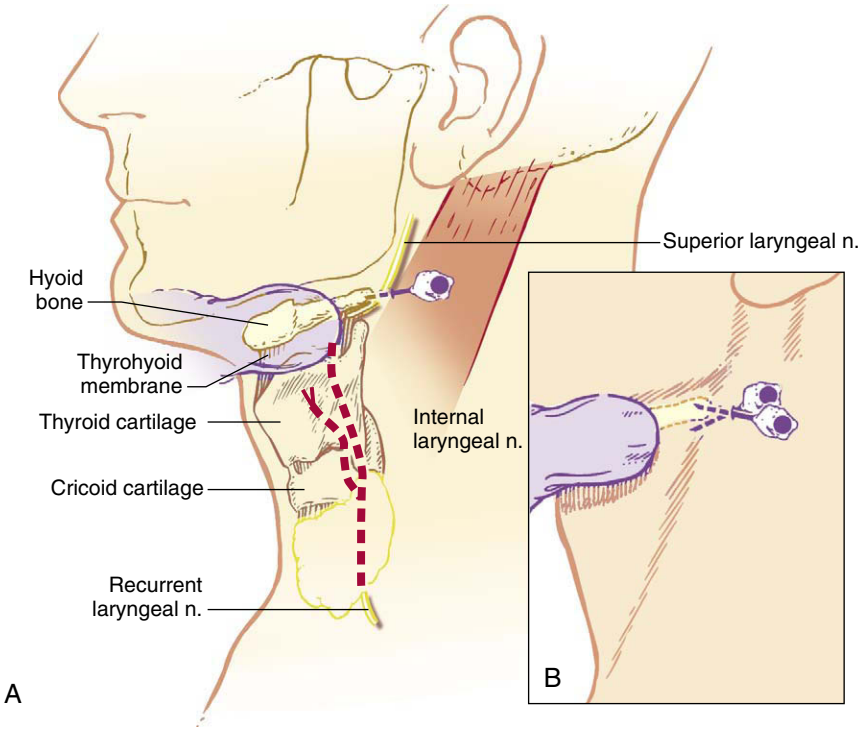

Figure 52-29 Needle placement for a translaryngeal nerve block.

block should be avoided in patients in whom coughing is undesirable.

With the patient in the supine position, the cricothyroid membrane is located, and a 20-gauge or smaller, 3- to 5-cm plastic catheter over a needle is introduced in the midline (Fig. 52-30). The inner steel cannula is withdrawn with the plastic catheter held firmly in place; aspiration of air confirms correct catheter placement. Between 3 and 5 mL of a 4% lidocaine solution is injected rapidly and usually results in a vigorous cough, which aids in spread of the solution within the trachea.

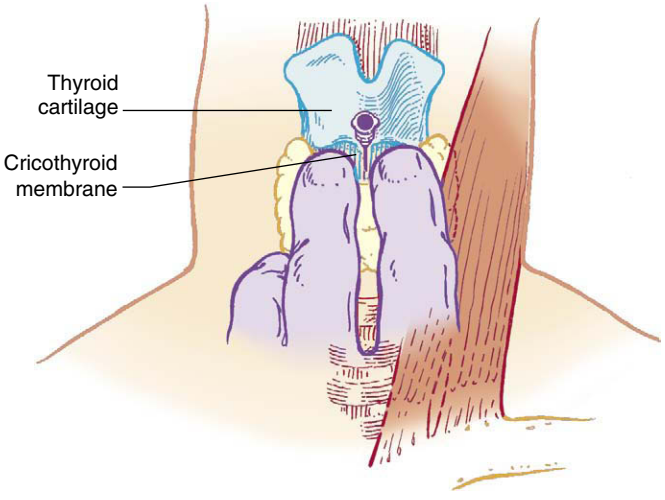

Figure 52-30 A, Anatomic landmarks and method of needle placement for a superior laryngeal nerve block. **B,** The needle is walked off the greater cornu of the hyoid bone inferiorly.

Intraoral Approach to a Glossopharyngeal Nerve Block

The glossopharyngeal nerve (i.e., cranial nerve IX) supplies sensation to the posterior third of the tongue, the pharynx, and the superior surface of the epiglottis. It can be blocked intraorally by injecting 5 mL of local anesthetic into the base of each posterior tonsillar pillar. An angled 22-gauge, 9-cm needle, which can be formed by bending the distal 1 cm of a spinal needle with its stylet removed, is used for this block. Visualization of the posterior pillar is facilitated by the gentle use of a no. 3 MacIntosh laryngoscope blade after topical anesthetic has been applied to the tongue. Careful aspiration before injection is mandatory because of proximity of the carotid artery.

Side Effects and Complications

The mucosa of the upper airway is well perfused, which results in rapid uptake of local anesthetics injected or applied topically in this area. Careful attention to total drug dosages, close observation of the patient, and compulsive aspiration before injection diminish the risk for local anesthetic toxicity. Other problems and complications are rare; however, caution should be used in a patient with a full stomach because these blocks abolish airway reflexes.

Retrobulbar and Peribulbar Blocks

Clinical Applications

Retrobulbar and peribulbar blocks and sub-Tenon blocks (see Chapter 75) provide anesthesia for corneal, anterior chamber, and lens procedures when combined with a block of the orbicularis oculi muscle. These blocks are often performed by the surgeon rather than the anesthesiologist, and they have gained increasing popularity for cataract surgery in the elderly outpatient population (also see Chapters 71 and 78). Retrobulbar and peribulbar

blocks provide equivalent akinesia and anesthesia.[76] The safety of these regional anesthetic techniques was documented by Backer and coworkers,[77] who demonstrated a zero incidence of reinfarction or death in 288 patients with a history of myocardial infarction undergoing local anesthesia or retrobulbar block, or both, for ophthalmologic procedures.

Technique

A *retrobulbar block* is performed with the patient supine and looking straight ahead. A 23-gauge, 3-cm blunted needle is inserted at the inferolateral border of the bony orbit and directed toward the apex of the orbit. A pop is often felt as the needle tip enters the orbital muscle cone, and 2 to 4 mL of solution is injected. With the *peribulbar approach*, the needle is inserted at the inferior orbital rim in the inferolateral quadrant and advanced along the floor of the globe to a depth of approximately 2.5 cm, and 5 mL of local anesthetic is injected. Many patients require a second injection to achieve complete akinesia and anesthesia. For the medial injection, the needle is inserted through the conjunctiva on the nasal side and directed straight back 2.5 cm, parallel to the orbital wall. An additional 5 mL of local anesthetic is injected. With both techniques, blockade of the facial nerve fibers that innervate the orbicularis oculi muscle is also performed to complete the anesthesia. Because these blocks may be uncomfortable for the patient, a small dose of a short-acting sedative, such as propofol, just before the injection prevents pain and patient movement.

Recently, a sub-Tenon (episcleral) block has been described.[78] The technique uses a blunt cannula inserted to contact the conjunctiva between the eyeball and the semilunaris fold. The needle is advanced in an anteroposterior direction, with the globe directed slightly medially by the needle until a "pop" is perceived, typically at a mean depth of 15 to 20 mm. This pop confirms the episcleral location of the needle tip. After an aspiration test, the local anesthetic is injected slowly.

Side Effects and Complications

Retrobulbar and peribulbar blocks are associated with several possible complications, including globe perforation, brainstem anesthesia, retrobulbar hemorrhage, optic nerve injury, local anesthetic toxicity, development of the oculocardiac reflex, and possible spinal anesthesia via the optic nerve sheath.[79] The risk of globe perforation is theoretically less with the peribulbar approach. The use of a blunt needle with the sub-Tenon block substantially decreases the incidence of complications when compared with the retrobulbar and peribulbar techniques.[78]

Stellate Ganglion Block

Clinical Applications

Blockade of the stellate ganglion is used primarily for the treatment of upper extremity sympathetic dystrophy and to increase blood flow to this area (Chapter 58).

Technique

The patient lies supine with the neck extended slightly. The most prominent cervical transverse process—the Chassaignac tubercle (C6)—is palpated between the sternocleidomastoid muscle and the trachea. The C6 tubercle is palpated between the index and middle fingers and the carotid artery is pushed laterally. A skin wheal is raised between the fingers over the tubercle, and a 22-gauge, 4-cm short-beveled needle with a 12-mL syringe attached is inserted in a perpendicular direction until the tip contacts the C6 transverse process (Fig. 52-31). The needle is then withdrawn 3 mm and fixed. After careful aspiration, 8 to 12 mL of local anesthetic solution is injected. Signs of a successful stellate ganglion block include Horner's syndrome, anhidrosis, injection of the conjunctiva, nasal stuffiness, vasodilation, and increased skin temperature.

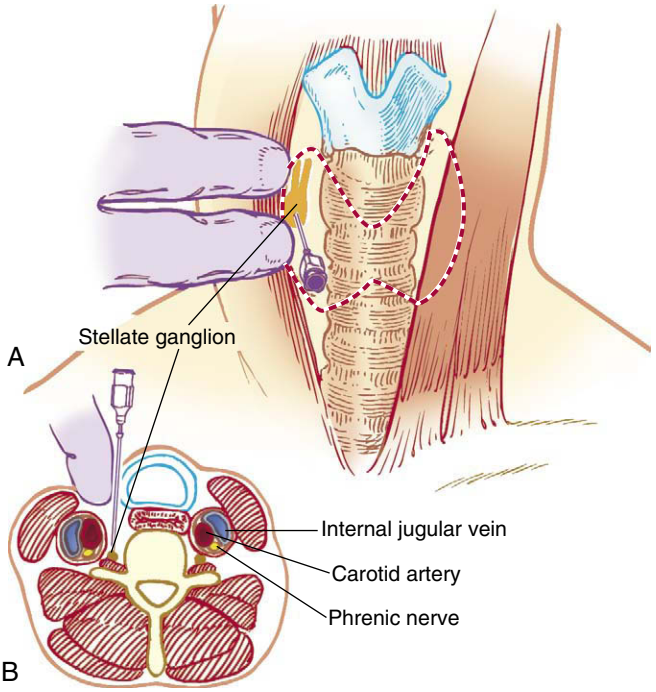

Figure 52-31 **A,** Anatomic landmarks and method of needle placement for a stellate ganglion block. **B,** Cross-sectional view of a stellate ganglion block.

Side Effects and Complications

Because of the proximity of several major neural and vascular structures to the site of needle insertion, side effects and complications can occur, including block of the brachial plexus and recurrent laryngeal nerves, hematoma formation, intravascular injection resulting in convulsions, and epidural and subarachnoid injection.[80]

Blocks of the Thorax and Abdomen

Intercostal Nerve Block and Interpleural Catheter Placement

The intercostal nerves are the primary rami of T1 through T11. T12 is technically a subcostal nerve and supplies branches to the ilioinguinal and iliohypogastric nerves. Fibers from T1 contribute to the brachial plexus; T2 and T3 provide a few fibers to formation of the intercostobrachial nerve, which supplies the skin of the

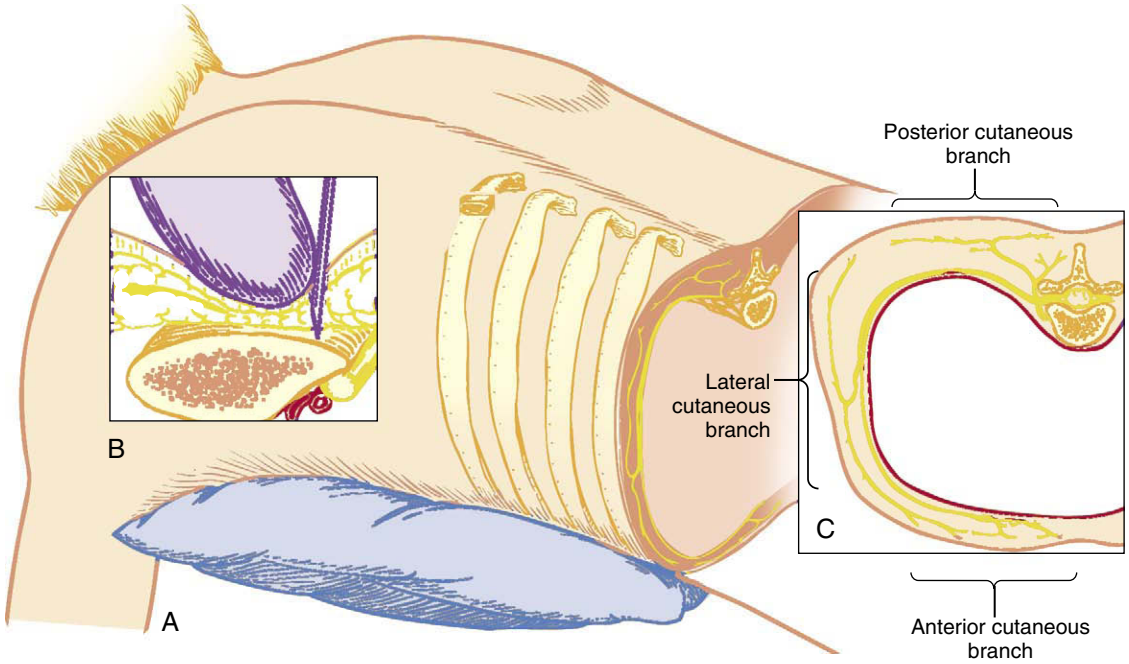

Figure 52-32 **A,** Patient positioning for an intercostal nerve block. **B,** The index finger displaces the skin up over the rib. The needle is inserted at the tip of the finger and rests on the rib. The needle is walked off the lower rib edge and inserted 3 to 5 mm. **C,** An intercostal nerve and its branches.

medial aspect of the upper part of the arm. Each intercostal nerve has four branches: the gray ramus communicans, which passes anterior to the sympathetic ganglion; the posterior cutaneous branch, which supplies the skin and muscle in the paravertebral area; the lateral cutaneous branch, which arises just anterior to the midaxillary line and sends subcutaneous branches anteriorly and posteriorly; and the anterior cutaneous branch, which is the termination of the nerve (Fig. 52-32C).

Medial to the posterior angles of the ribs, the intercostal nerves lie between the pleura and the internal intercostal fascia. At the posterior angle of the rib, the nerve lies in the costal groove accompanied by the intercostal vein and artery.

Clinical Applications

Few surgical procedures can be performed with an intercostal block alone, and application of these blocks in combination with other techniques has largely been supplanted by epidural blockade. However, in patients with contraindications to neuraxial blockade, these techniques can be used alone or combined with celiac plexus blocks and light general anesthesia to provide excellent surgical conditions for intra-abdominal procedures. In similar fashion, intrathoracic surgery can be accomplished with the use of intercostal and stellate ganglion blocks along with endotracheal sedation. Although surgical applications are possible, the majority of indications are for postoperative analgesia.

Interpleural catheter placement for management of postoperative pain was first described by Reiestad and Stromskag in 1986.[81] Enthusiasm for this technique has waxed and waned. Its mechanism of action is poorly understood, and reports of efficacy vary. Overall, the results with cholecystectomy have been most favorable.[82-85] The advantages of interpleural analgesia are more difficult to prove in patients undergoing thoracotomy, perhaps because of technical problems related to blood in the pleural space and chest tube drainage. More recent applications include analgesia after minimally invasive cardiopulmonary bypass surgery.[86]

Technique

Intercostal Block

The intercostal nerve can be readily blocked at the angle of the rib just lateral to the sacrospinalis muscle group. The patient is placed in the prone position with a pillow under the abdomen to reduce the lumbar curve (see Fig. 52-32A). A line is drawn along the posterior vertebral spines. Nearly parallel lines are drawn along the posterior angles of the rib, which can be palpated 6 to 8 cm from the midline. These lines angle medially at the upper levels to prevent overlying of the scapula. The inferior edge of each rib is palpated and marked on a line intersecting the posterior angle of the rib. After appropriate skin preparation, skin wheals are raised at each of these points. A 22-gauge, short-beveled 4-cm needle is attached to a 10-mL syringe. Beginning at the lowest rib, the index finger of the left hand displaces the skin up over the patient's rib. The needle is inserted at the tip of the finger until it rests on the rib. The fingers of the left hand are shifted to grasp the needle hub firmly. The left hand then walks the needle 3 to 5 mm off the lower rib edge, where 3 to 5 mL of local anesthetic is injected (see Fig. 52-32B). This process is repeated at each rib. Appropriate intravenous sedation to provide analgesia and some degree of amnesia is desirable for the patient's comfort.

Alternatively, an intercostal block can be performed in a supine patient at the midaxillary line. Theoretically, the lateral cutaneous branch of the nerve can be missed, but CT studies show that injected solutions spread several centimeters along the

costal groove.[68] Further injection of 1 to 2 mL of solution as the needle is withdrawn blocks the subcutaneous branches.

Interpleural Catheter

The technique for interpleural catheter placement is quite simple and can be performed with the patient in a lateral (and slightly oblique) or sitting position. The sixth or seventh intercostal space is identified. The needle is inserted about 10 cm lateral to the posterior midline, and an epidural needle tip is advanced until it rests on the cephalad edge of the rib below the intercostal space to be entered. A glass syringe filled with saline or air is then attached to the needle, and the unit is advanced slowly over the superior edge of the rib. When the tip of the needle enters the parietal pleura, the solution in the syringe is drawn into the chest cavity because of the negative intrathoracic pressure. This effect can be observed in mechanically and in spontaneously ventilating patients, but it is accentuated in the latter group.

The catheter is then inserted approximately 5 to 8 cm into the interpleural space and secured on the chest wall. During needle positioning and catheter placement, care must be taken to minimize entrainment of air through the needle. Lung parenchymal damage can occur with loss-of-resistance techniques or insertion of excessive lengths of catheter.

Side Effects and Complications

The major complication feared with intercostal blockade is pneumothorax. The actual incidence, however, was as low as 0.07% in a large series performed by anesthesiologists at all levels of training. Routine postoperative chest radiographs showed a 0.42% incidence of nonsymptomatic pneumothorax.[87] If this unusual complication occurs, treatment is usually limited to observation, administration of oxygen, or needle aspiration. Rarely, chest tube drainage is required when these treatments are unsuccessful.

A risk of systemic local anesthetic toxicity is present with multiple intercostal blocks because of the large volumes and rapid absorption of the solutions. Use of epinephrine has been shown to decrease blood levels. Patients should be monitored and observed carefully during the block and for at least 20 to 30 minutes afterward. An interpleural block should not be performed in patients with pleural fibrosis or inflammation, pleural effusion, lung parenchymal disease associated with pleural disease, or bleeding diatheses. Pleural disease can result in poor spread of local anesthetic solutions or rapid uptake in the case of inflammation. Patients with severe pulmonary disease who rely on their intercostal muscles may exhibit respiratory decompensation after bilateral intercostal blockade.[88]

Celiac Plexus Block

Clinical Applications

A celiac plexus block can be combined with an intercostal block to provide anesthesia for intra-abdominal surgery. Because it results in blockade of the autonomic nervous system, this block may help reduce stress and endocrine responses to surgery.

Anatomy and Technique

The celiac plexus contains visceral afferent and efferent fibers derived from T5 to T12 by means of the greater, lesser, and least splanchnic nerves. The plexus has no somatic fibers and is composed of a number of ganglia and nerve fibers. It innervates most of the abdominal viscera. Knowledge of the surrounding structures is important for correct needle placement. The plexus lies in close relation to the L1 vertebra. The vena cava lies anteriorly to the right, and on the left anteriorly is the aorta. The kidneys lie laterally, with the pancreas anterior. The number of ganglia varies from one to five, and each ganglion is 0.5 to 4.5 cm in diameter. Left-sided ganglia are usually lower than those on the right.

Bony surface landmarks can be used reliably for needle placement. With the patient in the prone position and a pillow beneath the abdomen, lines are drawn connecting the spine of T12 with points 7 to 8 cm laterally at the lower edges of the 12th ribs. These lines form a flattened isosceles triangle, the equal sides of which serve as directional guides for the needles (Fig. 52-33B). A 20-gauge, 10- to 15-cm needle is inserted on the left side through a skin wheal at a 45-degree angle toward the body of T12 or L1. Bone contact should be made at an average depth of 7 to 9 cm. The needle is then withdrawn and reinserted to allow the tip to slide off the vertebral body anterolaterally. The needle is advanced 1.5 to 2 cm past this point; aortic pulsations can be felt as they are transmitted along the needle when it is correctly placed (see Fig. 52-33). After this depth is ascertained, the right-sided needle is inserted in similar fashion to a depth of 1.0 to 1.5 cm farther (see Fig. 52-33A). When the needles are in position, observation for leakage of blood, urine, or cerebrospinal fluid is made before careful aspiration. A 3- to 5-mL test dose of local anesthetic is given before injection of 20 to 25 mL of solution through each needle.

Side Effects and Complications

Side effects associated with celiac plexus blockade include hypotension; spinal, epidural, or intravascular injection; pneumothorax; puncture of viscera, such as the kidney, ureter, or gut; and retroperitoneal hematoma.

Paravertebral Block

Clinical Applications

This block may be used to provide anesthesia or analgesia, or both, to patients undergoing thoracic, abdominal, or pelvic procedures, as well as surgery on the breast. Bilateral and continuous applications have been described.[89,90] In patients undergoing thoracotomy, a thoracic paravertebral block provides analgesia comparable to epidural techniques, but with fewer side effects.[91] A paravertebral block may be useful in the diagnosis and treatment of certain chronic pain disorders, including post-thoracotomy and postmastectomy pain.

Technique

Thoracic Paravertebral Block

Thoracic paravertebral blockade occurs at the point where the spinal nerves emerge from the vertebral foramina. This results in somatic and sympathetic blockade of multiple contiguous thoracic dermatomes above and below the injection site.

A thoracic paravertebral block can be performed with the patient in the sitting, lateral, or prone position; the sitting position

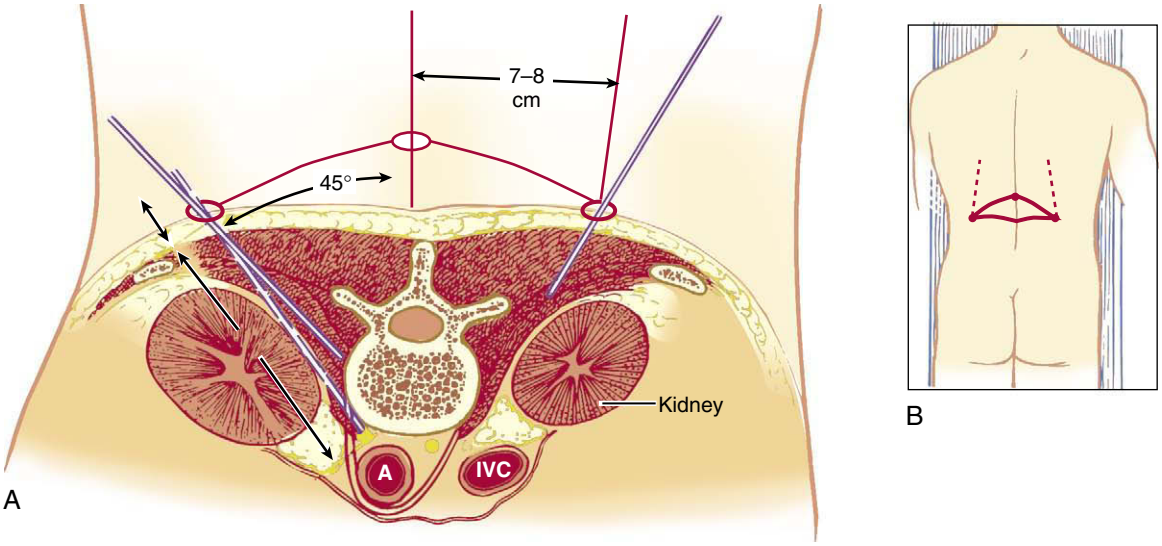

Figure 52-33 **A,** For a celiac plexus block, the needle is inserted at a 45-degree angle toward the body of L1. The tip slides off the vertebral body anterolaterally and is advanced 1.5 to 2 cm. **B,** Patient positioning and surface landmarks for a celiac plexus block. A, aorta; IVC, inferior vena cava.

allows easy identification of landmarks. The thoracic spinous processes are identified, and the needle is inserted 2.5 to 3 cm lateral to the most cephalad aspect of the spinous process and advanced perpendicular to the skin in all planes to contact the transverse process of the vertebra below, typically at a depth of 2 to 4 cm. After the transverse process is identified, traditionally the needle is redirected cephalad and gradually advanced until loss of resistance is felt 1 to 1.5 cm past the superior edge. However, walking the needle caudad may decrease the risk for pneumothorax.[90]

Although spread of local anesthetic is variable, a single injection of 15 mL produces unilateral somatic blockade over four or five dermatomes; there is a tendency for caudad (versus cephalad) spread.[90] To achieve greater spread, 3 to 4 mL of local anesthetic may be injected at each segment.[92]

Lumbar Paravertebral Block

Lumbar nerves exit the vertebral foramina inferior to the caudad edge of the transverse process. Each nerve divides into anterior and posterior branches; the anterior branches of L1 through L4 (with a contribution from T12) form the lumbar plexus.

The patient is placed in the prone position as described for intercostal blockade. Lines are drawn across the cephalad edges of the lumbar vertebral spinous processes. These lines lie opposite the caudad edges of the homologous transverse processes (see Fig. 52-14A). A skin wheal is raised 3 cm lateral to the midline, and a 20-gauge, 8-cm needle is advanced perpendicularly until it contacts the transverse process at a depth of 3 to 5 cm. The needle is then redirected to walk off the caudad edge of the transverse process. At 1 to 2 cm (the thickness of the transverse process) beyond this point, 6 to 10 mL of local anesthetic is injected (see Fig. 52-14B). Elicitation of a paresthesia or the use of a nerve stimulator is helpful in confirming correct needle placement.

Side Effects and Complications

Because of proximity of the neuraxis, epidural or subarachnoid injection of local anesthetic is a risk. Intravascular injection through the lumbar vessels, vena cava, or aorta is possible. Pleural puncture and pneumothorax have occurred at frequencies of 1.1% and 0.5%, respectively.[90]

Continuous Catheter Techniques

Advantages cited for continuous nerve blockade include prolongation of surgical anesthesia, decreased risk for toxicity because of lower incremental doses, and postoperative pain relief and sympathectomy. Catheter placement using over-the-needle and through-the-needle methods have been described. Advances in equipment technology, including the development of stimulating needles and catheters and portable pumps allowing infusion of local anesthetic after hospital dismissal, have increased the success rate and popularity of continuous peripheral blockade (Fig. 52-34).[93,94] Although concern regarding accurate catheter placement and maintenance still exists, the use of stimulating catheters and radiographic confirmation may further improve the functionality of this method.[95] Overall, continuous peripheral nerve blockade provides analgesia superior to that of conventional opioid therapy. Minor technical problems, such as catheter kinking, displacement, or leakage and bacterial colonization, are frequent, with no adverse clinical consequences in the large majority of cases. However, major neurologic and infectious adverse events are rare.[96]

Methods of providing continuous brachial plexus anesthesia have been described since at least the 1940s and frequently offer ingenious solutions for placement and securing of the needle or catheter. This technique is especially applicable to patients undergoing upper extremity or digit replantation or total-shoulder or total-elbow arthroplasty and in patients with reflex sympathetic dystrophies, in whom prolonged pain relief and sympathectomy are advantageous.[97]

Continuous lower extremity techniques were also described decades ago but remained underused in relation to continuous upper extremity and neuraxial approaches until recently. Reliable, improved success rates and the risk of spinal hematoma after

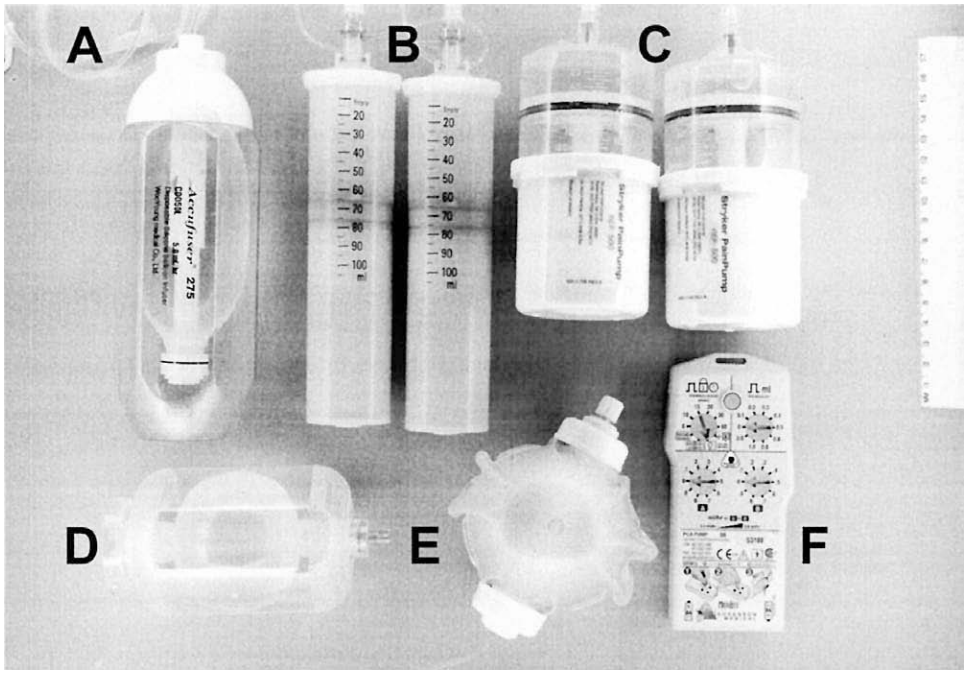

Figure 52-34 Portable infusion pumps. **A,** Accufuser (McKinley Medical, Wheat Ridge, CO). **B,** Sgarlato (Sgarlato Labs, Los Gatos, CA). **C,** Stryker PainPump (Stryker Instruments, Kalamazoo, MI). **D,** MedFlo II (MPS Acacia, Brea, CA). **E,** C-Bloc (I-Flow Corp., Lake Forest, CA). **F,** Microject PCA (Sorenson Medical, West Jordan, UT). *(From Ilfeld BM, Morey TE, Enneking FK: The delivery rate accuracy of portable infusion pumps used for continuous regional analgesia. Anesth Analg 95:1331, 2002.)*

neuraxial techniques led clinicians to again consider continuous lower extremity blocks. Contemporary applications for continuous psoas compartment and sciatic, femoral, and popliteal fossa blockade have been reported.[96] When compared with conventional systemic and neuraxial analgesic methods, continuous lower extremity blocks provide superior analgesia with fewer side effects, improve perioperative outcomes, and accelerate hospital dismissal after major joint replacement.[98,99]

Choice of Local Anesthetic

The choice of local anesthetic for a peripheral nerve block obviously depends to some degree on the duration of the surgical procedure, although other factors are also important (see Chapter 30). Prolonged blockade for up to 24 hours often occurs with long-acting agents such as bupivacaine or ropivacaine. Although such blockade results in superb postoperative pain relief for an inpatient, it may be undesirable for an ambulatory patient because of the possible risk of nerve or tissue injury in a partially blocked limb. A short- or medium-acting agent, such as lidocaine or mepivacaine, may be more appropriate in the outpatient setting. Whatever drug is chosen, the total dosage should be calculated for each patient and be kept within acceptable safe limits (see Chapter 30).

The highest concentrations of local anesthetic drugs are not appropriate for peripheral neural blockade; therefore, 0.75% bupivacaine or ropivacaine, 2% lidocaine, 2% mepivacaine, and 3% 2-chloroprocaine are not recommended. Conversely, the lowest concentrations of the same agents (i.e., 0.25% bupivacaine or ropivacaine and 0.5% mepivacaine or lidocaine) may not provide complete motor blockade.

Vasoconstrictors, usually epinephrine, can be added to the chosen local anesthetic to improve the onset of action, to decrease drug uptake, and to prolong action. A concentration of 1:200,000 epinephrine is usually recommended. Ideally, the epinephrine should be added to the local anesthetic at the time that the block is to be performed. Commercially prepared solutions with epinephrine have a lower pH than those in which it is freshly added, which results in a higher percentage of ionized drug molecules. These ionized molecules do not readily cross the neural membrane, thereby delaying the onset of drug action after injection. Epinephrine should not be added to the local anesthetic for blocks of the digits or penis because tissue ischemia may result. Various other additives, including clonidine, opioids, and ketamine, have been reported to enhance or prolong local anesthetic peripheral nerve blockade.[7]

Neurologic Complications

Nerve injury is a recognized complication of peripheral regional techniques. In a combined series involving more than 250,000 regional anesthetics, the frequency of neurologic complications after peripheral blockade was less than that seen with neuraxial techniques, and peripheral blockade was associated with pain on needle placement or injection of local anesthetic.[65,100] Risk factors contributing to neurologic deficit after regional anesthesia include neural ischemia, traumatic injury to nerves during needle or catheter placement, infection, and inappropriate selection of the local

anesthetic solution. However, postoperative neurologic injury as a result of pressure from improper patient positioning, tightly applied casts or surgical dressings, and surgical trauma is often attributed to the regional anesthetic. Patient factors such as body habitus or preexisting neurologic dysfunction may also contribute.

Although needle gauge, type (i.e., short versus long bevel), and bevel configuration may influence the degree of nerve injury after peripheral nerve blockade, the findings are conflicting and there are no confirmatory human studies. Theoretically, localization of neural structures with a nerve stimulator would allow a high success rate without increasing the risk for neurologic complications, but this has not been established. Serious neurologic injury has been reported after uneventful brachial plexus blockade with use of a nerve stimulator technique.[23] Likewise, prolonged exposure or high concentrations of local anesthetic solutions may also result in permanent neurologic deficits. In laboratory models, the addition of epinephrine increases the neurotoxicity of local anesthetic solutions and decreases nerve blood flow. However, the clinical relevance of these findings in humans remains unclear. Nerve damage caused by traumatic needle placement, local anesthetic neurotoxicity, and neural ischemia during performance of a regional block may worsen the neurologic outcome in the presence of an additional patient factor or surgical injury.[7,47]

Prevention of neurologic complications begins during the preoperative visit with a careful evaluation of the patient's medical history and appropriate preoperative discussion of the risks and benefits of the available anesthetic techniques. It is imperative that all preoperative neurologic deficits are documented to allow early diagnosis of new or worsening neurologic dysfunction postoperatively. Postoperative sensory or motor deficits must also be distinguished from residual (prolonged) local anesthetic effect. Imaging techniques such as CT and MRI are useful in identifying infectious processes and expanding hematomas. Although most neurologic complications resolve completely within several days or weeks, significant neural injuries necessitate neurologic consultation to document the degree of involvement and coordinate further workup. Neurophysiologic testing, such as nerve conduction studies, evoked potentials, and electromyography, are often useful in establishing a diagnosis and prognosis.

Summary

It is possible to perform all surgical procedures while the patient is under general anesthesia, but the addition of peripheral nerve block techniques to the anesthesiologist's armamentarium adds flexibility and skills that benefit the patient intraoperatively and postoperatively. Successfully mastering these techniques and applying them to the appropriate clinical situations add valuable options to anesthetic care. For the anesthesiologist, knowledge of regional anesthesia is essential for the diagnosis and treatment of acute and chronic pain syndromes (see Chapters 58 and 87).

53 Ultrasound Guidance for Regional Anesthesia

Key Points

1. Ultrasound imaging elucidates the structure of peripheral nerves and adjacent anatomy for regional block.
2. Ultrasound also provides real-time imaging for needle tip placement and drug injection.
3. Peripheral nerves have a characteristic "honeycomb" echotexture formed by their connective tissue and nerve fibers. Sliding the ultrasound transducer along the known course of a nerve with it viewed in short axis is often the best way of visualizing fascicles to confirm nerve identity. With training, operators will learn to naturally tilt the transducer to enhance the received echoes from a nerve.
4. Successful local anesthetic injections clarify the border of the nerve and track along the nerve path and its branches. Anatomic variation in nerve location, which is a potential source of block failure, can be directly visualized.
5. Ultrasound imaging can prevent and detect critical events such as intravascular or intraneural injection, which may improve safety during regional anesthesia procedures.
6. The use of ultrasound imaging has become a common adjunct for regional block anesthetics techniques.

Ultrasound allows direct visualization of peripheral nerves, the block needle, and local anesthetic distribution.[1] This imaging modality has proven highly useful to guide targeted drug injections and catheter placement. The last several years have witnessed a tremendous increase in the use of ultrasound guidance for regional anesthesia. General principles of ultrasound imaging for regional block are presented in this chapter with specific examples of block procedures.

Principles of Ultrasound Imaging

Ultrasound is sound with frequency above the audible range (>20,000 cycles/sec). Frequencies used in clinical imaging are in the 1- to 20-MHz range. Ultrasound waves have velocity of 1540 msec in soft tissue (13 µsec/cm tissue back and forth for the total fly-back time of received echoes).

The velocity of sound is determined by the bulk modulus and density of the medium (Table 53-1). Therefore, the speed of sound in a given medium is essentially independent of frequency. The product of the frequency and wavelength of sound waves is the wave velocity (velocity = frequency × wavelength). For example, the wavelength of a 10-MHz sound wave in soft tissue is 0.154 mm. The attenuation of ultrasound in soft tissue is approximately 0.75 dB/(cm-MHz). This attenuation is primarily from absorption. Other tissues absorb sound waves less (e.g., fluids) or more (e.g., bone) than soft tissue. A reflective wave is generated at the interface of two media with different acoustic impedances. The acoustic impedance is the product of the density and velocity. The reflection coefficient $R = (Z1 - Z2)/(Z1 + Z2)$, where Z1 and Z2 are the acoustic impedances of the two media. If $Z1 = Z2$ there is no reflected wave.

The first imaging modality used with ultrasound was A-mode echo (Amplitude, displayed with an oscilloscope). Today, most imaging is performed with B-mode echo (Brightness). This modality uses postprocessing maps to assign gray-scale values to pixels from the received echo amplitudes. Frame rates for 2D imaging are approximately 30/sec. Ambient lighting has a large effect on visual discrimination, so dim lighting without glare is especially useful for imaging low-contrast targets such as nerves. Another useful imaging modality is M-mode echo (Motion). The sampling rates for M-mode are very high (around 1800/sec, with high resolution in time but only one spatial dimension).

There are no independently confirmed adverse biologic effects of diagnostic ultrasound. Although absorption of sound waves can contribute to heating, this effect is small in comparison to changes in body temperature in daily living (e.g., diurnal variation, exercise, sunbathing, fever). Bone has a high absorption coefficient; therefore, the largest thermal effects are seen at the bone–soft tissue interfaces. The propensity of ultrasound to cause heating is estimated by the thermal index. The bone thermal index (TIB) and soft tissue thermal index (TIS) track maximum temperature increases in those respective tissues. Cavitation is

Table 53-1 Acoustic Properties of Tissues and Materials

Substance	Attenuation (dB/[cm-MHz])	Impedance (Mrayls)	Speed of Sound (msec)	References

when dissolved gases become microbubbles. This can result in extravasation of blood cells in the lung. The mechanical index is probably the best index to indicate likelihood of this effect. Pulse-echo ultrasound does not produce cavitation because the pulses are very short (only sufficiently intense continuous-wave ultrasound will produce cavitation).

Limits of Ultrasound Resolution

Ultrasound imaging is limited in resolution because the acoustic pulse duration and beam width are finite.[2] Axial resolution along the beam depends on the spatial pulse length (SPL). The axial resolution is at best SPL/2, where SPL = nλ, with n the number of cycles per pulse and λ the wavelength. Axial resolution is essentially independent of depth. Lateral resolution depends on depth because the beam width changes with depth. The beam width also depends on the insonation frequency and focus. The effective beam cross section increases with transmission output or receiver gain. An increase in receiver gain causes the line widths to increase because the receiver now detects echoes at more lateral positions from the central ray.[3] The out-of-plane beam width (slice thickness or elevational resolution) can be estimated using a diagonally placed diffuse scattering plane.[4] These slice thickness estimates are not receiver gain dependent within a well-adjusted range because scattering plane echoes are substantially higher than background sound.

In clinical imaging the lateral and elevational resolution will be governed by local image contrast. In general, lateral and elevational resolution are worse than axial resolution.

Spatial Compound Imaging

Spatial compound imaging combines multiple lines of insonation within a planar scan to produce a single image (Fig. 53-1). The ultrasound beam in each frame of the scan sequence is steered by a different, predetermined angle (typically within 20 degrees from the perpendicular). This sonography reduces speckle (the granular appearance from scattering). Because the displayed image is acquired from multiple angles of insonation, anisotropic effects in musculoskeletal imaging will be reduced (see later).[5] Spatial compounding reduces acoustic shadows following a strong reflector (e.g., bone).[6] Another advantage for regional block is that definition of tissue planes and detection of nerve borders are improved.

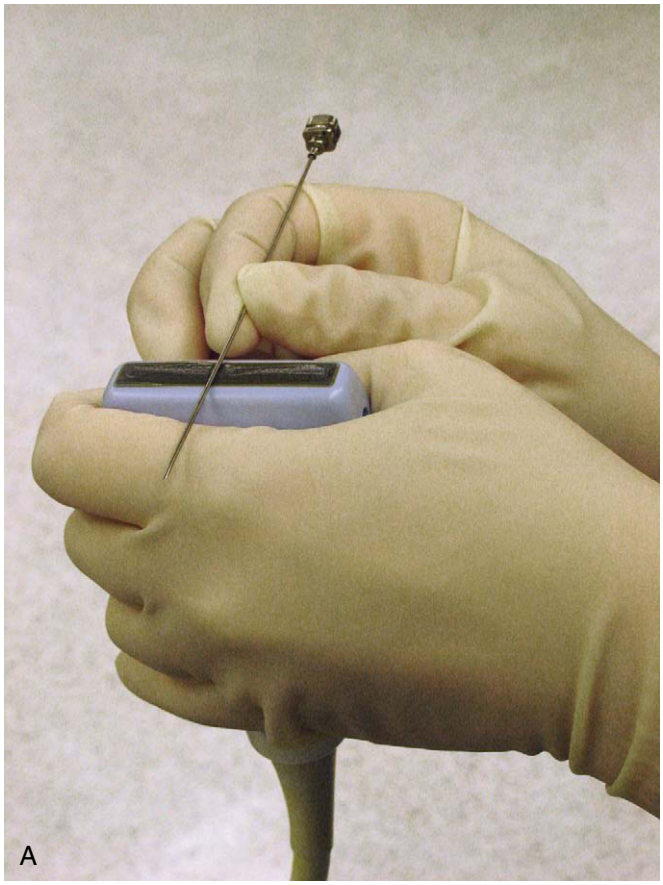
In the systems that have been tested, compound imaging improves needle tip visibility over a limited range of needle angles (<30 degrees).[7] Algorithms for beam steering are being developed to specifically enhance needle tip visibility.[8] Compounding imaging can result in lower frame rates and image blurring, which can be a disadvantage for some applications where temporal resolution related to tissue or transducer motion is important.

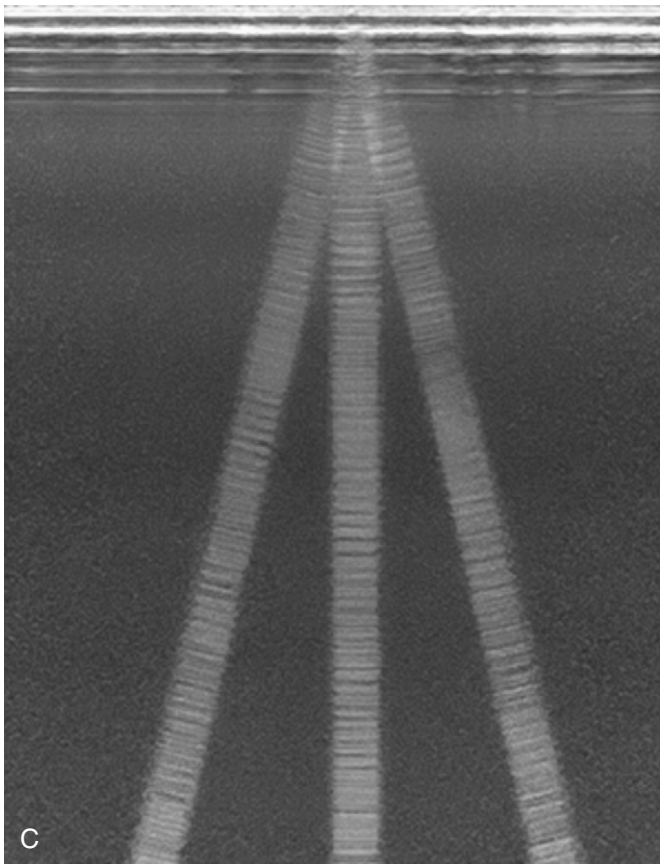
The linear array test tool is a metal rod (e.g., the solid metal stylet of a 17-gauge needle) that functions as a low-attenuating, reverberating structure in the path of the ultrasound beam.[9] A thin layer of gel is used so that only a single element acoustically couples to the rod (see Fig. 53-1). The size of contact between rod, transducer, and gel determines the extent of acoustic coupling. Actual test tool images will contain a broad line (or several lines with spatial compounding) whose width equals the transmit/receive aperture (typically several elements of a multi-element array). High overall receiver gain is necessary to obtain adequate images. Linear array test tools can be used to estimate the angles subtended by the ultrasound beam. Nonfunctioning elements of a linear or curvilinear array also can be detected. If the scanning surface is damaged, do not use it because of the potential for high-voltage injury.

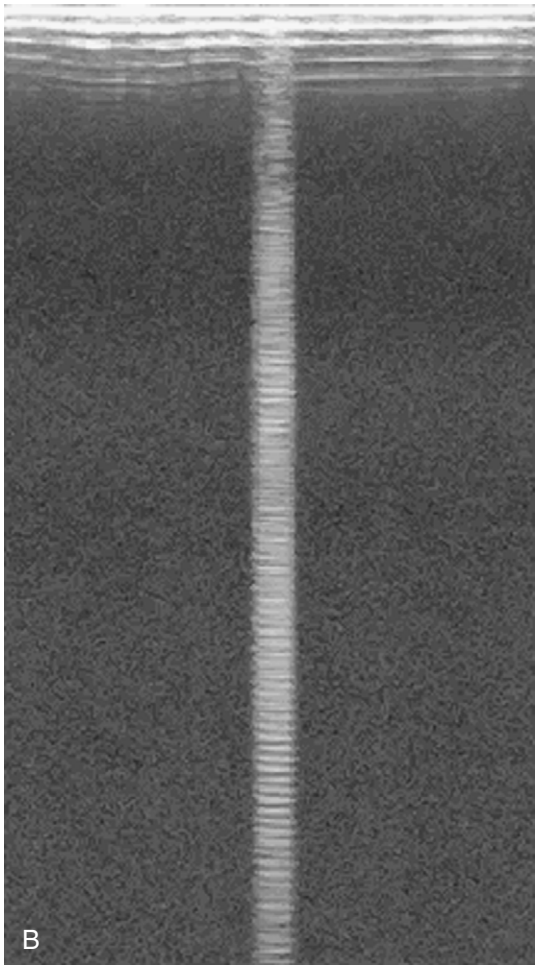
The Doppler Shift

The Doppler shift occurs when a wave source and receiver are moving relative to each other. This produces a change in frequency such that the frequencies of the transmitted and reflected sound waves are not the same. When a wave source and receiver are moving toward each other, the observed frequency is greater than the source frequency (and when moving away, the observed frequency is lower). The change in frequency is related to the velocity of moving reflectors and the angle of insonation. Red blood cells are the primary reflectors that produce Doppler shifts in clinical medicine.

There are different modes of Doppler ultrasound. Traditional color Doppler encodes pseudocolor based on mean-frequency shifts to provide directional velocity information (blue color indicates flow away from the transducer, whereas red color indicates flow toward the transducer by convention). More recently, a more sensitive Doppler technology has been developed that encodes color based on integration of the Doppler power spectrum.[10] Power Doppler is less angle dependent and not subject to aliasing. The disadvantages are that no directional information is provided and there is high motion sensitivity (flash artifact). Both Doppler modes are useful for detecting blood vessels. Small longitudinal vessels within the epineurium (lines) or microvasculature within nerves (spots) can occasionally be detected with color Doppler in normal subjects.[11]







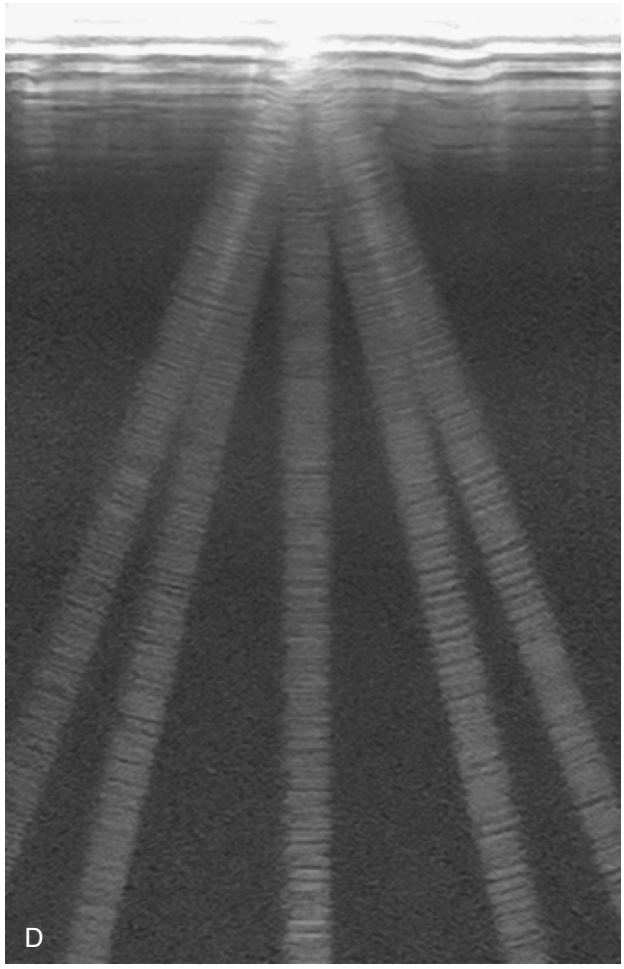


Figure 53-1 Spatial compound imaging. Some forms of ultrasound imaging utilize multiple lines of sight by electronically steering the beam to different angles. These sonograms were obtained by placing a linear array test tool (the solid metal stylet of a 17-gauge epidural needle) over the active face of the transducer to isolate a single element. **A,** External photograph of the linear array test tool applied to the active face of the ultrasound transducer. **B,** Single beam imaging. **C,** Three lines of sight are used to form a compound image (narrow range of angles). **D,** Five lines of sight are used to form a compound image (broad range of angles). Note that the test tool images do not display the beam itself but rather the transmit/receive apertures.

Ultrasound Transducers and Manipulation

Ultrasound transducers consist of piezoelectric crystals that emit and receive high-frequency sound waves by interconverting electrical and mechanical energy. Linear-array transducers have a high scan line density and therefore produce the best image quality. These transducers, in particular the high-frequency broad band linear probes, have proven the most useful for nerve imaging. Images from linear arrays are displayed in rectangular format. When a linear transducer is needed but the space at the block site is small, a compact linear ("hockey stick") transducer can be very useful. Peripheral nerves can be viewed in short axis or long axis (Fig. 53-2).

Curvilinear arrays produce images in sector format. These transducers are useful when the working room at the anatomic

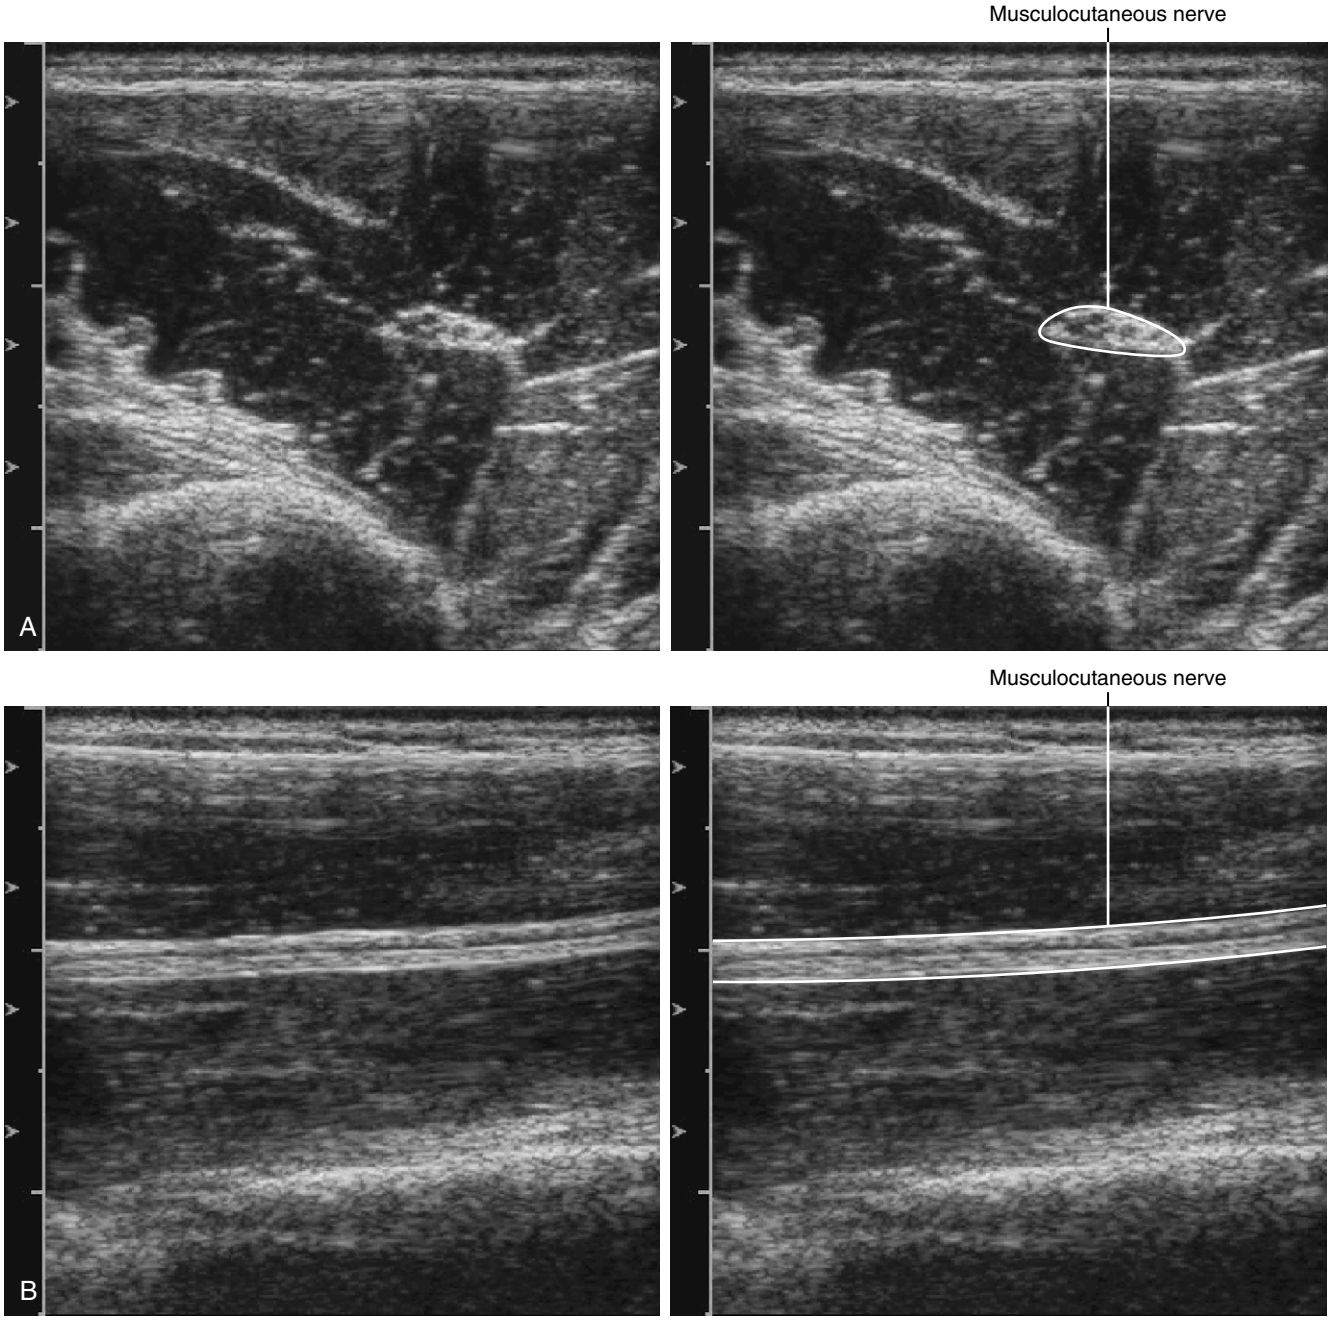

Figure 53-2 Imaging planes for regional block. Short-axis (**A**) and long-axis (**B**) views of the musculocutaneous nerve in the axilla. Short-axis views of peripheral nerves have dominated regional anesthesia practice. By musculoskeletal convention for long-axis views (**B**), proximal is shown on the left side of the image and distal on the right side.

site for the block is limited (e.g., the infraclavicular region). Curved probes are easier to rock (see later) and provide a broader view.

One of the essential skills to acquire for regional block with ultrasound is transducer manipulation. Standardized nomenclature has been established[12]:

- Sliding (moving contact). Sliding the transducer along the known course of the nerve using a short-axis view often helps with nerve identification.
- Tilting (cross-plane, side-to-side). The echobrightness of peripheral nerves will vary with the degree of tilt. Optimizing this angle is critical to promote nerve visibility.
- Compression. Compression is often used to confirm venous structures. To improve imaging, compression not only provides better contact but also brings the structures closer to the surface of the transducer. Soft tissue is subject to compression and therefore estimates of tissue distances will vary.
- Rocking (in-plane, toward/away from indicator). Rocking is often necessary to improve needle and anatomic structure visibility when the working room is limited.
- Rotation. Some rotation of the probe will produce true short-axis views rather than oblique or long-axis views.

Anisotropy is the change in echogenicity with inclination of the transducer. In general, when objects are imaged obliquely, they appear less echogenic (Figs. 53-3 and 53-4). This relationship is most pronounced for tendons but also occurs for muscle and nerves.[13,14] Although the term *anisotropy* was first used to describe changes in received echoes when rocking the transducer with structures viewed in long axis, it has also been used for short-axis views when tilting the transducer. With experience, operators will learn to naturally rock and tilt the transducer to fill in the received echoes.

Universal precautions should be used when handling dirty equipment. External surface probes require low-level disinfection between every use and after extended periods of nonuse. DO NOT soak or spray the probes with isopropyl alcohol (this will lead to lens delamination). DO NOT drop any ultrasound transducer (the active face of the transducer is especially sensitive to contact with hard surfaces).

Nerve Imaging with Ultrasound

Fascicles of peripheral nerves can be detected with high-resolution ultrasound imaging.[15] This fascicular echotexture is

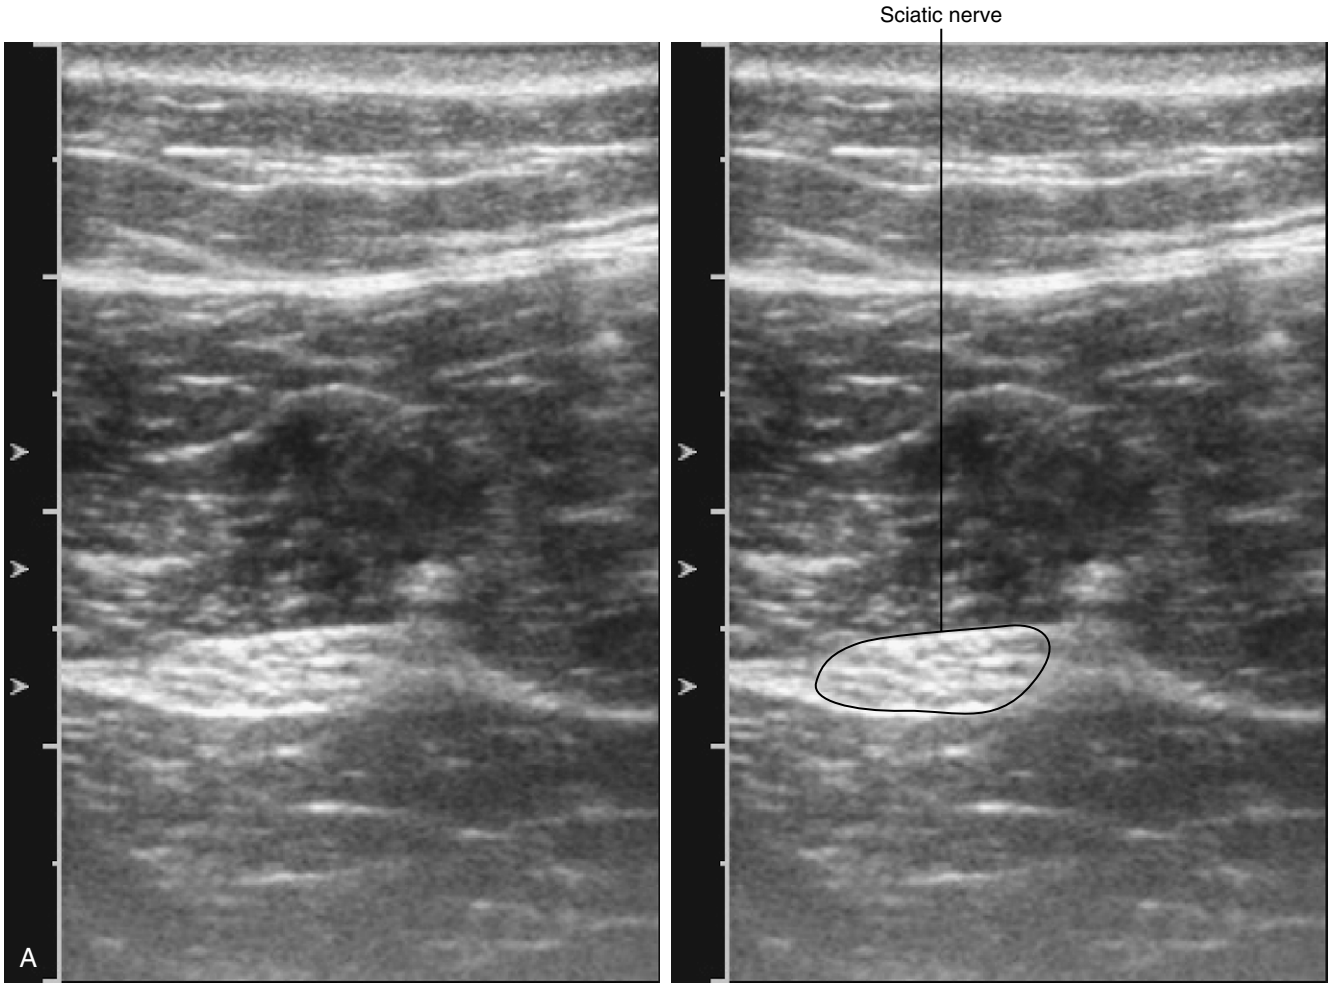

Figure 53-3 A, Sciatic nerve imaging in the subgluteal region.

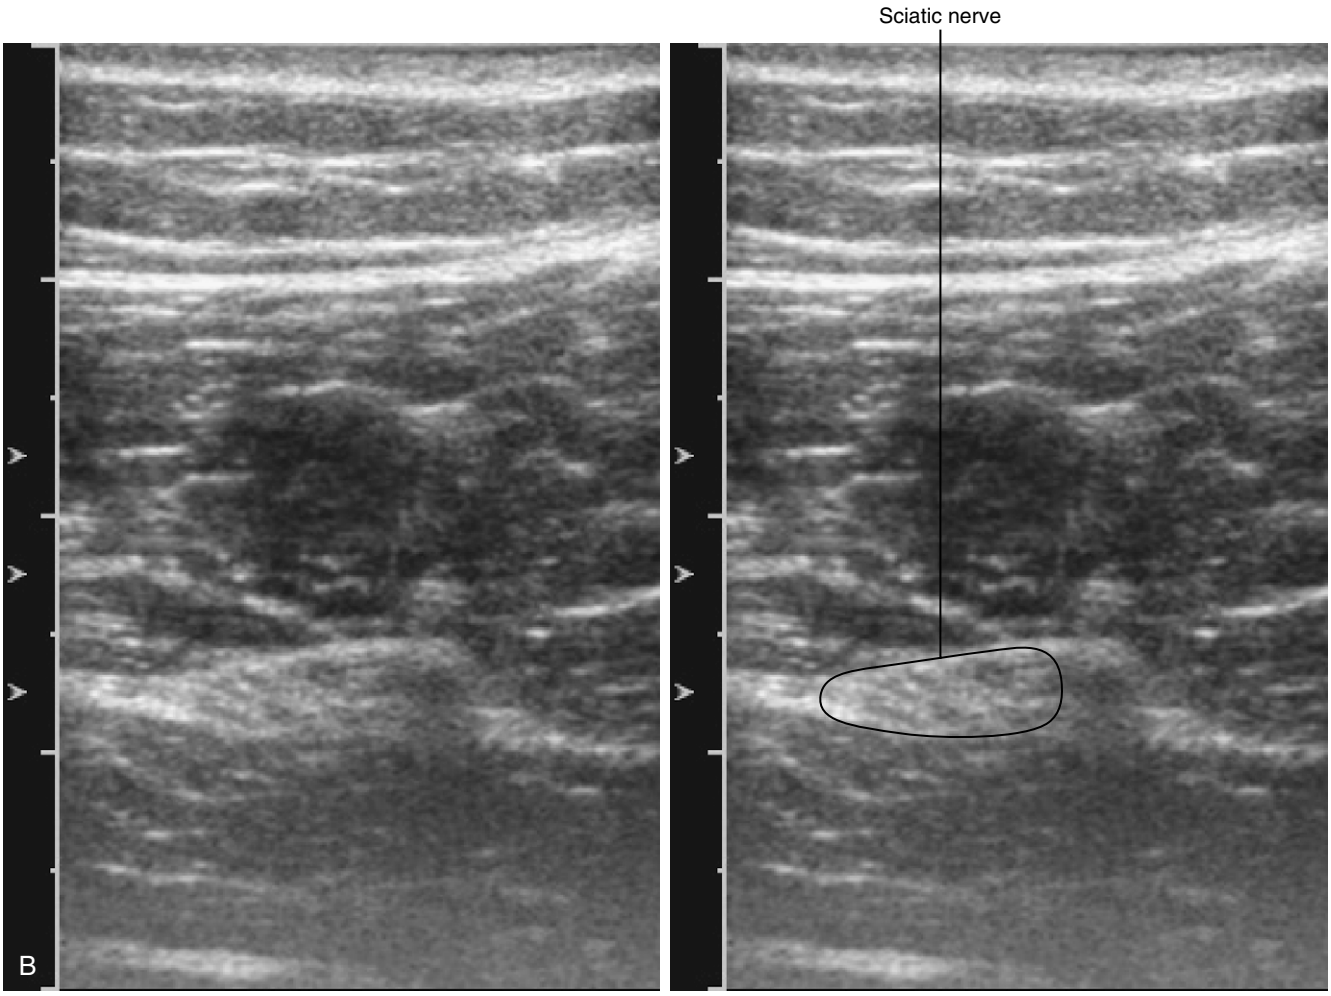

Figure 53-3, cont'd B, The amplitude of the received echoes diminishes when the angle of insonation is changed away from perpendicular to the nerve path, thereby demonstrating anisotropy.

the most distinguishing feature of nerves ("honeycomb" architecture) (Fig. 53-5). More central nerves, such as the cervical ventral rami, have fewer fascicles and therefore can appear monofascicular on ultrasound scans.[16,17] Ultrasound frequencies of 10 MHz or higher are required to distinguish tendons from nerves based on echotexture alone. One of the most powerful techniques to identify nerve fascicles is to slide a broad linear transducer over the known course of a peripheral nerve with the nerve viewed in short axis (transverse cross section).

Nerves can be round, oval, or triangular. Although nerve shape can change along the nerve path, the cross-sectional nerve area is constant in the absence of major branching (Fig. 53-6).[18] Peripheral nerves are pathologically enlarged by entrapment or in certain neuromuscular disorders such as Charcot-Marie-Tooth disease type IA (Fig. 53-7).[19] There is some evidence to suggest that patients with diabetic neuropathy also have enlarged peripheral nerves.[20]

Although direct nerve imaging has led to a phenomenal increase in ultrasound-guided regional anesthesia, the identification of other nearby structures (e.g., fascia and other connective tissues) also is critical in this endeavor. These structures permit favorable distribution of local anesthetic so that nerve contact with the block needle is not necessary. Successful drug injections should clarify the borders of the nerve (Fig. 53-8).

Block Needles for Ultrasound-Guided Procedures

Metal needles are hyperechoic and can cause reverberation artifact (see later). Needle tip visibility is best when the needle path is parallel to the active face of the transducer. Under this condition, the needle is perpendicular to the sound beam so strong specular reflections will be produced (mirror-like reflections from a smooth surface). As the angle of incidence is increased, the mean brightness will decrease.[21] In that same study, the bevel angles were ground from 10 to 70 degrees but were found to have no effect on the needle tip echo. However, bevel orientation does influence the needle tip echo, with best visibility with the bevel either directly facing or averting the transducer.[22] Because needle

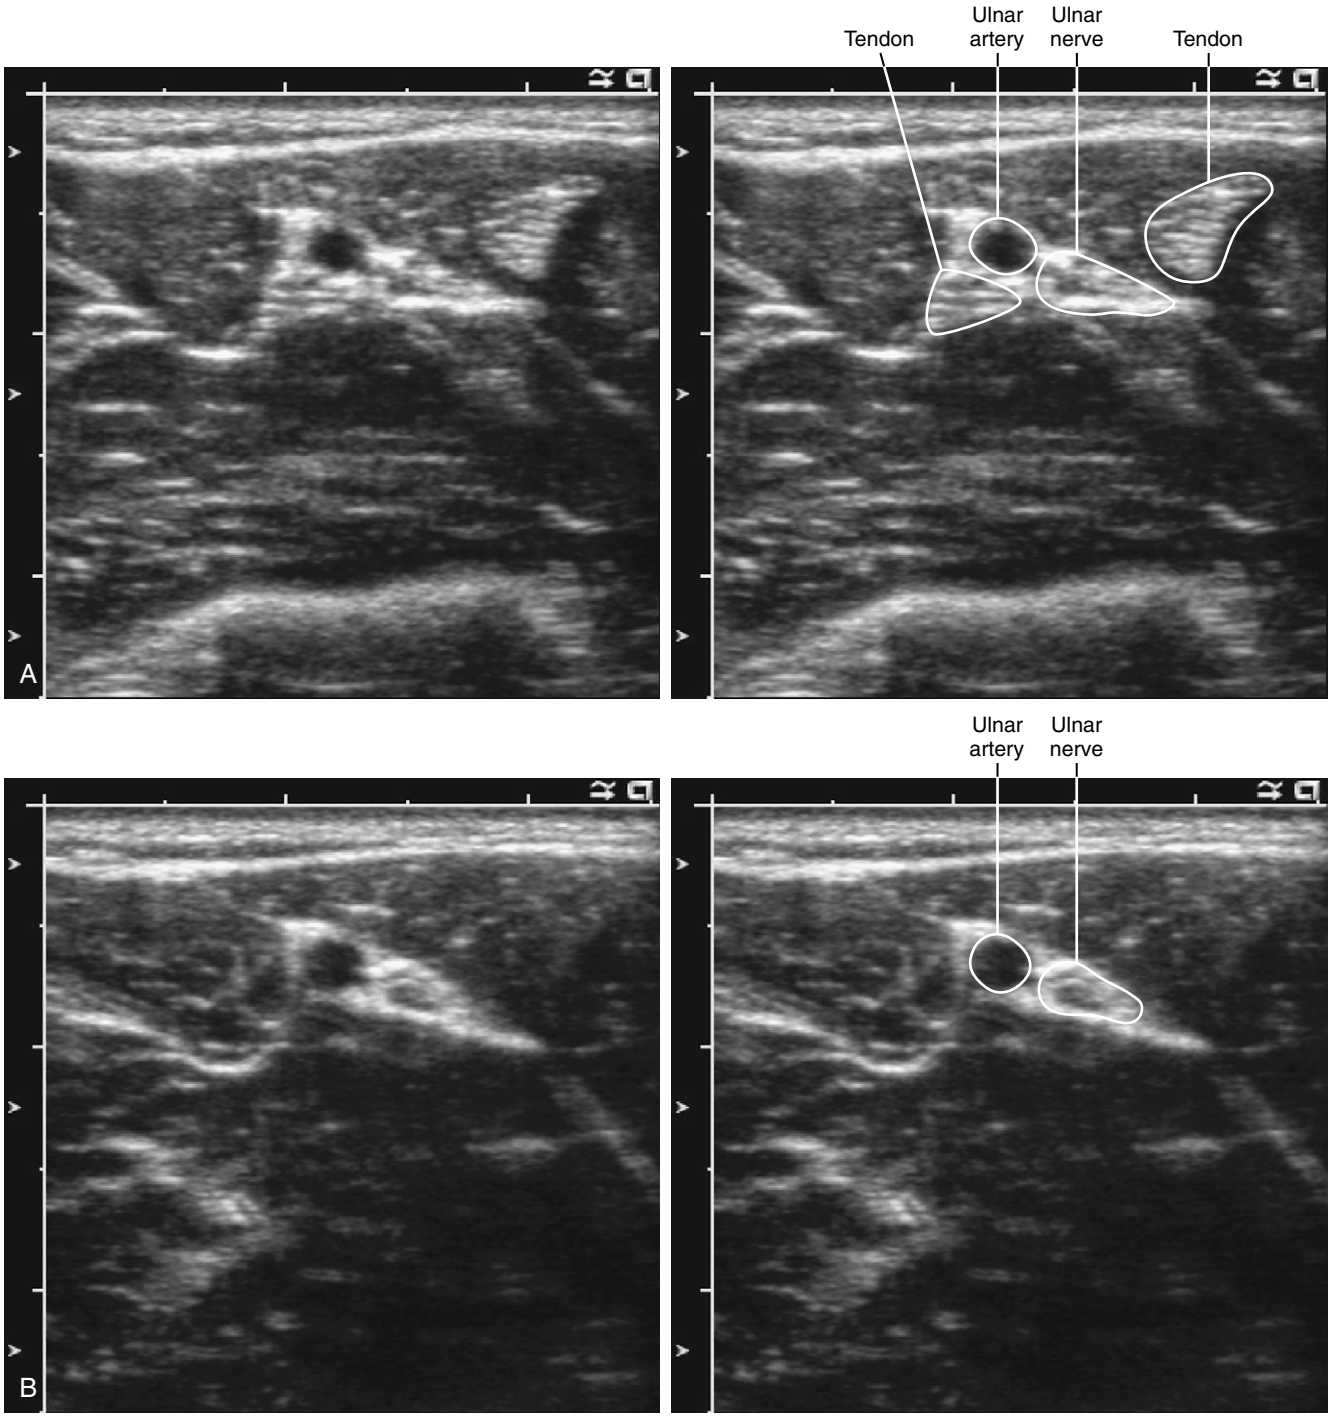

Figure 53-4 Ulnar nerve anisotropy in the forearm. **A** and **B,** These two sonograms were obtained by tilting the transducer just a few degrees with the ulnar nerve viewed in short axis. The received echoes from the adjacent tendons changes much more markedly than the ulnar nerve itself. Tendons are almost always more anisotropic than peripheral nerves.

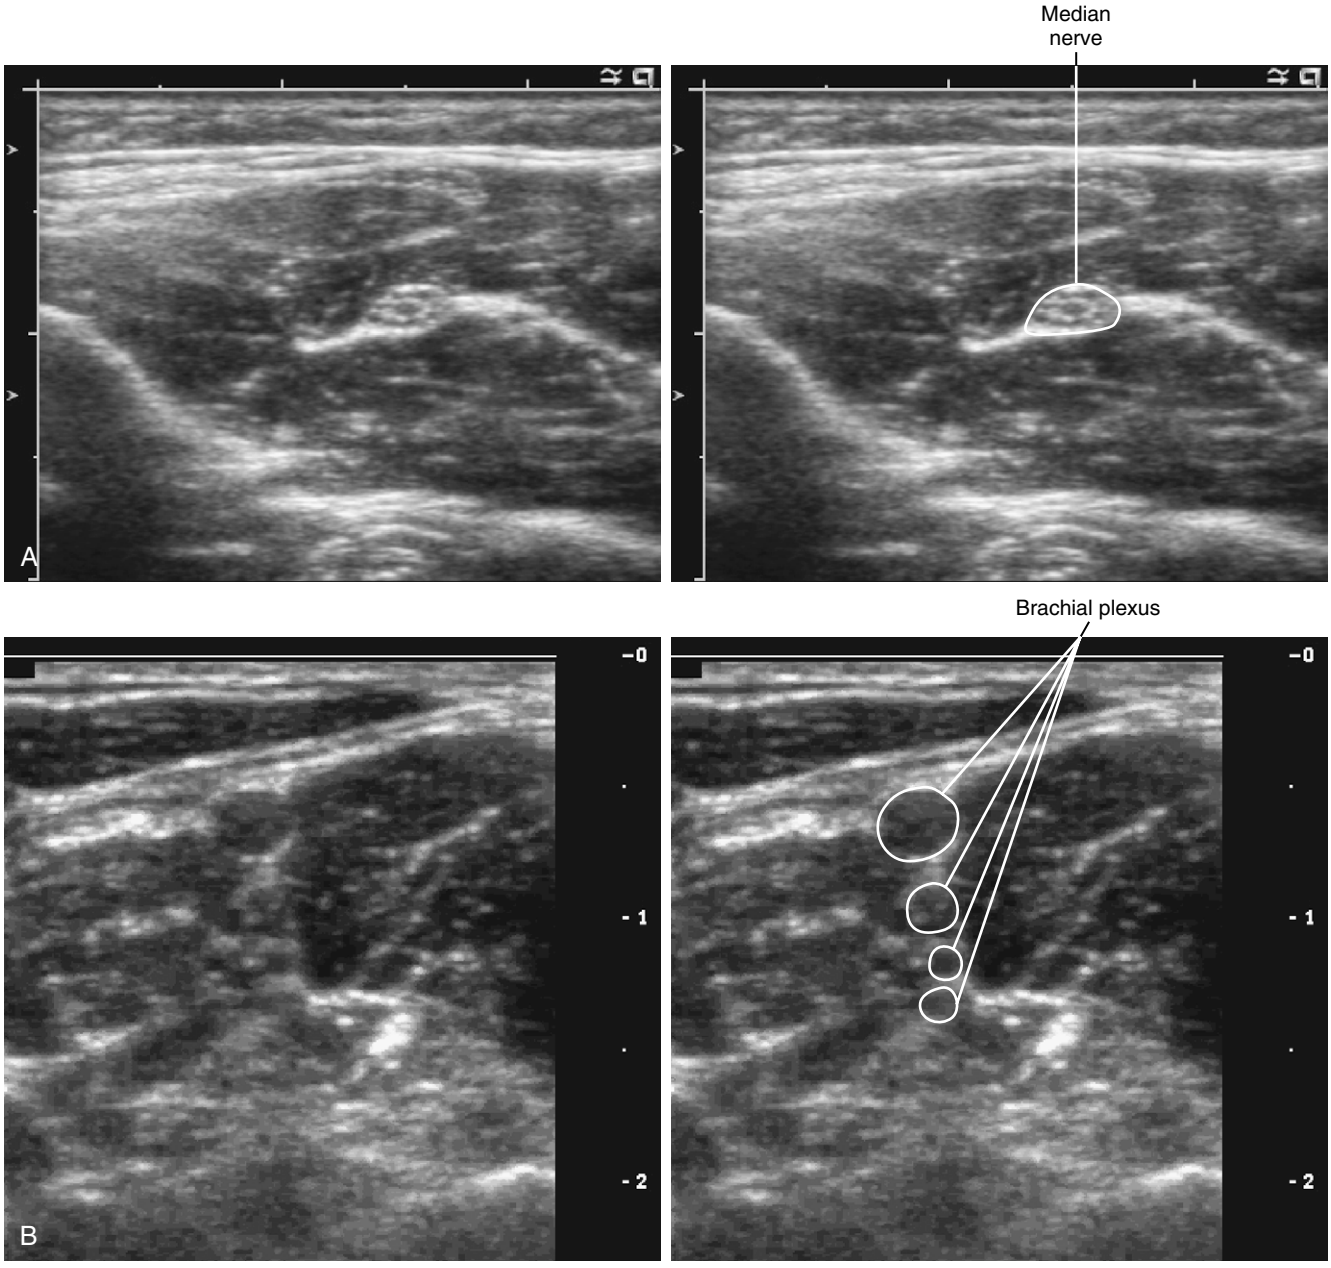

Figure 53-5 Nerve echotexture. **A,** Fascicles of the median nerve in the forearm. In this sonogram the "honeycomb" appearance of a polyfascicular peripheral nerve is observed. **B,** Monofascicular echotexture of the brachial plexus in the neck. This sonogram was obtained by scanning the interscalene region with the brachial plexus viewed in short axis. A large superficial nerve is identified, which probably is the superior trunk. In contrast to more peripheral nerves, cervical ventral rami and trunks often have monofascicular echotexture, consistent with the low number of fascicles observed in anatomic specimens from this region.

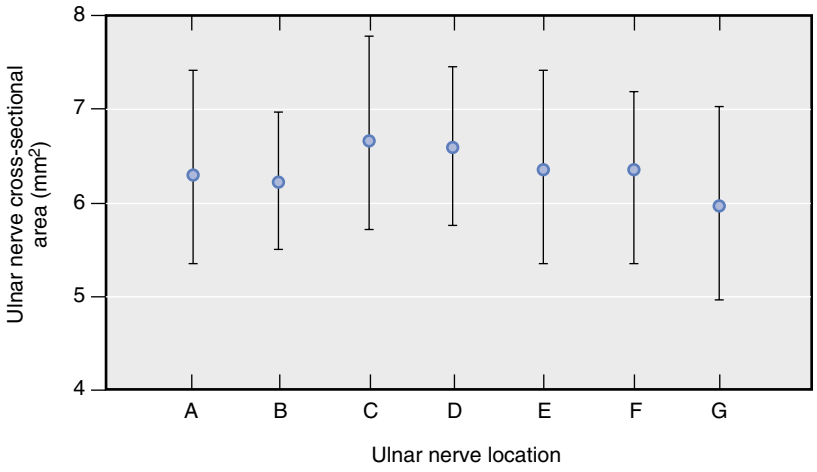

Figure 53-6 Cross-sectional area of a peripheral nerve as a function of nerve path length. In this figure the cross-sectional area of the ulnar nerve is shown at various points in the upper extremity. A = axilla, B = midhumerus, C = 2 cm proximal to medial epicondyle, D = medial epicondyle, E = 2 cm distal to medial epicondyle, F = arterial split, and G = wrist crease. Data are shown as mean values with standard deviations. Despite changes in shape that can occur, the cross-sectional area of nerves is relatively constant along the nerve path in the absence of major branching. (*Data from Cartwright MS, Shin HW, Passmore LV, Walker FO: Ultrasonographic findings of the normal ulnar nerve in adults. Arch Phys Med Rehabil 88:394-396, 2007.*)

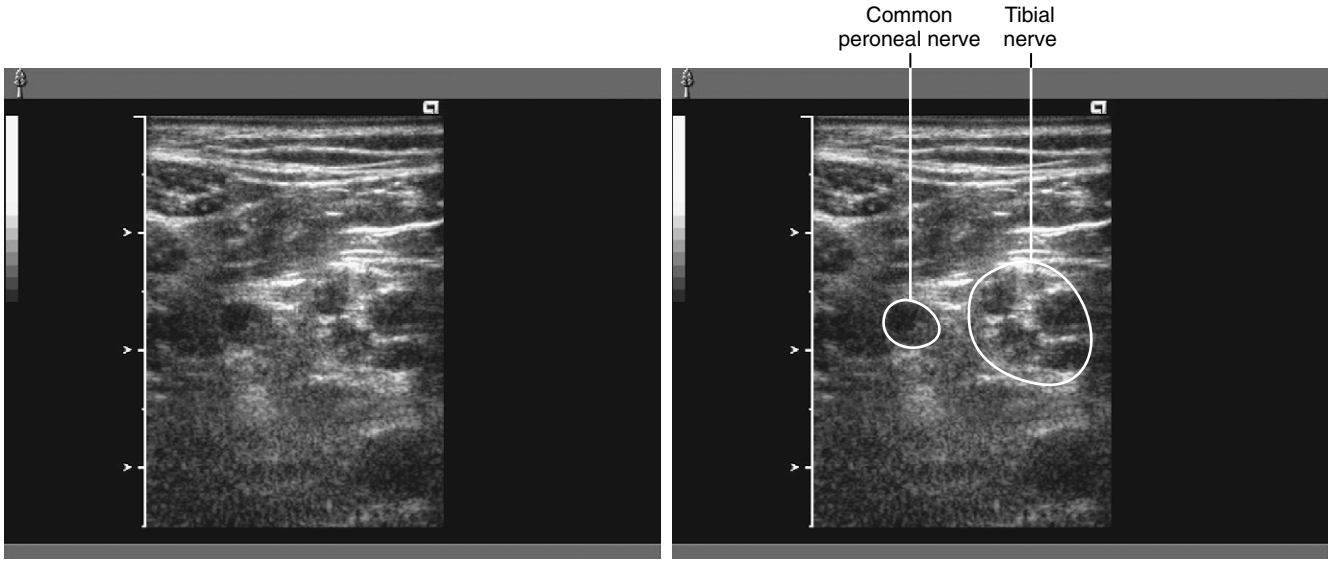

Figure 53-7 Sonogram of the popliteal fossa of a patient with Charcot-Marie-Tooth disease type 1A. The peripheral nerves are markedly enlarged because of the large fascicles. Nerves of the symptomatic and asymptomatic sides can appear similar in these patients. Large tick marks are 10 mm apart.

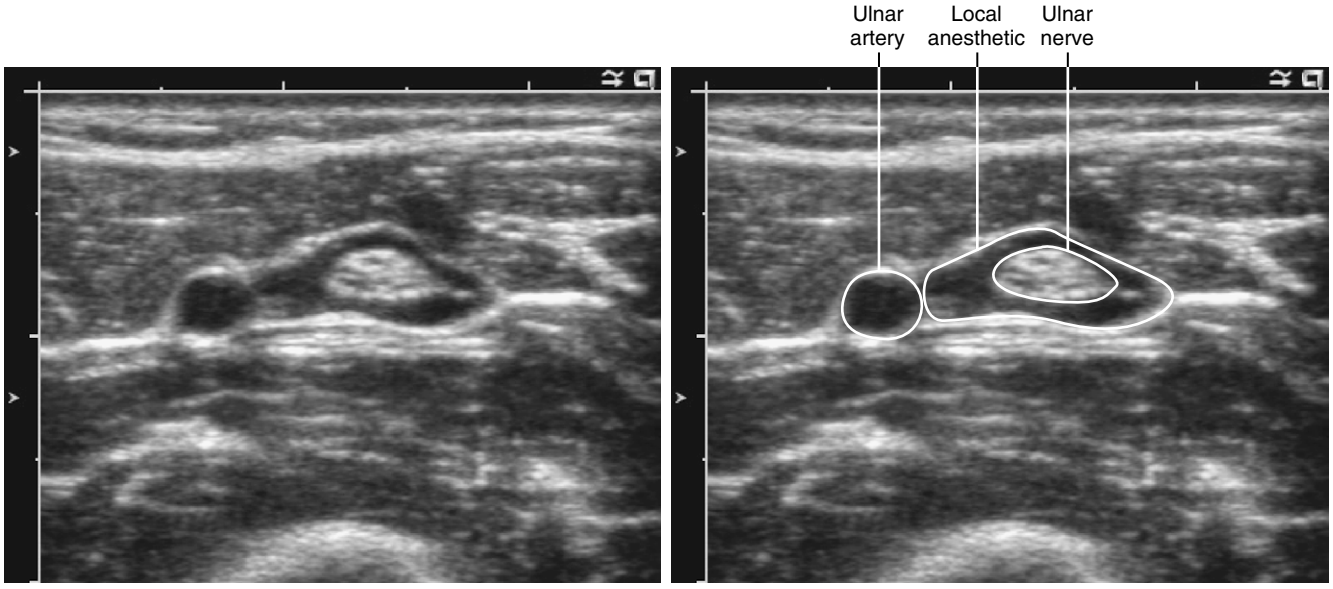

Figure 53-8 Local anesthetic injection for successful peripheral nerve block. In this sonogram, the ulnar nerve and ulnar artery are viewed in short axis in the forearm. The nerve is surrounded with anechoic local anesthetic.

diameters are smaller than the scan plane thickness, larger needles are more echogenic than finer ones.

Visualization of needles within echogenic tissue is difficult, particularly adipose tissue. A number of strategies have been proposed to improve needle tip visibility. A low receiver gain can improve detection of the needle tip echo. Spatial compound imaging can help identify the needle tip when the needle path is at an angle with respect to the transducer. Needles with echogenic modifications are now commercially marketed. Among needles developed for use in regional anesthesia, the Hustead needle has a bevel that tends to be more visible in contrast to side port needles, which lack cutting bevels.[23]

Ultrasound Artifacts in Regional Anesthesia

There are several common assumptions in ultrasound imaging.[24] First, the velocity of sound is assumed to be 1540 msec. This estimate was derived from measurements on soft tissue at body temperature. When local heterogeneities exist, artifactual bending of the block needle can be observed with sonography, the so-called bayonet artifact (Fig. 53-9).[25,26] Speed of sound artifacts relate to time-of-flight considerations and to refraction at the interface of tissues with different speeds of sound.

Second, sound waves are assumed to take a straight path to and from tissue. When this does not occur, reverberation artifacts occur from the multipath echoes. The comet tail artifact is a type of reverberation artifact. At low receiver gain, the comet tail is seen as a tapering series of discrete echo bands just deep to a strongly reflecting structure. The spacing between the bands represents the distance between the anterior and posterior walls of the object.[27] Internal reverberations (arising from within the object) cause the comet tail artifact, which is most intensely observed when the object is perpendicular to the beam. The pleura is a strong reflector that causes comet tail artifact. Reverberation echoes are seen when the block needle is near parallel to the active face of the transducer when strong specular reflections are received.

During supraclavicular block, mirror-image artifacts can be observed from reverberation. Where the pleura is adjacent to the subclavian artery, mirror-image artifacts can occur with gray-scale sonographic imaging and both spectral and color Doppler flow imaging.[28] The lung apex, which is located immediately posterior to the subclavian artery, acts as the highly reflective acoustic interface to form this artifact.

Third, all reflectors are assumed to be on the central ray of the transducer beam. When this is not true, out-of-plane artifacts are observed (slice thickness artifacts). Definitive proof of out-of-plane artifacts requires multiple views, which are recommended when ambiguities arise.

Unlike adjacent tissue, biologic fluids do not significantly attenuate the sound beam and therefore cause acoustic enhancement.[29] Acoustic enhancement artifacts deep to vessels can be erroneously interpreted as nerves. For example, acoustic enhancement deep to the axillary artery in the axilla can be mistaken for the radial nerve. In the infraclavicular region, acoustic enhancement deep to the axillary artery can be mistaken for the posterior cord of the brachial plexus.[30]

Anatomic Variation

Anatomic variation can be a source of frustration when nerve stimulation or surface landmarks are used for regional block. Even experienced clinicians cannot anticipate anatomic variation when these techniques are used. Ultrasound imaging not only

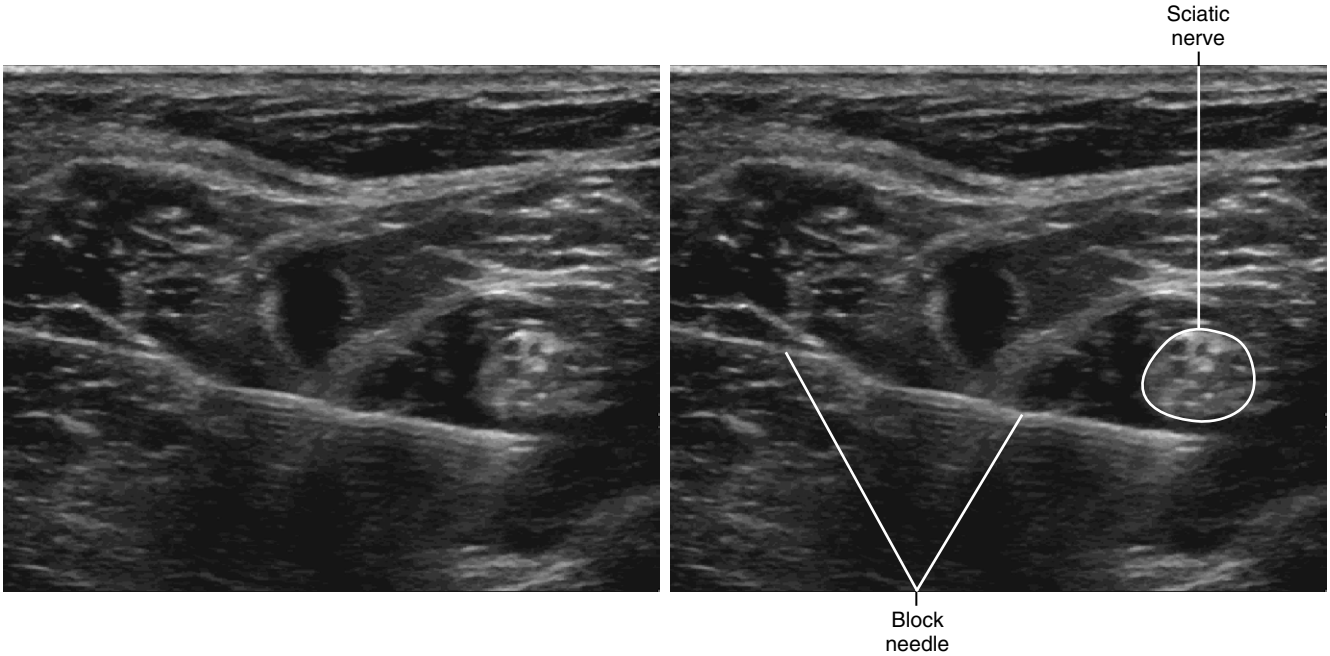

Figure 53-9 Bayonet artifact observed during popliteal block. In this sonogram, the block needle appears to bend as it approaches the sciatic nerve in the popliteal fossa.

Table 53-2 Anatomic Variation in Regional Block

Anatomic Variation	Location	Incidence	Implications and Significance	References
Passthrough/passover brachial plexus	Above clavicle	10-15%	Possible association with incomplete brachial plexus block	Kessler, 2007[36]
Cervical rib	Above clavicle	0.5-1.0%	Bony obstruction to brachial plexus block Preexisting nerve compression possible	Tubbs, 2006[37]
Duplicate axillary vein	Infraclavicular	10%	Duplicate vein lies adjacent to the lateral and posterior cords of the brachial plexus and therefore vascular puncture risked	Gusmao, 2002[88]
Duplicate axillary artery	Axilla	5-10%	Palpation of pulse for transarterial injection problematic	Bigeleisen, 2004[49]
Median-MCN fusion	Axilla	19%	If recognized will expedite MCN scanning and block	Orebaugh, 2006[50]
Passover MCN	Axilla	8-30%	Palpation of coracobrachialis muscle for MCN block problematic MCN usually more laterally positioned	Flatow, 1989[51] el-Naggar, 2001[52] Eglseder, 1997[53]
Superficial ulnar artery	Forearm and wrist	1-5%	Usual landmark for ulnar nerve now absent	Schafhalter-Zoppoth, 2004[89]
Persistent median artery	Forearm and wrist	25%	Associated with bifid median nerve	Gassner, 2002[90]
Sciatic nerve division by piriformis	Gluteal	1.5-21%	Incomplete block of divided nerve Possible association with piriformis syndrome	Benzon, 2003[73]

MCN, musculocutaneous nerve.

provides a means of recognizing anatomic variation but also modifies the approach to regional block based on the findings. It is important to develop the skill to accurately identify anomalies and understand their clinical implications (Table 53-2).

The overall incidence of anatomic variation is relatively low (usually in the 5% to 10% range). However, the reported rates of block failure are not substantially different. Studies examining an association between the two are in progress, and it is likely that anatomic variation is overrepresented among block failures for surface landmark–based techniques.

Although the spectrum of anatomic variation within the normal (asymptomatic) population is enormous, several themes recur. Venous anomalies are more common than arterial or nerve anomalies. Most visible nerve anomalies relate to abnormal nerve paths through or around muscles. Distal (peripheral) anomalies are more common than proximal (central) anomalies.

Supraclavicular and Interscalene Blocks

The first descriptions of ultrasound-guided blocks were in the supraclavicular region.[31,32] The advantages of the supraclavicular block are that the brachial plexus is compact, the nerve visibility is very good, and the structures are shallow (20-30 mm field). In the supraclavicular region, sonography will image the divisions of the brachial plexus.[33] Excellent block characteristics have been reported from ultrasound-guided supraclavicular blocks.[34] The principle concerns are the risk of vascular puncture in an area that is difficult to compress and the risk of pneumothorax.

An in-plane approach from medial to lateral so that the needle will pass over the subclavian artery can be used to reach the brachial plexus (Figs. 53-10 to 53-12). One current technique is to place the patient in a semi-sitting position with the head turned to the opposite side and the arms flush with the body. The operator will be standing at the head of the bed or at the patient's side depending on the side of the block and the handedness of the operator. Interscalene blocks can be performed in a similar fashion by sliding the transducer slightly more cephalad. In the interscalene view the brachial plexus is stacked between the scalene muscles. Proximity to the phrenic nerve will occur if the block location is too cephalad.

A compact linear transducer (20-30 mm footprint) is used for the procedure[35] to provide working room and allow rocking of the transducer. Some authors also have recommended a specialized compact linear "hockey stick" transducer for supraclavicular blocks.[30]

Anatomic Variation in the Supraclavicular and Interscalene Regions

Passover Brachial Plexus

The C5 ventral ramus (and other contributions to the brachial plexus) can pass over the anterior scalene muscle rather than between the scalenes. When this condition is identified, the block is usually performed at a more caudal position in the neck to avoid incomplete brachial plexus anesthesia.

Passthrough Brachial Plexus

C5 and C6 ventral rami can pass through the anterior scalene. Again, when this condition is identified, the brachial plexus block

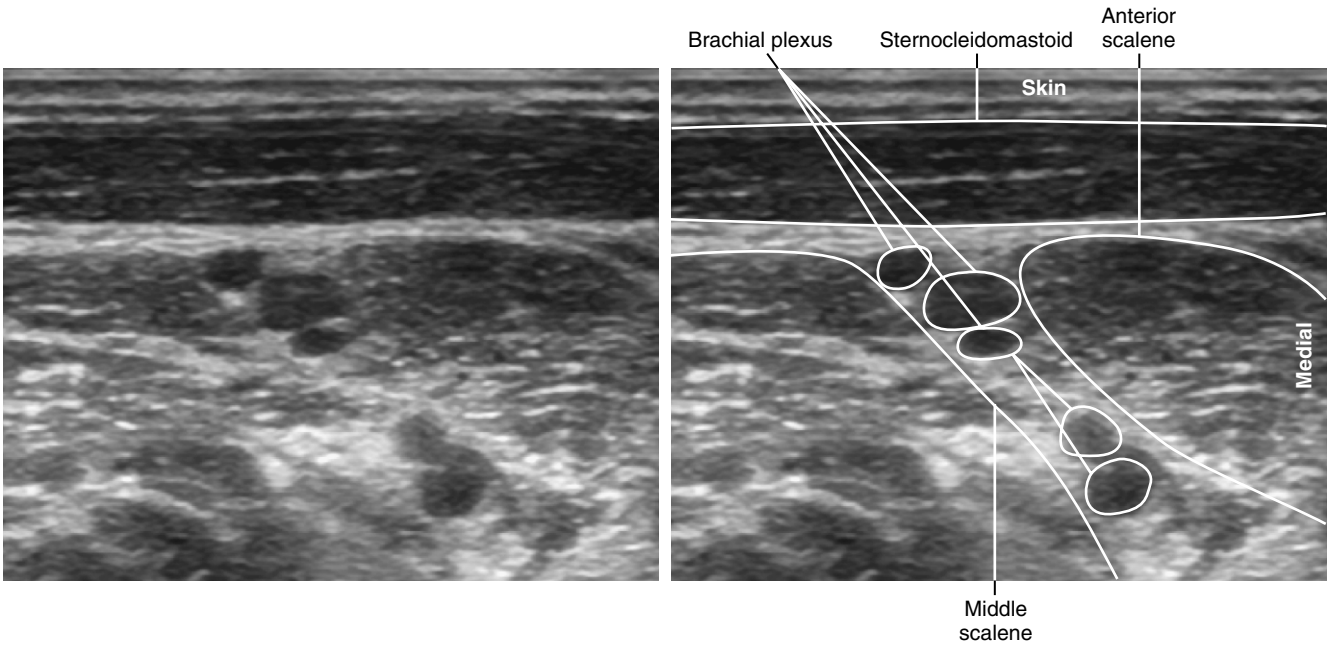

Figure 53-10 Interscalene view of the brachial plexus in the neck. In this sonogram the complexity of the brachial plexus is shown by identification of many components of the plexus in short-axis view. The cervical ventral rami have monofascicular echotexture as they lie between the anterior and middle scalene muscles.

is performed at a more caudal position in the neck to avoid incomplete brachial plexus anesthesia.

The incidence of scalene muscle anomalies is similar for sonography of volunteers and in cadaveric dissections, suggesting that ultrasound can accurately detect these anomalies.[36]

Cervical Ribs

Cervical ribs are relatively uncommon and occur in 0.5% to 1% of the population.[37] Partial cervical ribs usually present no difficulty for regional block. However, complete or large cervical ribs will make any approach to brachial plexus block

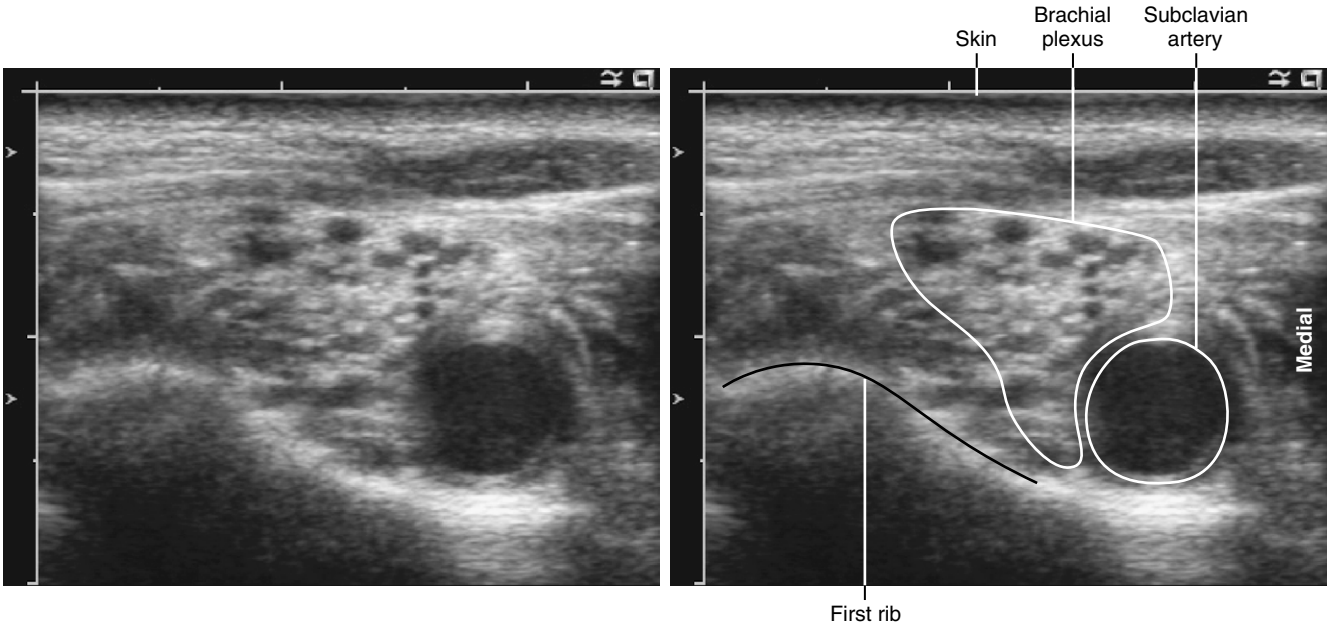

Figure 53-11 Ultrasound imaging for supraclavicular block. The compact brachial nerve plexus is seen superficial and lateral to the subclavian artery, pleura, and first rib.

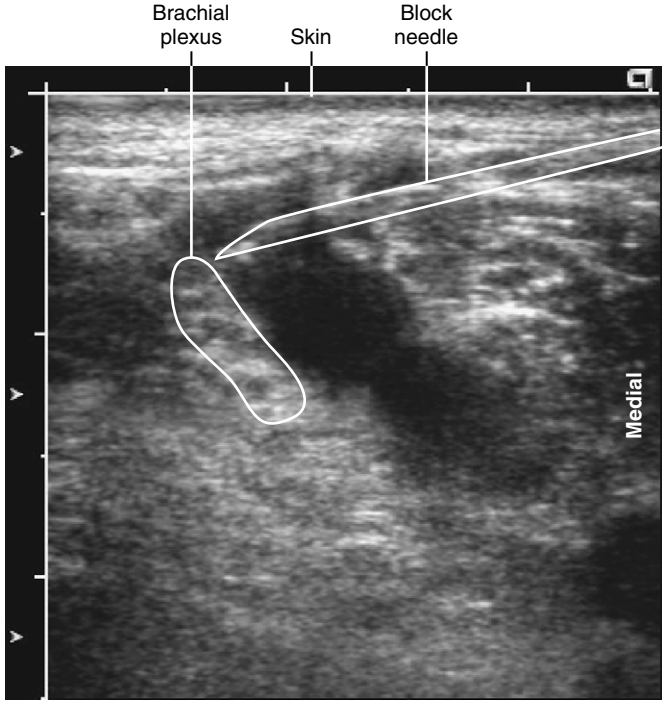

Figure 53-12 A, Ultrasound-guided supraclavicular block. In this clinical view, the needle approaches the brachial plexus from medial to lateral. **B,** Sonogram. For this procedure, the block needle approaches from medial to lateral within the plane of imaging. Local anesthetic is seen to distribute around the compact brachial plexus.

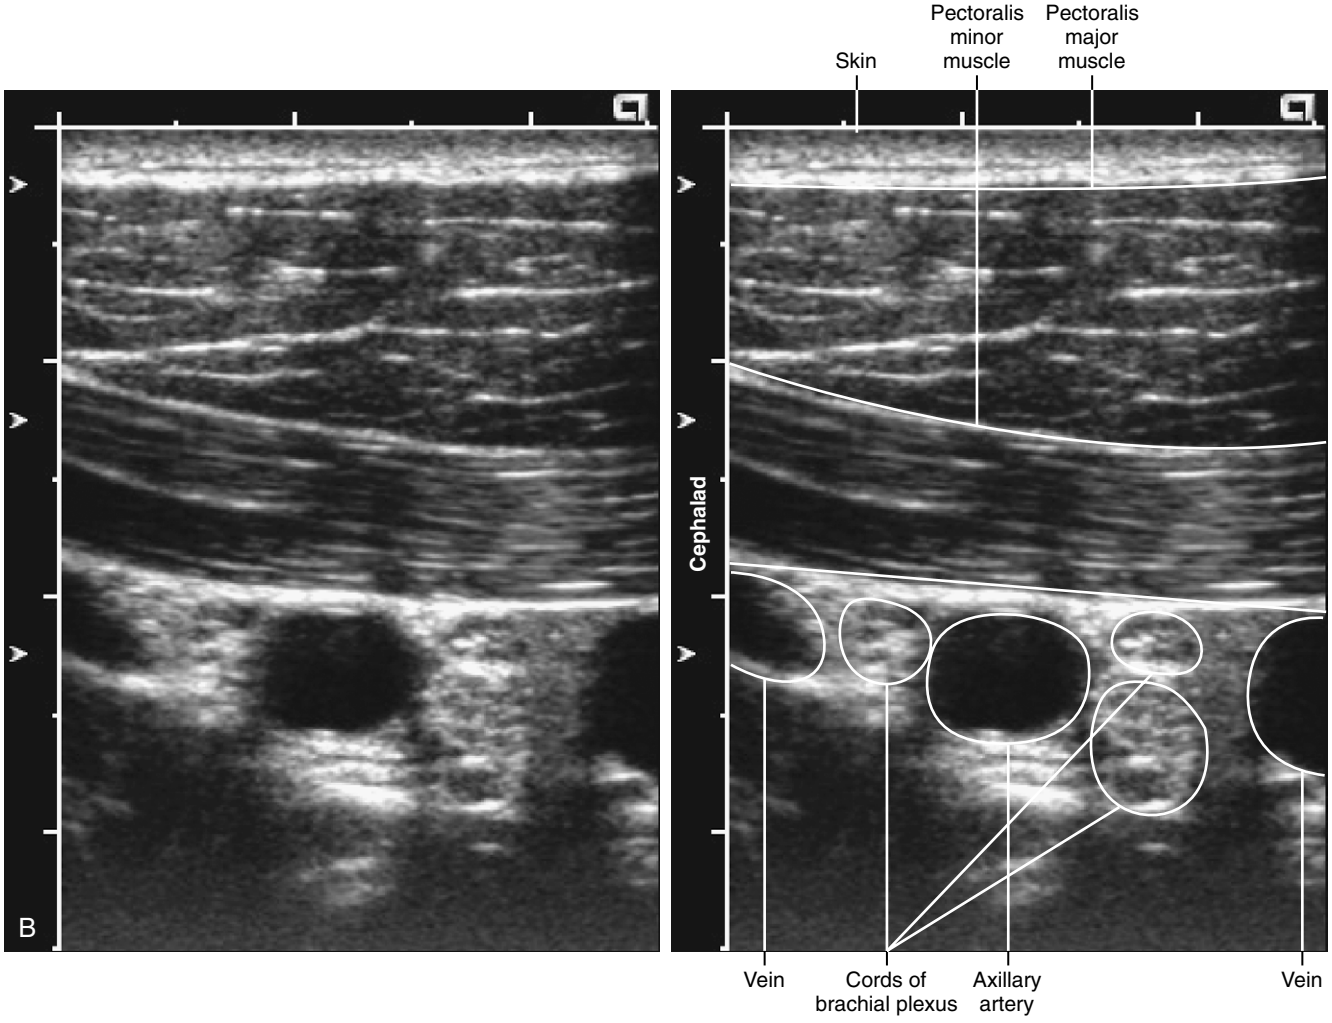
above the clavicle difficult (including an ultrasound-guided approach).

Infraclavicular Block

The advantages of the infraclavicular block are that it usually results in complete brachial plexus anesthesia, it is a stable place for a catheter, and no manipulation of the arm is necessary. The disadvantages are that it is a deeper block, and therefore needle/probe manipulation is necessary along with steep angles that result in needle tip visibility issues. Although the arm can remain at the side of the patient, the block is easier when the arm is abducted to straighten the neurovascular bundle.[38] The three arterial wall hugging cords are named with respect to the second part of the axillary artery so the expected positions are medial, lateral, and posterior. The artery is visualized in short-axis view deep to the pectoralis major and minor muscles (Fig. 53-13). Most practitioners use an in-plane approach from the head of the bed with the probe as lateral as possible. The ideal place for local anesthetic distribution to achieve complete infraclavicular block of the brachial plexus is posterior to the axillary artery for single-shot or catheter placement. There is substantial evidence that local anesthetic distribution posterior to the axillary artery produces complete brachial plexus block in the infraclavicular region.[39,40] The cords of the brachial plexus do not need to be directly visualized for successful block. A large retrospective clinical series supports

Figure 53-13 A, Clinical view of the setup for infraclavicular block. In this case, the arm has been abducted. **B,** Sonogram of the cords of the brachial nerve plexus are adjacent to the axillary artery. Anatomic variation in the infraclavicular region is rare, but in this patient, duplication of the axillary vein is seen deep to the pectoralis minor muscle.



the utility and safety of ultrasound-guided infraclavicular block.[41]

Anatomic Variation in the Infraclavicular Region

Duplicate Axillary Vein

Duplicate axillary vein is one of the few anatomic variations in the infraclavicular region. The clinical problem is that the accessory vein lies adjacent to the lateral cord of the brachial plexus and near the usual desired position of the needle tip. In the infraclavicular region, this vein will be difficult to compress with the ultrasound probe. When this anomaly is identified, caution and deliberate needle tip positioning are used to avoid intravenous injection.

Axillary Block

The axillary block is a versatile block for upper extremity anesthesia. Although relatively safe and commonly used with classic approaches, the one major limitation has been failure to block the musculocutaneous nerve. Now with the advent of ultrasound imaging, this sparing can be overcome by directly visualizing the musculocutaneous nerve itself.

The axillary block provides surgical anesthesia of the elbow and areas more distal, with adequate prevention of tourniquet pain.[42] The shallow depth of the neurovascular bundle (a 20-mm field is typical) and the large amount of working room make this a relatively easy block with ultrasound guidance. There are usually three arterial wall-hugging branches (median, ulnar, and radial) and one branch that has a characteristic medial to lateral course in the axilla (musculocutaneous). The musculocutaneous nerve also has a characteristic change in shape as it moves from adjacent to the artery (round), to within the coracobrachialis muscle (flat), to exit the muscle (triangular). Both out-of-plane (with needle approaching from distal to proximal) and in-plane (with needle approaching from the lateral side of the arm) techniques can be used. The neurovascular bundle is viewed in short axis with sufficient pressure to just coapt the walls of the axillary veins. Nerve location can be described with clock notation with respect to the axillary artery as viewed from the skin surface (with 3 o'clock indicating medial position). The usual locations are median (noon to 1 o'clock), ulnar (3 o'clock, between the artery and vein), radial (6 o'clock), and musculocutaneous (9 o'clock, with lateral takeoff expected).[43]

The block is performed in the proximal axilla, with the transducer gently pressed against the chest wall (Figs. 53-14 to 53-17). A high-frequency linear probe with a small footprint (25 to 30 mm) with sterile cover can be used for axillary block. The ideal location for local anesthetic injection is between the nerves and the artery so that separation between the two structures occurs, to ensure distribution within the neurovascular bundle. These injections result in excellent clinical blocks. The musculocutaneous nerve is usually blocked within the coracobrachialis, where its flat shape gives a large amount of surface area for rapid block of both sensory and motor fibers.[44]

Studies of the functional anatomy of the brachial plexus in the axilla suggest that multiple injections are required for complete brachial plexus anesthesia.[45,46] The approach described here is an ultrasound-guided modification of previously reported multiple injection techniques for axillary block. Ultrasound imaging has been shown to improve the success rate of axillary block compared with alternative approaches.[47,48] The low overall rates of axillary block success may reflect the strict clinical assessments in these carefully controlled trials.

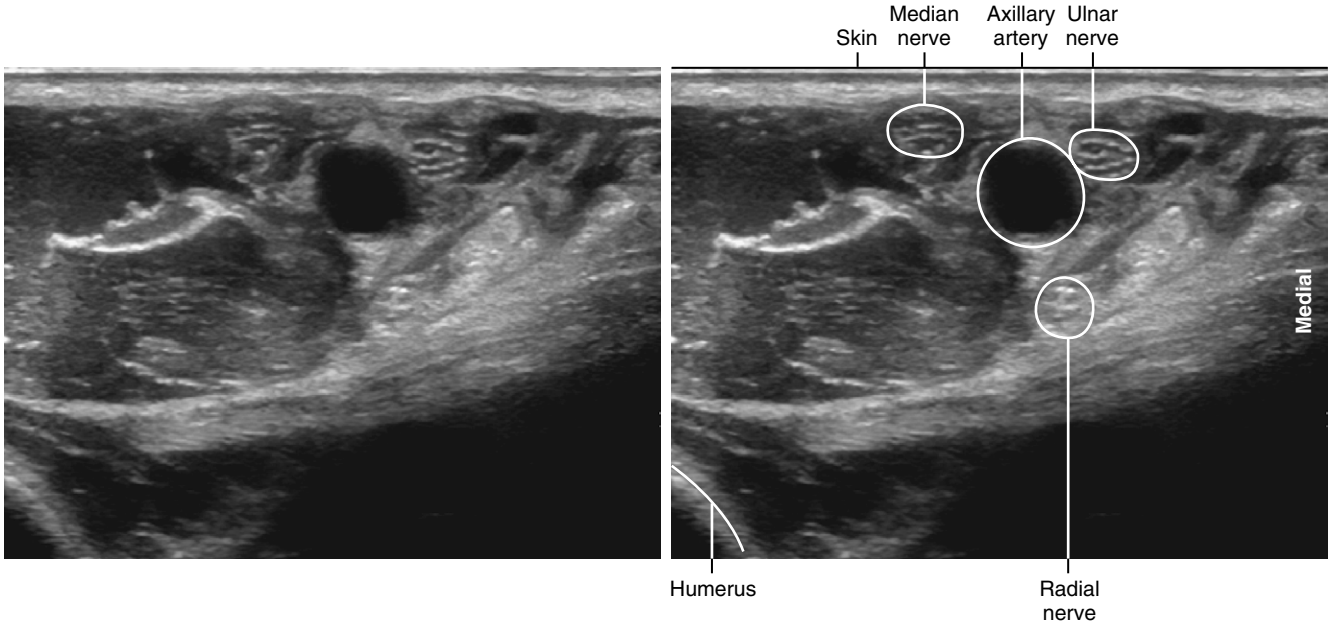


Figure 53-14 Ultrasound imaging in the axilla. In these sonograms, the median, ulnar, and musculocutaneous nerves are identified around the axillary artery. The radial nerve can be difficult to visualize.

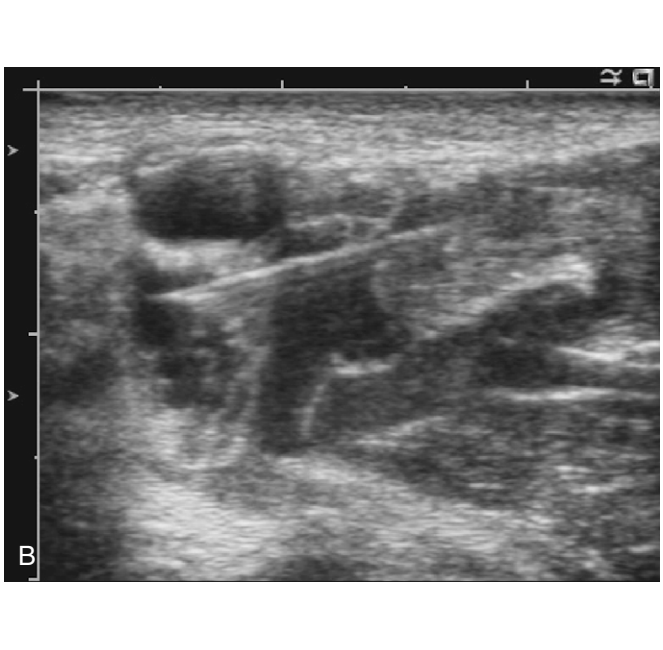

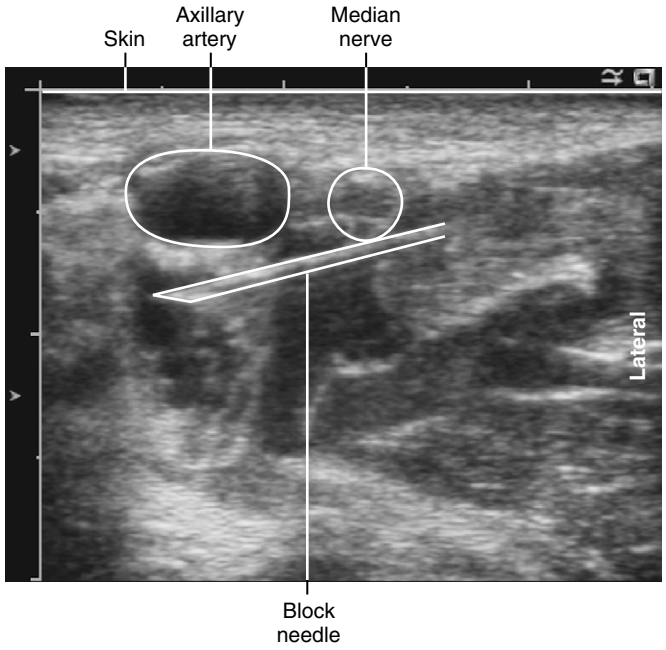

Figure 53-15 Axillary block with ultrasound guidance (in-plane approach). **A,** Clinical view of the approach. **B,** Sonogram of the neurovascular bundle in short-axis view with the needle tip in plane. The median nerve is identified adjacent to the axillary artery. The probe compression is just sufficient to coapt the walls of the satellite veins.

The disadvantages of the axillary block are that the patient must abduct the arm, catheter placement can be problematic due to incomplete blocks and catheter dislodgement, and in some individuals, the radial nerve takes off from the axillary artery proximally. The radial nerve exits the neurovascular bundle between the medial and lateral heads of the triceps muscle. In most subjects, the nerve travels with the profunda brachii artery (the deep branch of the axillary artery) to the spiral groove of the humerus. The radial nerve can be difficult to visualize and is often confused with acoustic enhancement deep to the back wall of the axillary artery.[30] When the radial nerve is not directly identified, the operator must be confident that there is local anesthetic distribution deep to the axillary artery proximal to the takeoff point of the profunda brachii artery to ensure block.

When first learning this technique with ultrasound, it will take 40 mL of local anesthetic for adequate block. With experience, volume reduction is possible to the 15- to 20-mL range. However, if the block is too targeted for the four nerves named previously, sparing of other smaller nerves (e.g., the medial antebrachial, medial brachial, and intercostobrachial nerves) can sometimes occur. Anatomic variation is relatively common in the axilla (see later).

Anatomic Variation in the Axilla

Duplicate Axillary Artery

One to 2% of adults have duplication of the axillary artery.[49] If direct nerve imaging is suboptimal, a more proximal approach to brachial plexus block can be indicated.

Musculocutaneous–Median Nerve Fusion (Low-Lying Lateral Cord in the Axillary Region)

Although the overall incidence is low,[50] this anomaly is probably the leading cause for failure to image the musculocutaneous nerve in the axilla. When identification of the musculocutaneous nerve is not possible, the operator should trace the course of the

Figure 53-16 Axillary block with ultrasound guidance (out-of-plane approach). **A,** External photograph of the approach. **B,** Sonogram of the neurovascular bundle in short-axis view with the needle tip crossing the plane of imaging. The probe compression is just sufficient to coapt the walls of the satellite veins.

median nerve down the arm. The median–musculocutaneous fusion bundle is larger than the normal median nerve and will give off branches laterally. It is important to recognize this anomaly so that time is not wasted (the nerve complex is usually already blocked by previous injections).

Passover Musculocutaneous Nerve

Rather than pass through the coracobrachialis muscle, the musculocutaneous nerve can pass over it.[51-53] The estimated incidence of passover musculocutaneous nerve ranges from 8% to 30%. This condition can be difficult to detect with ultrasound (not because the nerve is difficult to see but because the borders of the coracobrachialis are difficult to establish). Furthermore, in these cases the same shape changes occur, perhaps because the short head of the biceps muscle plays a similar mechanical role as the coracobrachialis. If the musculocutaneous nerve can be directly identified, this anatomic variation is easy to manage.

Ilioinguinal Block

The lower abdominal wall is primarily innervated by four peripheral nerves: the subcostal nerve, ilioinguinal nerve, iliohypogastric nerve, and genitofemoral nerve.[54] The first three nerves emerge between the transversus abdominis, internal oblique, and external oblique muscle layers. The extended course of these nerves through the abdominal wall within the layer between the transversus and internal oblique muscles makes this the desired anatomic location for regional block. The most common

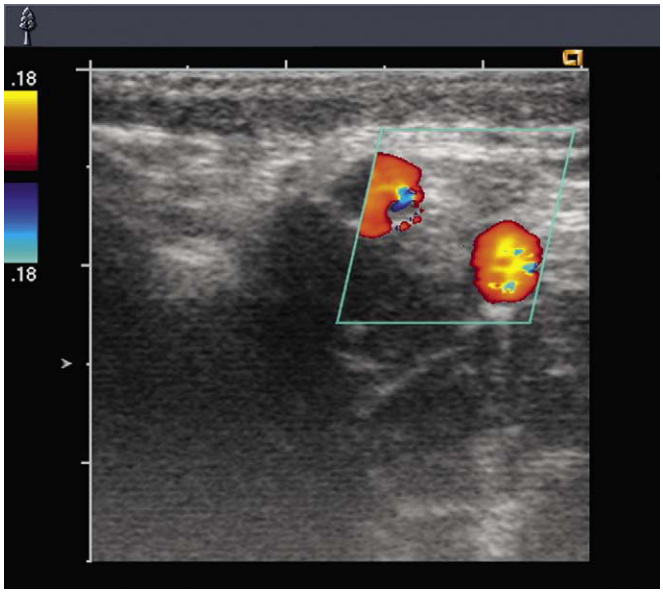

Figure 53-17 Duplication of the axillary artery. In this duplex sonogram, color Doppler reveals two axillary arteries in the axilla of this patient undergoing axillary block.

indication for ilioinguinal block is unilateral inguinal hernia repair.

For ultrasound-guided ilioinguinal block, the patient is placed supine (Figs. 53-18 to 53-20). The transducer is placed between iliac crest and costal margin (more cephalad than the usual location for ilioinguinal block). In this location, the muscle layers of the abdominal wall are well defined.[55] Of the three muscle layers (external oblique, internal oblique, and transversus), the internal oblique is usually the thickest.[56] In the more traditional location for ilioinguinal block, the muscles are often aponeurotic and therefore difficult to image.[57]

Injection must be within the fascial layer that separates the internal oblique muscle and the transversus muscle. Direct visualization and proximity to the nerves is not critical if 20 mL of local anesthetic is injected in the correct layer. The needle approach is in-plane from the anterior side, similar to transverse abdominal plane blocks.[58,59] Fine adjustments of the needle angle are not necessary because the probe can slide to find the crossing point of the tissue plane and the needle tip. The intent is to first visualize the needle tip in the external or internal oblique muscles before advancing deeper. The respiratory motion of the peritoneal cavity makes general anesthesia an appealing option for the block. The transversus muscle is thin, so the margin of safety between it and the peritoneal cavity is relatively small. For more complete blocks, local anesthetic can be injected into the other layers (between external oblique and internal oblique, and subcutaneous infiltration done between external oblique and skin) when pulling back the block needle.

For low-volume blocks, the needle tip is positioned between the ilioinguinal and iliohypogastric nerves within the fascial plane separating the internal oblique and transversus muscles. The iliohypogastric nerve runs superior and medial to the ilioinguinal nerve. The deep (medial) circumflex branch of the external iliac artery pierces the transversus muscle as it ascends the abdominal wall. Branches of the deep circumflex iliac artery often accompany the ilioinguinal nerves.

Clinical assessment of block is made difficult because of the anatomic variation in cutaneous innervation of the ilioinguinal and iliohypogastric nerves. The ilioinguinal and iliohypogastric nerves have small motor contributions to the transversus and internal oblique muscles. There is a tissue plane between the transversus abdominis muscle and the transversalis fascia that communicates with the femoral nerve,[60] so deep infiltration of sufficient volumes of local anesthetic can result in unintended femoral nerve block.

Femoral Block

Advantages of using ultrasound to guide femoral nerve block include more complete block, local anesthetic volume sparing, and fewer vascular punctures.[61,62] To be successful with this technique, detailed knowledge of the sonographic anatomy of the femoral nerve in the inguinal region is required.

The femoral nerve usually lies lateral to the femoral artery in the groove formed by the iliacus and psoas muscle. The nerve can be oval or triangular in cross-sectional shape with an anteroposterior diameter of approximately 3 mm and a mediolateral diameter of 10 mm.[63] Best depiction of the femoral nerve is from 10 cm proximal to 5 cm distal to the inguinal ligament. Some tilt of the ultrasound probe is necessary according to the pelvic inclination for the sound beam to meet the nerve perpendicularly for optimal scanning. In addition, the femoral nerve has a slight medial to lateral course so some rotation of the probe is also necessary to best view the nerve. Because the femoral nerve is covered by echobright adipose tissue and fascia, it can be difficult to establish the echogenic outer sheath of the nerve.[14]

In some subjects the psoas tendon can appear similar to the femoral nerve. However, the psoas tendon lies deep within the muscle. If the profunda femoris artery (the deep branch of the femoral artery) is visualized, then the transducer is too distal for complete femoral nerve block. The femoral nerve is often identified as a slight indentation of the iliacus and psoas muscles.

For femoral nerve block, a broad (35- to 50-mm footprint) linear transducer is used (Figs. 53-21 to 53-23). A short-axis view of the femoral nerve and vessels is obtained as described previously. Both out-of-plane (from distal to proximal) or in-plane (from lateral to medial) approaches have been used. The out-of-plane approach is often used for catheter placement.[64] The advantage of in-plane approach is visualization of the approaching needle. The disadvantages are the longer needle path and the fact that the needle has a tendency to skim over the fascia iliaca, thereby deforming it rather than puncturing it.

For either approach, the needle tip is positioned between the fascia iliaca and the iliopsoas muscle near the lateral corner of the femoral nerve to avoid the femoral vessels, similar to the method for fascia iliaca block.[65] The fascia iliaca has a characteristic mediolateral inclination, so lateral approaches are advantageous because they are more superficial and shallow than medial approaches. The desired distribution is local anesthetic layering under or completely around the femoral nerve. When layering of local anesthetic is observed over the nerve, the major concern is that the fascia iliaca is intact and block failure will result. For obese patients, femoral nerve imaging is challenging. In these patients, ultrasound can be combined with nerve stimulation for successful block. After successful injection of local anesthetic,

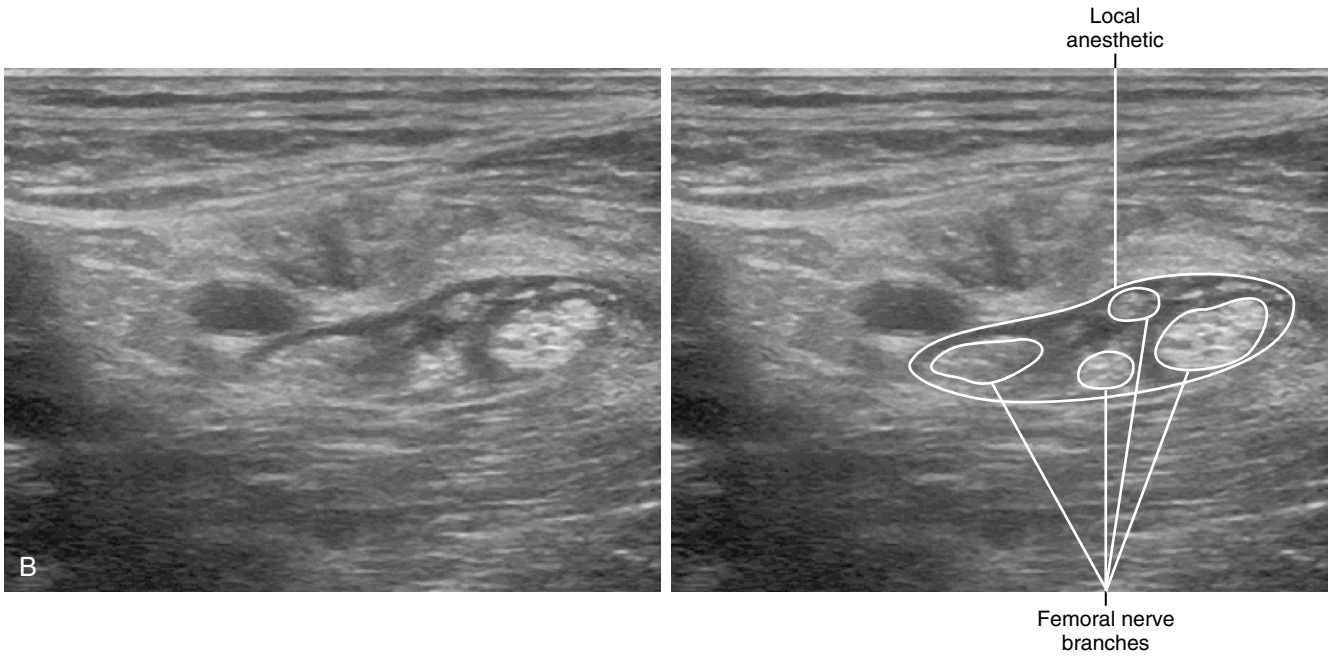

Figure 53-23, cont'd

branches of the femoral nerve can be appreciated by sliding the transducer along the known course of the nerve.

Sciatic Block

The sciatic nerve can be blocked anywhere along its course from the gluteal region to the popliteal fossa.[66] In this section, several common approaches to sciatic nerve block with ultrasound imaging are described (Figs. 53-24 and 53-25).

One of the first descriptions of sciatic nerve block used a short-axis view of the nerve(s) in the prone position with an out-of-plane approach in the popliteal fossa.[67] The advantage of a prone approach to popliteal sciatic nerve block is the stable imaging with the ultrasound transducer. In addition, the nerves can be blocked close to the surface. The division of the sciatic nerve provides a broad target with large surface area to promote block characteristics. This approach also allows a natural anatomic orientation of the field and monitor.

For this technique, the needle tip is positioned between the tibial and common peroneal components of the sciatic nerve near the division so that a single injection distributes to both nerves. By sliding the transducer along the known course of the sciatic nerve, its characteristic division in the popliteal fossa can be identified.[68] This method of sliding assessment is also important for verifying the local anesthetic distribution after injection. The tibial nerve has a more straight course than the common peroneal nerve and has about twice the cross-sectional area. The tibial nerve lies posterior to the popliteal artery and vein at the popliteal crease, and this can be a useful starting point when imaging is difficult. When the foot is moved, the nerves of the popliteal fossa have characteristic motions that can be helpful for nerve identification.[69]

The major disadvantage of the prone approach is that this position can be difficult for some patients. With the out-of-plane approach, inadvertent paresthesias and patient movement sometimes occur.

A similar approach to popliteal block can be used in supine position. For this the nerve(s) are viewed in short axis and the needle approach is in-plane from the lateral side of the thigh.[70] The leg must be elevated in a stable fashion to allow access for the ultrasound transducer. The advantages of this approach are the convenient position, the transducer position is remote from the site of needle entry, and the parallel in-plane approach of the block needle results in optimal needle tip visibility.

Analogous approaches to sciatic nerve block can be performed more proximally.[71] In some subjects the proximal biceps femoris tendon or semimembranosus tendon can appear similar to the subgluteal sciatic nerve. Some authors have suggested blocking the sciatic nerve deep to the gluteal muscles because the adjacent soft tissue permits favorable distributions of local anesthetic.[72]

Anatomic Variation in the Subgluteal Region

In some subjects, the sciatic nerve is divided by the piriformis muscle.[73] This can be detected in the subgluteal region by distinct common peroneal and tibial nerves. Multiple injections may be required for complete sciatic nerve anesthesia.

Phantom Training and Safety

Interventional sonography is not without risks.[74] Many recent studies have demonstrated efficacy of ultrasound-guided regional

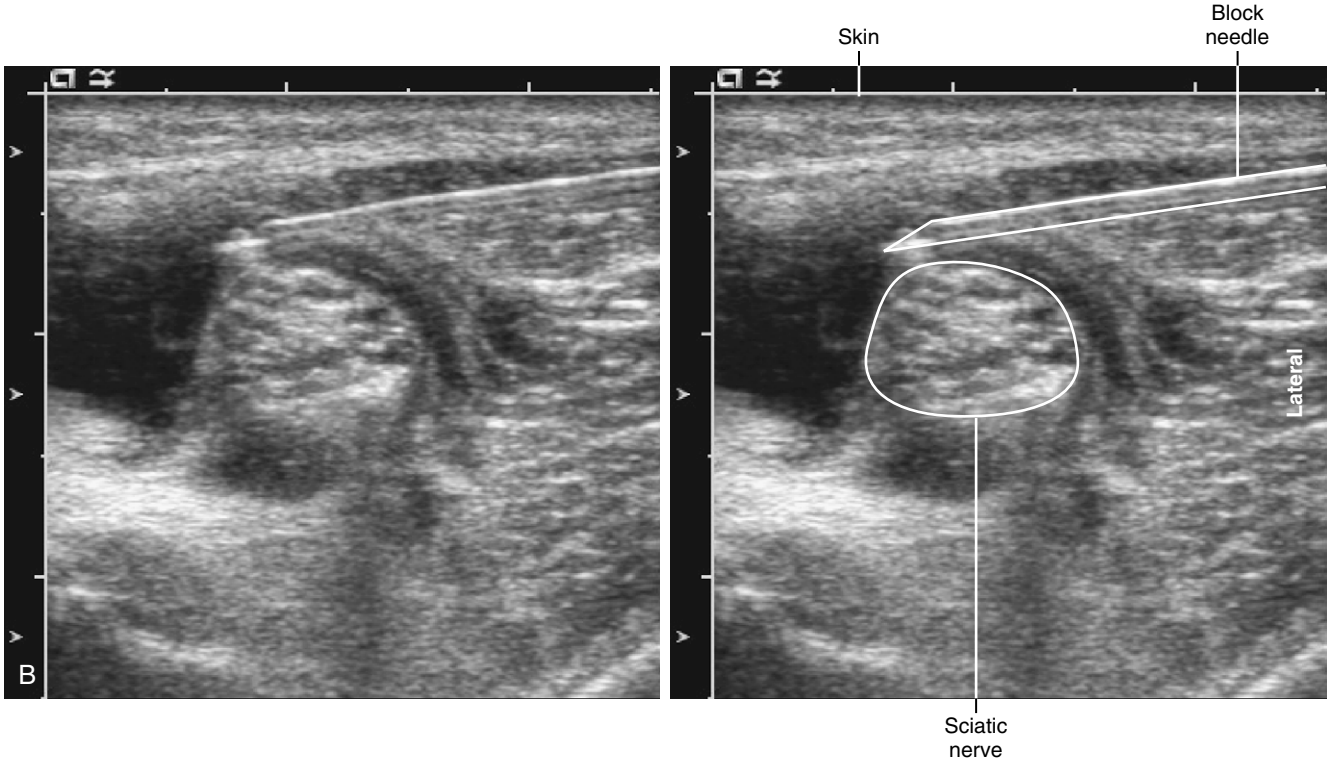

Figure 53-24 Popliteal block with ultrasound imaging (in-plane approach). **A,** Clinical view of the setup for popliteal nerve block in supine position. The leg is elevated and the transducer is applied to the posterior surface of the leg. **B,** The needle approaches the sciatic nerve in the plane of imaging from the lateral side of the leg.

blockade. Ultrasound has potential to prevent and detect two important adverse events during peripheral nerve blocks: intravascular injection and intraneural injection (Figs. 53-26 and 53-27).[75] Whereas ultrasound has tremendous promise in improving safety of regional blockade, this remains to be established in clinical practice.

One of the original techniques developed for training novices in ultrasound-guided interventions was use of a tissue-equivalent phantom.[76] The phantom consisted of simulated tissue for needle placement practice. To be realistic, the speed of sound must be the same as in soft tissue. In the first prototype, the phantom and container were clear so that visual confirmation was possible. Several phantoms are now marketed for regional anesthesia purposes, and biologic tissue models that simulate nerve blocks have been developed.[77]

Other teaching tools are being used. Cadavers have the advantage of realistic regional anatomy and can be used for simulated interventions. However, the cost and use of specialized embalming methods that preserve nerve imaging and flexibility have limited this approach to a few institutions.[78-80] We have yet to identify which tools are most effective at teaching ultrasound-guided regional blocks. Most training studies have concluded that

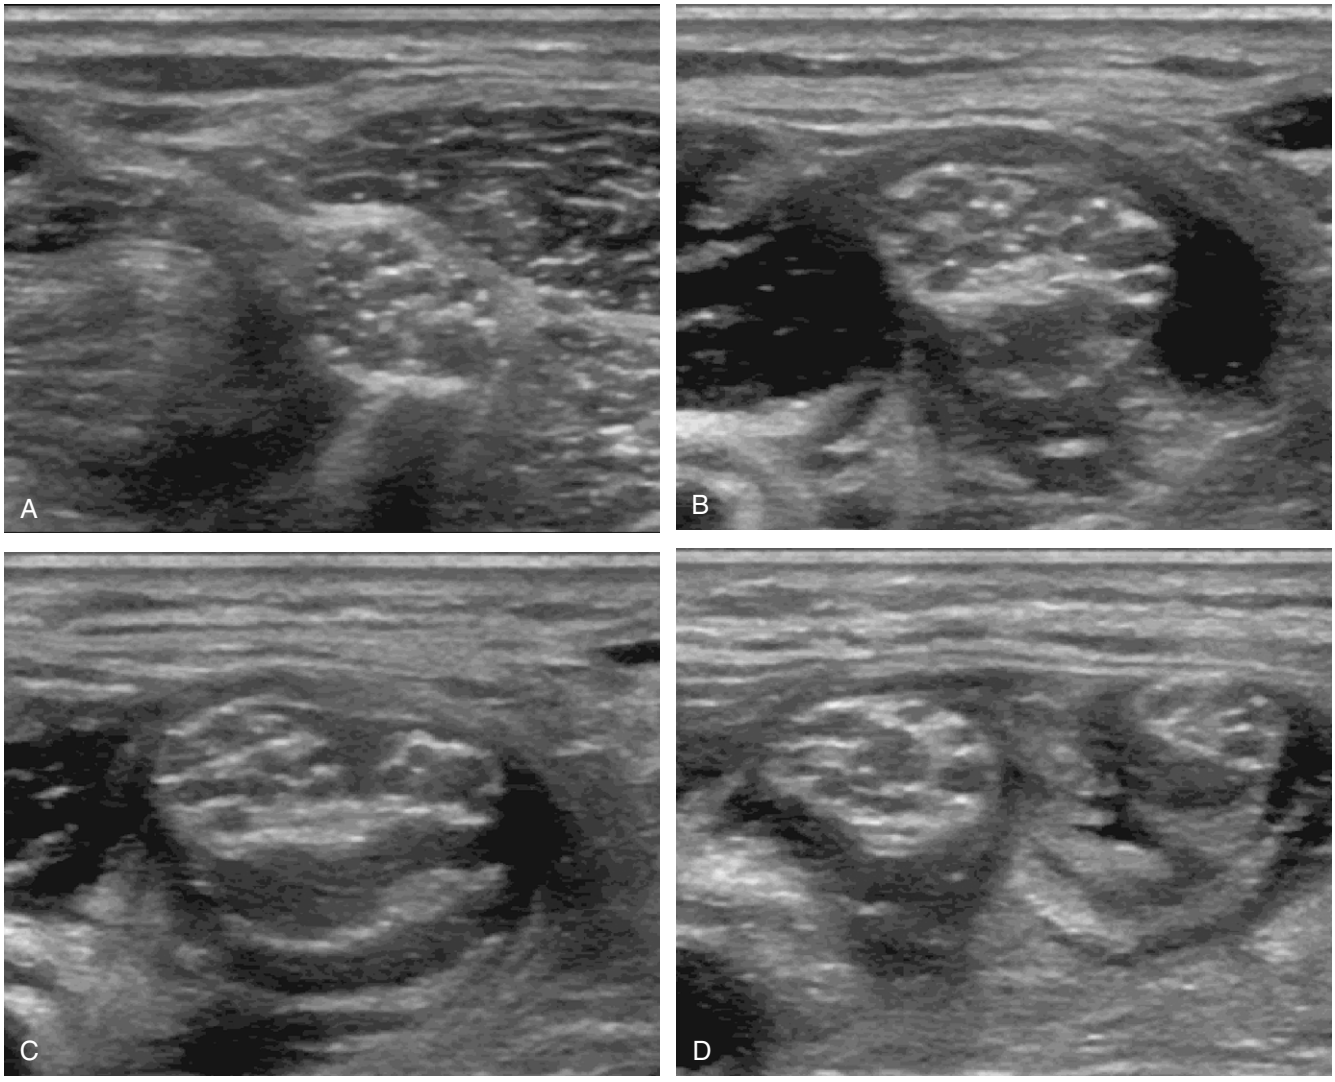

Figure 53-25 Sciatic nerve imaging in the popliteal fossa before (**A**), during (**B** and **C**), and after (**D**) division into the tibial and common peroneal nerves. Local anesthetic is seen to track with both individual nerves, thereby confirming successful block.

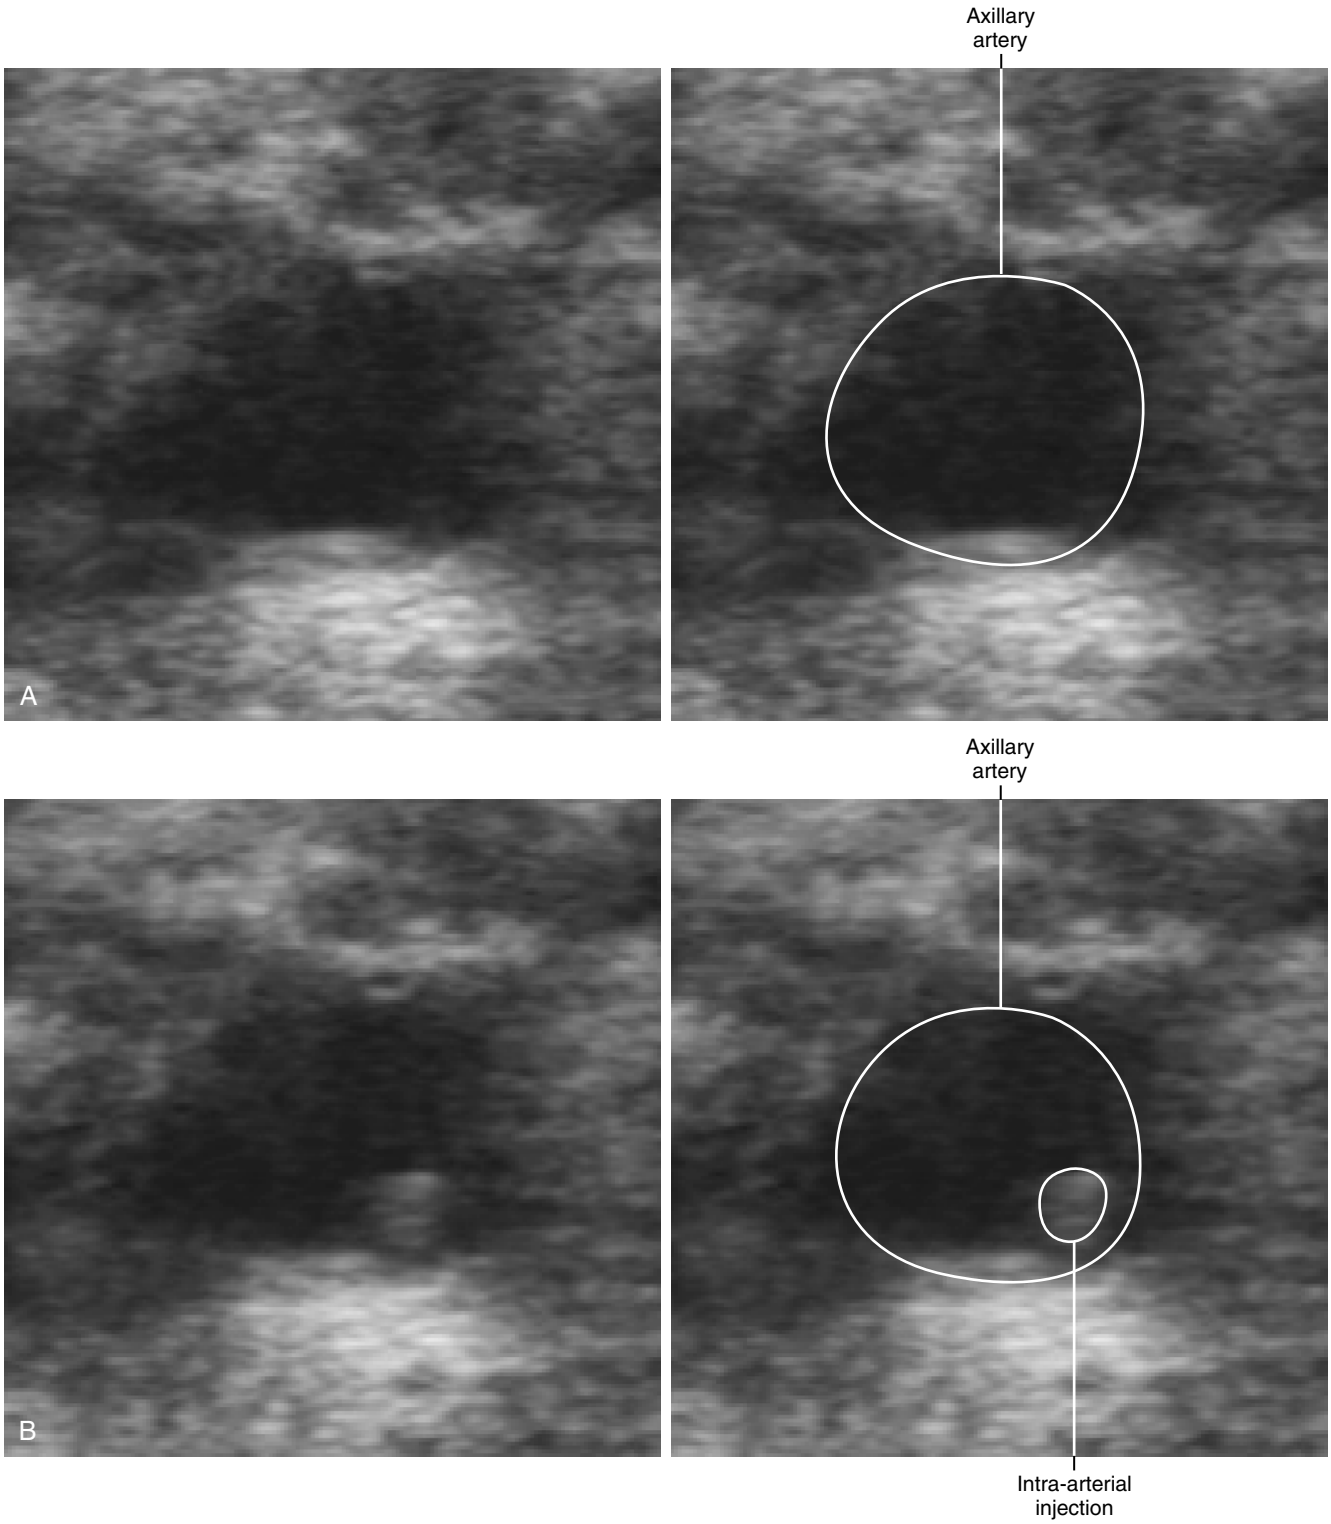

Figure 53-26 Intravascular injection detected by ultrasound imaging. These sonograms were obtained before (**A**) and during (**B**) a small local anesthetic injection within the axillary artery in the axilla.

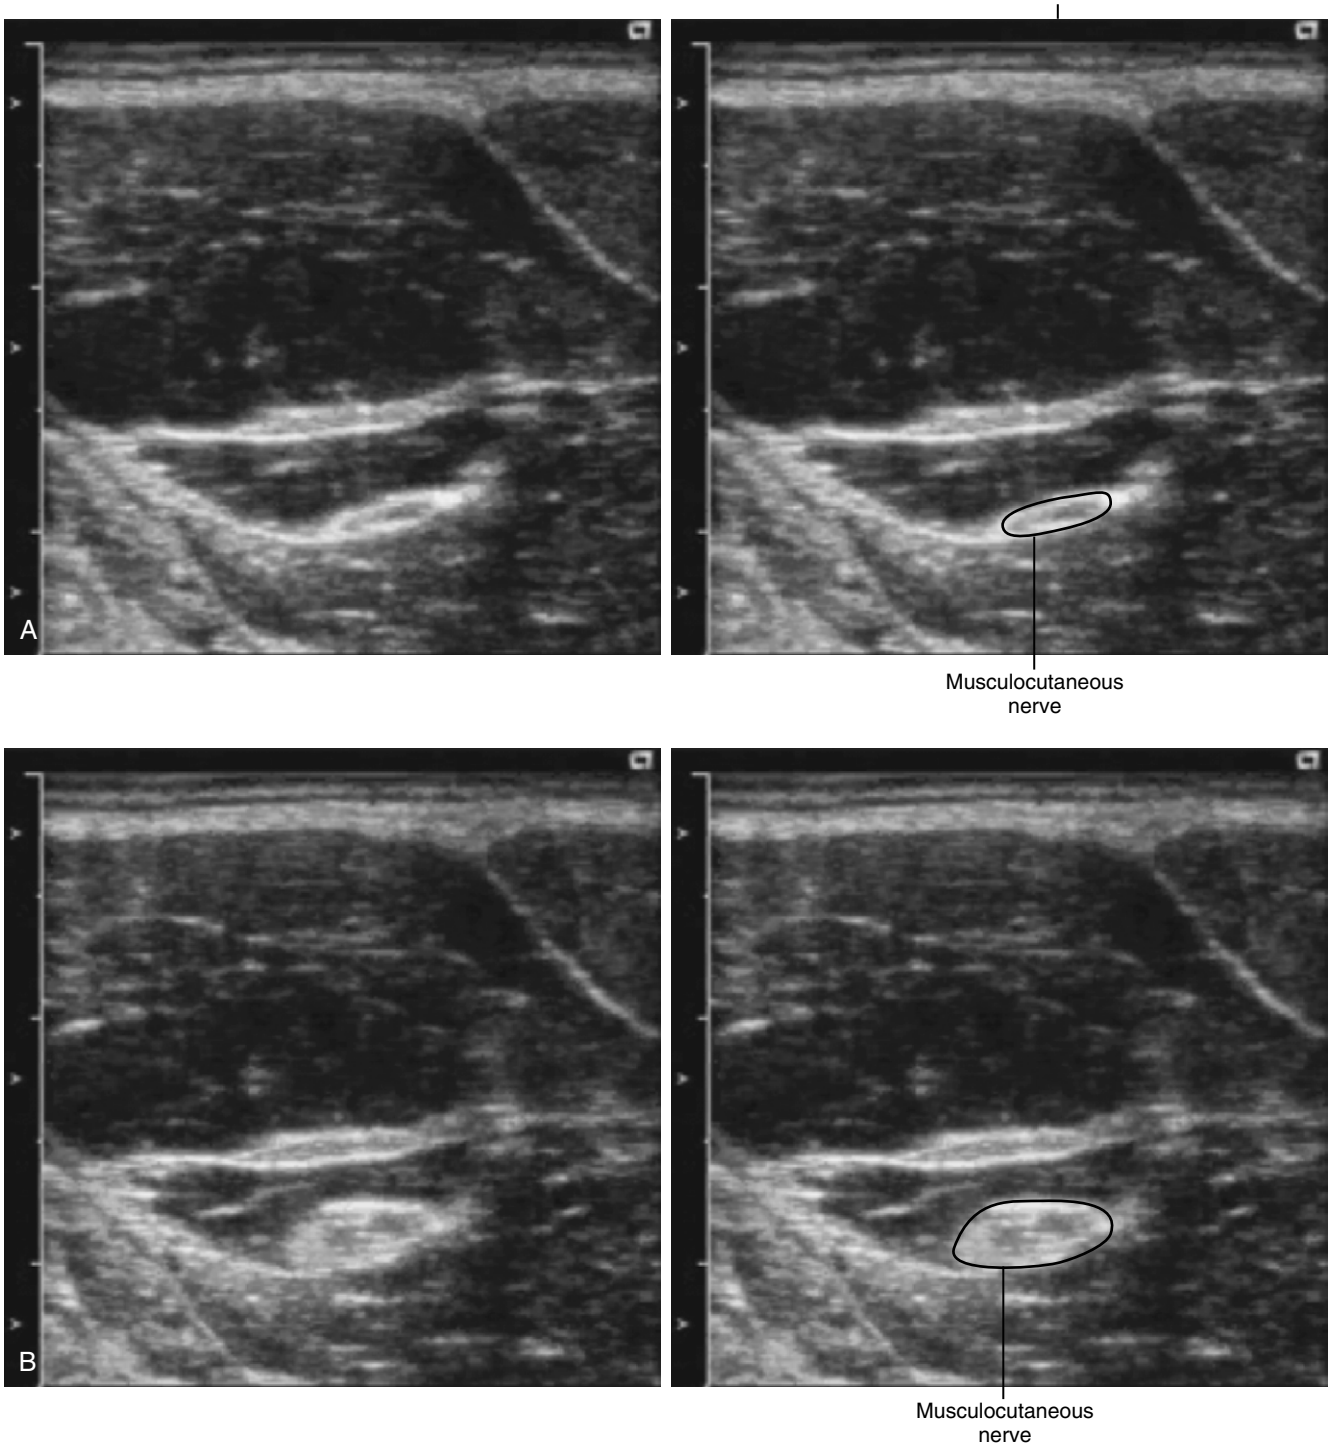

Figure 53-27 Intraneural injection revealed by ultrasound imaging. These sonograms were obtained in the axilla before (**A**) and after (**B**) injection within the musculocutaneous nerve. Nerve expansion is detected, but with preservation of the overall integrity of the nerve borders. No paresthesias were observed during or after the procedure. Neurologic outcome was favorable after this low-volume, low-pressure injection.

minimal training is necessary to acquire skills for ultrasound-guided procedures. Novices with 1 hour of training and supervised phantom work were proficient at ultrasound-guided nerve blocks (of the terminal branches of the brachial plexus) in the forearm.[81]

A recent training study identified common errors of novices while learning ultrasound-guided regional blocks.[64] These errors included advancing the needle when it was not visualized and unintentional probe movement. Novices often advance the needle even when it is not visualized, presumably because the natural inclination is to assume the needle has not reached the field of view. The potentially quality-compromising behaviors were largely eliminated by the end of the study period (which ranged from 66 to 114 blocks per training subject).

54 Intravascular Fluid and Electrolyte Physiology

Key Points

1. Water is the major component of all fluid compartments within the body and represents approximately 60% of body weight.
2. Sodium is the most abundant positive ion of the extracellular fluid (ECF) compartment and is crucial in determining the extracellular and intracellular osmolality.
3. Potassium is the most abundant positive ion in the intracellular fluid and plays an important role in the membrane potential of cells.
4. Calcium is the key component that mediates muscle contraction; exocrine, endocrine, and neurocrine secretion; cell growth; and the transport and secretion of fluids and electrolytes.
5. Magnesium is essential for many biochemical reactions; its pharmacologic properties have only more recently been appreciated.
6. Phosphate stores and releases energy through high-energy phosphate bonds and is integral to the structure of proteins, lipids, and bone.
7. Chloride is the predominant anion in the ECF.
8. Glucose is a crucial fuel source, and insulin facilitates glucose movement into cells in a process that also requires potassium and phosphate.
9. Diabetes affects multiple organ systems, and the perioperative effect of diabetes can be profound.
10. The most common causes of metabolic alkalosis are antacid therapy, incidental administration of citrate with blood products, sodium bicarbonate administration, gastric drainage, and renal bicarbonate retention.
11. Metabolic acidosis is commonly caused by low cardiac output and end-stage liver disease.
12. Transfusion of blood products improves tissue oxygenation and decreases bleeding, but it also increases the risk of transmission of infectious diseases, transfusion reactions, immunosuppression, and alloimmunization.
13. Anesthetics may blunt the normal physiologic responses to hypovolemia and the stress response.
14. Shock is dysfunction of intracellular processes caused by the lack of energy.

Water Physiology

Water is the major component of all fluid compartments within the body (see Chapter 88). Total body water represents approximately 60% of the body's total weight in an average adult. In a 70-kg man, total-body water is about 600 mL/kg, or 40 L. The percentage of water varies significantly, however, with age, gender, and adiposity because muscle contains 75% water, whereas adipose tissue contains only 10% water. The percentage water content of a fetus is higher initially, but decreases progressively during late gestation and the first 3 to 5 years of life.

Total-body water may be divided into its two basic components, intracellular and extracellular. The compartments are separated by water-permeable cell membranes. In a 70-kg man, the intracellular fluid volume averages 400 to 450 mL/kg (about 30 L), and the extracellular fluid (ECF) volume averages 150 to 200 mL/kg (about 14 L). ECF volume is greater in young individuals and men than in elderly individuals and women (Table 54-1). The blood volume is 60 to 65 mL/kg, and is distributed as 15% in the arteries and 85% in the venous system.

The major components of the extracellular compartment are the plasma volume (30 to 35 mL/kg) and the interstitial fluid (120 to 165 mL/kg). Other constituents of the ECF include pleural fluid, peritoneal fluid, aqueous humor, sweat, urine, lymph, and cerebrospinal fluid. Plasma warrants special consideration because of its importance in clinical practice. Plasma is the noncellular component of blood and is continuously seeking equilibrium with the interstitial fluid. A major difference of plasma compared with interstitial fluid is the much higher concentration of proteins. This higher concentration of protein results in plasma having an osmotic pressure 20 mm Hg greater than the interstitial fluid and ECF. This gradient helps maintain the intravascular volume. The ECF compartment contains higher concentrations

Table 54-1 Electrolyte Composition in Body Fluids (Normal)

Electrolyte	Plasma (mEq/L)	Interstitial Fluid (mEq/L)	Intracellular Fluid (mEq/L)
Na^+	142	145	10
K^+	4	4	159
Mg^{2+}	2	2	40
Ca^{2+}	5	3	1
Cl^-	103	117	10
HCO_3^-	25	27	7

Adapted from Campbell I: Physiology of fluid balance. Anaesth Intensive Care Med 7:462-465 2006.

of sodium, chloride, and bicarbonate. Permeability to ions and proteins varies with each organ, with the brain having the lowest and the liver having the highest permeability.

Control of body water and its composition is multifactorial and involves many factors, including atrial natriuretic peptide (ANP), vasopressin (i.e., antidiuretic hormone [ADH]), aldosterone (e.g., renin, angiotensin), parathyroid hormone, calcitonin, prostaglandins, dopaminergic receptors, α-adrenergic receptors, the thirst mechanism, and intrinsic renal properties. Water balance describes the difference between water intake and water loss. The kidneys are the major regulators of water output.

Approximately 60% of the daily water loss is excreted in the urine. At high ambient temperatures or with significant exercise, the amount of water lost by sweating increases and may reflect most of the total daily water loss (Table 54-2). Heavy exercise can increase the loss of water through sweating 50 times the normal rate. Increased ventilation amplifies the insensible loss of water through the respiratory tract. Under these conditions, renal water loss decreases to compensate for the increased sweating and insensible water losses.[1]

Sodium Physiology

Sodium is the most abundant positive ion of the ECF and is crucial in determining the extracellular and intracellular osmolality. Serum osmolality is tightly regulated between 275 and 290 mOsm/kg, primarily through the influence of ADH, and is estimated by the following equation:

$$\text{Serum osmolality} = (2 \cdot \text{Na}) + (\text{glucose} \mid 18) + (\text{urea} \mid 2.8)$$

Osmoreceptors in the hypothalamus can detect changes of 1%. Most patients with hyponatremia have urine osmolality of more than 200 mOsm/kg, reflecting impairment in water excretion.[2] With regard to sodium physiology, the ratio of sodium between plasma and interstitial fluid is roughly 5:1 at equilibrium. The distribution equilibrium is usually complete within 15 to 20 minutes. Extracellular sodium balance is determined by sodium intake relative to sodium excretion. Most humans consume far more salt than they need. In normal, healthy individuals, the kidney's main function in sodium balance is excretion of excess sodium.

Sodium requirements vary with age. For infants born before 32 weeks' gestation, requirements are 3 mEq/kg/day, and at term, requirements are 2 to 3 mEq/kg/day (see Chapters 82 and 84).[3] Neonatal stool losses are about 1 mEq/kg/day, and the growth process uses 0.5 mEq/kg/day. Adult requirements decrease to about 1.5 mEq/kg/day. Urinary sodium excretion represents most of the sodium loss and approximately equals the daily intake of sodium. Extrarenal sodium loss by profuse sweating, burns, severe vomiting, or diarrhea is important.

Normally, 10 mL of urine can initially be formed for each 1 mOsm of solute excreted by the kidney. Normal kidneys respond to a free water challenge with diuresis and to a sodium load with natriuresis; if there is decreased sodium intake or volume depletion, the kidney responds with antinatriuresis and antidiuresis (e.g., a patient undergoing surgery may excrete only 1.2 to 1.6 mOsm/mL of solute). In various pathophysiologic processes, abnormally high or low urinary sodium excretion can occur.

Many of the factors that control tubular sodium reabsorption are affected during the perioperative period, including hemodynamic and physical factors (e.g., increased intra-abdominal pressure during laparoscopic procedures), hormonal factors, and renal sympathetic nerve activity. The balance of Starling forces (hydrostatic versus osmotic) is responsible for sodium and water transport across peritubular capillary walls. The net pressure in the peritubular capillaries is about 10 mm Hg in favor of uptake of reabsorbed fluid. Volume expansion with isotonic saline decreases plasma protein concentration and reduces colloidal osmotic pressure (COP) in peritubular capillaries.

The renin-angiotensin system (RAS) is involved in control of arterial blood pressure and blood volume along with the sympathetic nervous system, the kinin-kallikrein system, and arginine vasopressin. The RAS plays a role in sodium homeostasis and renal function, particularly under stress conditions. The RAS may be initiated by decreases in blood pressure in the renal artery, by decreases in sodium delivery to the macula densa, or by sympathetic nervous system activation. In response, renin is synthesized from its precursor, prorenin, and secreted by the juxtaglomerular cells of the kidney. Renin, an aspartyl-protease (similar to pepsin and cathepsin), cleaves its substrate, angiotensinogen, which is an α_2-globulin, to generate the decapeptide angiotensin I. Although renin is mostly produced by the kidney, renin isoenzymes have been found in many tissues, including brain, adrenals, vascular beds, uterus, and placenta.[4] The gene for human renin has been cloned. Angiotensinogen levels are increased after nephrectomy, by estrogens, by thyroid hormones, by glucocorticoids, and during angiotensin I–converting enzyme inhibition.[5,6]

Angiotensin I is rapidly converted to the octapeptide angiotensin II by angiotensin I–converting enzyme or by an endopepti-

Table 54-2 Daily Loss of Water

Source of Loss	Normal Activity and Temperature (mL)	Normal Activity High Temperature (mL)	Prolonged Exercise (mL)
Urine	1400	1200	500
Sweat	100	1400	5000
Feces	100	100	100
Insensible losses	700	600	1000
Total	***2300***	*3300*	***6600***

From Rhoades RA, Tanner GA: Medical Physiology. Boston, Little, Brown, 1995.

dase. The pulmonary circulation seems to be the major site of angiotensin-converting enzyme activity, although angiotensin-converting enzyme also is found in the vascular endothelium of the heart, kidney, adrenal cortex, testes, and brain.[7]

Angiotensin II is a potent vasopressor that stimulates aldosterone secretion through the adrenal cortex. Angiotensin II has a vagal inhibitory effect and causes ganglionic stimulation.[8-10] Angiotensin II partially suppresses renin secretion by a direct effect on the juxtaglomerular cells. Angiotensin II may stimulate a local increase of adenosine, a known inhibitor of renin release, and may participate in a negative feedback loop whereby angiotensin II limits its own biosynthesis.[11] Angiotensin II is degraded in the plasma to the carboxyl-terminal heptapeptide angiotensin III or the amino-terminal heptapeptide angiotensin (1-7), both of which seem to be biologically active.[12] A decline in arterial blood pressure, a decrease in sodium delivery to the macula densa, or sympathetic stimulation may activate the RAS, generating angiotensin II. This results in an increase in blood pressure and sodium retention caused by enhanced aldosterone secretion. The RAS does not have an active role in maintaining blood pressure in a normal, sodium-replete, intact individual. Hydrostatic forces act to maintain a stable glomerular filling pressure. This activity affects venous return, cardiac output, and blood pressure. Superimposed on this mechanism under stress conditions are various neurohumoral control systems, including the sympathetic nervous system, ADH, atrial natriuretic hormone, and prostaglandins (Table 54-3).

Nitroprusside-induced hypotension is associated with increases in renin activity and marked elevations in the plasma concentrations of ADH, which are not seen with the older agent trimethaphan used to induce blood pressure reductions.[13] Conversely, administration of the β-adrenergic blocker propranolol during nitroprusside-induced hypotension prevents increases in plasma renin activity.

Hyponatremia

Hyponatremia, typically defined as a plasma sodium concentration less than 135 mEq/L, can result from excessive loss of sodium from excessive sweating, vomiting, diarrhea, burns, and the administration of diuretics. The most common cause of hyponatremia is an excess of total-body water, not a deficiency of total-body sodium. Under normal conditions, water intake rarely exceeds the kidney's ability to excrete free water. Hyponatremia is usually associated with nonphysiologic vasopressin (i.e., ADH) release and impairment of the renal diluting capacity.

Table 54-3 Major Causes of Natriuresis and Antinatriuresis

Mechanism	Clinical Syndromes
Natriuresis	
Volume-expanded state	High sodium intake, inappropriate antidiuretic hormone secretion
Volume-depleted state	Addison's disease, renal salt wasting, diuretic excess/abuse
Antinatriuresis	
Edematous states	Heart failure, chronic liver disease, nephrotic syndrome, acute glomerulonephritis, idiopathic edema
Nonedematous states	Hemorrhage, low sodium intake, diuretic withdrawal, acute mineralocorticoid administration, nonrenal sodium loss by sweating or vomiting or both

Table 54-4 Causes of Hyponatremia as Related to Intravascular Volume Status

Hypovolemic	Hypervolemic	Euvolemic
Hemorrhage	Congestive heart failure	SIADH
Burn wound edema	Nephrotic syndrome	Pseudohyponatremia syndrome
Peritonitis	Cirrhosis	
Cerebral salt-wasting syndrome	TURP syndrome	

SIADH, syndrome of inappropriate secretion of antidiuretic hormone; TURP, transurethral resection of prostate.

Normal ADH secretion is mediated by an increase in plasma osmolality greater than 280 mOsm or a decrease in effective circulating volume. Other factors that result in release of ADH include pain, sympathetic stimulation, and nausea. After release, ADH binds to the V2 receptors in the medullary collecting ducts. ADH increases the water permeability of these segments by facilitating the fusion of water channels to the apical cell membrane.[14,15] When ascertaining the cause of hyponatremia, serum osmolality must be obtained to determine whether the hyponatremia reflects true hypotonicity; this gives insight into the underlying cause of low sodium levels. Hyponatremia can occur in patients who are hypotonic, normotonic, or hypertonic. Patients' intravascular volume status must be evaluated to understand further the underlying problem leading to abnormalities in sodium physiology (Table 54-4).

Factitious hyponatremia (normotonic hyponatremia) can be seen in hyperlipidemia (i.e., chylomicronemia) or hyperproteinemia. Hyperosmolality resulting from nonsodium molecules (e.g., hyperglycemia, mannitol overdose) draws water from the intracellular space to dilute the intravascular sodium concentration. Significant decreases in total-body sodium most commonly occur from diuretic administration.

Transurethral resection of prostate (TURP) syndrome is a recognized cause of hyponatremia (see Chapter 65). TURP syndrome is caused by intravascular absorption of irrigation solution, which typically contains glycine, but no other electrolytes.[16] The absorption of free water causes hyponatremia because of the dilution of serum sodium. TURP syndrome is a case of true hypotonic hyponatremia and is defined as a serum sodium level of less than or equal to 125 mmol/L with two or more associated clinical symptoms or signs, which can be masked under general anesthesia. A similar syndrome has been reported in 6% of women undergoing transcervical endometrial ablation and in patients undergoing neuroendoscopic ventriculostomy.[17]

The syndrome of inappropriate secretion of ADH (SIADH) is associated with numerous processes, including pulmonary and cranial disorders and several neoplasms, particularly oat cell carcinoma of the lung. Sympathetic activation (e.g., from postoperative pain) also can lead to significantly increased levels of ADH in the absence of volume constriction. SIADH may occur with administration of various drugs, including oral hypoglycemics, tricyclic antidepressants, and diuretics.[18] High levels of ADH are

secreted intermittently at an abnormally low threshold or continuously despite low osmolality. The presence of hyponatremia plus a urine osmolality higher than maximal dilution confirms the diagnosis. In patients with SIADH, the urinary sodium concentration usually exceeds 30 mEq/L, the fractional excretion of sodium is greater than 1%, and the serum uric acid is reduced. Patients with SIADH exhibit a characteristic response to water restriction; a 2- to 3-kg weight loss is accompanied by correction of hyponatremia and cessation of salt wasting over 2 to 3 days. This is another example of true hypotonic hyponatremia.

Hyponatremia also occurs in mixed disorders, in which nonosmotic ADH release and reductions in the rate of urinary sodium excretion blunt urinary diluting capacity. This can occur in advanced volume contraction, intractable heart failure, and advanced hepatic cirrhosis with ascites.

It is crucial for the anesthesiologist to recognize the signs and symptoms associated with hyponatremia, particularly for TURP syndrome managed with regional anesthesia. An awake patient permits detection of the signs of hyponatremia, including nausea, vomiting, visual disturbances, depressed level of consciousness, agitation, confusion, coma, seizures, muscle cramps, weakness, myoclonus, coma, and death. Cerebral edema occurs at or below a serum level of 123 mEq/L, and cardiac symptoms occur at 100 mEq/L. Hyponatremia associated with increased intravascular volume can result in pulmonary edema, hypertension, and heart failure.[19]

Initially, stopping the infusion of hypotonic glycine solution can resolve or at least improve the progression of hyponatremia. Because TURP syndrome is a case of water overload, the treatment should include water restriction. A loop diuretic may be added to facilitate free water excretion. Hypertonic saline should be used only in cases of severe hyponatremia with neurologic symptoms.[20]

In any patient whose hyponatremia warrants correction, the dose of sodium required to correct a deficit may be calculated using the following formula:

$$\text{Dose}\,[\text{mEq}] = \left(\text{weight}\,[\text{kg}] \times \left[140 - \left(\text{Na}^{+}\,[\text{mEq/L}]\right)\right]\right) \times 0.6$$

The optimal rate of correction seems to be 0.6 to 1 mmol/L/hr until the sodium concentration is 125 mEq/L; correction then proceeds at a slower rate. One half the deficit can be administered over the first 8 hours, and the next half can be administered over 1 to 3 days if symptoms remit. The appropriate treatment of hyponatremia, particularly in patients with neurologic symptoms, is, however, an area of controversy. Sodium concentration should be monitored every 1 to 2 hours during rapid correction.

Menstruant female patients are at greater risk for developing significant neurologic sequelae after hyponatremia. Ayus and colleagues[21] found that despite equal incidence of postoperative hyponatremia among men and women, 97% of patients with permanent brain damage were women, and 75% of those were of reproductive age. The mechanism of this gender difference is unknown; however, a potential explanation involves alterations in the brain's adaptive processes to hyponatremia. Estrogens seem to alter the function of Na^+/K^+-ATPase in the rat brain, which could alter the brain's compensatory mechanisms for hyponatremia.[22] Several agents that interfere with urine concentration at the collecting duct, including lithium and demeclocycline, have been used to manage chronic hyponatremia. ADH antagonists and the administration of urea as an osmotic diuretic are under investigation.

Table 54-5 Major Causes of Hyponatremia

Mechanism	Clinical Syndromes
Pseudohyponatremia (normal osmolality)	Hyperlipidemia, hyperproteinemia
Dilutional hyponatremia due to serum hyperosmolality	Hyperglycemia, mannitol administration
True hyponatremia with normal effective osmolality	γ-globulins, lithium, THAM
True hyponatremia with edema (sodium excess)—low effective osmolality	Congestive heart failure, nephrotic syndrome, cirrhosis of the liver, idiopathic edema, hypoalbuminemia (e.g., due to malnutrition)
True hyponatremia (sodium depletion)—low effective osmolality	Renal wasting (diuretics, renal tubular acidosis, cerebral salt-wasting syndrome); extrarenal wasting (vomiting, diarrhea, ostomy losses)
Hyponatremia with normal or expanded effective arterial volume	SIADH, water intoxication due to primary polydipsia, water overload due to advanced renal failure or vascular or inflammatory renal disease
Reduced sodium delivery to diluting segment	Starvation, myxedema (?)

SIADH, syndrome of inappropriate secretion of antidiuretic hormone; THAM, tris(hydroxymethyl)aminomethane.
Adapted from Oh M, Carrol H: Disorders of sodium metabolism: Hypernatremia and hyponatremia. Crit Care Med 20:94, 1992; and from Andreoli TE: Disorders of fluid volume, electrolyte, and acid-base balance. *In* Wyngaarden JB, Smith LH Jr (eds): Cecil Textbook of Medicine, 17th ed. Philadelphia, WB Saunders, 1985, p 525.

Rapid treatment of hyponatremia can lead to cerebral edema or central pontine myelinolysis. Management of hyponatremia involves elimination of the underlying condition when possible (e.g., stop TURP syndrome as soon as possible). The use of normal saline (308 mOsm/L) alone may worsen the hyponatremia, depending on the patient's serum and urine osmolality.[23] Severe coma or seizures can be managed with one or more approaches, including 3% hypertonic saline (513 mEq/L), fluid restriction, or furosemide.[24] The most likely cause of postoperative hyponatremia is SIADH (Table 54-5). SIADH and cerebral salt-wasting syndrome can best be differentiated by determination of total-body water by clinical measurements, including skin turgor, body weight, central venous pressure (CVP), and overall vital signs.

Hypernatremia

Hypernatremia is defined as an increase in extracellular sodium concentration, and may be accompanied by the presence of low, normal, or high total-body sodium content. The major causes of hypernatremia are excessive loss of water, inadequate intake of water, a lack of ADH, or excessive intake of sodium (e.g., with solutions containing a high sodium concentration, such as sodium bicarbonate or hypertonic saline).

Diabetes insipidus may result from a deficiency of ADH (vasopressin) or inability of the kidney to produce a hypertonic medullary interstitium. Diabetes insipidus is characterized by production of a large volume of dilute urine. Deficiency of vasopressin is known as central diabetes insipidus and is an endocrine disorder. Vasopressin deficiency is seen after pituitary surgery, basal skull fracture, and severe head injury. Conversely, nephrogenic diabetes insipidus results if the kidney cannot produce a hypertonic medullary interstitium and is unable to concentrate urine. Nephrogenic diabetes insipidus is defined as renal tubule cell insensitivity to the effects of vasopressin. Nephrogenic diabetes insipidus can result from any systemic or kidney disease that impairs tubular function. In central or nephrogenic diabetes insipidus, the patient loses a significant amount of body water in a short period, which can cause profound hypovolemia if the patient does not have adequate access to water.

Approximately 50% of patients with central diabetes insipidus are classified as having idiopathic disease. This condition is thought to be caused by an autoimmune process affecting the response of the hypothalamus to hypertonicity. Patients with nephrogenic diabetes insipidus have marked increases in the plasma levels of vasopressin because of significant hyperosmolality of the plasma. Renal tubular cells can become poorly responsive to the effects of vasopressin for a variety of reasons. Various insults to the collecting system, such as after ureteral obstruction or medullary cystic disease, lead to decreased sensitivity to vasopressin. Many pharmacologic agents impair the ability of vasopressin to affect tubular water transport and result in nephrogenic diabetes insipidus (Table 54-6).

Patients with continued urine output of more than 100 mL/hr who develop hypernatremia should be evaluated for diabetes insipidus by determining the osmolalities of urine and serum. If the urine osmolality is less than 300 mOsm/L, and serum sodium exceeds 150 mEq/L, the diagnosis of diabetes insipidus is likely. In patients with central diabetes insipidus, 1-deamino-8-D-arginine vasopressin (DDAVP), a vasopressin analog also known as desmopressin acetate, may be administered to correct the deficiency in vasopressin. The underlying cause of nephrogenic diabetes insipidus should be sought and treated if possible.

In the presence of an intact thirst mechanism, a slight increase in serum sodium concentration (e.g., 3 to 4 mmol/L) above baseline values elicits intense thirst. The lack of thirst in the presence of hypernatremia in a mentally alert patient indicates a defect in the osmoreceptor or in the cortical thirst center. The most common objective sign of hypernatremia is lethargy or mental status changes, which can proceed to coma and convulsions. Additional signs and symptoms of hypernatremia include thirst, shock, peripheral edema, myoclonus, ascites, muscular tremor, muscular rigidity, hyperactive reflexes, pleural effusion, and expanded intravascular fluid volume. With acute and severe hypernatremia, the osmotic shift of water from the cells can lead to shrinkage of the brain with tearing of the meningeal vessels and intracranial hemorrhage. Slowly developing hypernatremia is usually well tolerated because of the brain's ability to regulate its volume. Treatment involves restoring normal osmolality and volume and includes removal of excess sodium by the administration of diuretics and hypotonic crystalloid solutions. The speed of correction depends on the rate of development of hypernatremia and associated symptoms. Because chronic hypernatremia is well tolerated, rapid correction offers no advantage and may be extremely harmful or lethal because it may result in brain edema.[25,26] Typically, a maximum of 10% of the serum sodium concentration, or about 0.7 mmol/L/hr, should be the goal rate of correction. Hypernatremia increases the minimum alveolar concentration of inhaled anesthetic agents, possibly because of enhanced sodium conductance during depolarization of excitatory membranes (Table 54-7).

Table 54-6 Drugs Causing Nephrogenic Diabetes Insipidus

Lithium
Foscarnet
Glyburide
Demeclocycline
Methoxyflurane
Amphotericin B

Table 54-7 Major Causes of Hypernatremia

Mechanism	Clinical Syndrome(s)
Impaired thirst	Stupor/coma, essential hypernatremia
Solute (osmotic) diuresis	Diabetic ketoacidosis, hyperglycemic nonketotic coma, mannitol administration
Excessive water losses	
Renal	Pituitary diabetes insipidus, nephrogenic diabetes insipidus
Extrarenal	Sweating
Combined	Stupor/coma *plus* hypertonic enteric feeding

Note: Hyperglycemia or mannitol administration also can result in hyponatremia. Sweating also can result in hyponatremia.

Potassium Physiology

Potassium is the most abundant positive ion in the intracellular fluid, and nearly 98% of total-body potassium is intracellular. In the short-term (minutes), potassium balance is influenced by insulin, pH, β-adrenergic agonists, and bicarbonate concentration. Long-term regulation of potassium excretion and balance primarily involves the kidney and aldosterone. Potassium concentration to average 0.4 to 0.5 mEq/L lower when measured on heparinized arterial samples compared with clotted venous samples is due to several factors, including extrusion of potassium from erythrocytes during the clotting process.

Increases in potassium intake increase renal excretion of potassium through various cellular mechanisms. In response to increases in extracellular potassium levels, aldosterone is secreted from the zona glomerulosa of the adrenal gland and acts on cortical collecting ducts to increase potassium secretion into the tubular fluid and increase potassium excretion.

Many of the effects seen during alterations in normal potassium levels result from potassium's importance in the membrane potential of cells. Potassium is the principal intracellular cation, with more than 98% of the body's potassium found within the intracellular water. In the resting state, cell membrane conductance is higher for potassium than for sodium. This increased

conductance leads to transmembrane potential being closer to the transmembrane value of potassium (−90 mV). Alterations in extracellular potassium concentration alter the resting membrane potential, which may cause the cell to be unresponsive or overresponsive to sodium shifts into the cell. High or low potassium levels can result in potentially lethal problems in excitatory tissue, particularly cardiac tissue.

Multiple factors regulate the normal maintenance of the transmembrane potassium gradient. The most important transcellular enzyme involved in potassium regulation is Na^+/K^+-ATPase, which maintains the transcellular gradient. β_2-Adrenergic drugs increase the activity of Na^+/K^+-ATPase by binding to cell surface receptors, linking potassium transport to the sympathetic nervous system. Insulin causes more sodium to enter the cell through an Na^+/H^+-antiporter, which decreases intracellular proton concentration. To maintain electric neutrality, any increase in sodium must occur via exchange for potassium, decreasing extracellular potassium. Shock can have an adverse impact on the activity of Na^+/K^+-ATPase by limiting the amount of adenosine triphosphate (ATP) available for ion transport because of the shift to anaerobic metabolism.[27] Potassium transport is affected by pH. The body uses potassium to decrease excess extracellular hydrogen ions by moving potassium out of cells and hydrogen ions into cells. Acidemia potentiates hyperkalemia by moving potassium out of cells.

Potassium requirements vary with age and growth. A typical term infant requires 2 to 3 mEq/kg/day,[28] whereas adults use 1 to 1.5 mEq/kg/day (see Chapters 82 and 84). Potassium demands are related to metabolic rate (2 mEq/100 kcal). In this regard, the requirement increases dramatically during cell growth after establishment of nutrition in previously starved individuals. An extremely high or low level of potassium is life-threatening.

Hypokalemia

Hypokalemia (<3.5 mEq/L) may occur because of an absolute deficiency or redistribution into the intracellular space. A reduction in serum potassium of 1 mEq/L indicates a net loss of 100 to 200 mEq of potassium in a normal adult. Hypokalemia in the range of 2 to 2.5 mEq/L is likely to cause muscular weakness, arrhythmias, and electrocardiographic abnormalities, including sagging of the ST segment, depression of the T wave, and U wave elevation. These electrocardiographic changes do not correlate with the severity of potassium depletion. Cardiac dysrhythmias are more predictable, however, and most frequently involve atrial fibrillation and premature ventricular systoles.

The four most common causes of hypokalemia are reduced intake, gastrointestinal losses, excessive renal losses of potassium (e.g., with excess of mineralocorticoids or diuretics), and potassium shifts from the ECF to the intracellular fluid (e.g., owing to insulin administration). Such shifts can occur with acute alkalosis, insulin therapy, stress-related catecholamine activity, and hypokalemic periodic paralysis. Surgical stress may reduce the serum potassium concentration by 0.5 mEq/L. The administration of exogenous catecholamines, such as isoproterenol, terbutaline, epinephrine, and ritodrine, also decreases potassium levels[29,30]; clinically, this includes pregnant patients receiving tocolytic therapy or respiratory treatment with β_2-agonists and critically ill patients requiring pharmacologic cardiovascular support (see Chapters 69 and 92).

No studies show increased morbidity or mortality for patients undergoing anesthesia with a potassium level of at least 2.6 mEq/L. Anesthesiologists commonly administer supplemental potassium chloride, but studies show that in many instances therapy is ineffective, with most of the supplemental potassium being excreted in the urine despite continued hypokalemia.[31,32] If perioperative therapy is indicated, intravenous potassium chloride should be used. Because the rate of administration of potassium must be adjusted for the rate of distribution through the extracellular space before entry into the intracellular space, the rate of potassium administration is typically limited to approximately 0.5 mEq/kg/hr. The typical replacement rate is 10 to 20 mEq/hr for a normal adult with constant monitoring of the electrocardiogram.[33,34] Clinical anesthesiologists should be aware that safe administration of potassium is enhanced by the use of continuous electrocardiogram monitoring, bedside potassium measurement, and delivery with an infusion pump (Table 54-8).

Hyperkalemia

Hyperkalemia (>5.5 mEq/L) can occur in various disease states, in response to drugs that diminish renal potassium excretion (Table 54-9), or after sudden transcellular shifts of potassium from the intracellular fluid to the ECF. Potentially lethal hyperkalemia during anesthesia may occur with reperfusion of a large vascular bed after a period of ischemia (usually >4 hours). Ischemia results in significant acidosis in the affected area, which causes an outflow of intracellular potassium. When the area is reperfused, the body receives a large bolus of potassium that cannot be redistributed rapidly enough, resulting in potentially fatal hyperkalemia. Any condition or drug resulting in adrenal inhibition or decreasing aldosterone levels can cause potassium retention. Factitious (e.g., spurious) hyperkalemia also should be considered in the differential diagnosis and occurs in response to lysis of the cellular components of blood.

Table 54-8 Major Causes of Hypokalemia

Mechanism	Clinical Syndromes
Inadequate intake	Anorexia nervosa, starvation, alcoholism, mineralocorticoid excess (primary and secondary hyperaldosteronism)
Excess renal loss	Bartter's syndrome; diuresis (diuretics with a pre-late distal locus osmotic diuresis, chronic metabolic alkalosis); impermeant anion antibiotics (carbenicillin, penicillin, nafcillin, ticarcillin); renal tubular acidosis; hypomagnesemia; myelomonocytic leukemia
Gastrointestinal losses	Vomiting; diarrhea, particularly secretory diarrheas; villous adenoma
Shifts of extracellular fluid to intracellular fluid with altered internal potassium balance	β_2-agonists, acute alkalosis, hypokalemic periodic paralysis, insulin therapy, vitamin B_{12} therapy, lithium overdose

Adapted from Andreoli TE: Disorders of fluid volume, electrolyte, and acid-base balance. *In* Wyngaarden JB, Smith LH Jr (eds): Cecil Textbook of Medicine, 17th ed. Philadelphia, WB Saunders, 1985, p 532.

Hyperkalemia can be separated into acute and chronic processes. Acute hyperkalemia can occur in various circumstances and usually is more poorly tolerated than chronic hyperkalemia. The most common cause of chronic hyperkalemia occurring with anesthesia is renal failure. A patient undergoing anesthesia with even moderately elevated potassium concentration (>5.5 mEq/L) should have continuous electrocardiographic monitoring to help determine the severity of hyperkalemia.

Clinically, hyperkalemia can cause muscle weakness and paralysis. Alterations in cardiac conduction increase automaticity and enhance repolarization. Mild elevations in potassium levels (6 to 7 mEq/L) may manifest with peaked T waves; as levels approach 10 to 12 mEq/L, a prolonged P–R interval, widening of the QRS complex, ventricular fibrillation, or asystole can occur.

Conceptually, treatments are divided into (1) physiologic antagonists (calcium); (2) agents to shift potassium into cells (glucose, insulin, hyperventilation, bicarbonate, and β-adrenergic agonists); and (3) drugs and treatments to eliminate potassium from the body (sodium polystyrene sulfonate [Kayexalate], diuretics, aldosterone agonists, dialysis). Clinical treatment of hyperkalemia is determined by the setting and presence of electrocardiographic changes; it involves first stabilization of the heart from effects of the potassium with intravenous calcium (500 mg of calcium chloride or 1 g of calcium gluconate in an adult) and redistribution of potassium from the plasma into cells. As stated earlier, in addition to intravenous calcium, intravenous glucose, insulin, and bicarbonate (1 mEq/kg) and hyperventilation are the major therapies used in the operating room. Intravenous regular insulin, 5 to 10 U, administered with dextrose at a dose of 25 to 50 g (i.e., one to two 50-mL ampules of 50% dextrose solution), reduces serum potassium levels within 10 to 20 minutes, and the effects last 4 to 6 hours.[35] Resin exchange, dialysis, diuretics (e.g., furosemide, 20-40 mg intravenously), aldosterone agonists (e.g., fludrocortisone), and inhaled or intravenous β-adrenergic agonists are established additional therapies (Table 54-10).

Calcium Physiology

Calcium is the key component that mediates muscle contraction; exocrine, endocrine, and neurocrine secretion; cell growth; and the transport and secretion of fluids and electrolytes. A 70-kg adult contains approximately 1300 g of calcium, 99% of which is in the bones and teeth. The kidneys are the major organ responsible for regulating calcium between 4.5 and 5 mEq/L (8.5 to 10.5 mg/dL). Calcium is abundant in milk and milk products, is poorly absorbed by the intestine, and is excreted primarily in the feces and urine. Circulating calcium exists in three forms: bound to plasma proteins (primarily albumin) and not filtered by glomerular capillaries (40% to 50%); ionized, physiologically active, filtered at the glomerular membrane, and maintained at a concentration of 2 to 2.5 mEq/L (50%); and nonionized and chelated with phosphate, sulfate, and citrate (10%). Because changes in pH alter the fraction of calcium that is bound to albumin, the level of ionized calcium can change without alteration of total calcium. Total calcium varies with protein-binding capacity and results, under hyperaluminemia, in pseudohypercalcemia (most commonly associated with dehydration and multiple myeloma). Most filtered calcium is reabsorbed in the proximal tubule, the thick ascending limb of the loop of Henle, and the distal tubule.

Because of the importance of calcium in virtually all cellular functions, its intracellular and extracellular concentrations are tightly controlled. Energy is expended to pump intracellular calcium out of the cytosol into the sarcoplasmic reticulum or ECF. As with potassium, during shock and depletion of intracellular energy, calcium accumulates within cells and can facilitate cell death.

The concentration of serum proteins is an important determinant of calcium ion concentration. Ionized calcium can be measured directly with the use of calcium-specific electrodes. When ionized calcium cannot be measured, the approximate amount of calcium bound to protein is given by the following equation:

$$\text{Protein-bound calcium (\%)} = -0.8 \times \text{albumin}\,(\text{g/L}) + 0.2 \times \text{globulin}\,(\text{g/L}) + 3$$

Alternatively, a correction of 0.8 mg/dL is added to the serum calcium for every 1 g/dL that serum albumin is less than 4 g/dL.[36] If the serum calcium is 7.8 mg/dL (a subnormal value), and the serum albumin is only 3 mg/dL, the stated serum calcium is corrected by adding 0.8 mg/dL; the corrected value of 8.6 mg/dL is within the normal range. One advance in the management of perioperative calcium includes the ease of bedside serum ionized calcium measurement.

Within minutes of a slight decrease in extracellular calcium concentration, the parathyroid glands release parathy-

Table 54-10 Major Causes of Hyperkalemia

Mechanism	Clinical Syndromes
Pseudohyperkalemia	Sample lysis, technical problems
Altered internal potassium balance	Acidosis; insulin deficiency; hypoaldosteronism; malignant hyperthermia; periodic paralysis; cell necrosis; drugs (succinylcholine, digitalis, nonselective β-blockers)
Altered external potassium balance	Increased uptake by replacement therapy; transfusions; antibiotics containing potassium salts; decreased excretion by renal disease; hypoaldosteronism; drugs (heparin, amiloride, triamterene, spironolactone, nonsteroidal drugs, angiotensin-converting enzyme inhibitors, angiotensin-receptor antagonists)

Adapted from Solomon RJ, Katz JD: Disorders of potassium homeostasis. *In* Stoelting RK (ed): Advances in Anesthesia. Chicago, Year Book Medical Publishers, 1986.

roid hormone, which increases calcium reabsorption in the thick ascending limb and distal tubule, decreasing calcium excretion. Excision of the parathyroid glands eliminates parathyroid hormone secretion, which can significantly disrupt calcium homeostasis.

Calcitonin, produced in the thyroid gland, decreases renal reabsorption of calcium acutely, but has little effect on long-term calcium homeostasis. Surgical removal of the thyroid gland eliminates calcitonin without changing extracellular calcium ion concentration.

Bone acts as the body's major reservoir of calcium. When the parathyroid gland releases parathyroid hormone in response to decreased calcium levels, bone reabsorption is favored, and calcium is released. Vitamin D increases absorption of calcium from the gastrointestinal tract, and its action is potentiated by parathyroid hormone.

Hypercalcemia

Hypercalcemia is associated with many disease processes and has many signs and symptoms. Mild to moderate hypercalcemia (11 to 14 mg/100 mL) often has no symptoms, but when levels reach 15 mg/100 mL, clinical changes become more common. Hypercalcemia produces changes primarily in the central nervous system (e.g., mental status changes), the gastrointestinal tract (e.g., vomiting), the kidneys (e.g., polyuria, renal calculi, oliguric renal failure), and the heart (e.g., cardiac conduction disturbances). Today, hypercalcemia is most commonly diagnosed in asymptomatic patients, whereas clinical features previously were the earliest manifestations. Potential causes of hypercalcemia include thiazide diuretic therapy, malignancy (now known as humoral hypercalcemia of malignancy), granulomatous disease (related to increased intestinal absorption of calcium induced by elevated calcitriol levels), vitamin D intoxication, or parathyroid hormone adenoma. Additional causes of hypercalcemia include lithium therapy, thyrotoxicosis, pheochromocytoma, immobilization, vitamin A intoxication, renal failure, and theophylline therapy.

Treatment of hypercalcemia essentially involves diuresis and administration of normal saline to dilute plasma calcium. These primary treatments also are useful because sodium inhibits the renal reabsorption of calcium. Additional therapies include bisphosphonates (pamidronate is the most commonly used), calcitonin, ambulation, hemodialysis, and treatment of the underlying condition. Certain conditions, including numerous cancer-related hypercalcemias, can be treated with calcium-lowering agents, such as mithramycin and glucocorticoids. The anesthetic management of a patient with hypercalcemia should involve avoidance of thiazide diuretics and maintenance of hydration and urine output with sodium-containing fluids. Monitoring the patient by means of electrocardiograms is useful to detect cardiac conduction abnormalities with shortened P–R or Q–T interval, with or without widening of the QRS complex. Patients who have muscle weakness should receive decreased doses of nondepolarizing muscle relaxants (Table 54-11).

Table 54-11 Major Causes of Hypercalcemia

Mechanism	Clinical Syndromes
Increased parathyroid hormone	Primary hyperparathyroidism (solitary or multiple adenoma, multiple endocrine neoplasia syndrome), lithium therapy, familial hypocalciuric hypercalcemia
Vitamin D related	Vitamin D intoxication; idiopathic hypercalcemia of infancy; increase in 1,25-dihydroxyvitamin D; sarcoidosis and other granulomatous diseases
Associated with high bone turnover	Hyperthyroidism, immobilization, thiazides, vitamin A intoxication
Malignancy related, including associated with renal failure	Solid tumors with metastases, solid tumors with humoral mediators of hypercalcemia, hematologic malignancies, severe secondary hyperparathyroidism (from chronic renal failure), aluminum intoxication, milk-alkali syndrome

Adapted from Potts JT: Diseases of the parathyroid gland and other hyper- and hypocalcemic disorders. *In* Isselbacher KJ, Braunwald E, Wilson JD, et al (eds): Harrison's Principles of Internal Medicine, 13th ed. New York, McGraw-Hill, 1995, p 2151.

Hypocalcemia

In the operating room, ionized hypocalcemia is most commonly caused by acute hyperventilation or the infusion of citrated blood greater than 1.5 mL/kg/min (see Chapter 55). The most common cause of hypocalcemia (plasma concentration <4.5 mEq/L) in hospitalized patients is a low albumin level, such as in critically ill patients with severe sepsis, burns, or acute renal failure, and in patients after extensive transfusions. Critically ill patients can have low plasma albumin and low plasma calcium levels with normal ionized calcium levels. There is no reason to correct the calcium deficiency, but overall nutrition should be improved. The major signs and symptoms of hypocalcemia include mental status changes, tetany, positive Chvostek and Trousseau signs, laryngospasm, hypotension, and dysrhythmias. Electrocardiographic evaluation may show prolongation of the Q–T interval or heart block in severe cases. Treatment, often prompted by hypotension, involves intravenous infusion of 10% calcium chloride (1.36 mEq/mL) or calcium gluconate (0.45 mEq/mL). When equivalent calcium doses are administered, both preparations are equally efficacious in restoring the calcium level to normal (Table 54-12). In this regard, calcium gluconate is especially advantageous in peripheral venous administration because extravasated calcium chloride solution can result in severe tissue destruction.

When hypocalcemia is caused by large-volume infusion of isotonic saline (as seen during resuscitation in shock), it may be accompanied by hypomagnesemia. Hypomagnesemia may impair the actions of vitamin D and delay correction of postresuscitation hypocalcemia. The magnesium level should be checked and corrected if necessary. In this regard, fluid resuscitation involving certain colloids can contribute to a hypocalcemic state.[37]

Magnesium Physiology

Magnesium sulfate has been used for many years on an empirical basis to control convulsions in patients with preeclamptic toxemia. Magnesium ions are essential for many biochemical reactions, and a deficiency may produce clinically important consequences. Many of the pharmacologic properties have only more recently been appreciated. Magnesium is excreted through the gastrointestinal tract and kidneys.

Table 54-12 Major Causes of Hypocalcemia Excluding Neonatal Conditions

Mechanism	Clinical Syndromes
Parathyroid hormone absent	Hereditary hypoparathyroidism, acquired hypoparathyroidism, hypomagnesemia
Parathyroid hormone ineffective	Lack of active vitamin D (decrease in intake or lack of sunlight), defective metabolism from anticonvulsant therapy, vitamin D–dependent rickets type I
Pseudohyperparathyroidism	Ineffective vitamin D (intestinal malabsorption), vitamin D–dependent rickets type II
Parathyroid hormone overwhelmed	Severe, acute hyperphosphatemia; tumor lysis; acute renal failure; rhabdomyolysis; osteitis fibrosa after parathyroidectomy

Adapted from Potts JT: Diseases of the parathyroid gland and other hyper- and hypocalcemic disorders. *In* Isselbacher KJ, Braunwald E, Wilson JD, et al (eds): Harrison's Principles of Internal Medicine, 13th ed. New York, McGraw-Hill, 1995, p 2165.

Total-body magnesium is approximately 2000 mEq. Magnesium is the fourth most prevalent cation in the body and activates approximately 300 enzyme systems, including many involved in energy metabolism.[40] It is essential for the production and functioning of ATP, which is fully functional only when chelated to magnesium. Other processes dependent on magnesium include the production of DNA, RNA, and protein synthesis.[40]

Magnesium is an essential regulator of calcium access into the cell and of the actions of calcium within the cell. Magnesium plays an essential role in the regulation of most cellular functions and may be regarded as a natural physiologic calcium antagonist.[40]

Hypomagnesemia

With an absence of magnesium in the diet, the kidneys are able to decrease excretion significantly; however, hypomagnesemia is common in hospitalized patients, especially patients in critical care areas, and it manifests with signs and symptoms similar to hypocalcemia. Slight hypomagnesemia occurs in athletes, in hypermetabolic states such as pregnancy, and during cold acclimatization. Magnesium stores can become depleted in patients undergoing prolonged diuretic therapy or patients with chronic diarrhea. Chronic alchohol ingestion leads to significant loss of magnesium, and most hospitalized alcoholics have low magnesium levels. Magnesium deficiency alone or in combination with diuretic-induced hypokalemia and digitalis-induced arrhythmia responds to magnesium therapy.[38]

Anesthetizing patients with magnesium deficiency is likely to increase the risk of perioperative arrhythmias. Respiratory muscle power is impaired by hypomagnesemia, which may have important clinical consequences for anesthesia and critical care. Additional manifestations include central nervous system irritability with seizures and hyperreflexia (e.g., Chvostek sign) and skeletal muscle spasm (e.g., Trousseau sign). Treatment in a 70-kg adult with normal renal function in whom intravenous therapy is warranted includes magnesium sulfate 1 to 2 g (8 to 16 mEq) over 15 minutes followed by 1 g/hr until serial serum magnesium levels indicate the deficiency has been corrected.[39] For acute arrhythmias, magnesium sulfate can be administrated in a dose of 1 to 2 g over approximately 5 minutes intravenously with close monitoring of blood pressure and heart rate. Arterial pressure, deep tendon reflexes, and magnesium concentration may aid the clinical anesthesiologist when overtreatment is suspected. In asymptomatic patients with mild hypomagnesemia, oral replacement is preferred. Beyond the theoretical risks of magnesium deficiency and neuromuscular blockade, the clinical importance of hypomagnesemia is related to the conditions and pathophysiologic processes associated with management of these conditions (Table 54-13).

Hypermagnesemia

Hypermagnesemia (>2.5 mEq/L) occurs most commonly from iatrogenic causes and excessive use of magnesium-containing antacids or laxatives. It is rare in clinical medicine because magnesium is relatively poorly absorbed from the gastrointestinal tract, and renal elimination of excess magnesium is extremely rapid (within 4 to 8 hours of a magnesium load). Because elimination is directly related to the glomerular filtration rate, patients with kidney failure are at increased risk of developing hypermagnesemia. Signs and symptoms are directly related to the blood level and include alterations in the nervous, cardiovascular, respiratory, and genitourinary systems.

Magnesium depresses the central nervous system. In the early 1900s, it was used effectively as a general anesthetic. Magnesium penetrates the blood-brain barrier poorly, however, and its level in the cerebrospinal fluid is well controlled by an active transport mechanism.[40]

In the peripheral nervous system, magnesium interferes with the release of neurotransmitters at all synaptic junctions and potentiates the action of local anesthetics.[40] At the neuromuscular junction, magnesium concentrations of 5 mmol/L cause signifi-

Table 54-13 Major Causes of Hypomagnesemia

Mechanism	Clinical Syndromes
Primary nutritional disturbances	Inadequate intake, total parenteral nutrition, refeeding syndrome
Gastrointestinal disorders	Specific absorptive defects, malabsorption syndromes, prolonged diarrhea, prolonged nasogastric suction, pancreatitis
Endocrine disorders	Hyperparathyroidism, hypoparathyroidism, hyperthyroidism, primary hyperaldosteronism, Bartter's syndrome, diabetic or alcoholic ketoacidosis, administration of epinephrine, SIADH, hungry bone syndrome after parathyroidectomy
Chronic alcoholism, alcoholic withdrawal, increased renal excretion	Ethanol ingestion; idiopathic; after renal transplantation; drugs (cisplatin, aminoglycoside, amphotericin B, diuretics, pentamidine, theophylline); recovery phase of acute tubular necrosis; colony-stimulating factor therapy

SIADH, syndrome of inappropriate secretion of antidiuretic hormone.
Adapted from Potts JT: Diseases of the parathyroid gland and other hyper- and hypocalcemic disorders. *In* Isselbacher KJ, Braunwald E, Wilson JD, et al (eds): Harrison's Principles of Internal Medicine, 13th ed. New York, McGraw-Hill, 1995, p 2188.

cant presynaptic neuromuscular blockade and enhance the action of the nondepolarizing muscle relaxants.[40] It can precipitate severe muscle weakness in patients with Eaton-Lambert syndrome, patients with myasthenia gravis, or patients pretreated with a small dose of a defasciculating agent.[40] Magnesium prolongs the action of depolarizing neuromuscular blocker drugs (e.g., succinylcholine); administration before the use of succinylcholine prevents the release of potassium provoked by the neuromuscular blocking drug (see Chapter 29).

In the cardiovascular system, magnesium produces vasodilation by direct action on blood vessels and by interfering with a wide range of vasoconstrictor substances. It also reduces peripheral vascular tone by sympathetic blockade and inhibition of catecholamine release.[40] In the isolated heart, increased concentrations of extracellular magnesium ion markedly depress contractile force. Decreased myocardial performance has been shown after a bolus of 2.5 g of magnesium sulfate. Severe myocardial depression can occur with combinations of magnesium and diltiazem. In the isolated heart, magnesium produces bradycardia, but in an intact subject, the inhibition of vagal acetylcholine release produced by magnesium overrides the intrinsic slowing, and a mild tachycardia occurs. Magnesium is effective in treating various arrhythmias, including ventricular arrhythmias, torsades de pointes, arrhythmias associated with epinephrine administration, and digitalis-associated arrhythmias. It also is efficacious in certain arrhythmias induced by hypokalemia, alcoholism, and myocardial infarction, and may offer partial protection against bupivacaine-induced arrhythmias.

In the respiratory system, magnesium has no effect on central respiratory drive, and its only respiratory depressant effect is caused by the neuromuscular blockade that it produces. It is an effective bronchodilator and has been used successfully in severe acute asthma, although no study to date has shown benefit in chronic asthma.

In obstetric practice, magnesium, at supraphysiologic concentrations, is a powerful tocolytic and has been used for many years in the management of premature labor. Magnesium also is used in obstetrics to prevent patients with preeclampsia from developing seizures. Animal studies have shown that magnesium suppresses electroencephalographic spike activity (see Chapter 69). Therapeutic magnesium levels are 5 to 7 mg/dL when administered for preeclampsia. When levels exceed 15 to 20 mg/dL, respiratory depression can become profound. In the kidney, magnesium is a renal vasodilator and a diuretic.

Symptoms and electrocardiographic changes of hypermagnesemia correspond to serum levels. Depressed cardiac conduction, widened QRS complexes, prolonged P–R intervals, and nausea appear with levels of 5 to 10 mg/dL. Sedation, hypoventilation, decreased deep tendon reflexes, and muscle weakness appear with levels of 20 to 34 mg/dL, with hypotension, bradycardia, and diffuse vasodilation occurring at levels of 24 to 48 mg/dL. Areflexia, coma, and respiratory paralysis occur at 48 to 72 mg/dL. For these reasons, all patients being treated with magnesium therapy are clinically observed for magnesium intoxication.

Elimination of magnesium involves fluid loading followed by or with concomitant diuresis. Definitive therapy involves dialysis. Temporary reversal of the effects of magnesium can be managed with calcium therapy. Because hypermagnesemia potentiates the effects of depolarizing and nondepolarizing muscle relaxants, these agents must be carefully titrated in conjunction with appropriate assessment of neuromuscular blockade.

The deleterious effects of magnesium deficiency are well recognized, and most critical care units monitor magnesium levels. In coronary care units, several studies have shown that the infusion of magnesium sulfate can reduce the incidence and severity of cardiac arrhythmias associated with myocardial infarction. Numerous reports in the literature describe the bronchodilator effect of magnesium and its successful use in the management of asthma. Magnesium may decrease the incidence of adrenergically mediated arrhythmias without interfering with the bronchodilating action of β-stimulants and contribute to smooth muscle relaxation of bronchioles.[40]

Magnesium has several important pharmacologic actions. Its route of elimination is renal, and any patient who is oliguric or in a reduced urine output state requires downward dosing adjustment of magnesium therapy. Magnesium should be regarded as a cardiovascular drug, first and foremost, with calcium antagonistic and antiadrenergic properties that may be accompanied by minimal myocardial depression.[40]

Phosphate Physiology

Phosphate is the most abundant intracellular anion, and is essential for membrane structure, cellular energy, and cell transport. Specifically, phosphate is required to produce ATP, DNA, RNA, and 2,3-diphosphoglycerate, which facilitates oxygen release from hemoglobin. About 1 g of phosphorus is ingested daily. Intake generally exceeds metabolic requirements. Approximately 70% (700 mg) is absorbed primarily from the small intestine, with the rest (300 mg) eliminated in the feces. In addition to 1,25-dihydroxyvitamin D_3 (vitamin D), parathyroid hormone facilitates absorption of phosphate from the gut lumen. The gut secretes phosphate into the lumen and then reabsorbs it, unless it is bound there by calcium or antacids or is lost by diarrhea or drainage through ostomies or fistulas. Under normal dietary conditions, absorption of phosphate occurs through paracellular diffusive pathways with little regulation. When luminal phosphate concentrations are low, an active sodium-dependent transport mechanism is activated, and additional phosphate is absorbed.[41] When dietary intake is normal, phosphate absorption is essentially an unregulated process. Cations such as calcium, magnesium, and aluminum decrease phosphate absorption, however, by directly binding with phosphate in the gut lumen. This is useful clinically in renal failure to limit the amount of phosphate reabsorbed by the gut. Because of the unregulated nature of phosphate absorption in the gut, the kidneys become the primary organ of excretion of excess phosphate. The kidneys normally excrete 700 mg/day by filtering 6 g and reabsorbing 5.3 g. Urinary phosphate elimination approximately equals intestinal absorption.

As mentioned, phosphate stores and releases energy through high-energy phosphate bonds and is integral to the structure of proteins, lipids, and bone (hydroxyapatite). Bone functions as the primary reservoir of phosphate and calcium in the body. When the body requires extra calcium, bone is broken down to release calcium for the body's use. In addition to calcium, significant amounts of phosphate also are liberated. This balance is controlled by the regulatory processes discussed in the previous section.

Factors favoring cellular uptake include ingestion of glucose or fructose, alkalosis, insulin level, β-adrenergic stimulation, and anabolism. Phosphate occurs in organic or inorganic forms. Most

intracellular phosphate is organic. Plasma contains lipid phosphates, organic ester phosphates, and inorganic phosphates, including divalent (HPO_4^{2-}) and monovalent ($H_2PO_4^-$) phosphate. At physiologic pH, 80% of the inorganic phosphate is divalent. Normally, plasma inorganic phosphate is maintained at 3 to 4.5 mg/100 mL in adults and 4 to 5 mg/100 mL in children. Parathyroid hormone inhibits proximal tubular inorganic phosphate reabsorption and increases inorganic phosphate excretion. In animals that are thyroparathyroidectomized, parathyroid hormone is absent, and reabsorption of inorganic phosphate increases significantly and ultimately increases plasma inorganic phosphate levels. In patients with primary hyperparathyroidism, parathyroid hormone secretion is elevated, and plasma levels of inorganic phosphate are low; however, steady-state urinary inorganic phosphate excretion is not markedly increased because it depends largely on intestinal inorganic phosphate absorption. Dietary restriction of inorganic phosphate leads to almost 100% reabsorption of filtered inorganic phosphate and to reduction of urinary phosphate to zero.[42]

Hyperphosphatemia

Severe hyperphosphatemia occurs after tissue damage or cell death. Moderate to severe hyperphosphatemia may be caused by an impaired ability to excrete phosphorus because of renal failure. As renal failure worsens, and the glomerular filtration rate declines to less than 25 mL/min, hyperphosphatemia may develop. Other causes include iatrogenic, hypothermia, massive liver failure, and certain hematologic malignancies associated with high cell turnover. The increased cell turnover can be part of the malignancy or may result from cell destruction when chemotherapy is instituted.

Hypoparathyroidism can cause hyperphosphatemia in the presence of normal renal function. Rapid increases in serum phosphate can lead to development of severe hypocalcemia. Hypocalcemia results from decreased calcitriol production, which causes significant decline in gastrointestinal tract absorption of calcium. There may be frank precipitation of calcium and phosphate, decreasing serum calcium levels further. When the calcium-phosphorus product exceeds 70 mg^2/dL^2, the risk of abnormal calcification is increased. An elevated calcium × phosphorus level represents poor phosphorus control and often is associated with metastatic tissue calcifications. Treatment involves administration of phosphate-binding antacids, such as aluminum antacids and sucralfate, calcium citrate, or calcium carbonate, and may include dialysis, especially in patients with renal failure (Table 54-14).

Table 54-14 Major Causes of Hyperphosphatemia

Mechanism	Clinical Syndromes
Binding to serum proteins	Including plasma cell dyscrasias
Decreased renal excretion	Renal insufficiency, hypoparathyroidism, pseudohypoparathyroidism types I and II, tumoral calcinosis, pseudoxanthoma elasticum, infantile hypophosphatasia, hyperostosis, hyperthyroidism, adrenal insufficiency, bisphosphonate therapy
Increased intestinal absorption	Phosphorus-containing cathartics; medication with vitamin D compounds; granulomatous disease producing vitamin D, including sarcoidosis and tuberculosis
Internal redistribution	Acute metabolic or respiratory acidosis, reduced insulin level, clonidine administration
Cellular release	Rhabdomyolysis; organ infarction; tumor lysis, as in Burkitt's or lymphoblastic lymphomas or metastatic small cell carcinoma
Parenteral administration	Intravenous phosphate salts, lipid (phospholipid) infusion

Adapted from Potts JT: Diseases of the parathyroid gland and other hyper- and hypocalcemic disorders. *In* Isselbacher KJ, Braunwald E, Wilson JD, et al (eds): Harrison's Principles of Internal Medicine, 13th ed. New York, McGraw-Hill, 1995, p 2186.

Hypophosphatemia

The typical normal range of phosphorus is 2.4 to 4.1 mg/dL. Hypophosphatemia has many causes and is severe when serum phosphorus levels decline to less than 1 mg/dL. Conditions causing such low phosphate levels include prolonged respiratory alkalosis and rapid cellular uptake. Severe hypophosphatemia with total-body deficiency usually reflects poor dietary intake or consumption of phosphate-binding antacids, or both.

Hypophosphatemia occurs in alcoholism (50% of hospitalized alcoholics), refeeding syndrome (commonly in the intensive care unit), malnutrition, sepsis, trauma, diuretic or steroid therapy, ketoacidosis, osmotic diuresis, acidosis, and catabolic states. Depressed intake or absorption and increased urinary losses are common causes. Starvation for 48 hours and poor nutritional status predispose to hypophosphatemia. In individuals with chronic alcoholism, reduction of the phosphorus content of skeletal muscle occurs as a result of renal phosphate loss. The hypophosphatemic syndrome includes phosphate trapping, rhabdomyolysis, cardiomyopathy, respiratory insufficiency from profound muscle weakness, erythrocyte and leukocyte dysfunction, skeletal demineralization, metabolic acidosis, and nervous system dysfunction (Table 54-15).

Before initiating treatment, the cause of hypophosphatemia should be clearly identified with measurement of arterial blood gases and the concentrations of ionized calcium, magnesium, potassium, and serum and urinary phosphorus. Phosphate salts, such as sodium and potassium phosphate, are available for oral or intravenous administration. Multiplying the volume of distribution (400 mL/kg) by the desired change in inorganic phosphate provides the total amount to be administered. The rate of intravenous administration should not exceed 0.25 mmol/kg over 4 to 6 hours to avoid hypocalcemia and tissue damage. Oral supplementation is often limited to 30 mmol/day (1 g/day) because of the induction of diarrhea. Hyperphosphatemia should be avoided because it can cause hypocalcemia and crystal deposition in the eyes, heart, lung, blood vessels, and kidneys. Most hypophosphatemic patients, such as patients with diabetic ketoacidosis or recovering from exercise, are not severely phosphorus-depleted, unless they have been sick for an extended time. They typically may be treated with a glass of milk (100 mg/dL or 33 mmol/L of phosphorus). After achieving normal serum phosphate levels, the concentrations of serum inorganic phosphate and ionized calcium and a 24-hour urine sample should be monitored to ensure that balance has been achieved.

Table 54-15 Major Causes of Hypophosphatemia

Chronic alcoholism and alcohol withdrawal
Dietary deficiency and phosphate-binding antacids
Severe thermal burns
Recovery from diabetic ketoacidosis
Hyperalimentation

Significant hypophosphatemia is common after surgery and can contribute to respiratory and cardiac failure. In one study of elective cardiac surgery, 34.3% of patients had significant hypophosphatemia. These patients were characterized by prolonged ventilation, had a larger cardioactive drug requirement, and had prolonged hospital stays.[43]

Chloride Physiology

Chloride is the predominant anion in the ECF volume. Hyperchloremic, metabolic acidosis results from excess intake or inadequate excretion because of renal dysfunction. When administering infusions to such patients, bicarbonate, acetate, citrate, or phosphate salts should be substituted for chloride salts.

Excess loss of chloride in gastric secretions or urine causes hypochloremic alkalosis. Chloride depletion tends to limit bicarbonate excretion, and this may be caused by reduced delivery of chloride to the collecting tubules, where chloride is needed for bicarbonate secretion by means of bicarbonate-chloride exchange. Sodium reabsorption is enhanced in chloride-depleted states because it is generally associated with ECF volume depletion. When less chloride is available for reabsorption, a greater fraction of the sodium must be reabsorbed with bicarbonate through increased proton secretion.[44] Sodium or potassium chloride should be administered if intravascular volume depletion or hypokalemia is present. If these are not a problem, 0.1N hydrochloric acid should be administered through a central catheter:

$$\text{Chloride dose} = \left(\text{Cl}_{\text{desired}} - \text{Cl}_{\text{measured}}\right) \times 0.2 \times \text{weight (kg)}$$

Glucose Physiology and Fluid Implications

Close Monitoring

Glucose is a crucial fuel source, and insulin facilitates glucose movement into cells in a process that also requires potassium and phosphate. Red blood cells, healing wounds, brain, and adrenal medulla require glucose for fuel, totaling approximately 2 mg/kg/min. When controlling blood glucose, close monitoring is crucial. Reagent strips containing glucose oxidase, used in conjunction with glucometers, provide rapid and reliable results. It is imperative to know the insulin regimen or oral hypoglycemic agent of each patient and then measure the blood glucose preoperatively, intraoperatively, and postoperatively. The degree of end-organ damage, coronary artery disease, and autonomic neuropathy can contribute to the risk of aspiration, myocardial infarction, and peripheral neuropathy.

Hyperglycemia

Hyperglycemia (>180 to 200 mg/dL) is most often caused by insulin deficiency, insulin receptor resistance, or glucose overadministration. Hyperglycemia produces osmotic diuresis; exacerbation of brain, spinal cord,[45] and renal damage[46] by ischemia; delayed gastric emptying[47]; hypophosphatemia[47]; delayed wound healing[47,48]; and impaired white blood cell function.[48] Maternal hyperglycemia increases the risk of neonatal jaundice, the risk of neonatal brain damage, and fetal acidosis if the fetus becomes hypoxic.

Even with supramaximal levels of insulin, adults can use glucose only at a rate of 3 to 5 mg/kg/min at rest (approximately 240 mL/hr of 5% solution). The maximal rate of metabolism is less in stress states and more with increased metabolic rates. Generally, the rate of administration should be limited to 2 to 3 mg/kg/min (120 to 180 mg/kg/hr), which is 100 g/hr for a 70-kg person (200 mL/hr of a 5% dextrose solution). Healthy infants and children become hyperglycemic if 5% dextrose is included in maintenance fluids.[49] The maximal rate of glucose disposition in young children is 4 to 8 mg/kg/min, and the optimal rate is less than 5 mg/kg/min.[50] It is unclear that glucose administration is necessary for intraoperative management of most patients.[51]

Diabetes Mellitus

Diabetes mellitus (see Chapter 35) is the most common endocrine disease and is characterized by long-term complications involving the eyes, kidneys, nerves, and blood vessels. Diabetes is a major risk factor for heart disease, stroke, kidney disease, blindness, and nontraumatic amputations. The cause of diabetic complications is multifactorial, including glycosylation of proteins and glucose reduction to sorbitol, which functions as a tissue toxin. This pathophysiologic process is associated with a decrease in *myo*-inositol content and metabolism and with a decrease in Na^+-K^+/ATPase activity. Hyperglycemia is recognized as a major factor in the development of complications associated with diabetes. The patient population is not homogeneous, and several diabetic syndromes have been delineated. There are almost 8 million diagnosed diabetics in the United States and another 8 million who are unaware of their diabetes. These numbers approach 10% of the overall U.S. population (Table 54-16).[52]

Pathology

Hyperglycemia of diabetes is the consequence of relative or absolute deficiency of insulin and a relative or absolute excess of glu-

Table 54-16 Classification of Diabetes

Class	Causes and Characteristics
Primary	IDDM, type 1—without insulin, the patient develops ketoacidosis and dies NIDDM, type 2—the patient does not always develop ketoacidosis without insulin Nonobese NIDDM (type 1 IDDM in evolution?) Obese NIDDM Maturity-onset diabetes of the young
Secondary	Pancreatic disease, hormonal abnormalities, drug or chemical induced, insulin receptor abnormalities, genetic syndrome, other

IDDM, insulin-dependent diabetes mellitus; NIDDM, non–insulin-dependent diabetes mellitus.

cagon. In type 1 diabetes, there is an absolute deficiency in insulin production, and without insulin, patients die. These patients eventually become dependent on exogenous insulin to prevent lipolysis and eventually ketoacidosis. The onset of type 1 diabetes usually occurs by adolescence, although it may occur at any age and is thought to result from autoimmune destruction of islet cells in the pancreas.

Type 2 diabetes is characterized by a relative deficiency in insulin, typically caused by insulin resistance. The onset of this type of diabetes is usually in adulthood, although evidence suggests that the mean age of onset of type 2 diabetes is decreasing.[53] Type 2 diabetes almost certainly has a heterogeneous group of etiologic factors. Commonly associated findings in type 2 diabetes are obesity, abnormal insulin levels, and a strong genetic component (Table 54-17).[54]

A third type of diabetes mellitus is gestational diabetes (see Chapter 69). Gestational diabetes is defined as any degree of glucose intolerance with the onset first recognized during pregnancy. Gestational diabetes complicates approximately 4% of all pregnancies in the United States, resulting in about 135,000 cases annually.[55] Clinical recognition of gestational diabetes is important because therapy and antepartum fetal monitoring can reduce perinatal morbidity and mortality. Maternal complications related to gestational diabetes include an increased rate of cesarean delivery.

During the past decade, a new disorder known as syndrome X has been described. As the name implies, it is a syndrome rather than a specific disease state. The hallmark of syndrome X is insulin resistance with hyperinsulinemia. The underlying pathology is similar to type 2 diabetes; however, patients with syndrome X do not exhibit hyperglycemia. Patients with syndrome X may never develop type 2 diabetes. The clinical significance of this condition stems from its association with multiple metabolic abnormalities, including low levels of high-density lipoprotein, increased blood pressure, and increased plasminogen activator inhibitor-1 levels. All these abnormalities have a definite or possible association with coronary artery disease. Whether syndrome X and type 2 diabetes are on a spectrum of disease with insulin resistance as a common denominator or are totally separate entities has yet to be clarified.

Management and Evaluation of Diabetes Mellitus

Treatment and evaluation of diabetes (see Chapter 35) includes diet, oral hypoglycemic drugs, exercise, exogenous insulin, and weight reduction if warranted. Insulin preparations are produced from pork, beef, and human or recombinant sources. Most diabetics are prescribed a combination of rapid-acting and intermediate-acting insulin before breakfast and before bedtime. Rebound hyperglycemia may follow a hypoglycemic reaction (i.e., Somogyi effect). In the past decade, newer therapies for new-onset insulin-dependent diabetes mellitus (type 1 diabetes) have been introduced, including transplantation of pancreatic tissue and immunosuppression. Fifteen percent of patients with type 1 diabetes have other autoimmune processes, and the elevated glucose levels are probably caused by destruction of pancreatic β cells in these instances (Table 54-18).

Table 54-17 Characteristics of Type 1 and Type 2 Diabetes Mellitus

Characteristic	Type 1	Type 2
Genetic locus	Chromosome 5	Chromosome 11 (?)
Age at onset	≤40	>40
Body habitus	Normal to wasted	Obese
Plasma insulin	Low to absent	Normal to high
Plasma glucagons	High, suppressible	High, resistant
Acute complications	Ketoacidosis	Hyperosmolar coma
Insulin therapy	Responsive	Responsive to resistant
Sulfonylurea therapy	Unresponsive	Responsive

Table 54-19 Insulin Analog Comparison

Analog	Brand Name	Manufacturer	Onset (min)	Peak (hr)	Duration (hr)
Lispro	Humalog	Eli Lilly	5-15	1-2	2-3
Glargine	Lantus	Hoechst-Marion Roussel for Aventis	1-3 hr	No true peak	24
Aspart	NovoRapid	NovoNordisk	5-15	1-2	2-3

Insulin therapy can result in anaphylactic and anaphylactoid reactions, especially when using protamine-containing insulin preparations. Protamine-derived insulin is made from fish sperm and can cause immunologic sensitization when protamine reversal is administered after cardiopulmonary bypass or heparin reversal.[56] The protamine reaction can be devastating and includes profound hypotension, pulmonary vasoconstriction, and noncardiogenic pulmonary edema. Insulin analogs have been developed with improved time-action profiles.

The first insulin analog was introduced in the mid-1990s. Several other insulin analogs subsequently have been formulated (Table 54-19). Insulin lispro (Humalog) is a genetically engineered protein identical to human insulin except for a reversal of the amino acids, proline and lysine, at positions 28 and 29 of the β chain.[57]

This reversal in the amino acid sequence allows for a more rapid absorption and faster onset of action compared with regular insulin.[58-61] Reversal of the proline-lysine sequence eliminates two crucial hydrophobic interactions responsible for the β-sheet conformational changes and dimerization. Decreased propensity for dimerization is the key to understanding the absorptive characteristics of insulin lispro.

Another insulin analog that has been released is insulin glargine (Lantus), which resembles the human insulin protein with addition of two arginine amino acids to the β chain and replaces asparagine with glycine at the α-21 position. The addition of the two arginine units causes a shift in the isoelectric point to 6.7 ± 0.2, which allows for precipitation of the insulin glargine in the neutral pH of human tissue. The substitution of glycine in the α chain and the addition of 30 μg/mL of zinc increase the hexamer stability of the precipitate.[62,63] This precipitate slowly dissolves and results in a constant time-action profile with no pronounced peak. This time-action profile allows for once-daily dosing and a duration of action of 18 to 24 hours. These new preparations are being encountered more often in patients being assessed for surgery, and understanding their time-action profiles is essential in clinical management.

Anesthetic Considerations

Because diabetes affects multiple organ systems, the perioperative impact can be profound. Several clinically relevant issues should be considered during perioperative anesthetic management, as follows:

1. Diabetes affects oxygen transport by causing glucose to bind covalently to the hemoglobin molecule, and alters the allosteric interactions between β chains. This alteration in normal hemoglobin has been shown to decrease oxygen saturation and red blood cell oxygen transport in pregnant diabetic patients.[64]
2. A common complication of diabetes is autonomic dysfunction. Patients in whom diabetes has been poorly controlled for many years often have damage to the autonomic nervous system. One study[65] showed that diabetic patients with previously diagnosed autonomic dysfunction are at increased risk for intraoperative hypothermia. The pathogenesis may be related to inappropriate regulation of peripheral vasoconstriction to conserve body heat.
3. Autonomic dysfunction also affects the body's ability to regulate arterial blood pressure, leading to significant orthostatic hypotension. This underlying defect is caused by a lack of appropriate vasoconstriction. This denervation also may involve vagal control of the heart rate. The changes in heart rate seen with atropine and β-blockers are blunted in patients with significant autonomic dysfunction.[66]
4. Damage to the autonomic nervous system can significantly affect the choice of anesthetic technique. Patients are at significantly increased risk of hypotension caused by induction agents, such as thiopental or propofol. For this reason, etomidate may be a better induction agent because of its considerably lower incidence of cardiovascular side effects.
5. Diabetes has well-defined adverse effects on the cardiovascular system. Men who have diabetes have twice the age-adjusted risk for coronary artery disease. The risk for women is tripled, indicating that they may be even more sensitive to the cardiovascular effects of diabetes.[67] Data show that patients with diabetes may be at even greater risk for coronary artery disease than was previously suspected. One study revealed that patients with type 2 diabetes had as great a risk for myocardial infarction as nondiabetic patients who already had a previous myocardial infarction.[68] This information reinforces the point that diabetic patients must be carefully evaluated preoperatively for coronary artery disease. Also, diabetic patients are more likely to have silent ischemia. They may not experience the classic chest pain and tightness associated with ischemic heart disease. Questions regarding exercise tolerance and shortness of breath with exertion may provide important information regarding underlying heart disease or the degree of compensation.
6. Diabetes affects the gastrointestinal tract in several ways. First, it damages the ganglion cells of the gastrointestinal tract, inhibiting motility, which delays gastric emptying and overall transit time through the gut. This increased transit time has a significant impact on the practice of anesthesia in that all diabetic patients should be treated as if they have a full stomach. Preoperative treatment with agents that inhibit acid secretion and neutralize stomach acid is essential. Rapid-sequence induction is commonly employed to try to minimize this risk of aspiration.

Perioperative and intraoperative glycemic-control regimens depend on several factors. First, differentiating type 1 from type 2 diabetes is crucial. Patients with type 1 diabetes are at risk for ketonemia if they are without insulin. The risk of ketosis is amplified when the patient undergoes the stress of surgery.

Second, the degree to which blood glucose levels are controlled long-term affects management. Glycosylated hemoglobin (hemoglobin A_{1c}) is the most accurate way to assess glucose control over the previous 2 to 3 months. As levels of hemoglobin A_{1c} increase, so does the complication rate of diabetes. The amount of exogenous insulin a patient normally requires is important in deciding how blood glucose should be treated intraoperatively. The magnitude of the surgery plays an important role in determining therapy. There are many different protocols for preoperative and intraoperative insulin management, but there are few prospective studies comparing regimens. Common protocols are discussed subsequently.

Successful perioperative glucose management depends on careful monitoring. Perioperative management of blood glucose during a brief surgical procedure in a patient with diet-controlled diabetes generally involves only monitoring of blood glucose immediately perioperatively and every 3 hours until oral intake is resumed.[69,70] The preoperative physical examination and history may reveal extensive diabetic neuropathy, which may be seen as orthostatic hypotension, syncopal episodes, mononeuropathies or polyneuropathies, erectile or bladder dysfunction, and an electrocardiogram showing a loss of R-to-R variability. Patients may present with numerous additional findings, including nonfamilial short stature, cerebrovascular disease, renal dysfunction, microalbuminemia, and tight, waxy skin. In an estimated 30% to 40% of diabetic patients, glycosylation of the atlanto-occipital joint may limit joint mobility and cause difficulty with airway management (i.e., stiff-neck syndrome).[71,72] Laboratory evaluation of hemoglobin A_{1c} is an accurate measure of the severity of hyperglycemia and has been shown to correlate directly with increasing rates of complications. Conversely, lower hemoglobin A_{1c} values are associated with decreased risk and can be considered a measure of the quality of the diabetic care. Hemoglobin A_{1c} provides the best evidence of overall blood glucose control over the past 1 to 2 months and should replace the oral glucose tolerance test as the gold standard for diagnosing diabetes.[73] Basic electrolyte and renal function tests should be evaluated, especially if the patient has frequent urinary tract infections or renal impairment.[74]

The preoperative hemoglobin A_{1c} level gives the anesthesiologist a reasonable idea about the patient's blood glucose level over the past several months, and this information can be used to evaluate the need for preoperative and intraoperative insulin requirements. The regimen selected to manage patients with diabetes undergoing surgery depends on the severity of the diabetes and the magnitude of the surgery. Frequent glucose monitoring and preparation for insulin administration are essential for a diabetic patient. Recommendations include discontinuation of long-acting insulin or oral hypoglycemic agents 1 to 2 days preoperatively. Short-acting insulin should be administered every 4 to 6 hours subcutaneously, with the dose adjusted according to glucose levels just before administration. Metformin, a biguanide oral hypoglycemic, also possesses a low risk of lactic acidosis (0.03 cases per 1000 patient-years). Despite these low figures, metformin should not be used in patients with mild renal dysfunction (serum creatinine >1.5 mg/dL in male patients or >1.4 mg/dL in female patients), congestive heart failure, recent myocardial infarction or any other condition producing a hypoxic state, current alcohol abuse, or impaired hepatic function. Metformin should be discontinued 24 hours before and for at least 48 hours after any procedure using intravenous contrast dye. It should be reinstituted only after renal function has been reevaluated and found to be normal.[75,76]

The typical "sliding scale" is destined to fail because it involves the administration of a fixed dose after documentation of hyperglycemia. A small modification improves control. The selected dose should be administered every 4 to 6 hours, based on response. If the glucose level is less than 60 mg/dL, the dose should be with held for at least 1 hour, and 50% dextrose should be given intravenously (0.01 to 0.02 mL/kg/min), with blood glucose monitored hourly. When the blood glucose is greater than 125 mg/dL without supplemental dextrose infusion, the next insulin dose should be 20% to 40% smaller. If the glucose is less than 100 mg/dL or is less than 125 mg/dL and decreasing, the scheduled dose should be maintained until the hourly measured glucose is greater than 125 mg/dL, followed by resumption with a 10% to 20% smaller dose. If the glucose level is 100 to 200 mg/dL and stable, the current dose and interval are continued. If the glucose level is 200 to 350 mg/dL, the scheduled dose is increased by 10% to 20%. If the glucose level is more than 350 mg/dL, the dose is increased by 20% to 40%.

On the day of surgery, a dextrose infusion (2 mg/kg/min) is started at the time a meal would have been ingested, and glucose is measured preoperatively. For patients currently receiving insulin, an insulin infusion is started at a rate of 0.5 to 1.25 U/hr, depending on the amount of insulin normally administered and the current glucose level. Blood glucose is monitored hourly, and the infusion rate is adjusted to maintain glucose concentration based on which glucose homeostasis protocol has been selected for use. Patients with obesity, liver disease, severe infections or on steroid therapy may require increased hourly insulin doses as may patients undergoing cardiopulmonary bypass.[77] After the blood glucose level is stable, urine glucose levels and ketone bodies are checked to ensure that glycosuria resulting from a low threshold does not confuse interpretation of urine output.

Oral intake may be stopped 12 hours before anesthesia because some element of gastroparesis exists in these patients. Typically, patients are administered a histamine blocker along with a gastric-emptying drug, such as metoclopramide, the night before and the morning of surgery. Because the gastrointestinal tract is a prime target for autonomic neuropathy, there may be esophageal dysfunction with difficulty swallowing, constipation, or diarrhea.

Diabetic ketoacidosis, dehydration, impaired wound healing, and electrolyte imbalance are minimized with the proper use of exogenous insulin. There is no clear consensus about the method of insulin therapy or the exact range of blood glucose that can affect morbidity or mortality.[78]

If a general anesthetic is used, clinical consideration should include a rapid-sequence induction because of the high rate of gastroparesis. Cerebrovascular accidents, peripheral vascular disease, and cardiovascular infarction are 2 to 10 times more common in diabetics. Strategies designed to reduce the risk of labile blood pressures and myocardial ischemia related to autonomic or vascular disease may include β-blockade to blunt the stress of induction, a narcotic-based anesthetic to minimize cardiopulmonary depression, and prophylactic nitroglycerin in these patients with their significant risk of coronary artery disease. Commonly associated conditions include obesity and stiff cervical joints, which may make airway management challenging. Associated cardiovascular conditions often result in the need for additional invasive monitoring.

Acute Hyperglycemia

The cellular effects of acute hyperglycemia are poorly understood, but reports have begun to shed some light on alterations in normal cell functions at the molecular level. One study[79] showed that acutely elevated glucose levels depress endothelin-induced calcium signaling in rat mesangial cells, depressing the contractile state of glomerular cells. Such information supports the hypothesis that acute hyperglycemia can affect cellular functions and may lead to clinically evident pathology.

National trends show a movement toward tighter control of glucose levels perioperatively. Acute consequences of elevated serum glucose levels include impaired wound healing, dehydration, impaired immune system response, and proteolysis. The dehydration seen during acute hyperglycemia results from the osmotic diuretic effect of high serum glucose levels. Patients with diabetes are well known for having poor wound healing, which is commonly believed to be caused by impaired blood flow to the wound. There is evidence, however, that acute hyperglycemia may impair fibroblast activity and impair vitamin C uptake by cells, inhibiting new collagen synthesis.[80]

In addition to delayed wound healing, elevated glucose levels inhibit immune function and increase the risk of postoperative infection. One study[81] suggested that continuous insulin infusions, used to control intraoperative and postoperative glucose levels, decrease the incidence of sternal wound infections after cardiac surgery. A second study[82] found that aggressive glucose control intraoperatively increased neutrophil activity in vitro significantly. Alveolar macrophages from normal hosts show impaired respiratory burst when exposed in vitro to elevated glucose concentrations.[83] Taken together, these data indicate that tight glucose control intraoperatively may significantly influence the ability of patients to recover more quickly from surgery and reduce morbidity.

Diabetic Ketoacidosis

Diabetic ketoacidosis is an emergent condition that often manifests in a diabetic patient with leukocytosis and an acute surgical abdominal emergency or with nausea, vomiting, lethargy, and signs of hypovolemia. The priorities are to restore intravascular volume (usually rapid intravenous administration of 1 L of saline), administer regular insulin (traditionally at a starting infusion rate of 0.1 U/kg/hr), eliminate the ketonemia, control blood glucose, and correct the underlying problem (e.g., antibiotics for urosepsis or pneumonia). Patients with ketoacidosis are dehydrated as a result of glucosuria; because the dehydration is caused by water and electrolyte loss, colloids are not indicated. If the patient's osmolality is elevated, 0.45% sodium chloride can be administered, and the volume administered should be guided by the hemodynamic response and urinary output. When the blood glucose declines to less than 250 mg/dL, dextrose should be added to the fluids. Urine or blood ketones are monitored every 2 hours after the blood glucose is within 100 to 200 mg/dL. If ketones are still present, the rates of glucose and insulin infusions should be increased.

Osmotic diuresis promotes loss of sodium, potassium, magnesium, and phosphate. Despite total-body deficiencies, however, their concentrations may be elevated at the time of presentation because of severe water loss. The best treatment for hyperkalemia in these patients is appropriate therapy for the diabetic ketoacidosis. Potassium levels decrease rapidly with appropriate volume replacement and insulin therapy. Most patients require electrolyte replacement after volume expansion has begun. Alternatively, severe hyperglycemia may extract water from the intracellular space and may dilute the electrolyte concentrations. If the initial potassium level is elevated, or the patient is anuric, potassium should not be administered. As hydration improves, and urinary output increases, potassium, magnesium, and phosphorus should be administered, and levels should be monitored frequently. Generally, acidosis should not be treated with buffers. Ketoacidosis is corrected as insulin and glucose levels improve, and lactic acidosis resulting from poor perfusion responds to intravascular fluid replacement. If the pH approaches 7.15, the bicarbonate ion concentration is less than 10 mEq/L, and hypotension fails to respond to intravascular fluid administration, sodium bicarbonate therapy may be required.

Hypoglycemia

Hypoglycemia (<50 mg/dL) is dangerous because glucose is the sole fuel source for much of the brain. Threshold levels depend on age. Signs of hypoglycemia include irritability, seizures, bradycardia, hypotension, and respiratory failure. Symptoms commonly occur in adults with blood glucose concentrations less than 57 mg/dL or in infants with levels of 30 to 50 mg/dL. Symptoms are seen at higher levels in diabetic patients than in nondiabetic patients and are obscured by general anesthesia. At about 70 mg/dL, a biochemical stress response occurs, including sympathetic nervous system stimulation and elevated levels of growth hormone or cortisol, or both. Neurologic and electroencephalographic depression appears at 50 to 55 mg/dL in nondiabetic patients and 70 to 85 mg/dL in diabetic patients.[84] Selective neuronal necrosis, not infarction, occurs in the caudate, putamen, and cortex. There is a compensatory increase in cerebral blood flow.

During labor, maternal starvation-induced ketosis has adverse fetal effects, including fetal ketonemia, hypoxia, and fetal lactic acidosis.[85] Neonates are at an increased risk for hypoglycemia because of limited glycogen stores and from large amounts of fetal insulin production in response to gestational hyperglycemic states. Adults also are at risk for hypoglycemia from inadequate gluconeogenesis coupled with inadequate nutritional intake or from excess insulin (e.g., from an insulinoma, pancreatic islet cell adenoma, or carcinoma; iatrogenic overadministration). Hypoglycemia also can follow too abrupt cessation of dextrose infusion during total parenteral nutrition (i.e., reactive hyperinsulinemic states). Inadequate gluconeogenesis occurs in liver failure, cortisol deficiency (primary or secondary), inadequate glucagon response, and growth hormone deficiency, and during β-adrenergic blockade. Fasting in women is likely to produce hypoglycemia in 24 hours, whereas men tolerate about 72 hours of fasting.[47] The incidence of hypoglycemia in healthy infants and children is low (2 of 446) with 4 to 8 hours of fasting.[50] Fetal hypoglycemia occurs if maternal glucose is greater than 150 mg/dL because glucose crosses the placenta, inducing fetal insulin secretion. Treatment consists of an intravenous bolus of

5 g of dextrose followed by increasing the rate of dextrose infusion by 1 to 2 mg/kg/min.

Acid-Base Factors

Metabolic Acidosis

The necessity for treating metabolic acidosis is judged largely on clinical grounds, with the metabolic acid level base excess (BE) used to determine the correct dose of bicarbonate (see Chapter 49). This prediction is based on the size of the treatable space and the magnitude of the problem:

$$\text{Dose}\,(\text{mEq}) = 0.3 \cdot \text{weight}\,(\text{kg}) \cdot \text{BE}\,(\text{mEq/L})$$

The dose calculated is sufficient to return the metabolic disturbance almost to zero. Bicarbonate therapy is reserved, however, for emergencies and situations in which indications for therapy are compelling. It is usual to give a reduced dose (about one half) for several reasons, as follows:

1. The bicarbonate is injected initially into the plasma volume (about 3 L) instead of into the calculated treatable space (21 L).
2. When bicarbonate is added to acid, it "fizzes." This does not occur literally in the blood. Nevertheless, most bicarbonate is converted to carbon dioxide and has to be eliminated. For each 100 mEq that is converted, about 2.24 L of carbon dioxide has to be exhaled, equivalent to 10 minutes of normal production.
3. The carbon dioxide that is produced enters the cells freely, in contrast to the bicarbonate ions that have been administered. The inside of the cell initially may become even more acid. Direct studies with nuclear magnetic resonance have not confirmed this, however (Severinghaus, personal communication, 1986).
4. The bicarbonate is accompanied by sodium ions that are responsible for a residual increase in the osmolality of the ECF. In combination with other therapy, such as intravenous glucose, the hyperosmolality may be critical and cause coma. In neonates, rapid infusion of bicarbonate may cause intracranial hemorrhage.
5. If the body deals with its metabolic acidosis, there is a residual metabolic alkalosis.

Anion Gap

Some causes of metabolic acidosis release anions into the ECF that are not normally measured. When this occurs, there is an unexpected discrepancy between the sums of the principal cations and anions. The usual sum is shown in the following equation:

$$Na^+ + K^+ = Cl^- + HCO_3^- + \text{gap}$$

$$140 + 5 = 105 + 25 + (-15)$$

When there are any additional, unmeasured anions, they become part of the gap, which is then correspondingly larger. A gap greater than 30 suggests that there is an increase in the concentration of the unmeasured anions. This method relies on the accuracy of the other measurements. Small errors in these large numbers cause a proportionately greater error in the result. If information is required about these anions, it is more appropriate to measure their concentration. In practice, it suffices to analyze lactate in cases of tissue hypoxia, 3-hydroxybutyrate in diabetic ketosis, and phosphate or sulfate in renal failure.

The common causes of perioperative metabolic alkalosis include antacid therapy, incidental administration of citrate with blood products, sodium bicarbonate administration, gastric drainage, or renal bicarbonate retention caused by diuresis or in compensation for respiratory acidosis. Sodium chloride or potassium chloride can be administered orally or through a peripheral intravenous catheter, or 0.1N hydrochloric acid may be administered slowly through a central venous catheter. The required dose is calculated as follows:

$$\text{Dose} = (Cl^-_{\text{desired}} - Cl^-_{\text{measured}}) \times 0.2\,(\text{L}) \times \text{weight}\,(\text{kg})$$

Clinical Acid-Base Balance Disturbances

This section provides practical clinical examples to assist in understanding acid-base balance.

Metabolic Acidosis from Low Cardiac Output

A patient with coronary artery disease and an ejection fraction of 15% experienced myocardial perforation while undergoing balloon angioplasty in the cardiac catheterization laboratory. After resuscitation, intubation, insertion of an arterial line, and initiation of dopamine by infusion, the patient was transferred to the operating room for emergency thoracotomy. Blood pressure was 80/50 mm Hg, and the heart rate was 120 beats/min. During preparation for central venous cannulation, the blood pressure decreased, followed by cardiac arrest. The patient underwent immediate thoracotomy. Blood gas determinations obtained at the time were as follows: pH_a 7.15, $Paco_2$ 35 mm Hg, BE −15 mEq/L, bicarbonate 12 mEq/L, and Pao_2 90 mm Hg. These values indicated a severe metabolic acidosis with mild respiratory alkalosis. After the administration of 4 U of packed red blood cells (PRBCs) and 88 mEq of sodium bicarbonate, repeat blood gas determinations were as follows: pH_a 7.14, $Paco_2$ 39 mm Hg, BE −14 mEq/L, bicarbonate 13 mEq/L, and Pao_2 95 mm Hg. These values still indicated a severe metabolic acidosis, but with no respiratory alkalosis.

The first blood gas determination revealed a metabolic acidosis attributable to the low cardiac output with tissue ischemia and with slight hyperventilation. The second blood gas determination showed almost no benefit from the bicarbonate, probably because of continuing low cardiac output. Bicarbonate is converted to carbon dioxide, which may explain the slightly higher level of $Paco_2$.

Metabolic Acidosis During Anhepatic Phase

A patient with end-stage liver disease caused by viral hepatitis underwent orthotopic liver transplantation. Blood gas analysis performed late in the anhepatic phase (see Chapter 67), after earlier administration of bicarbonate, revealed the following: pH_a 7.10, $Paco_2$ 28 mm Hg, BE −18 mEq/L, bicarbonate 8.6 mEq/L, Pao_2 260 mm Hg, and Na^+ 153 mEq/L. These values indicated a severe metabolic acidosis with a moderate respiratory alkalosis. The patient was treated with 500 mL (150 mEq, 18 g) of 0.3 M solution of tris(hydroxymethyl)aminomethane (THAM) by infusion over 20 minutes. Repeat blood gas analysis showed the following: pH_a 7.09, $Paco_2$ 30 mm Hg, BE −18 mEq/L, bicarbonate 9 mEq/L, Pao_2 251 mm Hg, and Na^+ 154 mEq/L. A second dose of THAM was administered by infusion. After transplantation, blood gas analysis showed the following: pH_a 7.30, $Paco_2$ 33 mm Hg, BE −9 mEq/L, bicarbonate 16 mEq/L, Pao_2 283 mm Hg, and Na^+ 149 mEq/L. These values indicated a marked metabolic acidosis with a mild respiratory alkalosis typical of a partially compensated metabolic disturbance.

The metabolic acidosis during the anhepatic phase showed the importance of the liver in metabolizing lactate to bicarbonate. The high sodium militated against repeat administration of sodium bicarbonate. In this case, THAM was used to minimize sodium administration while controlling the metabolic acidosis. On reperfusion (phase 3), the new liver started to function, and there was improvement in the metabolic acidosis.

Metabolic Alkalosis After Diuretics

A 3-month-old, 4-kg infant boy was presented for repair of an atrioventricular canal (see Chapter 83). The patient's congenital heart failure had been controlled with digitalis and furosemide. Before induction of anesthesia, blood gas analysis showed the following: pH_a 7.53, $Paco_2$ 44 mm Hg, BE 14 mEq/L, bicarbonate 35.9 mEq/L, and Pao_2 110 mm Hg. These values showed a severe metabolic alkalosis with a minimal respiratory acidosis typical of a partially compensated metabolic disturbance. After induction of anesthesia, blood gas analysis showed the following: pH_a 7.61, $Paco_2$ 35 mm Hg, BE 14 mEq/L, bicarbonate 34 mEq/L, and Pao_2 60 mm Hg. After completion of the procedure and cessation of cardiopulmonary bypass, the blood gas analysis showed the following: pH_a 7.40, $Paco_2$ 33 mm Hg, BE −4 mEq/L, and bicarbonate 20 mEq/L.

The hypochloremic alkalosis that accompanies prolonged administration of furosemide explains the first set of results. After induction of anesthesia, the hyperventilation decreased the $Paco_2$, but had no effect on the base excess. Two major factors explain the change during the procedure. Hemodilution tends to return the pH_a toward neutral (6.8 at body temperature), and low perfusion during bypass frequently produces a metabolic acidosis that, in this case, also helped to overcome the initial metabolic alkalosis.

Chronic Respiratory Failure in a Neonate

A 2.5-month-old, 3.5-kg infant boy with bronchopulmonary dysplasia was tracheally intubated and received supplemental oxygen (Fio_2 0.3). He presented for cryoablation for proliferative retinopathy (see Chapters 82 and 83). After the patient was transported to the operating room, blood gas analysis showed the following: pH_a 7.27, $Paco_2$ 65 mm Hg, BE 3 mEq/L, bicarbonate 29 mEq/L, and Pao_2 35 mm Hg. Anesthesia was induced, and ventilation was controlled, with a tidal volume of 60 mL, peak inspiratory pressure of 25 cm H_2O, positive end-expiratory pressure of 4 cm H_2O, respiratory rate of 40 breaths/min, no inspiratory pause, and Fio_2 of 0.3. Repeat analysis of blood gases showed the following: pH_a 7.36, $Paco_2$ 50 mm Hg, BE 3 mEq/L, bicarbonate 28 mEq/L, and Pao_2 48 mEq/L.

The mild metabolic alkalosis of the first analysis is compatible with compensation for chronic respiratory failure. The high $Paco_2$ value represented hypoventilation during transport. Appropriate selection of the ventilator settings returned the $Paco_2$ to a value more typical for a neonate with bronchopulmonary dysplasia with a pH_a about halfway between no compensation and complete compensation (see Chapters 82 and 83).

Preparation for Chronic Hyperventilation

A clinician was a member of a team providing plastic surgery at high altitude. For 2 days preceding the trip, he was advised to take a carbonic anhydrase inhibitor, acetazolamide, which would effectively slow the normal reversible reaction between carbonic acid and its dissociation products, carbonic acid and water. The drug alkalinizes the urine and produces a moderate metabolic acidosis, the typical response to hypoxic hyperventilation at altitude. A typical blood gas determination after acclimatization to altitude shows the following: pH_a 7.42, $Paco_2$ 31 mm Hg, BE 4 mEq/L, bicarbonate 19 mEq/L, and Pao_2 80 mm Hg.

The benefit of taking acetazolamide is debated by climbers, and the drug is not without side effects. During the initial experience of taking acetazolamide at sea level, a striking, if minor, side effect is the metallic taste associated with drinking any carbonated beverage, presumably attributable to the inability to convert the high carbon dioxide content in the beverages to carbonic acid.

Acute Hyperventilation and Hypotension

A 5-ft, 48-kg elderly woman had an arterial blood pressure of 115/75 mm Hg and heart rate of 70 beats/min (see Chapter 71). She was receiving no medications and was in otherwise normal health. She was scheduled for a laparotomy and hysterectomy. After induction of anesthesia and orotracheal intubation, controlled ventilation was initiated with a tidal volume of 900 mL and a respiratory rate of 12 breaths/min. Shortly before incision, the arterial blood pressure was 58/35 mm Hg, and the end-tidal Pco_2 was 22 mm Hg. (Blood gases were not tested, but typical values for a patient experiencing such acute hyperventilation are as follows: pH_a 7.53, $Paco_2$ 26 mm Hg, bicarbonate 21 mEq/L, and BE 0 mg/L.)

The ventilator was immediately reset to provide 4 breaths/min at a tidal volume of 500 mL. Arterial blood pressure about 2 minutes later was 85/55 mm Hg, and the next reading about 2 minutes later still was 95/65 mm Hg. The patient's end-tidal Pco_2 increased more slowly, and after about 8 minutes, it had returned to 36 mm Hg when the ventilatory rate was increased to 8 breaths/

min. (Typically, her blood gas values would be near-normal, such as pH_a 7.44, $Paco_2$ 38 mm Hg, bicarbonate 23.3 mEq/L, and BE 0 mg/L). Hyperventilation after induction is common and frequently contributes to hypotension by various methods, including increased intrathoracic pressure, diminished venous return, and depressed cardiac output.

Acute Hypoventilation

An obese, middle-aged woman was undergoing laparoscopic cholecystectomy. After a routine induction and orotracheal intubation, low-flow anesthesia was initiated, and the ventilator was set to provide a tidal volume of 700 mL at a rate of 10 breaths/min (measured exhaled tidal volume was 560 mL). Ten minutes after induction of anesthesia, the Pco_2 was 35 mm Hg, and the peak airway pressure was 28 mm Hg. Arterial blood gas determinations showed the following: pH_a 7.43, $Paco_2$ 35 mm Hg, bicarbonate 22.4 mEq/L, and BE −1 mEq/L. Thirty minutes into the procedure, the peak airway pressure was 48 mm Hg, the end-expired Pco_2 was 49 mm Hg, and the measured exhaled tidal volume was 380 mL. Repeat blood gas analysis showed the following: pH_a 7.27, $Paco_2$ 55 mm Hg, bicarbonate 24.9 mEq/L, and BE −1 mEq/L. The principal abnormality was a marked respiratory acidosis with no metabolic acidosis. It is characteristic of an acute respiratory disturbance.

The increase in $Paco_2$ can be attributed to two factors: uptake of the inflating gas (CO_2) in the abdomen and reduction of effective ventilation owing to increased airway pressure required to overcome abdominal distention. The discrepancy between end-tidal Pco_2 and arterial blood gas $Paco_2$ is typical and results from the patient's temperature being slightly less than that of the analyzer, lack of time between breaths to reach true end-tidal equilibration, normal pulmonary maldistribution, and the slight loss occurring on the length of the tubing.

Fluid Balance and Fluid Replacement Solutions

Transfusions of red blood cells, platelets, fresh frozen plasma, factor solutions, synthetic crystalloids and colloids, and cryoprecipitate have the potential for improving clinical outcomes in perioperative and peripartum settings. Potential benefits include improved tissue oxygenation and decreased bleeding; however, transfusions are not without risks or costs. Blood product transfusion can cause many complications. Although red blood cells and coagulation products have excellent volume-expanding capacity, they are not considered in this chapter (see Chapter 55).

The American Society of Anesthesiologists and the American Red Cross Blood Services have convened task forces and medical advisory boards on blood component therapy over the past decade to develop evidence-based guidelines on the proper indications for perioperative and peripartum administration of red blood cells, platelets, fresh frozen plasma, and cryoprecipitate. This section details only basic crystalloid, colloid, and hypertonic solution recommendations applicable to typical surgical and obstetric patients (Table 54-20). Information about infants, children, and special clinical settings can found elsewhere in this book (see Chapter 82).

Surgical Fluid Balance and Shock

Physiologic changes during surgery and anesthesia lead to shifts in fluid balance. Epidural, spinal, and caudal anesthesia all may cause variable amounts of sympathetic blockade (see Chapter 51). Although young, healthy, and well-hydrated patients may tolerate sympathectomy, patients who are older, severely dehydrated, or on antihypertensive drugs or diuretics may not be able to respond to the effects of sympathectomy. It is common to administer 1 L of fluid intravenously before placement of a spinal anesthetic, or to administer fluid concurrently when epidural anesthesia is being induced. Vasopressors, typically ephedrine or phenylephrine, are needed to overcome the hemodynamic effects of sympathetic block.

Although inhaled anesthetics do not directly alter fluid losses, all anesthetics may blunt the normal physiologic responses to hypovolemia and the stress response. The stress response to surgery involves an increase in ADH production, which can be blocked with anesthetics. Superimposed are the variable effects of intravenous and inhaled agents on the myocardium, venous return, blood pressure, and the vasculature. Mechanical ventilation can decrease the release of atrial natriuretic hormone and increase the release of ADH, resulting in retention of sodium and fluids.

Simple restoration of blood volume may not ensure survival. In addition to blood loss, significant third space loss may occur, which essentially involves fluid that is still in the body, but not contributing to intravascular volume, oxygen delivery, or waste removal; this is often difficult to measure. Patients undergoing major surgical procedures require fluid replacement beyond simple blood loss, and the anesthesiologist plays a vital role in assessing and ultimately administering appropriate fluid therapy in intraoperative and postoperative clinical settings. Even after normalization of cardiac output, cells in the liver and gut may remain ischemic after flow is reestablished in the macrocirculation because of occlusion of capillary networks caused by edema.[86]

The controversial issue of timing and volume of fluid resuscitation in uncontrolled hemorrhage has been reviewed. In 52 animal trials, fluid resuscitation seemed to decrease the risk of death in models of severe hemorrhage, but increased the risk of death in models with less severe hemorrhage. Hypotensive resuscitation, whenever tested, reduced the risk of death.[87]

Shock

Shock can be defined as dysfunction of intracellular processes as a result of lack of energy (see Chapter 72). This lack of energy is caused by deficient delivery of oxygen to tissue, resulting in an inability to maintain normal cellular respiration. Although shock is a cellular problem, therapy is directed at the systemic delivery of oxygen to the tissue.

Table 54-20 Composition of Replacement Fluids

Fluid	Sodium (mEq/L)	Potassium (mEq/L)	Glucose (g/L)	Osmolarity	pH	Other
Whole blood in CPD*	168-156	3.9-21	—	—	7.20-6.84	Hct = 35-40
PRBC,† AS-1	117	?-49	—	552	6.6	Hct = 59
PRBC,† CPD	—	?-95	—	—	6.6	Hct = 77
PRBC,† CPDA-1	169-111	5.1-78.5	—	—	7.55-6.71	Hct = 65-80
FFP	15.4	—	—	—	—	—
5% Albumin	145 ± 15	<2.5	0	330	7.4	COP = 32-35 mm Hg
2.5% Albumin	145 ± 15	<2	0	330	—	—
Plasmanate	145 ± 15	<2	—	—	7.4	COP = 20 mm Hg
10% Dextran 40	0	0	50	255	4.0	—
Hetastarch	154	0	0	310	5.9	—
0.9% Sodium chloride	154	0	0	308	6.0	—
Lactated Ringer's solution	130	4	0	273	6.5	Lactate = 28
5% Dextrose	0	0	50	252	4.5	—
D_5LR	130	4	50	525	5.0	—
$D_5$0.45% NaCl	77	0	50	406	4.0	—
Normosol	140	5	100	555	7.4	Mg = 3, acetate = 27, gluconate = 23
Normosol-M	40	13	50	363	5.0	Mg = 3, acetate = 16, gluconate = 27
Normosol-R	140	5	0	294	6.6	Mg = 3, acetate = 27, gluconate = 23
D_5 Normosol-R	140	5	0	547	5.2	Mg = 3, acetate = 27, gluconate = 23
Normosol-R pH 7.4	140	5	0	295	7.4	Mg = 3, acetate = 27, gluconate = 23

*The range of values refers to concentrations on day 1 and day 21 (CPD), 35 (CPDA-1), or 42 (AS-1) of storage.
†Fructose substituted for dextrose.
COP, colloid oncotic pressure; D_5LR, 5% dextrose in lactated Ringer solution; $D_5$0.45% NaCl, 5% dextrose in 0.45% sodium chloride; FFP, fresh frozen plasma; Hct, hematocrit; Mg, magnesium; PRBC, packed red blood cells.

In normal patients, the body maintains a balance between delivery of oxygen (Do_2) and global oxygen consumption (Vo_2). Global oxygen consumption is a measure of the total amount of oxygen consumed by all tissues per minute. The amount of oxygen consumed as a fraction of the amount delivered defines the oxygen extraction ratio (OER):

$$OER = Vo_2/Do_2$$

Vo_2 in a normal adult undertaking routine activities is approximately 250 mL/min with an extraction ratio of 25%. The OER can be increased to 75% during extreme exercise in a healthy adult. Oxygen not extracted from the blood returns to the lungs and can be measured as the mixed venous saturation ($S\bar{v}o_2$), which is a measure of global tissue oxygenation. $S\bar{v}o_2$ less than 60% to 70% usually indicates insufficient Do_2. A mixed venous blood sample is needed because the saturation of venous blood varies depending on the organ being measured. Venous blood returning from the liver has a saturation of 40% to 50%, and blood from the kidneys may have a saturation greater than 80%.

Oxygen consumption is directly related to cellular metabolic rate. Sympathetic activity, shivering, and physical activity all increase the cellular metabolic rate. As the delivery of oxygen decreases or the consumption increases, the OER increases to maintain aerobic metabolism. The OER can increase to approximately 60% to 70%, at which point further increase in consumption or decrease in delivery results in tissue hypoxia and anaerobic metabolism.

Tissue hypoxia and shock can result from inappropriate delivery of cellular oxygen or inappropriate cellular use of oxygen. There are two distinct types of shock. Type I involves patients who experience decreased delivery of oxygen, such as in hypovolemic or cardiogenic shock. Type II involves problems with inappropri-

ate distribution of oxygen delivery, such as in septic or neurogenic shock. Regardless of the underlying cause, appropriate fluid management is an absolute necessity.

Proper fluid management of shock can have a significant impact on the delivery of oxygen to tissues and prevention of anaerobic metabolism. Until more recently, vigorous fluid loading and inotropic agents were commonly used in what was called goal-directed therapy during the care of critically ill patients. Goal-directed therapy was based on the principle that critically ill patients had supranormal Vo_2 values. It was thought that by increasing Do_2 to supraphysiologic levels, cellular metabolism could be maintained in an aerobic state, and multisystem organ dysfunction could be avoided.[88] In the 1990s, two large, randomized trials showed this therapy to be ineffective and potentially dangerous, however.[89,90] Continuing research has shown that identifying and treating volume depletion and poor cardiac function early in shock is beneficial.[91-93]

The key to the different results between the early study by Shoemaker and colleagues[88] and later trials is recognizing the difference between early and late shock. Early shock involves acute tissue hypoxemia with end organs not yet sustaining irreversible damage. In type I shock (hypovolemic or cardiogenic), prompt treatment of the underlying cause of tissue hypoperfusion may prevent patients from progressing to late shock and multisystem organ failure. If tissue oxygenation is not restored soon enough, end-organ failure and endothelial cell dysfunction occur, signaling the onset of late shock. With end-organ failure and endothelial cell dysfunction, the body's normal control of regional blood flow is impaired, and further oxygen delivery to tissue is compromised. At this point, increasing the blood flow further with use of overaggressive volume loading and inotropic agents does not improve tissue oxygenation because blood is not being delivered to the tissue that needs it. During early shock, aggressive fluid resuscitation is appropriate to minimize end-organ hypoxemia as quickly as possible. After the patient has progressed to late shock, it is still important to maintain normal intravascular volumes, but overaggressive therapy with fluids and pressors has been shown to be detrimental.

Crystalloids

Crystalloids are fluids that contain water and electrolytes. They are grouped as isotonic, hypertonic, and hypotonic salt solutions. Crystalloid solutions are used to provide maintenance water and electrolytes and to expand intravascular fluid. The replacement requirement is threefold or fourfold the volume of blood lost because administered crystalloid is distributed in a ratio 1:4 similar to ECF, which is composed of about 3 L intravascularly (plasma) and about 12 L extravascularly (i.e., about 20% should remain in the intravascular space).

Balanced Salt Solutions

Balanced salt solutions have an electrolyte composition similar to ECF (e.g., lactated Ringer solution, Plasma-Lyte, Normosol). With respect to sodium, they are hypotonic. A buffer is included in place of bicarbonate, which hydrates to carbonic acid with the production of carbon dioxide, which diffuses from the solution. Compared with 0.9% NaCl, these solutions provide small quantities of other electrolytes, which are inadequate to meet daily maintenance requirements.

Normal Saline

Normal saline (0.9% NaCl) is isotonic and iso-osmotic, but contains more chloride than ECF. When used in large volumes, mild hyperchloremia (i.e., non–anion gap metabolic acidosis) results. Normal saline contains no buffer or other electrolytes. It is preferred to lactated Ringer's solution (which contains a hypotonic concentration of sodium) when brain injury, hypochloremic metabolic alkalosis, or hyponatremia occurs. Many patients with hyperkalemia, including patients with renal failure who are frequently in the operating room for vascular access bypass procedures, routinely receive normal saline because it contains no potassium.

Hypertonic Salt Solutions

Hypertonic salt solutions are less commonly used, and their sodium concentrations range from 250 to 1200 mEq/L. The greater the sodium concentration, the less the total volume is required for satisfactory resuscitation. This difference reflects the movement owing to osmotic forces of water from the intracellular space into the extracellular space. The reduced volume of water injected may reduce edema formation; this could be crucial in patients predisposed to tissue edema (e.g., prolonged bowel surgery, burns, brain injuries). Clinical studies have confirmed that a moderately hypertonic solution (250 mEq/L of sodium) can produce lower muscle interstitial pressure than lactated Ringer's solution. Bowel function returned earlier, although the pulmonary shunt fraction was no different.[94] Experimental studies have shown decreased intracranial pressures in animals receiving hypertonic solutions. The intravascular half-life of hypertonic solutions is no longer, however, than isotonic solutions of an equivalent sodium load. In most studies, sustained plasma volume expansion was achieved only when colloid was present in the resuscitation solution. The osmolality of these solutions can cause hemolysis at the point of injection.[95]

Hypertonic saline has been used for almost a century in clinical practice for a variety of reasons. Interest in its use in hemorrhagic shock was rekindled in 1980 in an experiment in dogs with severe hemorrhagic shock. These dogs were resuscitated solely with 7.5% NaCl or equal volumes of normal saline. All dogs in the hypertonic saline group survived; all dogs in the normal saline group died.[96] Many randomized trials have been conducted in the past 2 decades. Hypertonic saline increases mean arterial pressure, decreases systemic vascular resistance, decreases pulmonary vascular resistance, and reduces subsequent blood requirements.[97-99] Studies have shown no increase in complications, and there has been a trend toward decreased mortality.

There continues to be controversy regarding the use of hypertonic saline in hemorrhagic shock. During mass casualties as seen in natural or man-made disasters, hypertonic saline can be used during triage. It is particularly useful in this setting because of its ease of storage, low cost, and ability to expand

plasma volume rapidly. Results can be achieved with 250 mL of 7.5% saline that are comparable to resuscitation with 2 to 3 L of 0.9% saline.[87] Larger, randomized controlled studies are needed to evaluate thoroughly its use in standard practice. In this regard, to date, improved rates of survival with hypertonic saline were reported in seven of eight clinical trials, although statistically significant improvement in overall survival was seen in only one trial.[87]

Five Percent Dextrose

Five percent dextrose functions as free water because the dextrose is metabolized. It is iso-osmotic and does not cause the hemolysis that would occur if pure water were injected intravenously. Although it may be used to correct hypernatremia, 5% dextrose is most often used in the prevention of hypoglycemia in diabetic patients who have had insulin administered.

Crystalloids Versus Colloids

Much controversy exists about the role of crystalloids and colloids in fluid therapy (see Chapters 55 and 88). Proponents of colloid fluid point out that resuscitation with crystalloid solution dilutes the plasma proteins, with a subsequent reduction of plasma oncotic pressure resulting in fluid filtration from the intravascular to the interstitial compartment and the development of interstitial pulmonary edema. Proponents of crystalloid solutions have argued that albumin molecules normally enter the pulmonary interstitial compartment freely and then are cleared through the lymphatic system returning to the systemic circulation. Additional albumin should merely increase the albumin pool cleared by the lymphatics. A review of the literature by Moss and Gould[100] confirmed that all unflawed clinical and experimental studies showed that isotonic solutions are effective plasma volume expanders for resuscitation without the addition of a variety of colloid fluids. The additional cost and potential risks of colloids compared with crystalloids is another argument against colloid administration.

Colloids used in the United States include albumin, hydroxyethyl starch (hetastarch), and dextran. Because the molecules are large, colloids usually do not cross capillary membranes and remain intravascular. Distribution of fluid throughout the body is represented by the Starling-Landis equation:

$$J_v = K_h\ A\left(\left[P_{M\xi} - P_T\right] - \delta\left[COP_{M\xi} - COP_T\right]\right)$$

In this equation, J_v represents the net volume of fluid moving across the capillary wall per unit of time, expressed as $\mu m^3/min$; K_h is the hydraulic conductivity for water, which is the fluid permeability of the capillary wall, expressed as $\mu m^3/min$ per square micrometer of capillary surface area per 1 mm Hg pressure difference. The value of K_h increases up to fourfold from the arterial to the venous end of a typical capillary. $P_{M\xi}$ is the capillary hydrostatic pressure; P_T is the tissue hydrostatic pressure; *A* is the capillary surface area; and δ is the reflection coefficient for plasma proteins. This coefficient is necessary because the plasma proteins are slightly permeable to the microvascular wall, preventing full expression of the two COPs. When δ is 0, molecules cross the membrane freely; when δ is 1, molecules cannot cross the membrane. Typical δ values for plasma proteins in the microvasculature exceed 0.9 in most organs, and these values remain constant, but can be decreased significantly by pathophysiologic processes, including hypoxia, inflammation, and tissue injury. $COP_{M\xi}$ is the colloid oncotic pressure, and COP_T is the colloid oncotic pressure in the tissue.

The hydrostatic and colloid pressure differences across capillary walls (i.e., Starling forces) cause movement of water and dissolved solutes into the interstitial spaces. These movements play a minor role with regard to tissue nutrition relative to simple diffusion. The reflection coefficient that expresses the ability of the semipermeable membrane to prevent movement of a solute varies greatly among tissues. The lungs are moderately permeable relative to other organs, and during pathophysiologic processes such as surgical trauma, the reflection coefficient may change further to alter capillary permeability, resulting in increased capillary permeability or leak. In this setting, colloids move more easily into the interstitium and increase interstitial edema.

With leakage of colloid molecules into the interstitial space, further swelling of tissues occurs because of the unfavorable oncotic pressure gradient, and these molecules are removed by the lymphatic system. Removal of colloids requires longer periods than for crystalloids and can be a significant problem in burn patients and patients undergoing major surgery. A well-known meta-analysis by Velanovich[101] of mortality from eight studies published in 1989 concluded that trauma patients should be resuscitated with crystalloid solutions, whereas colloids were more effective in nonseptic, nontraumatic, elective surgical patients. Current data seem to support the concept that blood composition should be maintained as close to normal as possible in terms of directed transfusion of red blood cells and coagulation factors.[86]

Another factor that must be considered is the overall effect of resuscitation fluid on the coagulation cascade. It is a well-known phenomenon that after trauma, patients may have low levels of circulating coagulation factors. This deficiency may lead to transfusion of fresh frozen plasma to restore deficient factors. The clotting cascade is an extremely complex string of events, with many factors affecting the progression to clot. Studies using a thromboelastogram to measure trauma patients' clotting status have indicated that these patients may be hypercoagulable.[102] Another study using thromboelastographic profiles showed that patients undergoing major surgery who were given intraoperative lactated Ringer's solution also were hypercoagulable compared with baseline.[103] These studies suggest that the type of fluid used for volume resuscitation may play a role in the coagulopathy often seen in trauma patients (see Chapter 56). Definitive studies are still needed, however, to elucidate the true impact that resuscitation fluids play in the coagulation cascade.

Colloid Solutions and Blood Substitutes

Colloid solutions generally are administered in a volume equivalent to the volume of blood lost (see Chapter 55). The initial volume of distribution is equivalent to the plasma volume. The

half-life in circulation of albumin is normally 16 hours, but it can be only 2 to 3 hours in pathophysiologic conditions.[104] The synthetic colloids, processed albumin, and protein fractions have minimal or no risks of infection. Blood substitutes are useful to restore intravascular fluid volume temporarily until definitive treatment can be established. They are inexpensive, have a long storage life, and lack the risk of transmitting viral diseases.

Five Percent Albumin

Five percent albumin or plasma protein fractions (e.g., Plasmanate) have a COP of about 20 mm Hg (i.e., near-normal COP). Preparation methods eliminate infectious agents. These solutions are chosen when crystalloids fail to sustain plasma volume for more than a few minutes because of low COP. These solutions are most appropriate when there is an abnormal loss of protein from the vascular space, such as in cases of peritonitis or extensive burns.

Twenty-Five Percent Albumin

A colloid solution of 25% ("salt-poor") albumin contains purified albumin at five times the normal concentration. When administered, it has the potential to expand the plasma volume by up to five times the volume provided. It is selected when the current plasma volume is diminished, but blood pressure is acceptable, and the total ECF volume is expanded.

Six Percent Dextran 70

Dextran is available as dextran 40 or dextran 70. The numbers 40 and 70 refer to the average molecular mass of the molecules in the solution. The mean molecular weight of dextran 40 is about 40,000 daltons (40 kD), and the mean molecular mass of dextran 70 is about 70,000 daltons (70 kD). The dextran solutions are water-soluble glucose polymers synthesized by certain bacteria from sucrose. Both dextran solutions are ultimately degraded enzymatically to glucose. A colloid solution of 6% dextran 70 is administered for the same indications as 5% albumin. Dextran 40 is used in vascular surgery to prevent thrombosis and is rarely used as a volume expander.

Side effects include anaphylactic or anaphylactoid reactions in about 1 in every 3300 administrations, increased bleeding time caused by decreased platelet adhesiveness (at doses of 20 mL/kg/24 hr), rouleaux formation (i.e., interfering with crossmatching of blood), and rare cases of noncardiogenic pulmonary edema thought to be a direct toxic effect on pulmonary capillaries after intravascular absorption.[105]

Hydroxyethyl Starch

Hydroxyethyl starch (hetastarch) is a synthetic colloid solution in which the molecular mass of at least 80% of the polymers ranges from 10,000 to 2 million daltons. It is available in the United States as a 6% solution in 0.9% NaCl (Hespan). The pH of hetastarch is about 5.5, and the osmolarity is about 310 mOsm/L. The larger molecules are degraded enzymatically by amylase. It is stored in the reticuloendothelial system for several hours and is believed to be renally excreted. It produces dilutional effects similar to other volume expanders and reduces factor VIII:C and vWF levels by 50% to 80% in a dose of 1 to 1.5 L, with prolongation of the partial thromboplastin time.[106] Hetastarch also can interfere with platelet adhesion and clot formation by reduction in glycoprotein IIb/IIIa availability and direct movement of the hetastarch molecules into the fibrin clot.[106] In clinically recommended volumes (i.e., 20 mL/kg), there is minimal interference with subsequent crossmatching. Repeated doses can result in accumulation and side effects, which include allergic reactions and bleeding as described with higher doses (20 to 25 mL/kg). The combination of dextran with Hespan seems to blunt Hespan-induced neutrophil activation.[87]

A new form of hydroxyethyl cellulose has been approved for use in the United States. Hextend (Biotime, Berkeley, CA) contains 6% hetastarch in a solution that approaches physiologic concentrations of the major electrolytes. It also contains physiologic levels of glucose and lactate as a buffer. In contrast to Hespan, Hextend polymer units have an average molecular mass of 670 kd, with 80% within the range of 20 to 2500 kd, making these units significantly smaller than Hespan. Early studies have suggested that Hextend might not affect the coagulation process to the same degree as Hespan. In a study of 90 patients undergoing major surgery, the patients who were given Hextend had no significant change in their thromboelastogram profiles. Patients receiving lactated Ringer solution were found to be hypercoagulable, and patients receiving Hespan were found to be hypocoagulable compared with baseline.[103] In clinical practice, there is movement away from Hespan toward lower and medium molecular weight hetastarchs, which have less inhibitory effect on platelet function and coagulation factors, but a shorter intravascular half-life.

Pentastarch

Pentastarch is a lower molecular weight hetastarch with fewer hydroxyethyl groups per molecule. Pentastarch is undergoing clinical trials in the United States and has anticoagulant effects similar to those of hetastarch.

Perfluorochemical Emulsions and Hemoglobin-Based Oxygen Carriers

Perfluorochemical emulsions have linear oxygen-carrying capacity, but are insufficient to sustain human cellular function, and the first-generation emulsion, Fluosol-DA 20, was discontinued and is no longer available. The second-generation emulsion, Oxygent, discontinued clinical trials. Third-generation emulsions are currently in preclinical stages.

There are numerous classes of hemoglobin-based oxygen carrier solutions; these include cross-linked, polymerized, and conjugated hemoglobin solutions. Hemopure and PolyHeme have completed Food and Drug Administration phase II trials, and phase III trials are under way. Several newer generation hemoglobin-based oxygen carriers are in early preclinical evaluation (see Chapter 55).

Fluid Management of Specific Clinical Conditions

The following guidelines are intended to facilitate initiating therapy, but the choice of fluid and rate of administration must be adjusted to achieve physiologic goals. These guidelines are only a starting point for patients without other major comorbid diseases of vital organs. Careful observation of the patient's response forms the basis for ongoing modification in a continuous feedback loop.

Routine Maintenance Fluids

Routine maintenance fluids are described for a 70-kg postoperative patient. The patient requires 110 mL H_2O and 110 kcal/hr, or 2640 mL and 2640 kcal/day. This example is based on the 4-2-1 rule (Table 54-21), which provides a close approximation of water requirements. The sodium requirement (1.5 mEq/kg/day) is dissolved in the daily fluid requirement of 2.64 L; the 100 mEq/kg/day requirement for potassium is placed in the 2.64 L/day water requirement: 100 mEq K/2.64 L = 42 mEq/L. The potassium concentration needs to be limited, however, if the fluid is to be infused into a peripheral vein because of the chemical irritation induced by high concentrations of potassium.

The long-standing concept first presented in 1957 by Holliday and Seger of the 4-2-1 rule for crystalloid delivery has been challenged more recently. The focus of this challenge is on reduction of free water administration because of increased postoperative hyponatremia related to increased secretion of ADH. An alternative concept is for much lower glucose administration and isotonic sodium–containing solutions to avoid the rare problem of hyponatremic seizure and brain damage (seen mainly in children).[107]

The obligatory glucose needs of the brain and red blood cells are roughly 2 mg/kg/min. Because dextrose contains 3.41 kcal/g instead of 4 kcal/g of glucose, about 17% more dextrose than glucose is required. If carbohydrate is not provided, glycogenolysis and gluconeogenesis from amino acid pools provide the necessary glucose, but accelerate protein catabolism.

Carbohydrate is said to prevent catabolism (i.e., protein sparing), but the benefit of this dose of dextrose is unclear. Total starvation may be preferable because insulin concentrations decrease to very low levels, facilitating lipolysis as a caloric source.

Table 54-21 Calculations of Fluid Requirements by 4-2-1 Rule*

Body Weight (kg)	Fluid Rate (mL/kg)	Weight Category (kg)	Fluid (mL/hr)
0-10	4	10	40
11-20	2	10	20
>21	1	5	5
Total		*25*	***65***

*Assumes a patient weighing 25 kg, resulting in an estimated fluid requirement of 65 mL/hr.

Table 54-22 Volume and Composition of Gastrointestinal Fluids

Fluid Source	24-Hour Volume (mL)	Na^+ (mEq/L)	K^+ (mEq/L)	Cl^- (mEq/L)	HCO_3^- (mEq/L)
Saliva	500-2000	2-10	20-30	8-18	30
Stomach	1000-2000	60-100	10-20	100-130	0
Pancreas	300-800	135-145	5-10	70-90	95-120
Bile	300-600	135-145	5-10	90-130	30-40
Jejunum	2000-4000	120-140	5-10	90-140	30-40
Ileum	1000-2000	80-150	2-8	45-140	30
Colon	—	60	30	40	—

The osmolarity of 7.5% dextrose is 417 mOsm/L, to which is added 156 mOsm/kg H_2O, resulting in a highly hyperosmolar solution. A compromise between the need for glucose and hyperosmolality has been 5% dextrose.

If there are other losses (e.g., gastric drainage), additional sodium and water are required. Gastric drainage of 0.5 L/day loses 30 to 50 mEq of sodium and 50 to 65 mEq of chloride (Table 54-22). When these are added to the maintenance fluid, the concentration approximates 0.45% NaCl. This solution is commonly used as a maintenance intravenous fluid postoperatively in patients with nasogastric drainage.

Routine Intraoperative Fluid Administration

The goals of intraoperative fluid administration are to maintain adequate oxygen delivery, normal electrolyte concentrations, and normoglycemia. The total fluid requirement is composed of compensatory intravascular volume expansion (CVE), deficit replacement, maintenance fluids, restoration of losses, and substitution for fluid redistribution (i.e., third space fluids):

$$\text{Rate of fluid} = \text{CVE} + \text{deficit} + \text{maintenance administration} + \text{loss} + \text{third space}$$

Compensatory Intravascular Volume Expansion

Intravascular volume usually must be supplemented to compensate for the venodilation and cardiac depression caused by anesthesia. Sustaining adequate oxygen delivery in relation to oxygen consumption is an important goal of fluid therapy. Tissue oxygen delivery depends on hemoglobin concentration, oxygen tension, organ perfusion pressures, and organ vascular resistance. Organ perfusion pressures depend on systemic arterial pressure and the higher of organ venous pressure or tissue pressure. Arterial pressure depends on cardiac output and systemic vascular resistance. Cardiac output is related to stroke volume and heart rate, and stroke volume depends on preload, contractility, and afterload. Most general and regional anesthetics cause arteriolar and venous dilation, expanding the vascular capacity. The latter reduces peripheral venous pressure and venous return and cardiac

output. Fluid must be administered to expand the blood volume to compensate for venodilation.

General anesthetics produce myocardial depression (see Chapter 23). Increasing cardiac preload by infusing fluid intravascularly to take advantage of the Starling mechanism often returns stroke volume to an acceptable range. Postoperatively, venodilation and myocardial depression rapidly subside when administration of the anesthetic is stopped. Patients with impaired cardiac or renal responses may then become acutely hypervolemic. Compensatory intravascular volume expansion with 5 to 7 mL/kg of balanced salt solution must occur before or simultaneous with the onset of anesthesia.

Deficits

Characteristics of Fluid Deficits

The fluid deficit equals the maintenance fluid requirement multiplied by the hours since last intake plus unreplaced preoperative external and third space losses. When hypovolemia is present, sufficient fluid should be infused to restore mean arterial pressure, heart rate, and filling pressures to near-normal values before induction. If sufficient time is available, restoration of normal urine flow rate also is desirable. The fluid infusion rate for normal patients should be set to deliver three to four times the maintenance rate until the calculated deficit has been corrected.

Electrolyte abnormalities are common among hospitalized patients. Surgical urgency often forces us to evaluate and correct preexisting abnormalities that may be directly related to the surgical problem or to comorbid diseases or their therapy. The principles of management are outlined in other sections of this chapter. The induction of anesthesia and the onset of mechanical ventilation, fluid shifts, and stress responses induced by surgical trauma all lead to redistribution of water, protein, and electrolytes. The most common and most studied of these are abnormalities of potassium, calcium, and magnesium.

Maintenance Fluid

The maintenance fluid meets ongoing basal needs for water and electrolytes as described earlier. The onset of surgical stimulation and, to a smaller extent, onset of anesthesia elicit changes in catecholamines, cortisol, and growth hormone. These tend to reduce insulin secretion or impede its glucose-lowering effect, leading to hyperglycemia. If dextrose-containing solutions are infused at the usual 5% concentration at the rates often required during surgery, severe hyperglycemia results. The fluid used for volume maintenance should not contain dextrose.

Losses

External losses (e.g., blood, ascites) should be replaced to maintain normal blood volume and normal composition of the ECF volume. Blood loss is replaced initially with 3 mL of balanced salt solution or 0.9% NaCl for each 1 mL of blood loss. For each 1 mL of blood lost, 1 mL of colloid solution should be administered to provide improvement of filling pressures, arterial blood pressure, and heart rate. PRBC infusions are used at roughly 1 mL for each 2 mL of blood lost plus crystalloid or colloid, as previously described. Although the effect on volume is 1:1, the hematocrit of PRBCs (60% to 70%) is about twice the necessary hematocrit of the patient. In patients with reasonable cardiac reserve and without compromised regional circulations (e.g., coronary, cerebral, renal, intestinal), hemoglobin levels of 7.5 g/dL or greater are usually well tolerated.[108] If blood volume is normal, and cardiac failure is not a problem, signs of sympathetic activation, signs of mixed venous oxygen desaturation, or electrocardiogram signs of myocardial ischemia suggest the need for red blood cell administration. The following equation is used to calculate the necessary volume of red blood cells to be infused, and weight is measured in kilograms; because PRBCs have a hematocrit of 60%, the volume to be infused can be estimated:

$$\mathrm{PRBC_{infused}} = \left(\mathrm{Hct_{desired}} \times \mathrm{EBV} \times \mathrm{weight}\right) - \left(\mathrm{Hct_{observed}} \times \mathrm{EBV} \times \mathrm{weight}\right)/0.60$$

where EBV is estimated blood volume per kg: 55 mL/kg for women and 70 mL/kg for men. For a man with a hematocrit of 21% for whom the target hematocrit is 30%, the calculation would be $0.30 \times (70 \times 70) - 0.21 \times (70 \times 70)$ = PRBC infused, estimated at 735 mL, or about 3 U of PRBCs.

Ascites and pleural effusions drained during surgery reform at extremely variable rates. The electrolyte composition is the same as that at the ECF volume, but it also contains protein at concentrations 30% to 100% of the plasma value. Balanced salt solutions are most appropriate for replacement, but colloid should be added when dilution of the patient's COP becomes severe (<15 to 17 mm Hg), and the apparent volume of redistribution of crystalloid begins to increase.

The electrolyte composition of gastrointestinal tract losses depends on the site (see Table 54-22). Most gastrointestinal losses removed at the time of surgery entered the bowel lumen preoperatively and should be considered to be part of the deficit. Evaporation from exposed viscera is entirely water, but the electrolyte is left behind, leading to a need for free water. The amount evaporated is directly proportional to temperature and exposed surface area, and is inversely proportional to relative humidity. Excess urine caused by diuretics, glycosuria, or diabetes insipidus should be replaced with a solution based on urinary electrolyte measurements. The sodium concentration generally ranges from 50 to 100 mEq/L, and the potassium concentration ranges from 20 to 60 mEq/L.

Redistribution

Redistribution (so-called third space losses) results primarily from tissue edema and transcellular fluid displacement. Functionally, this fluid is not available to the vascular space.[109,110] The volume of edema formed is governed by the principles discussed earlier. Colloid enters the injured tissue at a more rapid rate than normal, but at a slower rate than electrolyte. Bowel wall edema may be lessened by using colloid-containing fluids compared with crystalloid.[111] The composition of third space losses is equivalent to the ECF volume electrolyte concentration plus a smaller amount of protein. Balanced salt solution is the most appropriate

Table 54-23 Fluid Calculations for a Simulated Case

Time	Compensatory (mL)	Deficit (mL)	Maintenance (mL)	Blood Loss (mL)*	Third Space (mL)	This Hour (mL)†	Cumulative‡
P-I§	350	220	110	0	0	680	680
I-S¶	—	220	110	0	0	330	1010
First hour¶	—	220	110	300	350	980	1990

replacement fluid. The volume redistributed correlates roughly with the degree of tissue manipulation. Intra-abdominal procedures with small incisions (e.g., hysterectomy) may require an additional 2 mL/kg/hr, whereas a major bowel resection requires an additional 4 to 6 mL/kg/hr.

Table 54-23 describes the fluid management, starting with a hemoglobin level of 15 g/dL, for a 70-kg patient undergoing gastrectomy who has been fasting for 10 hours. The maintenance rate is 110 mL/hr, producing a deficit of 1100 mL.

During the first and second hours of intra-abdominal activity, 100 mL of blood was lost and replaced at a 3:1 rate with a balanced salt solution. By the fourth hour, the deficit had been replaced, and because the abdomen was being closed during part of that hour, the estimate of third space losses was likewise reduced, and no further blood loss occurred. The assumption is made that urine flow was 50 to 80 mL/hr, and that heart rate and arterial blood pressure were in an acceptable range, and the CVP remained 6 to 9 mm Hg. Had the CVP or urine output begun to increase, the rate of fluid administration would have been slowed. If oliguria and tachycardia had occurred, a fluid bolus would have been administered.

Pediatric Patient

There are few special considerations relevant to pediatric fluid management in addition to those for adults (see Chapter 82). Neonates have limited ability to dilute or concentrate urine and have a high fluid requirement. Neonates should not be without fluid for more than 3 to 4 hours; otherwise, significant dehydration may result. Food should be offered until 6 to 8 hours before anesthesia induction, and glucose-containing clear liquids should be given about 4 hours before induction. Clear liquids are defined as transparent liquids that do not contain particulate material or protein, which coagulate in the acid medium of the stomach. Using the same principles as outlined for adults, a neonate requires maintenance fluids of 0.3% NaCl with potassium. Dextrose administration should not exceed 5 mg/kg/min. This requirement generally can be met by using 2.5% dextrose–containing fluids. During extensive, prolonged procedures, blood glucose should be monitored, and the rate of dextrose administration should be modified accordingly. Otherwise, the choice and volumes of fluid are as described for an adult.

Postoperative Patient with Bowel Obstruction

Patients with bowel obstruction are often older and have limited reserves in several organ systems. Estimating the degree of loss of fluids is difficult because fluid is retained in the bowel lumen, where it cannot be measured. The slowly developing volume depletion allows time for full expression of compensatory mechanisms that mask the degree of the deficit. Patients have often ingested no fluids for many hours before entering the hospital and are often vomiting. The patient may have ischemic bowel injury with severe bowel wall edema and continued sequestration of luminal fluid and formation of ascites. Perioperative fluid intake is much larger than measured output, leading consultants to suggest diuresis for fluid overload. Nutrition is impaired preoperatively, and protein losses into the bowel are increased, leading to hypoalbuminemia and exacerbating the loss of fluid from the vascular space. The clinical picture is one of ongoing fluid requirement in the absence of external fluid loss, commonly referred to as third spacing.

The goals of fluid management in this group are similar to the goals for other patients and include restoration of the vascular volume and interstitial volume, correction of electrolyte depletion, correction of acidosis, reduction of systemic vascular resistance into the normal range, and optimization of oxygen delivery and use. Initial fluid infusion can restore intravascular volume sufficiently for blood pressure and heart rate to improve. Intravascular volume still may be depleted, however, with a low cardiac output and severe arterial and venous vasoconstriction. The ECF volume (except for the bowel) remains dehydrated and continues to accept fluids from the vascular space. A patient with vasoconstriction fails to perfuse all tissues, limiting the rate at which the ECF volume can be replenished. If fluids are infused more rapidly than the rate at which they can enter the ECF volume, increased filling pressures may result in pulmonary edema. It is crucial to estimate filling pressures, cardiac output, and systemic vascular

resistance while aggressive intravascular fluid with balanced salt solution and colloid is pursued. It may be necessary to administer arterial vasodilators, such as nitroprusside, to facilitate correction.

Management of a typical patient includes frequent monitoring of arterial blood pressure, heart rate, CVP, pulse pressure, respiratory variation, urine output, and electrolytes. If these parameters are stable, the hemoglobin level and COP should be monitored every 2 to 4 hours until stable. An increasing hemoglobin level indicates ongoing loss of plasma water, with or without protein loss. An increasing COP indicates continued loss of plasma water greater than protein loss. Because maintenance fluid requirements persist, dextrose 5% is infused in 0.45% NaCl with 20 to 40 mEq/L of potassium chloride at maintenance rate.

The fluid lost to the bowel and ECF volume is similar to plasma water in electrolyte composition, and a balanced salt solution is a reasonable first choice for the fluid boluses required to sustain plasma volume. Because the fluid lost also contains protein, albumin or COP should be monitored, and colloid should be infused. If a low COP (approximately 15 to 18 mm Hg) coexists with hemodynamic instability, replacement should be started at 3 mL/kg/hr if the CVP (and pulmonary artery occlusion pressure [PAOP] if a pulmonary artery catheter has been placed) is within the patient's usual range. If COP is high, replacement should start at 1 to 2 mL/kg/hr. If the urine output increases to greater than 1.5 mL/kg/hr, the physician should check for glucosuria. If glucosuria is absent, the fluid infusion rate is reduced by 0.5 mL/kg/hr. If the CVP or PAOP value increases to greater than the patient's usual values, and urine output is 0.5 to 1.5 mL/kg/hr, the fluid infusion rate is reduced by 0.5 mL/kg/hr. If the values for CVP or PAOP or both decrease below the patient's baseline, and the urine flow rate is low, balanced salt or colloid solution is administered rapidly (0.5 to 2 mL/kg/min) with close monitoring of filling pressures.

Patient with Liver Failure

Fluid management in a patient with liver failure (see Chapters 66 and 67) is complicated by several interacting problems. These patients seem to be simultaneously hypervolemic and hypovolemic. Most infused fluid is retained, but renal function deteriorates, along with avid sodium retention and arterial underfilling. Neither sodium retention nor arterial underfilling explains all the clinical findings or leads to consistently successful therapy.

According to the arterial underfilling (primary vasodilation) hypothesis,[112] some factor produced by or not catabolized by the failing liver causes inappropriate arterial dilation. The relative hypotension leads to activation of the systematic nervous system and the RAS and vasopressin release. Subsequent sodium and water retention results in ascites and tissue edema.

Cirrhotic patients have a low systemic vascular resistance, high cardiac output, and relative hypotension. Persistent endotoxemia (shunting through portosystemic anastomoses and enhanced endotoxin absorption from the intestine as a result of bile salt deficiency) may contribute to the vasodilation by activation of a cascade of secondary mediators, beginning with tumor necrosis factor and interleukins. Other vasodilator neurotransmitters may be produced or may not be cleared by the damaged liver.

The primary sodium retention hypothesis explains the avid sodium retention on the basis of hormonal (aldosterone) hyperactivity because of failure of the liver to metabolize aldosterone. Given the ECF volume expansion, the distribution into ascites and tissue edema is explained by the abnormally high portal venous pressures and hypoalbuminemia. Abnormalities of ANP have been investigated. ANP levels are normal or low in cirrhotic patients; this contrasts with the increase usually found in volume-expanded patients.[113] ANP increased with water immersion or fluid administration, but natriuresis was not closely correlated with ANP levels. Water immersion of the lower body compresses the venous capacitance system, resulting in centralization of blood volume. This centralization of blood volume simulates a volume infusion without adding any sodium or water to the body and should cause ANP release. Water immersion did not increase ANP levels in patients with ascites, who have blunted responses. Impaired ANP release failed to explain sodium retention.[113] Patients with tense ascites had increased ANP, renin, and aldosterone concentrations. After paracentesis, ANP increased, but renin and aldosterone levels decreased.[114] The reasons for these findings were not clarified, but a reduction in intra-abdominal pressure could have decreased inferior caval pressure, facilitated venous return, and increased ANP levels. Decreased intra-abdominal pressures also would improve renal perfusion pressure, causing a reduction in renin release and subsequent aldosterone generation.

The role of increased intra-abdominal pressure may be important in sustaining sodium retention after ascites develops. Increased intra-abdominal pressure increases caval pressure; this decreases renal blood flow and glomerular filtration rate because the renal perfusion pressure gradient (i.e., mean arterial pressure minus renal venous pressure) is decreased by systemic hypotension and increased caval pressure. The hypotension and reduction in renal blood flow can lead to renin activation, with aldosterone production. Hypotension, increased aldosterone, and a decreased glomerular filtration rate lead to enhanced sodium reabsorption and low fractional excretion of sodium.

Hypoalbuminemia results from impaired synthesis by the liver, transudation into ascitic fluid owing to portal hypertension, and malnutrition. Low COP favors loss of fluid from the vascular space into the interstitial space, producing intravascular hypovolemia. Ascites results from high portal venous pressure and hypoalbuminemia, markedly increasing the volume of transcellular fluid, which is functionally excluded from rapid exchange in the ECF volume.

Splanchnic blood pooling resulting from increased portal venous resistance plus lower body pooling resulting from elevated caval pressures from ascites tend to decrease net systemic venous return. Patients are functionally hypovolemic despite normal or elevated total blood volume. Heart failure from alcoholic cardiomyopathy may complicate the clinical picture further.

The goals in these patients are to avoid increasing interstitial fluid overload, maintain normal potassium concentration, and maintain intravascular volume. If cardiac failure is present, treatment must include administration of inotropic drugs and diuretics when filling pressures are increased. Intravascular COP should be restored by infusion of 25% albumin when possible. If the patient is acutely hypovolemic, 5% albumin solutions should be preferred to crystalloid, which tend to expand further the already overexpanded ECF volume (i.e., produce more edema and ascites). Intra-abdominal pressure should be estimated from urinary bladder pressure, and paracentesis should be performed whenever it increases to greater than 20 to 25 mm Hg. Trials of

dopamine, norepinephrine, phenylephrine, or vasopressin may be performed in hypotensive patients with low vascular resistance and hypotension to increase renal perfusion pressure and renal blood flow.

Patient with Heart Failure

Fluid management of heart failure is directed to optimize cardiac preload, avoid overadministration of sodium, diminish edema, and correct common electrolyte abnormalities (see Chapter 60). Maintaining ideal cardiac preload during rapid fluid shifts that occur perioperatively is facilitated with direct or indirect measures of preload and cardiac contractile function. Measures of preload include CVP, thermodilution cardiac output, end-diastolic volume, echocardiography, PAOP, and left atrial pressure. Measures of cardiac contractile function include stroke volume, ejection fraction, and stroke work.

Patients with a history of cardiac failure scheduled for major or prolonged surgery should have monitoring instituted preoperatively, and an intravascular fluid challenge (i.e., 500 to 1000 mL/70 kg of crystalloid) should be performed to identify the optimal preload level. Tissue edema is avoided by frequent monitoring of preload and arterial blood pressure coupled with support of contractility and control of vascular resistance. These patients have impaired ability to excrete fluids during the fluid mobilization, which occurs postoperatively. Because the ECF volume is usually already expanded in these patients, the initial rates of fluid infusion intraoperatively should be at the lower ranges of estimates. Similarly, maintenance of intravascular volume without expansion of the interstitial space favors the use of colloid during the immediate perioperative period.

Postoperatively, hemodynamic monitoring is continued until fluid mobilization is complete. The goal postoperatively is to give as little crystalloid as required to maintain adequate overall cardiovascular performance. Perioperative patients commonly receive more than 200 mEq of sodium per day, including maintenance fluids, saline used to measure cardiac output, sodium from antibiotics administration, and sodium infused with vasoactive medications and inotropic agents. Fluid should be maintained at a low maintenance level, and flush fluids and sodium dosage should be measured. As soon as urine output begins to increase, or filling pressures or diastolic volume begins to increase, maintenance fluids should be stopped completely. If preload becomes excessive, diuretics should be administered.

Patients with heart failure have primary electrolyte problems because of compensatory physiologic mechanisms activated by the impaired cardiac performance. These are complicated by therapy with diuretics, digitalis, vasodilators, and angiotensin-converting enzyme inhibitors. Hyponatremia is common because of excess activation of the vasopressin system despite sodium retention. Treatment is directed at excreting the excess water load with diuretics, which should increase free water excretion more than sodium excretion. Sodium administration is not indicated, unless volume depletion is documented. Aldosterone activation and diuretics lead to loss of potassium and magnesium. These ions are crucial for maintaining the stability of cardiac electrophysiology and the effectiveness of digitalis and catecholamine. Ionized calcium is crucial for cardiac contractility, and hypocalcemia is extremely common during the perioperative period. Ionized calcium must be measured and corrected routinely. Severe hypophosphatemia often coexists with abnormalities of calcium, potassium, and magnesium, and leads to depressed contractility.

Patient with Cerebral Edema

Fluid management in patients with cerebral edema (see Chapters 13 and 63) is directed at maintaining cerebral perfusion pressure, avoiding elevations of cerebral venous pressure and hypertension, preventing large changes in plasma osmolality (particularly depression of plasma osmolality), and avoiding hyperglycemia. Cerebral perfusion pressure should be maintained in the high-normal range (see Chapter 63) because autoregulation is impaired in the damaged brain, with a baseline increase in cerebrovascular resistance. Avoidance of intracranial hypertension, the other determinant of cerebral perfusion pressure, is crucial to preserve blood flow to compromised but viable brain tissue. Cerebral edema formation is related to capillary pressure, COP, and permeability. The capillary pressure is between the arterial and venous pressures. Systemic arterial or venous hypertension should be prevented. The normal brain capillary bed is essentially impermeable to sodium, mannitol, and protein, although water crosses freely. The damaged capillary bed becomes excessively permeable, with conductivity being greatest for the smallest molecules, but less for colloids.

Free water restriction without hypovolemia is desired to maintain the plasma sodium level between 142 mEq/L and 148 mEq/L. It is common to provide 75% to 90% of maintenance fluids with 0.9% NaCl or lactated Ringer's solution and to minimize water volume required for other medications. Isotonic crystalloids or colloids do not cause edema in normal brain and can be used to sustain intravascular volume.[115] Hyponatremia is often caused by hypovolemia with inappropriate sodium loss[116] and subsequent water retention. Hyponatremia should be treated with intravascular volume expansion with isotonic or hypertonic sodium chloride. Parenteral nutrition can be prepared with 15% amino acid solutions, 20% lipid, and 70% dextrose to give full protein and caloric support in a minimal volume. Similarly, tube-feeding formulations with 2 cal/mL should be prescribed. Hypovolemia must be carefully avoided. Colloid infusion to sustain intravascular volume, guided by hemodynamic monitoring, tends to provide better long-term control of the intravascular volume than crystalloid. If diuretics or diabetes insipidus causes loss of greater than 2 mL/kg/hr for more than 2 to 4 hours, a pulmonary artery catheter may be indicated for closer monitoring. Blood glucose should be maintained at 80 to 175 mg/dL by close monitoring, initially hourly, with decreasing frequency as stability is exhibited. During acute resuscitation, dextrose administration is limited to no more than 2 mg/kg/min. Indications for steroid use have become fewer in recent years, lessening the problems of hyperglycemia.

Patient with Anuric Renal Failure Undergoing Nontransplantation Surgery

Fluid management in a patient with anuric renal failure for nontransplantation surgery should avoid excessive intravascular fluid

administration and ECF volume expansion, and should maintain or correct electrolyte and acid-base status (see Chapter 96). The anesthesiologist also should attempt to prevent precipitating conditions that would require dialysis during the immediate postoperative period (e.g., hyperkalemia, pulmonary edema, metabolic acidosis). Dialysis is difficult or impossible in a hemodynamically unstable patient, and anticoagulation may be strongly contraindicated for several hours postoperatively. Patients with chronic renal failure often present with hypertension, diabetes, and vascular disease. Avoidance of hypotension may be indicated to maintain coronary or cerebral perfusion pressure. In patients with acute renal failure, hypotension may worsen ischemic renal injury. In contrast, there is a lack of concern for an adverse effect on renal function in a patient with chronic renal failure. Recent dialysis often induces acute electrolyte shifts, hypovolemia, and acidosis. The best compromise seems to be dialysis 12 to 24 hours preoperatively. If dialysis is performed close to the time of surgery, volume removal should be minimal. Patients with renal failure are often malnourished, have hypoproteinemia, are anemic, and have poor glucose tolerance.

Hemodynamics should be closely monitored. If hypovolemia develops, colloid should be used early, but the physician should avoid producing vascular overexpansion. Likewise, interstitial fluid overload should be avoided because it would require acute postoperative dialysis. Crystalloid replacement of third space losses should be limited to 1 to 2 mL/kg/hr, whereas blood loss should be replaced with colloid or RBCs. Correction of sodium, potassium, and acidosis can be achieved by the use of isotonic fluid without potassium (to correct sodium), with reduced amounts of chloride (to correct potassium), and with increased amount of buffer (to correct acidosis). Initially, an infusion of 30% of calculated maintenance fluid rate is important because approximately 70% of normal fluid requirements are used in excreting solute through the kidney, a route no longer available. The pH and levels of sodium, potassium, bicarbonate, and glucose should be monitored at regular intervals.

Patient with Adult Respiratory Distress Syndrome

Fluid management in a patient with adult respiratory distress syndrome (ARDS) (see Chapters 91 and 92) involves maintaining COP and requires a CVP and PAOP value as low as possible that is consistent with good ventricular function. Oxygen delivery should be sustained, ideally greater than 600 mL/min/m^2, by increasing cardiac index and hemoglobin concentration. Compensation for hemodynamic effects of increased airway pressure is achieved by maintaining adequate right and left ventricular filling volumes. When airway pressure increases, the lung expands in proportion to its compliance. The intrapleural pressure increases in direct proportion to lung expansion and inversely with chest-diaphragm compliance. The increased intrapleural pressure increases CVP, which reduces the gradient between the periphery and the CVP. This reduces venous return, unless peripheral venous tone increases, or fluids are administered. The increased venous pressure increases fluid filtration out of the capillary bed, tending to produce hypovolemia. The increased pleural pressure is transmitted through the pericardium to reduce the filling pressure gradient for all cardiac chambers. The consequent reduction in end-diastolic volume diminishes preload to all chambers. The elevation of intrapulmonary pressure increases pulmonary artery pressure, which leads to augmented right ventricular afterload. The reduced venous return, decreased right ventricular preload, and increased afterload may severely compromise right ventricular stroke volume, cause stiffening of the interventricular septum, and reduce preload for the left ventricle.

All these consequences can be improved by intravascular volume expansion except for the increased afterload on the right ventricle. CVP and right ventricular end-diastolic volume are monitored to aid in the decision to institute inotropic therapy. An increase in CVP also compromises lymphatic return from the lung and periphery. Sepsis, the most common coexisting condition with ARDS, causes increased vascular capacity and vasodilation, decreases COP, and results in tissue edema. The net clinical outcome of these factors is that fluid intake usually exceeds output until ARDS and sepsis begin to subside. Studies comparing crystalloid and colloid management over the entire time course of ARDS are being evaluated. After 48 hours, pulmonary function may be better, however, in patients managed in part with colloid than with crystalloids alone.

Acutely Burned Patient

Fluid management in an acutely burned patient focuses on restoration of plasma volume and a shift of the ECF volume into the burned but viable tissue, accompanied by increased losses caused by loss of the normal barrier function of the skin. The tissue injury produced by the burn leads to an abrupt disruption of the capillary bed, manifested by local vasodilation, increased permeability, and, presumably, decreased reflection coefficient to proteins. Vasodilation increases the surface area for filtration and tends to increase capillary pressure. The lowered reflection coefficient diminishes the ability of colloids to retain fluid in the capillaries. Water, electrolytes, and protein enter the burned tissue at the expense of the intravascular volume. Fluid is mobilized from uninjured tissues by various processes, with a net result of transfer of fluid from normal tissue into the injured tissue and intravascular hypovolemia. Capillary permeability was formerly thought to increase in all tissues after a serious burn injury, but this is not the currently held view.[117] In addition to the tissue edema, there is a marked increase in loss of water by evaporation from the wound surface, and the metabolic rate increases dramatically, leading to proportionate increases in fluid requirements.

Several formulas have been developed to aid in writing the initial fluid prescription. The key to success is close hemodynamic monitoring with titration of therapy to the individual patient's physiology. If urine output increases progressively, or if filling pressures increase, fluid administration must be decreased. The Parkland formula[118] prescribes fluids based on the percentage of the body surface area (BSA) burned (% BSA-burned): 2 mL/kg/% BSA-burned during the first 8 hours and 2 mL/kg/% BSA-burned during the next 16 hours. The formula prescribes the following regimen of fluids:

Lactated Ringer's solution at $\left(\left[0.25\,\text{mL/kg}\right]/[\%\ \text{BSA-burned}]\right)/$ hr for 8 hours

Lactated Ringer's solution at $\left(\left[0.125\,\text{mL/kg}\right]/[\%\ \text{BSA-burned}]\right)/$ hr for 16 hours

5% dextrose in water at $\left(\left[0.8\,\text{mL/kg}\right]/[\%\ \text{BSA-burned}]\right)/$ hr plus 5% albumin at $\left(\left[0.015\,\text{mL/kg}\right]/[\%\ \text{BSA-burned}]\right)/$ hr for 24 hours

A 50-kg person with 50% BSA burn should receive fluids equal to (50 kg) × (0.25 mL/kg) × (50% BSA-burned), or 625 mL/hr for 8 hours. This is followed by fluids equal to (50 kg) × (0.125 mL/kg) × (50% BSA-burned), or 310 mL/hr for 16 hours. During the second 24 hours, fluids administered equal (50 kg) × (0.08 mL/kg) × (50% BSA-burned), or 200 mL/hr of 5% dextrose in water, plus (50 kg) × (0.015 mL/kg) × (50% BSA-burned), or 37.5 mL/hr of 5% albumin. Colloids are not contraindicated, even during the acute phase of fluid resuscitation. Although they pass into the injured tissue at an accelerated rate, they have a more sustained effect on plasma volume than crystalloid alone.

Pregnant Patient with Preeclampsia

Goals of fluid management in a pregnant patient with preeclampsia (see Chapter 69) are to restore the contracted intravascular volume,[119] avoid excessive intravascular fluid administration because of normal postpartum fluid mobilization, replace increased sensible (sweat) and insensible (respiratory) losses resulting from labor, be prepared to replace rapid blood loss, avoid hypotension resulting from anesthetic-induced vasodilation to preserve uteroplacental flow, maintain normoglycemia, avoid decreasing the COP further, and prevent pulmonary and cerebral edema. Restoration of depleted plasma volume to normal is crucial for control of hypertension and for administration of anesthesia. Plasma volume is decreased in preeclamptic patients because of elevated lower body venous pressure from uterine compression, pressure-induced natriuresis as seen in hypertension, severe vasoconstriction, and hypoproteinemia owing to proteinuria. After parturition, the fluid retained during pregnancy is usually quickly mobilized and excreted. The preeclamptic patient may have compromised hepatic, renal, or cardiac function, however, impeding the timely excretion of this fluid. These patients are at risk for pulmonary edema because of cardiac failure secondary to severe hypertension and lowered COP. Cardiac filling pressures should be monitored, and a PAOP of less than 12 to 15 mm Hg should be maintained. Plasma tonicity must be maintained by administration of isotonic fluid because these patients are at risk for cerebral edema.

Patient Undergoing Liposuction

Patients undergoing liposuction pose unique challenges in regard to intraoperative fluid management (see Chapter 64). A major factor determining the amount of intravascular volume changes during surgery is the type of liposuction being performed. Liposuction can be an office-based procedure using minimal sedation and subcutaneous infiltration of large volumes of dilute lidocaine and epinephrine solution. This is referred to as the tumescent technique and tends to be used to remove smaller volumes of fat (<3000 mL). Infiltration of large fluid volumes is used to make the tissue firm and to facilitate removal of adipose tissue. Because of the smaller volumes of fat removed and less damage to subcutaneous tissue, the tumescent technique has less risk of large fluid shifts. Semitumescent liposuction tends to involve removal of larger volumes of fat, larger volumes of lidocaine plus epinephrine solution, and more sedation. When a volume of more than 2000 to 3000 mL of fat is removed, the patient may require general anesthesia. These cases may lead to life-threatening complications involving fluid management. Ideally, the epinephrine in the tumescent solution decreases systemic absorption of the extremely large volumes of fluid administered subcutaneously. If the fluid is not removed before the effect of the epinephrine has worn off, however, the patient can absorb a significant amount of the administered fluid. Case reports[120-122] have described the development of pulmonary edema after liposuction.

Complicating the management of liposuction patients further are the large doses of lidocaine administered. During this procedure, patients receive 70 to 80 mg/kg of lidocaine. Vasoconstriction and removal of most of the infused solution is thought to prevent lidocaine toxicity.[123] One report[124] suggested, however, that lidocaine might impair alveolar epithelial fluid clearance. This impaired clearance of pulmonary fluid in conjunction with increased intravascular volume from the absorbed solution may explain some of the adverse occurrences, including death, reported after liposuction. There are significant data to support the increase in the maximum dose of lidocaine from the standard 7 mg/kg, but the maximum safe dosage of lidocaine for tumescent liposuction is still controversial.

The American Academy of Dermatology has published guidelines for liposuction.[125,126] The use of significant amounts of intravenous sedation or analgesic administration was considered to be potentially dangerous, particularly when conducted in an office-based setting. The recommended maximum dose of lidocaine was 55 mg/kg. This increased dosage mandates proper preoperative evaluation of patients' medications to determine whether they are using any drugs that inhibit the cytochrome 3A4 or 1A2 system. These are the major pathways by which lidocaine is metabolized, and even mild inhibition of these enzyme systems can lead to potentially lethal serum lidocaine levels.

Controlled trials regarding the best method for performing liposuction are lacking. A large body of practical knowledge suggests, however, that liposuction can be performed safely using large doses of lidocaine and large volumes of infused solution. Vigilance regarding potential volume overload and pulmonary edema is required to perform this procedure safely.

Intravascular Volume Resuscitation of Patient in Hemorrhagic Shock

The urgent priorities for the resuscitation of a seriously bleeding patient are (1) ensuring an adequate airway, (2) ensuring adequate respiration, and (3) supporting the circulation. Stopping blood loss is most often achieved through manual pressure on the bleeding site or operative intervention (rarely arterial tourniquet application), or both. Formerly, intravenous crystalloid (United States) or colloid (Europe) solution was administered to normalize blood

pressure. More recently, such intravenous fluids have been administered at rates just sufficient to maintain arterial systolic blood pressure between 80 and 100 mm Hg (with some centers limiting total infused volume during emergency medical services transport to 1 to 2 L of balanced salt solution [permissive hypotension]).[86] Benefits of this approach (achieved at the expense of non–vital organ hypoperfusion and lactic acidosis) include minimizing (1) the rate of additional blood loss, (2) hypothermia from the rapid intravenous administration of room temperature fluids, and (3) the dilution of blood hemoglobin and plasma coagulation factors.

When the patient is on the operating table, blood volume expansion is best achieved with fresh whole blood (now rarely available except at forward military trauma centers using a "walking blood bank" of pretyped soldiers) or the next best thing: combined infusion of warmed PRBCs, fresh frozen plasma, cryoprecipitate, and platelets in ratios sufficient to maintain normal coagulation status (e.g., PRBC-to-fresh frozen plasma ratio = 1 : 1 after the one blood volume exchange; 10 U of cryoprecipitate and platelets per 10 U of PRBCs for coagulopathic bleeding). More recently, there have been case reports of the administration of recombinant activated factor VII (NovoSeven) arresting exsanguinating hemorrhage owing to dilutional coagulopathy, but the precise use and dosing of this agent in trauma resuscitation have yet to be fully elucidated (see Chapter 72).

During massive transfusion of a severely hemorrhaging patient undergoing operative intervention, circulating volume can repeatedly alternate between hypovolemia and normovolemia, depending on the progress of surgery and the speed at which the hospital blood bank can provide blood components to the anesthesia team. Especially if balanced salt solutions are given in large quantities, overhydration (especially with mildly hypotonic Ringer's lactate solution) should be avoided in patients with head injury because this increases cerebral edema, increases intracranial pressure, and reduces cerebral perfusion pressure and brain oxygenation.

The patient's acid-base status should be corrected primarily through ensuring adequate ventilation and normalizing blood volume and composition. Metabolic acidosis usually can be rapidly reversed by intravenous administration of sodium bicarbonate, but at the expense of temporary elevation in sodium (which may be beneficial in head-injured patients). Ten percent calcium gluconate or calcium chloride solution (the latter being the more histotoxic of the two in the event of extravasation) should be administered to counteract the calcium-binding effects of the citrate in blood products if (1) laboratory or bedside monitoring reveals a low ionized calcium level, (2) the patient receives blood products at a rate of 10 combined units of PRBCs and fresh frozen plasma per hour, (3) hepatic function (cirrhosis) or hepatic blood flow (high aortic cross-clamp) is compromised, or (4) hypotension remains unresponsive to apparently adequate volume administration.

In addition to ensuring that all crystalloid, colloid, and blood product infusions are warmed (preferably to 40°C [104°F]), surface heating should be implemented (though use of forced-air heating blankets and, if necessary, warming the operating room to 26.6°C [80°F]). Hypotensive patients also should be evaluated for nonhemorrhagic mechanisms of shock, including cardiac/obstructive (tamponade, tension pneumothorax, air embolism) and distributive (head and spinal cord injury, anaphylaxis, transfusion reaction).

In addition to providing life support, the anesthesia team should administer central nervous system depressant medications as tolerated to provide unconsciousness (e.g., administer scopolamine for systolic blood pressure <60 mm Hg; administer ketamine or midazolam, or both, for systolic blood pressure 60 to 90 mm Hg; add fentanyl for systolic blood pressure 80 to 100 mm Hg; and add an inhaled agent when systolic blood pressure is sustained >100 mm Hg, with normal urine flow and minimal arterial pressure variation with mechanical ventilation). Complete muscle relaxation often must be achieved whether or not fully anesthetizing drug doses are tolerated, and brain wave monitors can be helpful beyond standard monitors, an arterial line, and a central venous catheter.

Acknowledgments

The authors thank Dr. Alan W. Grogono, former Chairman and Professor, Tulane Medical Center, and Dr. Ian Kucera, former Assistant Professor, Texas Tech Health Sciences Center, Lubbock, Texas, for their past contributions to earlier versions of this chapter. The authors also thank Dr. Casey Daste, Dr. Alex Hellman, and Dr. John Vu for their help in the preparation of the references in this chapter.

55 Transfusion Therapy

Key Points

1. The most common causes of transfusion-induced death are bacterial contamination transfusion-related acute lung injury, transfusion reactions (i.e., ABO mismatch), and bacterial contamination.
2. Although the overall condition of the patient is of prime importance, a transfusion trigger of a hemoglobin level of 8 g/dL or less can be tolerated by relatively healthy, younger patients. Those who are not critically ill or have severe cardiorespiratory disease may require a transfusion trigger of 9 to 11 g/dL.
3. Because of storage at room temperature, platelets are the blood component most frequently contaminated with bacteria, which is the cause of platelet-induced sepsis.
4. Transfusion-transmitted hepatitis and human immunodeficiency virus (HIV) infection are rare. West Nile virus infection was a rapidly emerging problem but now can be tested for and is now rare.
5. Like in many countries in Europe and also Canada, leukoreduction of blood products is becoming universal in the United States.
6. Human and bovine modified hemoglobin products are undergoing clinical trials as synthetic blood or oxygen carriers, similar to allogeneic blood. Whether they will ever be used routinely is very questionable.

Blood Therapy

Eighty percent of the world's population has access to only 20% of the world's "safe" blood, that is blood that is properly collected and tested. Only 30% of the world's countries have a nationwide transfusion service.[1] The conclusions presented in this chapter assume the use of contemporary concepts and technology via organized transfusion services. According to a survey conducted by the Committee on Blood and Blood Products of the American Society of Anesthesiologists,[2] much of all blood given to patients is during the perioperative period. The anesthesiologist should be an expert on the implications and the complications associated with blood transfusions and should be a leader of acute transfusion medicine in the hospital setting.

Indications for Transfusion

Allogeneic (Homologous) Blood

Blood transfusions are given to increase oxygen-carrying capacity and intravascular volume. Theoretically, increasing vascular volume is not an indication for blood transfusions because volume can be augmented with administration of fluids that do not transmit infections (e.g., crystalloids or some colloids). On the practical side, when a patient is hemorrhaging, blood is given to increase oxygen-carrying capacity and intravascular volume. The goals should be to restore intravascular volume, cardiac output, and organ perfusion to normal levels. By using crystalloids and/or colloids to treat hypovolemia, normovolemic dilutional anemia will be created. Increasing cardiac output will enhance oxygen delivery to the tissues to a limited extent. In fact, using normovolemic anemia clinically, Mathru and colleagues found inadequate splanchnic and preportal oxygen delivery and consumption when the hemoglobin level was 5.9 g/dL.[3] Additional oxygen delivery to organs and tissues can only be enhanced by red blood cells via whole blood or packed red blood cells, Thus, increasing oxygen-carrying capacity is the only real indication for blood transfusions.

What are the specific indications for blood transfusions? With a specific indication (i.e., increase oxygen-carrying capacity), this question, at first glance, should be easy to answer. Unfortunately, there is little or no way, except in severe life-and-death situations, to determine whether oxygen-carrying capacity is inadequate. The controversy revolves around how much emphasis should be placed on hemoglobin or hematocrit values. The limitation of such values is based on a potential extreme variability from one patient to another regarding the need for increased oxygen-carrying capacity. For example, young healthy patients with normal cardiorespiratory function may easily compensate

Table 55-1 American College of Surgeons' Classes of Acute Hemorrhage

Factors	Class I	Class II	Class III	Class IV
Blood loss (mL)	750	750-1500	1500-2000	2000 or more
Blood loss (% blood volume)	15	15-30	30-40	40 or more
Pulse (beats/min)	100	100	120	140 or higher
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure (mm Hg)	Normal or increased	Decreased	Decreased	Decreased
Capillary refill test	Normal	Positive	Positive	Positive
Respirations per minute	14-20	20-30	30-40	35
Urine output (mL/hr)	30	20-30	5-10	Negligible
Central nervous system: mental status	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Fluid replacement (3-1 rule)	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

for anemia (i.e., chronic or acutely induced by hemorrhage), whereas at an identical hematocrit value, elderly patients with cardiac disease may have serious problems with surgery and anesthesia. An individual patient's hemoglobin level may vary markedly in the perioperative period independent of and in addition to transfusions of red blood cells (RBCs). This concern has led many medical organizations to place emphasis on overall medical judgment rather than a specific laboratory value,[4] with some debate.[5] Conversely, other organizations have chosen to make far more complex directions, such as those in Table 55-1 from the American College of Surgeons. Despite the intellectual appeal of the latter approach, most of the American College of Surgeons' criteria cannot distinguish inadequate intravascular volume from diminished oxygen-carrying capacity.

The foundation for using the hemoglobin or hematocrit value as the initial consideration for defining transfusion requirements followed a 1988 National Institutes of Health Consensus Conference[6] that concluded that otherwise healthy patients with a hematocrit value more than 30% rarely require perioperative blood transfusions, whereas patients with acute anemia (as in intraoperative blood loss) of less than 21% frequently require blood transfusions. They also recognized that patients with chronic anemia (as in renal failure) might tolerate a hemoglobin concentration of less than 7 g/dL. Amazingly and despite many studies, publications, and debates, the fundamental guidelines have not changed substantially in the 20 years after this conference.

The ultimate determination of the hematocrit or hemoglobin value at which blood should be given will have to be a clinical judgment based on many factors, such as cardiovascular status, age, anticipated additional blood loss, arterial oxygenation, mixed venous oxygen tension, cardiac output, and blood volume. Oxygen extraction ratio has been recommended as an indicator for transfusions,[7] but this technique requires invasive monitoring. Even so, the results by this indicator were not dramatic between groups who were or were not transfused.

Several groups have attempted to define, usually in patients in intensive care units, the point at which blood transfusions should be given by measures of tissue oxygenation and hemodynamics (e.g., increase in oxygen consumption in response to added oxygen content).[8-10] No specific measure could consistently predict when a patient would benefit from a blood transfusion. However, evidence suggests that the quality (e.g., age) of the blood and its increased oxygen capacity (e.g., hemoglobin level > 10 g/dL) may benefit very sick patients. Purdy and colleagues,[11] found that patients who received 17-day-old blood (range, 5 to 35 days) versus 25-day-old blood (range, 9 to 36 days) had a higher survival rate. In 1999, the length of storage of banked blood was associated with the development of postoperative pneumonia after cardiac surgery.[12] However, in 2003, prolonged storage of blood was not associated with increased morbidity after cardiac surgery.[13]

Yet the saga continues. In 2006, Weiskopf and coworkers performed studies in healthy volunteers who were evaluated by a standard computerized neuropsychological test 2 days and 1 week after acute isovolemic anemia was induced.[14] When correcting the anemia, they concluded that erythrocytes stored for 3 weeks are as efficacious as those stored for 3.5 hours. Spahn[15] wrote an accompanying editorial agreeing with Weiskopf and coworkers[2] and, furthermore, postulated that 2,3-diphosphoglycerate (2,3-DPG) levels may not be the key factor in determining the oxygen-delivery of oxygen (i.e., 2,3-DPG levels are reduced in older blood, but the blood still delivers oxygen).

Two years later, different conclusions were published. Koch and colleagues[16] concluded that giving erythrocytes (packed red cells) older than 14 days was associated with an increased risk of postoperative complications along with reduced short-term and long-term survival in patients undergoing coronary artery bypass surgery. This article also had an accompanying editorial that concluded that "to the extent possible, newer blood might be used in clinical situations that seem to call for it."[17] Rather than continuing the ongoing saga and debate regarding the influence of the age of blood transfused, all of the available studies need to be analyzed together that probably relate to the underlying health of the patient and the condition that requires blood transfusions. This debate is not close to being resolved. Because the quality of blood decreases with length of storage, an association with morbidity would not be surprising. The influence of the age of blood infused is discussed later in this chapter.

Perhaps the development of more sensitive indicators of tissue oxygenation (e.g., intramucosal pH) will provide indicators for transfusion. In the 1990s, several efforts could not relate postoperative hemoglobin levels to specific outcomes. Furthermore, Weiskopf and coworkers[18] found that decreases in hemoglobin concentration to 5.0 g/dL did not produce any evidence of inade-

quate oxygenation in healthy patients. However, these patients were not subjected to the stresses of recovery from surgery and anesthesia. Still, Weiskopf and coworkers[18] found that these patients compensated for their low hemoglobin levels by increasing heart rate and stroke volume. It is tempting to argue that patients who have a more rapid than expected heart rate or who cannot increase their cardiac output should receive a transfusion to a higher hemoglobin level than 10 g/dL. Unfortunately, precise conclusions cannot be derived from these helpful and suggestive data.

To arrive at some conclusions in the presence of incomplete data, two complementary recommendations are given. In 2006, the American Society of Anesthesiologists Practice Guidelines[4] offered these recommendations:

1. Transfusion is rarely indicated when the hemoglobin concentration is greater than 10 g/dL and is almost always indicated when it is less than 6 g/dL, especially when the anemia is acute.
2. The determination of whether intermediate hemoglobin concentrations (6 to 10 g/dL) justify or require RBC transfusion should be based on the patient's risk for complications of inadequate oxygenation.
3. The use of a single hemoglobin "trigger" for all patients and other approaches that fail to consider all important physiologic and surgical factors affecting oxygenation is not recommended.
4. When appropriate, preoperative autologous blood donation, intraoperative and postoperative blood recovery, acute normovolemic hemodilution, and measures to decrease blood loss (i.e., deliberate hypotension and pharmacologic agents) may be beneficial.
5. The indications for transfusion of autologous RBCs may be more liberal than those for allogeneic RBCs because of less frequent (but still significant) risks associated with the former.

The following indications were recommended in the 6th edition of *Anesthesia* with the rule of thumb that administration of 1 unit of packed RBCs will increase hematocrit value by 3% to 5%:

1. Blood loss greater than 20% of blood volume when more than 100 mL
2. Hemoglobin level less than 8 g/dL
3. Hemoglobin level less than 10 g/dL with major disease (e.g., emphysema, ischemic heart disease)
4. Hemoglobin level of less than 10 g/dL with autologous blood
5. Hemoglobin level less than 12 g/dL and ventilator dependent

Although these recommendations are current, the elusive "transfusion trigger" remains in a prominent part of the debates in anesthesia specifically and in medicine in general. Both recommendation lists[4] agree that a transfusion trigger of 8.0 g/dL or less can be tolerated by patients who are not critically ill or do not have severe cardiorespiratory disease. That conclusion is still valid.

In the past 5 years, research has been directed toward how liberal the transfusion trigger should be in critically ill patients. Unfortunately, there are almost no data regarding intraoperative transfusion triggers. Still, critical care physicians have suggested that administration of blood transfusions is related to the incidence of ventilator-assisted pneumonia[19] and nosocomial infections[20]; while this possibility cannot be excluded, these are complicated problems with many variables. Despite the problem with identifying a specific transfusion trigger, Ely and Bernard[21] have generally confirmed the conclusions listed above in the sixth edition of *Miller's Anesthesia*. Subsequent efforts and editorials have leaned toward a lower transfusion trigger for even critically ill patients.[22,23] Ensuing studies have found no apparent benefit or a trend toward better outcomes with transfusion-induced hemoglobin levels more than 8.0 g/dL (i.e., 9.0 to 10.0 g/dL).[24,25] Yet most recently, Vincent and associates, using a multicenter observational study, found that "blood transfusions may no longer be associated with increased mortality rates and may be associated with improved survival."[26] Although these multicenter studies have statistical challenges,[27] a more liberal transfusion trigger is suggested. Perhaps the margin of safety should be increased by increasing the hemoglobin in critically ill patients, including those with cardiorespiratory disease. There is increasing concern about the underuse of blood transfusion therapy.[28] However, blood is a valuable resource that sometimes is in short supply. Perhaps with the availability of erythropoietin and synthetic RBCs, a more liberal hemoglobin concentration can be used. As concluded by Weiskopf,[29] "We merely await advances in technology that will enable us to measure directly the value of concern and thereby free us from arguments over which surrogate (e.g., hemoglobin) to measure and what value indicates the need for augmented oxygen delivery."

Autologous Blood

Autologous blood (see also Chapter 57) is assumed to be much safer than allogeneic blood, mainly because of the decreased risk of infection. Because of a marked decrease in infectivity from allogeneic blood (see "Infectivity of Blood"), the difference in safety compared with autologous blood is much less. Not surprisingly, the proportion of autologous blood collected has significantly decreased since the peak in 1992. In fact, autologous blood may not be safer than allogeneic blood. Furthermore, autologous blood does have risks. One of every 16,000 autologous blood donations results in a reaction severe enough to require hospitalization.[30] Complications associated with autologous blood transfusions include the following:

- Anemia
- Preoperative myocardial ischemia from anemia induced by preoperative donation
- Autologous units given to wrong patient (1 per 13,000 to 62,000)[31]
- Need for more frequent blood transfusions

In fact, transfusion-related bacterial sepsis may be more frequent with use of autologous blood because of the underlying medical condition of the donor and less stringent donor selection. Also, autologous blood must be tested the same as allogeneic blood.

The testing and screening of blood donors is by no means perfect. Ask yourself a question: If given a choice, would you want your own blood or allogeneic blood?[32]

Compatibility Testing

The ABO-Rh type, crossmatch, and antibody screen are frequently referred to as compatibility tests (see Chapter 57). These tests were designed to demonstrate harmful antigen-antibody interactions in vitro so that harmful in-vivo antigen-antibody interactions could be prevented. Donor blood used for emergency transfusion of group-specific blood must be screened for hemolytic anti-A or anti-B antibodies or both. All donor blood must be tested for the correct ABO and Rh type and screened for unexpected antibodies. Similarly, recipient blood must also undergo ABO-Rh typing, as well as testing for unexpected antibodies. Once this has been completed, proper selection of donor blood requires a test for compatibility between recipient blood and donor blood; this test is known as a crossmatch (Fig. 55-1).

ABO-Rh Typing

Determination of the patient's correct blood type is exceedingly important because the most serious and tragic reactions are usually caused by accidental transfusion of ABO-incompatible blood. These reactions result from naturally occurring antibodies (i.e., anti-A and anti-B), which activate complement and lead to rapid intravenous hemolysis. Anti-A or anti-B antibodies, or both, are formed whenever the individual lacks either or both of the A and B antigens. In essence, antibodies are directed against those antigens that are lacking in the individual's own cells. ABO typing is performed by testing RBCs for the A and B antigens and the serum for the A and B antibodies before transfusion (Table 55-2).

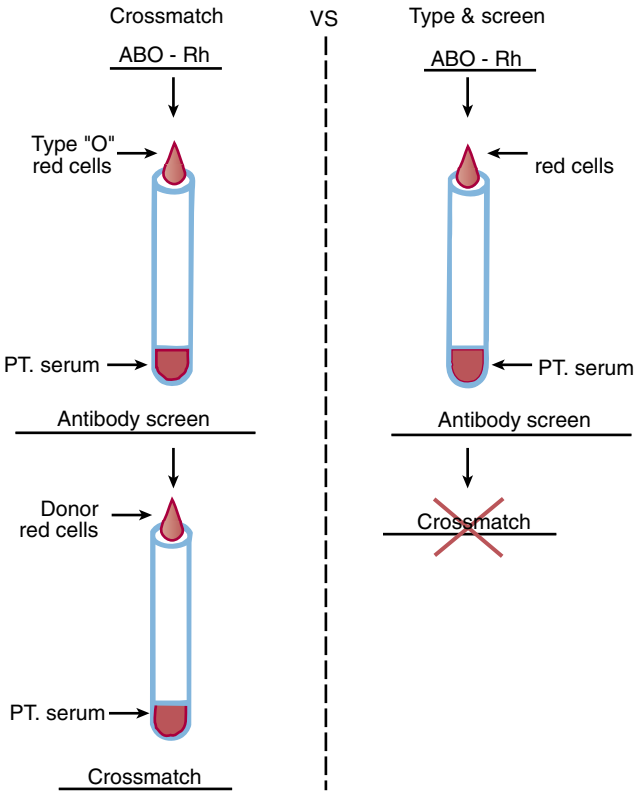

Figure 55-1 Outline of the tests used for a crossmatch. The X over the word crossmatch means that the crossmatch is not included in the type and screen.

Table 55-2 ABO Compatibility Testing

	Red Cells Tested With		Serum Tested With	
Blood Group	**Anti-A**	**Anti-B**	**A Cells**	**B Cells**
A	+	–	–	+
B	–	+	+	–
AB	+	+	–	–
O	–	–	+	+

The only additional required testing is that for the Rh(D) antigen. Antigen D is a very common one and, except for the A and B antigens, the one most likely to produce immunization. Sixty to 70 percent of Rh(D)-negative recipients are immunized (produce anti-D) if they are given blood transfusions with Rh(D)-positive blood. About 85% of individuals possess the D antigen and are classified as Rh(D) positive; the remaining 15%, who lack the D antigen, are classified as Rh(D) negative. Because anesthesiologists and surgeons often have difficulty understanding the blood grouping system, Table 55-3 is included to facilitate identification of donor blood groups whose blood patients can receive.

Crossmatching

A crossmatch is essentially a trial transfusion within a test tube in which donor RBCs are mixed with recipient serum to detect a potential for serious transfusion reaction. The crossmatch can be completed in 45 to 60 minutes and is carried out in three phrases: an immediate phase, an incubation phase, and an antiglobulin phase.

The first phase is conducted at room temperature and is a check against errors in ABO typing. It detects ABO incompatibilities and those caused by naturally occurring antibodies in the MN, P, and Lewis systems. This takes 1 to 5 minutes to complete.

The second phase involves incubation of the first-phase reactions at 37°C in albumin or low-ionic strength salt solution. The addition of albumin and low-ionic-strength salt solution aids in the detection of incomplete antibodies or those antibodies that are able to attach to a specific antigen (i.e., sensitization) but are unable to cause agglutination in a saline suspension of RBCs. This phase primarily detects antibodies in the Rh system. The incubation of 30 to 45 minutes in albumin and of 10 to 20 minutes in

Table 55-3 Donor Blood Groups that Patients Can Receive

Donor	Recipient
O	O, A, B, AB
A	A, AB
B	B, AB
AB	AB

low-ionic-strength salt solution in this phase is of sufficient duration to allow antibody uptake sensitization by cells so that incomplete antibodies missed in this phase can be detected in the subsequent antiglobulin phase.

The third phase of the crossmatch, the indirect antiglobulin test, involves the addition of antiglobulin sera to the incubated test tubes. With this addition, antihuman antibodies present in the sera become attached to the antibody globulin on the RBCs, causing agglutination. This antiglobulin phase detects most incomplete antibodies in the blood group systems, including the Rh, Kell, Kidd, and Duffy blood group systems.

Although all three phases of the crossmatch are important, the first two stages are of prime importance in preventing serious hemolytic transfusion reactions (see "Type and Screen"). The incubation and antiglobulin phases are especially important because the antibodies appearing in these phases are capable of causing serious hemolytic reactions. Except for hemolytic reactions involving anti-A and anti-B, reactions caused by antibodies appearing in the immediate phase (RT) are frequently less severe. This is because many of the antibodies appearing in this phase are naturally occurring antibodies present in a low titer and are not reactive at physiologic temperatures.

Antibody Screening

The antibody screen is also carried out in three phases and is similar in length to the crossmatch. The screen, however, is a trial transfusion between the recipient's serum and commercially supplied RBCs that are specifically selected to contain optimal numbers of RBC antigens or those antigens that will react with antibodies that are commonly implicated in hemolytic transfusion reactions.

The screen for unexpected antibodies is also used on donor serum and is performed shortly after withdrawal of blood from the donor. It is necessary to screen donor serum for unexpected antibodies to prevent their introduction into the recipient serum. This screen is performed primarily to prevent reactions between transfused donor units.

Approaches Requiring Less Than a Complete Crossmatch

Type and Screen

The term *type and screen* refers to elimination of the crossmatch in which blood is set aside with only the ABO-Rh type having been determined and antibody screening having been performed. The type and screen without crossmatch determines the ABO-Rh of the patient and the presence of the most commonly found unexpected antibodies. Specifically, the patient's serum is screened for the presence of unexpected antibiotics by incubating it with selected reagent RBCs (i.e., screen cells).[33] These cells contain all antigens capable of inducing clinically significant RBC antibody reactions.

Complete transfusion testing for compatibility between donor and recipient blood ensures optimal safety and therapeutic effect of transfused blood. In some cases, however, the crossmatch is eliminated and blood can be set aside in which only the ABO-Rh type and antibody screen are performed (i.e., type and screen). For those few patients in whom the antibody screen reveals the presence of unexpected antibody, the antibody is subsequently identified in the blood bank and units of blood lacking the corresponding antigen are set aside for surgery. If an emergency transfusion is required after type and screen alone, an immediate-phase crossmatch is performed before transfusion to eliminate reactions that may result from human errors in ABO-Rh typing. Blood given in this manner is more than 99% effective in preventing incompatible transfusion reactions due to unexpected antibodies.[34] The type and screen without the complete crossmatch does not protect against reactions due to antibodies reactive against lower-incidence antigens, those not represented on the screening cells but present on the donor RBCs. Generally, antibodies that are not detected in the type and screen are weakly reactive antibodies that do not result in serious hemolytic transfusion reactions. In a study of 13,950 patients, Oberman and associates[35] discovered only eight "clinically significant" antibodies after complete crossmatch that were not detected during the antibody screening. The antibodies were all in lower titer and were believed by Oberman and coworkers to be unlikely to cause serious hemolytic reactions.

Type and screen should not be confused with the term *type and hold*. This term refers to a sample of blood from a potential blood recipient received by the blood bank in which the blood type but no crossmatch has been ordered. This term is misleading because it does not denote how long the blood should be held, nor does it indicate that an antibody screen has been performed on the sample. However, in most cases in which a type and hold has been ordered, an antibody screen is performed on that sample. Because of the confusion that has arisen with type and screen, the type and hold terminology and method of ordering blood have been abandoned by most blood banks.

Maximal Surgical Blood Order Schedule

Routine preoperative crossmatching of blood for surgical cases means that crossmatched blood is unavailable for others for 24 to 48 hours. During this time, 1 to 2 days is lost and the chance for outdating increases. A second aspect relates to the growing realization that, for certain elective surgical procedures, the number of crossmatched units that are ordered frequently far exceeds the number actually transfused. To quantify this problem better, the crossmatch-to-transfusion (C/T) ratio has been used. If the C/T ratio is high, the blood bank is burdened with keeping a large blood inventory, using excessive personnel time, and having a high incidence of outdated units. Sarma[36] recommended that for surgical procedures in which the average number of units transfused per case is less than 0.5, determination of the ABO-Rh type and a screen of the patient serum for unexpected antibodies (type and screen) should be used. This would be in lieu of a complete type and crossmatch for patients with negative antibody screens. For those with a positive antibody screen, the blood bank must provide compatible units that lack the corresponding antigen. Blood banks attempt to maintain C/T ratios of 2.1 to 2.7.[36] To increase the rate of use and lower the C/T ratio, blood banks attempt to decrease the emphasis on crossmatching of blood through such means as the type and screen and such programs as the maximal surgical blood order schedule.[37] This schedule consists of a list of surgical procedures and the maximal number

of units of blood that the blood bank will crossmatch for each procedure. This schedule is based on the blood transfusion experience for surgical cases in hospitals in which the schedule is employed. Each hospital's maximal surgical blood order schedule is developed by the suppliers and the users of blood in that hospital, such as blood bankers, anesthesiologists, and surgeons.

Is the Crossmatch Really Needed?

In previously transfused or pregnant patients, only about 1 patient in 100 may have an irregular antibody other than the anti-A and anti-B antibodies. However, some of these irregular antibodies are reactive only at temperatures below 30°C and therefore are insignificant in most transfusions. Others that are reactive at about 30°C can produce serious reactions if the transfused cells contain appropriate antigen. In order of probable significance, anti-Rh(D), Kell, C, E, and Kidd are the most common of clinically significant antibodies. After anti-A and anti-B, anti-Rh(D) is the most common significant antibody. If the correct ABO and Rh blood type is given, the possibility of transfusing incompatible blood is less than 1 chance in 1000. Put in other terms, ABO-Rh typing alone results in a 99.8% chance of a compatible transfusion, the addition of an antibody screen increases the safety to 99.94%, and a crossmatch increases this to 99.95%.[38]

The blood bank can reduce the chance of incompatibility by performing an antibody screen. The chance of this screening test missing an antibody that is potentially dangerous has been estimated to be no more than 1 in 10,000.

Emergency Transfusion

In many situations, there is urgent need for blood before completion of compatibility testing (ABO-Rh, antibody screen, and crossmatch) (see Chapter 72). For those situations that do not allow time for complete testing, an abbreviated format for testing can be used. The preferred order for the selection of partially crossmatched blood is as follows.

Type-Specific, Partially Crossmatched Blood

When using uncrossmatched blood, it is best to obtain at least an ABO-Rh typing and an immediate-phase crossmatch. This incomplete crossmatch is accomplished by adding the patient's serum to donor RBCs at room temperature, centrifuging it, and then reading it for macroscopic agglutination. This takes 1 to 5 minutes and eliminates serious hemolytic reactions resulting from errors that may occur in ABO typing. Only a few unexpected antibodies outside the ABO systems are detected, such as those directed against antigens in the MN, P, and Lewis systems, most of which are not clinically significant.

Type-Specific, Uncrossmatched Blood

For proper use of type-specific blood, the ABO-Rh type must be determined during the patient's hospitalization. Blood types from historical records, relatives, ambulance drivers, and other hospitals are frequently inaccurate. For those who have never been exposed to foreign RBCs, most ABO type-specific transfusions are successful. Caution should be used for patients who have previously received transfusions or have had pregnancies. In my experience in the military, type-specific uncrossmatched blood was frequently used in emergencies with no serious consequence. In the civilian setting, using 1 year's experience with 56 patients, uncrossmatched, type-specific blood for emergency transfusion produced no adverse effects, even though complete serologic testing had not been performed.[39] These investigators concluded that although the use of uncrossmatched blood is usually safe, the potential for serious reaction still exists, and they cautioned against its indiscriminate use. About 1 in 1000 patients has an unexpected antibody detected in crossmatch. For those who have previously been exposed to RBC antigens, transfusion of the ABO-Rh type-specific, uncrossmatched blood may be more hazardous. For every 100 of these individuals, 1 has an antibody detected by the crossmatch.

Type O Rh-Negative (Universal Donor), Uncrossmatched Blood

Type O blood lacks the A and B antigens and consequently cannot be hemolyzed by anti-A or anti-B antibodies in the recipient's blood (see Tables 55-2 and 55-3). Because of this, people with type O blood have been called universal donors and their blood can be used in emergency transfusions when typing or crossmatching is not available. However, some type O donors produce high titers of hemolytic IgG, IgM, anti-A, and anti-B antibodies. High titers of these hemolysins in donor units are capable of causing destruction of A or B RBCs of a non–type O recipient. Type O Rh-negative, uncrossmatched packed RBCs should be used in preference to type O Rh-negative whole blood because packed erythrocytes have smaller volumes of plasma and are almost free of hemolytic anti-A and anti-B antibodies. If type O Rh-negative whole blood is to be used, the blood bank must supply type O blood that is free of hemolytic anti-A and anti-B antibodies.

During emergency transfusion of more than two units of type O Rh-negative, uncrossmatched whole blood, the patient probably cannot be switched to his or her blood type (A, B, or AB) as soon as the blood bank determines the correct blood type. Switching could cause major intravascular hemolysis of donor RBCs by increasing titers of transfused anti-A and anti-B. Continued use of O Rh-negative whole blood results only in minor hemolysis of recipient RBCs, with hyperbilirubinemia as the only complication. The patient must not be transfused with his or her correct blood type until the blood bank determines that the transfused anti-A and anti-B has decreased to levels that permit safe transfusion of type-specific blood.

Specific Recommended Protocol

In view of the aforementioned considerations, the following steps are recommended for patients who are hypovolemic and require blood transfusion:

1. Infuse crystalloids or colloids.
2. Draw a blood sample for typing and crossmatching.

3. If crossmatched blood is not ready to give, use type-specific or type O Rh-negative cells or type O Rh-positive cells for males or postmenopausal females without a history of transfusions; type-specific, partially crossmatched blood; or type-specific, crossmatched blood.

Storage of Blood

Citrate phosphate dextrose adenine (CPDA-1) is an anticoagulant preservative in which blood is stored at 1°C to 6°C. Citrate is an anticoagulant, phosphate serves as a buffer, and dextrose is a red cell energy source. The addition of adenine to CPD solution allows RBCs to resynthesize adenosine triphosphate (ATP), which extends the storage time from 21 to 35 days. As a result, RBCs or whole blood can be stored for 35 days when stored in CPDA-1.[40] The shelf life can be extended to 42 days when AS-1 (Adsol), AS-3 (Nutricel), or AS-5 (Optisol) is used.[41,42] Adsol contains adenine, glucose, mannitol, and sodium chloride; Nutricel contains glucose, adenine, citrate, phosphate, and sodium chloride. Optisol contains only dextrose, adenine, sodium chloride, and mannitol. On a local level, 90% of our RBCs are mostly stored in AS-1 at the University of California, San Francisco. On a national level, 85% of the RBCs are collected in AS-1. The hematocrit of packed red cells stored in AS-1 is approximately 60%. This duration of storage has been set by U.S. federal regulation and is determined by the requirement that at least 70% of the transfused RBCs remain in circulation for 24 hours after infusion. RBCs that survive 24 hours after transfusion disappear from the circulation at a normal rate. Those that do not survive are subsequently removed from the circulation by the blood recipient.

That blood can be stored for 42 days is a mixed blessing. The obvious advantage is the increased availability of blood. However, there are increasing numbers of articles whose authors believe that blood stored for long periods is less effective than fresher blood in critically ill patients, probably because of a leftward shift in the oxygen-dissociation curve (see "Changes in Oxygen Transport").[13] An increased incidence of postoperative pneumonia in cardiac patients has been associated with the use of older blood.[12]

The citrate ion prevents clotting by binding calcium; dextrose allows the RBCs to continue glycolysis and maintain sufficient concentrations of high-energy nucleotides (ATP) to ensure continued RBC metabolism and subsequent viability during storage. The storage at 1°C to 6°C assists preservation by slowing the rate of glycolysis approximately 40 times the rate at body temperature. The addition of adenine prolongs storage time by increasing RBC survival by allowing RBCs to resynthesize the ATP needed to fuel metabolic reactions. Without adenine, RBCs gradually lose their ATP and their ability to survive after transfusion.

During storage of whole blood and packed RBCs, a series of biochemical reactions occur that alter the biochemical makeup of blood and account for some of the complications that are discussed later. During storage, RBCs metabolize glucose to lactate, hydrogen ions accumulate, and plasma pH decreases. The storage temperatures of 1°C to 6°C stimulate the sodium-potassium pump, and RBCs lose potassium and gain sodium. The osmotic fragility of RBCs increases during storage, and some cells undergo lysis, resulting in elevated plasma hemoglobin levels. Storage is associated with progressive decreases in RBC concentrations of ATP and 2,3-DPG.

Packed RBCs have a slightly lower survival than whole blood (Table 55-4), although values for hemoglobin and potassium concentrations may appear somewhat high in 35-day stored RBC concentrates. However, the total plasma volume in the concentrates is only 70 mL.

Innovative methods of storing blood are being developed. For example, storing blood in an electrostatic field of 500 to 3000 V decreases hemolysis and attenuates the decrease in pH associated with prolonged storage.[43]

Complications

Changes in Oxygen Transport

RBCs are transfused primarily to increase transport of oxygen to tissues. An increase in the circulating red cell mass produces an increase in oxygen uptake in the lungs and a corresponding probable increase in oxygen delivery to tissues. The respiratory function of red cells may be impaired during preservation, making it difficult for them to release oxygen to the tissues immediately after transfusion.

Table 55-4 Properties of Whole Blood and Packed Red Cell Concentrates Stored in CPDA-1

	Days of Storage		
Parameter	**0**	**35 (Whole Blood)**	**35 (Packed Cells)**
pH	7.55	6.73	6.71
Plasma hemoglobin (mg/dL)	0.50	46.00	246.00
Plasma potassium (mEq/L)	4.20	17.20	76.00
Plasma sodium (mEq/L)	169.0	153.00	122.00
Blood dextrose (mg/dL)	440.0	282.00	84.00
2,3-Diphosphoglycerate (μM/mL)	13.20	1.00	1.00
Percent survival*	—	79.00	71.00

*Percent recovery of O_R-tagged red blood cells at 24 hours.
CPDA-1, citrate phosphate dextrose adenine-1.

Review of the Oxygen Dissociation Curve

The oxygen dissociation curve is determined by plotting the partial pressure of oxygen (Po_2) in blood against the percentage of hemoglobin saturated with oxygen (Fig. 55-2). As hemoglobin becomes more saturated, the affinity of hemoglobin for oxygen also increases. This is reflected in the sigmoid shape of the curve, which indicates that a decrease in Pao_2 makes considerably more oxygen available to the tissues. The sigmoid shape of the curve implies greater efficiency of blood transportation of oxygen from the lungs to tissues.

Shifts in the oxygen dissociation curve are quantitated by the P_{50}, which is the partial pressure of oxygen at which hemoglobin is half saturated with oxygen at 37°C and pH 7.4. A low P_{50} indicates a left shift in the oxygen-dissociation curve and an increased affinity of hemoglobin for oxygen; in other words, the left shift of the curve indicates that a lower-than-normal oxygen tension saturates hemoglobin in the lung and the subsequent release of oxygen to the tissues occurs at a lower-than-normal capillary oxygen tension. An increased affinity may be enough to ensure that oxygen is released to the tissues unless the tissue Po_2 is in the hypoxic range. The clinical evidence supporting the accuracy of this hypothesis during infusion is discussed in the following section.

Clinical Evidence

The clinical evidence is not consistent, reflecting the difficulty of conducting a systematic study of seriously ill patients in varied clinical settings. For 40 years, various clinicians in a variety of clinical settings have tried to establish a firm relationship between the 2,3-DPG levels associated with stored blood and patient welfare (e.g., organ function). In 1993, Marik and Sibbard[8] found that the administration of blood that had been stored for more than 15 days actually decreased intramucosal pH, suggesting that splanchnic ischemia had occurred. In the past 10 years, numerous studies have tried to prove that older blood (and therefore decreased oxygen delivery) is not as beneficial as fresher blood in critically ill patients. Although a definitive conclusion cannot be made, I believe that blood with less than 15 days of storage should be used in very ill patients.

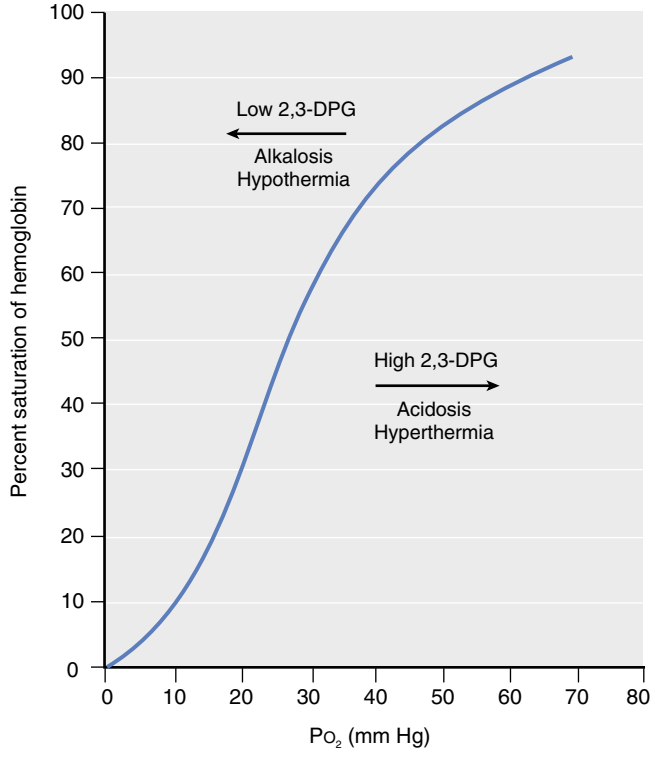

Figure 55-2 Factors that shift the oxygen dissociation curve. 2,3-DPG, 2,3-diphosphoglycerate. *(From Miller RD: The oxygen dissociation curve and multiple transfusions of ACD blood.* In *Howland WS, Schweizer O [eds]: Management of Patients for Radical Cancer Surgery. Clinical Anesthesia Series, vol 9. Philadelphia, FA Davis, 1972, p 43.)*

Coagulation

Unless a patient has a preoperative coagulopathy (e.g., aspirin, antiplatelet drugs, hemophilia), major trauma and/or blood loss in itself will initiate a cascade of coagulation abnormalities, including a consumptive coagulopathy from tissue hypoperfusion as manifested by increased protein C levels.[44] The addition of a large amount of blood (e.g., 6 to 10 units of packed RBCs) only augments this coagulopathy. Various protocols have been developed for approaches to massive blood transfusion administration (Fig. 55-3). This coagulopathy is caused by a combination of factors, of which the most important are the volume of blood given and the duration of hypotension or hypoperfusion. Patients who are well perfused and are not hypotensive for a long period (e.g., 1 hour) can tolerate multiple units of blood without developing a coagulopathy. The patient who is hypotensive and has received many units of blood probably has a coagulopathy from a condition that resembles disseminated intravascular coagulation (DIC) and dilution of coagulation factors from stored bank blood. When such bleeding occurs, the differential diagnosis for a patient who did not have a pretransfusion coagulopathy (e.g., hemophilia) is dilutional thrombocytopenia, low factors V and VIII, a DIC-like syndrome, or hemolytic transfusion reaction. Clinical manifestations include oozing into the surgical field, hematuria, gingival bleeding, petechial bleeding from venipuncture sites, and ecchymoses.

Dilutional Thrombocytopenia

Dilutional thrombocytopenia is a cause of a hemorrhagic diathesis in a patient who has received multiple units of bank blood. Independent of whether whole blood or packed RBCs are given, few viable platelets exist when storage has been for more than 24 hours. For whole blood at a storage temperature of 4°C, platelets in stored blood are damaged sufficiently to be readily trapped and absorbed by the reticuloendothelial system soon after infusion. Even those platelets that are not immediately stored have a reduced survival time. Considering survival time and viability, total platelet activity is only 50% to 70% of the original in vivo activity after 6 hours of storage in bank blood at 4°C. After 24 or 48 hours of storage, platelet activity is only about 10% or 5% of normal, respectively. Infusion of bank blood stored for longer than 24 hours dilutes the available platelet pool. In my colleagues and my study during the U.S.-Vietnam conflict, platelet counts decreased to less than 100,000/mm^3 when 10 to 15 units of blood had been given to acutely wounded, previously healthy soldiers.[45] The platelet count in smaller, older patients may decrease to 100,000/mm^3 after being given fewer units of blood because these patients have a

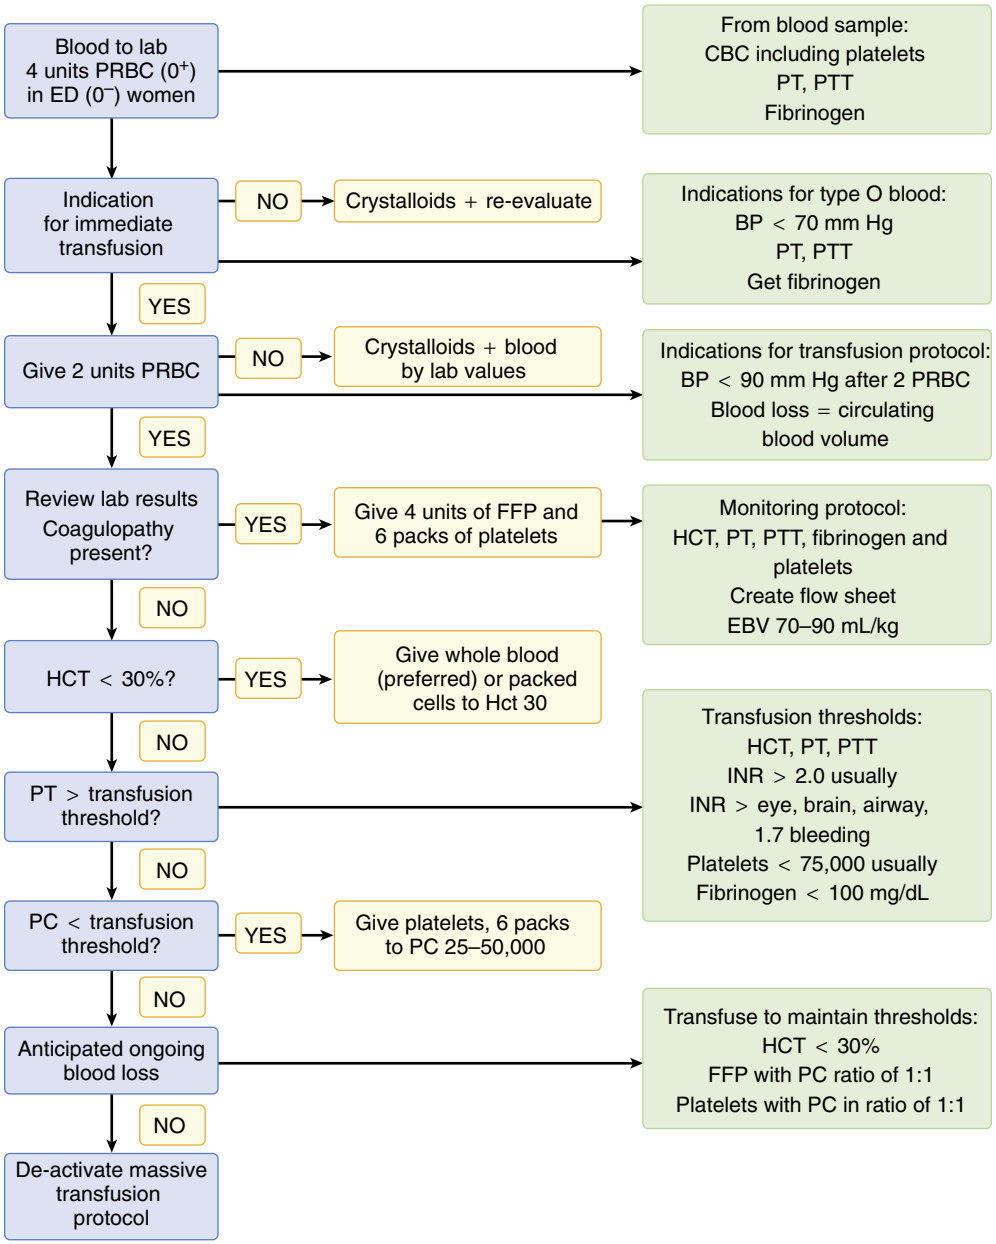

Figure 55-3 This algorithm for diagnosing and treating a massive transfusion was modified from the massive transfusion protocol used at the San Francisco General Hospital. There are many other similar approaches (e.g., Figure 55-7 provides an algorithm for a pure coagulation). This protocol suggests how to approach a patient with major blood loss but does not include the use of recombinant activated factor VII, which may be possible in the future.[76] BP, blood pressure; CBC, complete blood cell count; EBV, effective blood volume; ED, emergency department; FFP, fresh frozen plasma; Hct, hematocrit; INR, international normalized ratio; PC, platelet count; PRBCs, packed red blood cells; PT, prothrombin time; PTT, partial thromboplastin time.

smaller blood volume and possibly a lower preoperative platelet count than soldiers do. We[45] defined the importance of the platelet count because when it is approximately 75,000/mm^3 or less, a hemorrhagic diathesis is likely to occur (Table 55-5).

Although major emphasis had been placed on monitoring the platelet count, several investigators[46,47] have questioned the role of dilutional thrombocytopenia in the coagulopathy of massively transfused patients. They correctly point out that the platelet count rarely decreases to as low a level as would be predicted from dilution alone (Fig. 55-4). This is probably because platelets are released into the circulation from the spleen and bone marrow and because of the presence of nonfunctional platelets. Reed and associates[47] found no benefit to prophylactic platelet administration during massive transfusion. Platelets should not be given to treat laboratory evidence of thrombocytopenia unless clinical coagulopathy is also present. Treating laboratory numbers without correlation with the clinical status is fundamentally contrary to good medical practice; transfusion medicine is no exception. When the platelet count is less than 50,000 to 75,000/mm^3, a bleeding problem is likely and is probably a combination of dilutional thrombocytopenia and DIC. Platelet therapy would be appropriate in this situation (see "Platelet Concentrates" later).

To place such emphasis on the platelet count as a guide is appropriate, as defended previously, with some exceptions. For example, patients with chronic thrombocytopenia or leukemia are commonly known to survive and not have a hemorrhagic

Table 55-5 Correlation between Platelet Count and Incidence of Bleeding

Platelet Count (cells/mm^3)	Total No. of Patients	No. of Patients with Bleeding
>100,000	21	0
75,000-100,000	14	3
50,000-75,000	11	7
<50,000	5	5

Data from Miller RD, Robbins TO, Tong MJ, et al: Coagulation defects associated with massive blood transfusions. Ann Surg 174:794, 1971.

diathesis with a platelet count lower than 15,000 cells/mm^3. However, this does not negate the general guideline that patients with a platelet count of less than 75,000 cells/mm^3 are likely to bleed. For unexplained reasons, patients with an acutely induced thrombocytopenia (e.g., from blood transfusions) develop a hemorrhagic diathesis at a much higher platelet count than do patients with a chronically induced thrombocytopenia (e.g., idiopathic thrombocytopeniac purpura). A higher platelet count is required to maintain adequate hemostasis with a surgical incision or trauma because damaged capillaries require platelets to plug the holes. The platelet count is a reasonably accurate guide as to when patients will develop a bleeding problem from dilutional thrombocytopenia (see Table 55-5).

Low Levels of Factors V and VIII

Most of the factors are stable in stored blood, with two exceptions: factors V and VIII.[48] These factors gradually decrease to 15% and 50% of normal, respectively, in whole blood after 21 days of storage. Packed RBCs even have fewer coagulation factors. Consequently, administration of fresh frozen plasma (FFP), which contains all the factors except platelets, has been recommended on a therapeutic or a prophylactic basis. However, this practice is of questionable benefit because only 5% to 20% of factor V and 30% of factor VIII are needed for adequate hemostasis during surgery. In other words, in spite of a patient's receiving massive blood transfusion, factors V and VIII rarely decrease below those levels required for hemostasis. My colleagues and I[45] examined this problem by giving 500 to 1000 mL of FFP to 5 patients who had received more than 15 units of bank blood and who had a clinically significant hemorrhagic diathesis. Despite the partial thromboplastin times (which measure all factors except VII and XIII) and platelets' having returned to normal, bleeding persisted in every patient. Only when platelets in the form of fresh blood were administered did bleeding cease.[45] Although low factors V and VIII appear to be an unlikely primary cause of bleeding during massive blood transfusion, such deficiencies may intensify bleeding from other causes, usually dilutional thrombocytopenia in the case of blood transfusion.

In 1985, the National Institutes of Health conducted a consensus conference on this issue.[49] The conference concluded that there was little or no scientific evidence for the administration of FFP as part of the therapy for coagulopathy induced by multiple blood transfusions. The following criteria should be used:

1. Generalized bleeding that cannot be controlled with surgical sutures or cautery
2. Partial thromboplastin time at least 1.5 times normal
3. Platelet count greater than 70,000/mm^3 (to ensure that thrombocytopenia is not the cause of bleeding)

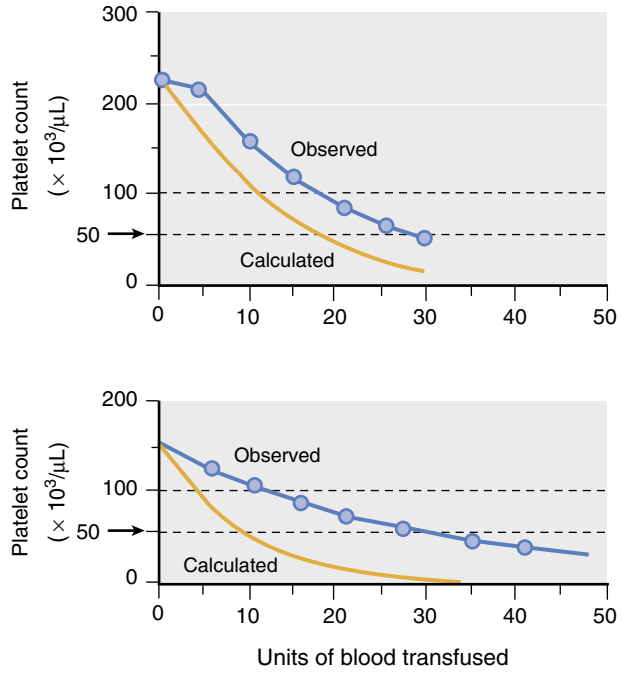

Figure 55-4 Mean platelet counts after massive transfusions in relation to number of units of blood transfused. Observed versus predicted values calculated on the basis of blood exchange model. *(From Myllylä G: New transfusion practice and haemostasis. Acta Anaesthesiol Scand Suppl 89:76, 1988.)*

Disseminated Intravascular Coagulation-like Syndrome (DIC)

The coagulation system consists of clotting and fibrinolytic mechanisms. The function of the former is to prevent excessive blood loss, and that of the latter is to ensure circulation within the vasculature. With this DIC-like syndrome, the clotting system is deranged and this leads to disseminated fibrin deposition, which renders the fluid blood unclottable. The deposited fibrin may severely alter the microcirculation and lead to ischemic necrosis in various organs, particularly the kidney. The unclottable blood or circulating serum may induce a severe hemorrhagic diathesis.

The specific reasons for the development of DIC syndrome are usually not apparent. However, hypoxic acidotic tissues with stagnant blood flow probably release tissue thromboplastin

directly or through liberation of some toxin as possibly modulated through the protein C pathway.[44] The release of tissue plasminogen activator from damaged tissue may cause fibrinolysis. In sepsis and eventual organ failure, the pathogenesis of this DIC syndrome is more apparent. The extrinsic route of coagulation is activated by tumor necrosis factor and endotoxins. Presumably, tumor necrosis factor induces tissue factor expression on the surface of activated monocytes and possibly by exposure to subendothelially localized tissue factor in blood[50] (see Chapter 56 for more details). Although the intrinsic system does not induce DIC, it may contribute to hypotension. This triggers the coagulation process, resulting in consumption of factors I, II, V, and VIII and platelets. Supposedly, thrombi and fibrin are deposited in the microcirculation of vital organs, interrupting their blood flow.

In an attempt to counteract the hypercoagulable state, the fibrinolytic system is activated to lyse the excessive fibrin almost simultaneously; this is called secondary fibrinolysis (see Chapter 56). DIC should not be considered a distinct disease entity but rather a sign of another disease. DIC has been associated with almost all life-threatening diseases. Any condition in which tissue damage is sufficient to release tissue products or toxins into the circulation can be associated with DIC. If enough thromboplastin lodges in the circulating blood, the result is massive focal necrosis or more generalized activation of the coagulation system.

Hemolytic Transfusion Reaction

The appearance of a hemorrhagic diathesis after blood transfusion should signal the possibility of a hemolytic transfusion. This entity is discussed later in this chapter.

Diagnosis and Treatment of a Hemorrhagic Diathesis after Whole Blood Transfusions

Although treatment is more likely to be successful when the cause of the bleeding problem has been identified, precise diagnosis is often difficult. One approach is to obtain a blood specimen on which the following tests can be performed: platelet count, partial thromboplastin time, plasma fibrinogen level, and observation of a clot for size, stability, and lysis and of the plasma for evidence of hemolysis. Provided that the partial thromboplastin time is 1.5 times normal or more and other tests are normal, the bleeding is probably a result of very low levels of factors V and VIII. This can be treated with FFP, which contains all the coagulation factors except platelets, or with cryoprecipitate. Although the preceding situation is a nice textbook description, I have never observed a clinical situation involving blood transfusions in which the partial thromboplastin time was increased without the presence of thrombocytopenia.

Dilutional thrombocytopenia in association with DIC and hypoperfusion is the most likely cause of bleeding from blood transfusion.[45,48] When the platelet count is less than 100,000/mm^3, a bleeding problem is likely to develop (see Table 55-4); therefore, platelets are ordered. The rule of thumb is based on the fact that a bleeding diathesis probably will develop after infusion of 20 units of stored blood in healthy patients and after lesser amounts in debilitated or small patients (Fig. 55-5).

Whether platelets are administered in the form of fresh blood, platelet-rich plasma, or platelet concentrates depends on

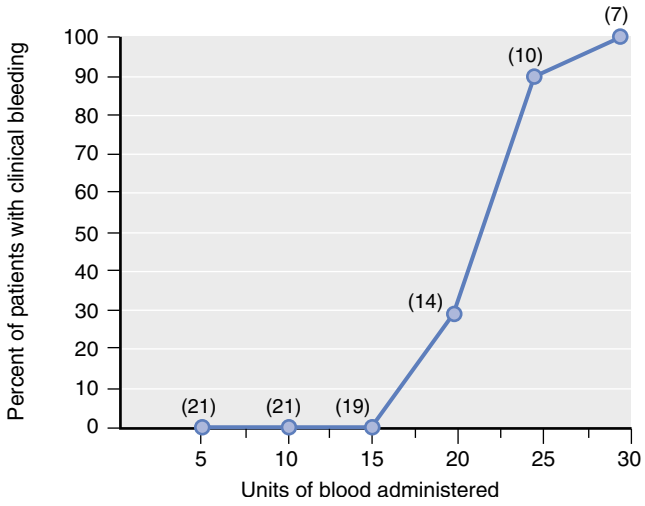

Figure 55-5 Correlation between units of blood administered and percent of patients who had a hemorrhagic diathesis. The numbers in parentheses represent the number of patients at each data point. *(From Miller RD: Transfusion therapy and associated problems. Reg Refresher Course Anesthesiol 1:101, 1973.)*

intravascular volume replacement requirements, personal preference, and availability of laboratory personnel. Fresh blood (≤6 hours old) supplies the largest number of platelets per donation. More than 80% of the platelets can be given by platelet-rich plasma, which has one half of the volume of a unit of blood. However, because most blood banks advocate giving patients only those components that are necessary, platelet concentrates are frequently recommended. The remainder of the unit of blood, such as RBCs, plasma, and albumin, can be saved for other patients. Platelet concentrates are contained in a 50-mL unit and provide about 70% of the platelets in a unit of blood. In a 70-kg person, about 10 units of platelet concentrates are required to increase the platelet count by 100,000/mm^3.

Although logistically difficult to obtain, fresh blood is extremely effective in treating transfusion-induced coagulopathies. My personal and subjective observations in Vietnam indicated that fresh blood (i.e., 6 hours or less and unrefrigerated blood) had a dramatic effect in patients with extensive hemorrhage.[45] About 20 years later, Lavee and associates[51] found that 1 unit of fresh whole blood was as effective as, if not superior to, 8 to 10 platelet units. In 1996, Erber and colleagues,[52] used fresh unrefrigerated whole blood in surgical patients with ongoing extensive bleeding despite adequate component replacement therapy and adequate surgical hemostasis. An accompanying editorial expressed caution and described the unfortunate problems with conducting a larger trial with fresh blood.[53] I believe that fresh blood also contains unidentified factors that make it far more effective than blood components.

Determining the plasma fibrinogen level is useful because this coagulation factor does not decrease in bank blood. If the in vivo plasma fibrinogen level is low (<150 mg/dL), it is not a result of a dilutional coagulopathy and strongly suggests DIC or a DIC-like syndrome. DIC is likely with thrombocytopenia, hypofibrinogenemia, and lysis of a clot within 2 hours.[48] Unfortunately, fibrinogen levels in packed RBCs decrease with increasing storage time. As a result, hypofibrinogenemia occurs on a dilutional basis when multiple units of packed RBCs are given.[54]

ε-Aminocaproic acid (EACA) inhibits the formation of plasmin and attenuates fibrinolysis. EACA should not be used in the treatment of DIC. Blocking the fibrinolytic system and having the coagulation system activated have resulted in disseminated thrombosis. Because primary fibrinolysis is rare other than in prostatectomy and liver transplantation[55] (see Chapter 56), EACA should probably not be given unless the preceding diagnosis is clearly established after expert consultation. Despite all of the previous recommendations, bleeding from a transfusion-associated coagulopathy occasionally persists. A new approach has been described. Administration of recombinant activated coagulation factor VII (rfVIIa, Novo Nordisk Pharmaceuticals, Plantation, FL) has produced successful treatment of such coagulopathies intraoperatively. Most of these patients also had other conditions, such as necrotizing pancreatitis, cirrhosis, or severe trauma. This exciting product is extremely expensive and should be viewed as a rescue therapy until approval by the U.S. Food and Drug Administration (FDA) is more broadly based[56] (see Chapter 56 for details).

Drugs Used to Improve Hemostasis

In addition to EACA, three other drugs have been recommended for perioperative coagulation problems.[57] Two of those drugs have received special attention. The first is desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]), a synthetic analog of the antidiuretic hormone vasopressin. It increases the levels of factor VIII and von Willebrand factor and is a well-established therapy for hemophilia and von Willebrand disease. It also reduces blood loss and transfusion requirement in patients with normal preoperative coagulation status who are undergoing spinal or cardiac surgery. However, the ultimate role of desmopressin remains to be determined.[57] It can cause hypotension, hyponatremia, and increased platelet adhesion.

Another drug is aprotinin, a serine protease inhibitor that inhibits fibrinolysis and improves platelet function. It has been used to decrease blood loss in multiple surgical procedures, including cardiopulmonary bypass. However, its ultimate place in the treatment of coagulopathies has not been established.

The third drug is tranexamic acid, which is also an antifibrinolytic drug. Two studies found a decreased blood loss from total-knee arthroplasty. Presumably, release of the pneumatic tourniquet releases fibrinolytic material, which is inhibited by tranexamic acid.

A large meta-analysis using perioperative blood transfusion as the outcome in cardiac surgery concluded that aprotinin and tranexamic acid, but not desmopressin, decreased the exposure of patients to allogeneic blood transfusion perioperatively.[58] The ultimate use of these drugs is evolving.

Diagnosis and Treatment of Hemorrhagic Diathesis after Packed Red Blood Cell Transfusions

With much less plasma, dilution of certain coagulation values may be more profound with the use of packed RBCs rather than whole blood. Murray and coworkers[54] specifically examined the question of using packed RBCs for major blood loss. In general, the direction of coagulation changes was similar to that seen with whole blood, with one major exception. With use of packed RBCs, fibrinogen levels decreased significantly in contrast to use of whole blood, in which fibrinogen levels remained unchanged unless DIC was present (see Fig. 55-6). Although all the coagulation factors decreased, the decrease was less than expected from dilution. The researchers believed that factors such as factor VIII are probably stored in endothelial cells and released from the endothelium during surgical stress. When packed RBCs are used to replace major blood loss, the clinician may be tempted to give FFP prophylactically. However, Murray and associates[54] specifically recommended not following the policy; they stated that FFP was needed only when prothrombin time and partial thromboplastin time were at least 1.5 times normal and fibrinogen levels were less than 75 mg/dL. These recommendations are similar to those stated in the section "Fresh Frozen Plasma." Leslie and Toy[59] provided more specific guidelines when packed RBCs are used for massive transfusions. They believed that when 12 or more units of packed RBCs or cell-saver blood had been given, coagulation factors (i.e., FFP) were necessary. Patients who received 20 or more units often required platelet therapy, a finding identical to that of patients given whole blood.

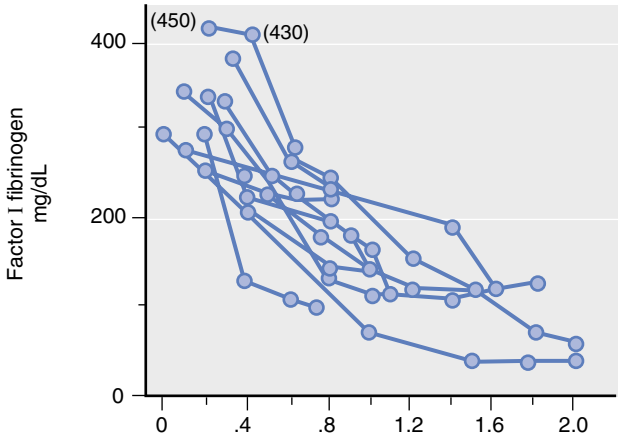

Figure 55-6 Decreases in fibrinogen level as blood volume is replaced with Adsol-packed red blood cells and crystalloid solutions. Each patient is represented by a *solid line. (From Murray DJ, Olson J, Strauss R, Tinker JH: Coagulation changes during packed red cell replacement of major blood loss. Anesthesiology 69:839, 1988.)*

An algorithm for the evaluation and initial therapy of a patient with a suspected coagulopathy is given in Figure 55-7.

Citrate Intoxication and Hyperkalemia

Citrate intoxication is not caused by the citrate ion per se; it occurs because citrate binds calcium. The signs of citrate intoxication are those of hypocalcemia: hypotension, narrow pulse pressure, and increased intraventricular end-diastolic pressure and central venous pressure. However, citrate intoxication is very rare. Having hypothermia, liver disease, liver transplantation, or hyperventilation or being a pediatric patient[60] increases the possibility of citrate intoxication. The appearance of severe hypocalcemia during liver transplantation is well documented (see Chapter 67). The combination of infusion of large amounts of citrate (i.e., through blood transfusions) and of reduced

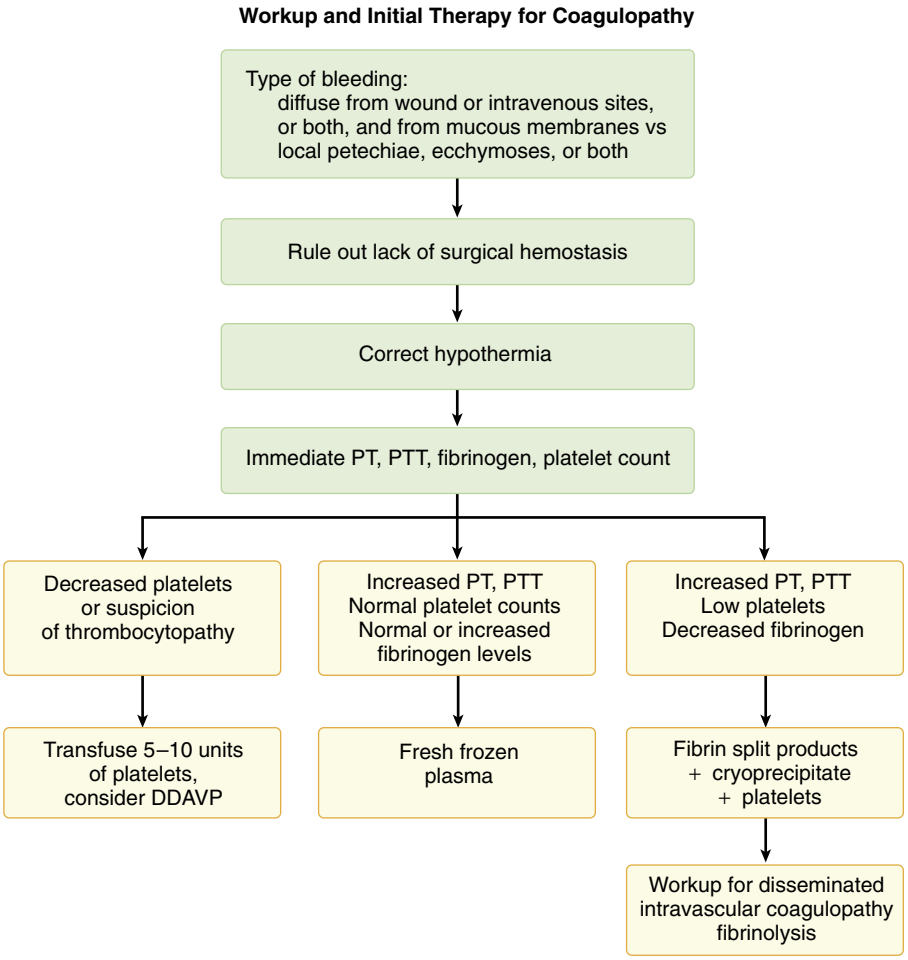

Figure 55-7 Algorithm of the evaluation and initial therapy of a patient with suspected perioperative coagulopathy. The evaluation is based on the clinical scenario and is affected by the type and location of injury, the amount of fluid administered, and the age and body temperature of the patient. DDAVP, 1-deamino-8-D-arginine vasopressin, a vasopressin analog also known as desmopressin acetate; PT, prothrombin time; PTT, partial thromboplastin time. *(Adapted from Habibi S, Corrsin DB, McDermott JC, et al: Trauma and massive hemorrhage. In Muravchick S, Miller RD [eds]: Atlas of Anesthesia: Subspecialty Care. New York, Churchill Livingstone, 1998, pp 6.2-6.17.)*

metabolism from absent or reduced liver blood flow (i.e., in the anhepatic phases of liver transplantation) leads to citrate intoxication. As a result, calcium infusions are common during liver transplantation. The rate of citrate metabolism is decreased by 50% when body temperature is decreased from 37° to 31°C. Excluding these conditions, infusion of more than 1 unit of blood every 10 minutes is necessary for ionized calcium levels to begin to decrease. Even at these rates of infusion, ionized calcium levels do not decrease enough to cause bleeding. As indicated previously, if a hemorrhagic diathesis starts after administration of blood, low calcium levels are not part of the differential diagnosis.

As evidenced from the preceding discussion, citrate intoxication is rare. Serum potassium levels may be as high as 19 to 30 mEq/L in blood stored for 21 days. Although hyperkalemia is occasionally reported,[60,61] large amounts of blood must be given. For significant hyperkalemia to occur clinically, bank blood must be given at a rate of 120 mL/min or more. The fact that such rapid infusion rates of blood are required for the production of hyperkalemia suggests that the potassium ion must leave the intravascular spaces by diffusion into extravascular spaces, by reuptake into RBCs, or through the kidneys. As with citrate intoxication, hyperkalemia is rare and this also rules against the routine administration of calcium. Calcium may cause cardiac arrhythmias, particularly in patients anesthetized with halothane. Calcium administration should be based on diagnostic signs of hyperkalemia (i.e., peak T wave). Although irritating to veins, 10% calcium chloride provides three times more calcium than an equal volume of 10% calcium gluconate because chloride has a molecular mass of 147 and gluconate has a molecular mass of 448.

Temperature

Administration of unwarmed blood that has been stored at 4°C can decrease the recipient's temperature. If the temperature decreases to less than 30°C, ventricular irritability and even cardiac arrest may occur. This can be prevented by warming the blood to body temperature before transfusion. There are more subtle reasons for warming all blood, even in patients receiving only 1 to 2 units intraoperatively. Because of the cool temperature of the operating room, body temperature often decreases, particularly in patients undergoing extensive abdominal surgery; administration of cold blood further decreases temperature. Maintaining a patient's normal temperature is considered to be increasingly important (see Chapter 48).

Perhaps the safest and most common method of warming blood is to pass it through plastic coils or plastic cassettes in a warm water (37° to 38°C) bath or warming plates. These heat exchangers should have upper (e.g., 43°C) and lower (e.g., 33°C) temperature limits (see Chapter 48).

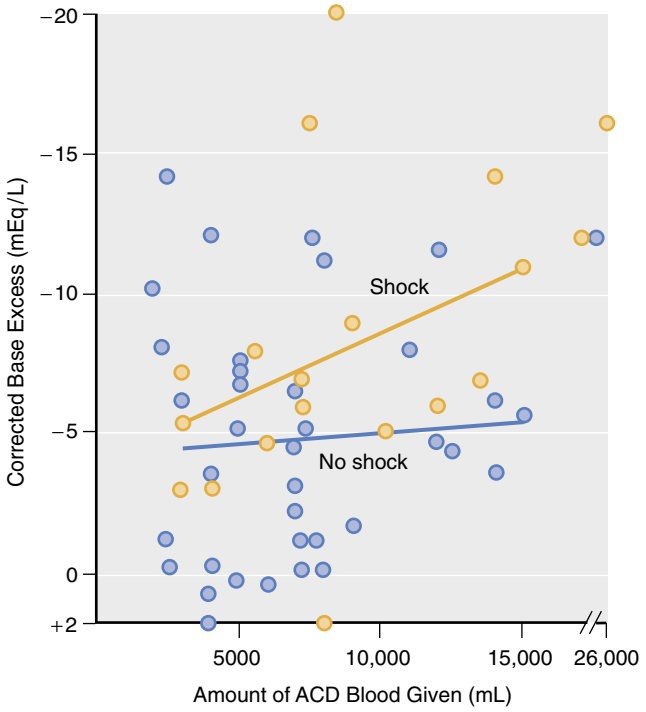

Figure 55-8 Correlation between the amount of blood administered (mL) and corrected base excess intraoperatively. *(From Miller RD, Tong MJ, Robbins TO: Effects of massive transfusion of blood on acid-base balance. JAMA 216:1762, 1971.)*

Acid-Base Abnormalities

The pH of most storage media is very acidotic (e.g., 5.5 for CPD). When this solution is added to a unit of freshly drawn blood, the pH of the blood immediately decreases from 7.0 to 7.1. As a result of accumulation of lactic and pyruvic acids by RBC metabolism and glycolysis, the pH of bank blood continues to decrease to about 6.9 after 21 days of storage. A large portion of the acidosis can be accounted for by the P_{CO_2} of 150 to 220 mm Hg. The P_{CO_2} is high mainly because the plastic container of blood does not provide an escape mechanism for carbon dioxide. With adequate ventilation in the recipient, the high P_{CO_2} should be of little consequence. Even when the P_{CO_2} is returned to 40 mm Hg, metabolic acidosis is still present in blood (see Table 55-4). Other reasonably well-controlled clinical studies have indicated that not only is empirical administration of sodium bicarbonate not indicated but it actually may also be unwise without concomitant analysis of arterial blood for P_{CO_2} and pH.[62] Miller and colleagues[63] found that the metabolic acid-base response to blood transfusion was variable (Fig. 55-8). Blood transfusions provide a substrate, namely, citrate, in large quantities for the endogenous generation of bicarbonate, and this accounts for the significant incidence of metabolic alkalosis after blood transfusions.[62] There is little logic in the empirical administration of bicarbonate for prophylactic treatment of an unpredictable acid-base abnormality.

Transfusion Reactions

Hemolytic Transfusion Reaction

From 2004 to 2006, three of the four most common causes of transfusion-related deaths were hemolytic transfusion reactions, septic transfusions (e.g., bacterial contamination), and transfusion-related acute lung injury (TRALI) (Table 55-6).[64] Since 1975, the FDA has required that all fatal reactions occurring in blood recipients or donors must be reported within 24 hours by telephone or within 7 days in writing by all FDA-registered transfusion services. In the 10-year period from 1976 to 1985, 328 deaths have been reported and analyzed.[65] Of these deaths, 159 were acute from hemolytic reactions and 23 from delayed reactions. Of the 159 deaths due to acute hemolytic reaction, 137 were caused by errors involving ABO incompatibility. More than one half of these mistakes occurred after the blood had been issued by the blood bank and were committed by nurses and physicians in the operating room, emergency department, or ward. The incidence of hemolytic transfusion reaction is sufficient enough that the Joint Accreditation of Healthcare Organizations (JCAHO)[66] requires peer-review programs to reduce transfusion errors and complications. Specifically, two patient identifiers are required before a blood product can be given. New technologies (e.g., radiofrequency identification bar coding) are being used to facilitate a decreased incidence of transfusion-related errors. However, when delayed hemolytic reactions (discussed later) are included, the incidence of ABO-incompatible RBC transfusions is higher.[67] One of the most catastrophic transfusion reactions is that arising from intravascular hemolysis. Intravascular hemolysis occurs when there is a direct attack on transfused donor cells by recipient antibody and complement. Such a reaction can occur from infusion of as little as 10 mL of blood.[68] If properly treated, death is

Table 55-6 Transfusion-Related Fatalities in the United States, 2004-2006

Cause of Fatality	2004-06	Average per Year
TRALI	86	29
Other reactions (non-ABO hemolytic therapy; anaphylaxis)	67	22
Bacterial contamination	20	7
ABO hemolytic transfusion therapy	15	5
Transfusion not ruled out	31	10

TRALI, Transfusion-related acute lung injury.

rare.[66] However, prevention of kidney failure and a coagulopathy (DIC) is crucial. Hemolytic transfusion reactions involving extravascular RBC destruction are generally less serious than those of the intravascular variety. In these cases, recipient antibody coats but does not immediately hemolyze the transfused RBCs. Destruction occurs primarily in the reticuloendothelial system.

Signs and Symptoms

The clinical consequences of incompatible blood transfusions are very serious but quite variable. Factors include volume of transfused blood, number of antigenic sites on the red cell membrane, and activity of the reticuloendothelial system. The properties of the antibody, including concentration and ability to activate complement, are also important.

The classic signs and symptoms (Table 55-7) of a hemolytic transfusion reaction—chills, fever, chest and flank pain, and nausea—are masked by anesthesia. Under general anesthesia, the only signs may be hemoglobinuria, bleeding diathesis, or hypotension. The presenting sign is usually hemoglobinuria. As little as 50 mL of incompatible blood may exceed the binding capacity of haptoglobin, which is a protein that can bind about 100 mg of hemoglobin per 100 mL of plasma. When hemoglobin not exceeding this amount is injected or liberated into the bloodstream, the hemoglobin circulates as a complex with haptoglobin, which is cleared by the reticuloendothelial system (Fig. 55-9). A sample of plasma that contains 2 mg/dL of hemoglobin is faintly pink or light brown. When the level of hemoglobin reaches 100 mg/dL, the plasma is red. When the level of plasma hemoglobin reaches 150 mg/dL, hemoglobinuria occurs. In general, the quantity of the free hemoglobin in the plasma correlates with the volume of incompatible blood transfused. Also, complement activation causes release of all sorts of substances including histamines and vasoactive amines. The symptoms can be so alarming that cessation of blood is indicated, even if hemoglobin is not seen in plasma. Laboratory tests that should be performed if hemolytic transfusion reaction is suspected include serum haptoglobin, plasma and urine hemoglobin, bilirubin, and direct antiglobulin determinations. The direct antiglobulin test can confirm the presence of hemolytic transfusion reaction because it shows that there is antibody attached to transfused donor RBCs.

Table 55-7 Frequency and Signs and Symptoms of Hemolytic Transfusion Reactions in 40 Patients

Sign or Symptom	No. of Patients
Fever	19
Fever and chills	16
Chest pain	6
Hypotension	6
Nausea	2
Flushing	2
Dyspnea	2
Hemoglobinuria	1

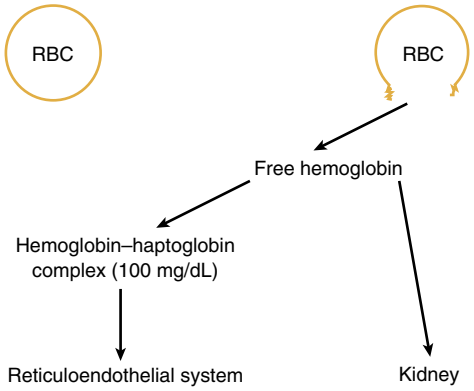

Figure 55-9 Schematic representation of what happens to hemolyzed erythrocytes (RBC) as a result of the administration of incompatible blood.

Treatment

If a hemolytic reaction is suspected, blood and urine samples should be sent to the laboratory for examination. The blood bank should check all paperwork to ensure that the correct blood component was transfused to the patient. Laboratory tests should be performed to determine the presence of hemoglobinemia: a direct antiglobulin test, repeat compatibility testing, repeat other serologic tests (i.e., ABO and Rh), and analysis of urine for hemoglobinuria.

Although there are several consequences of intravascular hemolysis, mainly the renal and coagulation systems are affected. The exact cause of acute renal failure from intravascular hemolysis is controversial, but the most common hypothesis is that hemoglobin in the form of acid hematin precipitates in the distal tubule and causes mechanical tubular blockage. The magnitude of the precipitation probably is inversely related to the volume of urine flow and its pH. The primary emphasis of therapy should be directed toward maintaining urinary output in excess of 75 mL/hr by generous administration of intravenous fluids and diuretics. One approach is summarized in Table 55-8 and includes the administration of lactated Ringer's solution to maintain the central venous pressure between 10 and 15 cm H_2O while initially administering 12.5 to 50 g of mannitol. If this is ineffective, the dose of mannitol may be increased or the use of more potent diuretics, such as furosemide, which increases blood flow to the renal cortex, may be required to maintain adequate urinary output. Alkalinization of the urine to prevent precipitation of acid hematin in the distal tubules is of questionable value but is easy and therefore recommended. DIC commonly occurs with hemolytic transfusion reactions, probably because RBC stroma is severed, releasing erythrocytin, which activates the intrinsic system of coagulation. This activated coagulation leads to fibrin formation. Subsequently, platelets and factors I, II, V, and VII are consumed. As soon as a hemolytic transfusion reaction is recognized, platelet count, prothrombin time, and partial thromboplastin time should be determined to provide baseline values with which subsequent laboratory values can be compared. Hypotension during a hemolytic transfusion reaction may result from activation of the kallikrein system.[69] After a series of reactions, plasma kininogen is converted to bradykinin, a potent vasodilator that can cause hypotension.

Table 55-8 Steps in the Treatment of a Hemolytic Transfusion Reaction

1. STOP THE TRANSFUSION.
2. Maintain the urine output at a minimum of 75 to 100 mL/hr by the following methods:
   a. Generously administer fluids intravenously and possibly mannitol (12.5 to 50 g, given over 5 to 15 minutes).
   b. If intravenously administered fluids and mannitol are ineffective, administer furosemide (20 to 40 mg) intravenously.
3. Alkalinize the urine; because bicarbonate is preferentially excreted in the urine, only 40 to 70 mEq of sodium bicarbonate per 70 kg of body weight is usually required to raise the urine pH to 8, whereupon repeat urine pH determinations indicate the need for additional bicarbonate.
4. Assay urine and plasma hemoglobin concentrations.
5. Determine platelet count, partial thromboplastin time, and serum fibrinogen level.
6. Return unused blood to blood bank for repeat crossmatch.
7. Send patient's blood and urine sample to blood bank for examination.
8. Prevent hypotension to ensure adequate renal blood flow.

Another approach to treatment of a severe hemolytic transfusion reaction has been proposed by Seager and coworkers,[70] who postulated that the kidneys might be spared from exposure to massive amounts of hemolyzed red cells by removing all blood from a patient and replacing it with compatible blood. This was accomplished in a patient who had received 3000 mL of incompatible blood by hemodilution by use of an extracorporeal circuit. Because the patient had rapid recovery of urinary function, this method shows much promise.

In summary, hemoglobinuria or hemolysis should be assumed to be a hemolytic transfusion reaction until proved otherwise. The steps outlined in Table 55-8 should be taken when the diagnosis is suspected or confirmed.

Delayed Hemolytic Transfusion Reaction (Immune Extravascular Reaction)

An immediate hemolytic transfusion reaction often is a dramatic event because the concentration of the antibody is high enough to cause immediate and appreciable RBC destruction. In many cases of hemolytic transfusion reaction, the transfused donor cells may survive well initially, but after a variable delay (2 to 21 days) they are hemolyzed.[71] This type of reaction occurs mainly in recipients sensitized to RBC antigens by previous blood transfusions or pregnancy. As a result, this type of delayed reaction is more common in females who have a known disposition of alloimmunization. These reactions are delayed hemolytic transfusion reactions and are those in which the level of antibody at the time of transfusion is too low to be detected or too low to cause RBC destruction. RBC destruction occurs only when the level of antibody is increased after a secondary stimulus (i.e., anamnestic response). These delayed reactions are often manifested only by a decrease in the post-transfusion hematocrit value. However, jaundice and hemoglobinuria can occur in these patients and can cause some impairment in renal function but only rarely do they lead to death. Unlike immediate reactions, antibodies most commonly involved in delayed hemolytic reactions are those in the Rh and Kidd systems rather than the ABO system. Although improved blood-banking procedures have decreased the incidence of immediate hemolytic transfusion reactions, the delayed hemolytic reaction may not be preventable, because pretransfusion testing is unable to detect very low levels of antibody present in potential blood recipients.

Although impairment of renal function is uncommon, the surgical team should include in their differential diagnosis a delayed hemolytic transfusion reaction in any patient who has an unexplained decrease in hematocrit 2 to 21 days after a transfusion, even without obvious manifestation of hemolysis. This is especially important in a postoperative patient when the decrease in hematocrit value is thought to be from blood loss and may be an important criterion as to whether additional surgery is necessary.

Nonhemolytic Transfusion Reactions

Nonhemolytic reactions to blood transfusions usually are not serious and are febrile or allergic in nature. Specific infectious causes of febrile reactions are discussed in "Infectivity of Blood." Occasionally, fever may be the first sign of a hemolytic reaction or of bacterial contamination.

The most common adverse reactions to blood transfusions are the less serious febrile reactions. The symptoms consist of chills, fever, headache, myalgia, nausea, and nonproductive cough occurring shortly after blood transfusion caused by pyrogenic cytokines and intracellular contents released by donor leukocytes. Use of leukoreduced blood will reduce the incidence of febrile reactions.[72] Less frequently, the patient may have hypotension, chest pain, vomiting, and dyspnea. Even pulmonary infiltrations with x-ray evidence of prehilar nodule formation and lower lung infiltrates along with overt pulmonary edema have been reported.[72] Because febrile reactions obviously involve fever, they can be easily confused with a hemolytic transfusion reaction. A direct antiglobulin test readily differentiates a hemolytic reaction from a febrile reaction because this test rules out the attachment of an RBC antibody to transfused donor RBCs. More serious complications need to be ruled out (hemolytic and septic reactions), which may also be associated with fever and chills. There is no clear consensus on whether the transfusion should be terminated when a febrile reaction occurs.[73,74]

Allergic reactions can be minor, anaphylactoid, or anaphylactic. Anaphylactoid is similar to anaphylaxis clinically but are not mediated by IgE. Most allergic transfusion reactions are minor and are thought to be caused by the presence of foreign protein in the transfused blood. The most common symptom is urticaria associated with itching. Occasionally, the patient has facial swelling. When these reactions are clearly not a serious hemolytic reaction, the transfusion does not need to be discontinued. Antihistamines are used to relieve the symptoms of the allergic reaction. Infrequently, a more severe form of allergic reaction involving anaphylaxis occurs in which the patient has dyspnea, hypotension, laryngeal edema, chest pain, and shock. These are anaphylactic reactions caused by the transfusion of IgA to patients who are IgA deficient and have formed anti-IgA. This type of reaction does not involve red cell destruction and it occurs very rapidly, usually after the transfusion of only a few milliliters of blood or plasma. The patients who experience these anaphylactic reactions can be given transfusions with washed RBCs from which all traces of donor IgA have been removed or with blood lacking the IgA protein. Several investigators have reviewed many other rare transfusion reactions.[65,68,75,76]

Infectivity of Blood

For the past 25 years, transfusion-induced hepatitis and AIDS were dominant concerns regarding allogeneic blood administration. Intensified blood donor evaluation, deferral of high-risk donors, and the use of more sensitive screening tests have made these infectious risks quite rare (Table 55-9).

Non–donor-transmitted issues have become dominant concerns (see "Transfusion Reactions") (see Table 55-6). The summary of Fiebig and Busch[77] provides definitive information on this topic.

Several blood-safety changes made from 1982 to 2008 have made the risk of disease transmission by allogenic blood so small, that even the demand for autologous blood has decreased because of the safety of allogeneic blood. Perhaps the West Nile virus story illustrates how rapidly our blood banks can respond. In 2002, West Nile virus caused the largest outbreak of arboviral encephalitis ever recorded in the United States (i.e., about 4200 patients). Twenty-three cases of transfusion-transmitted infections resulted in seven deaths. In 2003, we had testing that now makes that infection very rare (see Table 55-9).

Yet many questions arise. What about variant Creutzfeldt-Jakob disease? There are three probable transfusion-transmitted cases in Great Britain. How strict should testing be? As described recently,[78] "the sheer number of potential pathogens that have threatened the blood supply[79,80] since 1995 renders it impractical to keep adding expensive safety measures" for each new agent. Surveillance needs to be added to all these tests as a safety measure.

Hepatitis B

Testing for hepatitis B is an example of a practical decision. Hepatitis B virus (HBV) is hepatotropic DNA virus that has an incubation period of 4 to 10 weeks but may be as long as 6 months. Prevention of blood-transfusion–induced hepatitis B is dependent on exclusion of high-risk donors and detection of antibodies to HBcAg. It is controversial whether HBV nucleic acid technology testing should be used. Quantitation of risk is more complicated with hepatitis B virus than for human immunodeficiency virus (HIV) and hepatitis C virus because the accurate measurement of HBV donor incidence is uncertain as described by Kleinman and Busch.[79] The possible gain in safety versus cost is too small.

As indicated earlier, one of the major reasons for the decrease in blood-borne infections has been the use of nucleic acid technology. The changes in blood transfusion testing can be appreciated when comparing tests used in 1998 (Table 55-10) with those used in 2008 (Table 55-11). The use of nucleic acid technology testing has decreased the window of infectivity (i.e., time from being infected to a positive test result), which is a major reason for the decrease in infectivity with hepatitis, HIV, and West Nile virus.[81] Better donor screening and restrictive donor eligibility also have helped. The near-elimination of transfusion-transmitted hepatitis, HIV, and West Nile virus has made the exact incidence difficult to determine. However, emerging infectious risks, including Chagas' disease, malaria, and even variant Creutzfeldt-Jakob disease are of increasing concern (Table 55-12). Because hepatitis and AIDS have been dominant concerns for years, their history is discussed in the following sections.

Hepatitis C

When blood transfusions became a reality in the 1940s, viral hepatitis was recognized as a major complication. The concern is mainly with hepatitis B, C, and rarely D, which are parenterally transmitted viruses. Before 1985, the overall incidence of post-transfusion hepatitis ranged from a low of 3% to a high of 19%, depending on the institution and the location (e.g., donors from large cities have a more frequent incidence of the hepatitis virus). In most areas, the incidence of hepatitis has ranged from 3% to 10%. Ninety percent of post-transfusion hepatitis is caused by the hepatitis C virus. Less than one third of these patients develop jaundice.[82] To determine their ultimate fate, Tong and colleagues[82] monitored 131 patients with chronic post-transfusion hepatitis C for several years and found the following incidence of signs, symptoms, and conditions:

- Fatigue (67%)
- Hepatomegaly (67%)
- Chronic hepatitis (23%)
- Chronic active hepatitis (51%)
- Hepatocellular carcinoma (11%)

It was found that 20 patients had died of the following:

Table 55-9 Percentage Risk of Transfusion-Transmitted Infection with a Unit of Screened Blood in the United States

Infection	Risk	Window Period (days)
Human immunodeficiency virus-1	1/2,135,000	11
Human T-lymphotropic virus (HTLV-II)	1/2,993,000	51
Cytomegalovirus (CMV)	Infrequent with leukocyte-reduced components	
Hepatitis C virus (HCV)	1/1,935,000	40
Hepatitis B virus (HBV)	1/205,000	
West Nile virus (WNV)	1/1,100,000	?

- Complications of cirrhosis (8 patients)
- Hepatocellular carcinoma (11 patients)
- Chronic active hepatitis-pneumonia (1 patient)

Since 1985, the incidence of post-transfusion hepatitis has decreased, probably for three reasons. The first is improved donor screening. In 1984, donors who were in a high-risk category for AIDS were requested not to donate blood on a volunteer basis. Second, in 1985, all donor blood was tested for antibodies to HIV (see "Acquired Immunodeficiency Syndrome"). Third, a specific test for hepatitis C was developed. Specifically, molecular techniques were used to derive clones from the genome of hepatitis C. The derived proteins from these clones were used to develop an enzyme-linked immunosorbent assay to detect antibodies to hepatitis C. Nucleic acid technology testing is now being used, which makes post-transfusion hepatitis so uncommon that its actual incidence is difficult to determine (see Tables 55-9 and 55-11). Despite the effectiveness of this test, donor infectivity is important as a screening device. The demographics of infectivity among donors are variable, and HIV infection is especially common in intravenous drug users. Many blood components, such as FFP and platelet concentrates, also transmit hepatitis at an incidence equal to that of whole blood and packed RBCs. Certainly the HCV nucleic acid technology testing represents a dramatic increase in blood safety, although HCV RNA can be below detection by this process, which probably represents the occasional ongoing transmission risk.[78]

Acquired Immunodeficiency Syndrome

AIDS is characterized by severe depression of cellular immunity. Several measures have been recommended to decrease the chances that donor blood will be infected with HIV. Blood banks have instituted procedures to discourage members of high-risk groups from donating blood. Designated donors and surrogate testing were recommended.[83] Despite these measures, there were hundreds of cases of transfusion-transmitted HIV. In March 1985, all donor blood was tested for the presence of antibodies to HIV-1. It is a major health care advance or even a miracle that HIV is only rarely transmitted by blood transfusions except in some developing countries[2] (see Table 55-9).

Human T-Cell Lymphotropic Virus Type 1

Human T-cell lymphotropic virus type 1 (HTLV-1) can be transmitted by blood transfusions and has been causally associated with adult T-cell leukemia and progressive myelopathy. Cohen and coworkers[83] found that there is a very small risk of HTLV-1 infection from transfused blood and blood products that have been screened for antibodies to HIV but that risk is nearly 10-fold higher than risk of HIV infections. The estimated risk is about 1 in 641,000 (see Table 55-9). Even though there is no firm association between transfusion and leukemia or myelopathy, the decision was made to test all donor blood for antibodies to HTLV-1 (see Table 55-11).

Cytomegalovirus

Asymptomatic chronic infection with cytomegalovirus (CMV) is so common in healthy adults that this agent can almost be viewed as normal flora. CMV survives best within cells and is thought to exist in latent form in the monocytes of many people with antibodies indicative of earlier infection. Fortunately, the primary concern is recipients who are at risk because of pregnancy (multiple), immaturity, or immunosuppression. CMV seroconversion usually occurs in subsets of patients receiving multiple transfusions. CMV causes a heterophil antibody-negative response that closely resembles infectious mononucleosis in many respects. An infectious mononucleosis–like syndrome that can occur 1 to 2 months after open-heart surgery is known as the postperfusion syndrome or post-transfusion mononucleosis.[84] The evidence for transmission of CMV is most convincing when the recipient changes from a seronegative state before transfusion to a seropositive state accompanied by the mononucleosis-like illness several weeks after transfusion.

Transfusion-transmitted CMV can cause significant clinical problems in certain patient populations, such as premature neonates, allograft recipients, and patients who have had their spleens removed.[85] To prevent infection in high-risk populations, use of leukocyte-depleted blood, use of frozen deglycerolized RBCs, and screening of donors for the absence of antibody to CMV have been sometimes recommended (see "Leukoreduction

Table 55-11 Tests Used for Detecting Infectious Agents in All Units of Blood, 2008

Virus	RNA Minipool	Antibody To
Human immunodeficiency virus (HIV)	Nucleic acid technology	HIV-1, HIV-2
Hepatitis C virus (HCV)	Nucleic acid technology	HCV
Hepatitis B virus (HBV)		HCV
Human T-cell lymphotropic, virus (HTLV)		HTLV-1, HTLV-2
West Nile virus	Nucleic acid technology	

Table 55-12 Infectious Diseases Theoretically Transmissible by Blood Transfusion for Which No Test Is Available, 2004

Disease	Risk
Malaria	<1 : 1 million in the United States
Chagas' disease	<1 : 1 million
Severe acute respiratory syndrome (SARS)	?
Variant Creutzfeldt-Jakob	3 cases (?) in the United Kingdom

of Red Blood Cell Transfusions" and "Acquired Immunodeficiency Syndrome"). The risk of seroconversion is about 0.14% overall, or 0.38% per unit of seropositive donor blood. Wilhelm and associates[86] concluded that it is not necessary to provide blood products from CMV-seronegative donors for most patients who receive blood transfusions. They continue to use CMV-seronegative blood to prevent CMV infection in preterm and newborn infants.

Plasma components, such as fresh frozen plasma and cryoprecipitate, components from seronegative donors, and leukoreduced components are considered to be CMV safe.

Other Transfusion-Associated Infectious Diseases

Although many other infectious diseases can theoretically be transmitted by blood transfusion, only a few are of real concern. They include *Yersinia enterocolitica* infection, syphilis, malaria, Chagas' disease, variant Creutzfeldt-Jakob disease, parvovirus B19, and severe adult respiratory syndrome (SARS) (see Table 55-12).

During the late 1980s, Tripple and colleagues[87] described seven cases of fatal transfusion-associated *Y. enterocolitica* sepsis. These investigators also reviewed the literature and found 26 cases of gram-negative bacterial sepsis with whole blood or packed RBCs. *Y. enterocolitica* is a bacterium that can cause mostly mild gastrointestinal problems. However, in severe cases, sepsis and death can occur. Unfortunately, storage of blood at 4°C in phosphate buffer enhances its growth.

Post-transfusion syphilis is unlikely because the infective agent cannot survive during storage at 1°C to 6°C. The only blood products that have the potential to transmit syphilis are those stored at room temperature. Platelet concentrates are the blood component most likely to be implicated because they commonly are stored at room temperature.

Post-transfusion malaria has never been a significant cause of blood recipient morbidity. Nevertheless, malaria can occur, especially if blood donors at risk of harboring parasites are not excluded. Consequently, blood banks thoroughly question donors for history of travel or migration from areas where malaria is endemic.

Several other diseases have been reported to be transmitted by blood transfusion, including herpesvirus infections, infectious mononucleosis (i.e., Epstein-Barr virus), toxoplasmosis, trypanosomiasis, leishmaniasis, brucellosis, typhus, filariasis, measles, salmonellosis, and Colorado tick fever.

Like malaria, several infectious agents are feared as possibly transmitting disease to patients through blood transfusions for which there are no blood testing methods (Table 55-13). Without a specific test, donor screening with increasingly restrictive criteria are used. For example, in 2003 in the United States, donors with suspected SARS or who traveled to certain countries in Southeast Asia would not be accepted. Even though there are no cases of variant Creutzfeldt-Jakob disease from blood transfusions, the virus can be transmitted by blood in animal models, and stringent donor policies based on travel and residence in England or other countries in Europe are in place. Do these increasingly restrictive donor policies increase the risk of an inadequate blood supply[88] (see "Synthetic Oxygen-Carrying Substances")?

Other Adverse Effects of Blood Transfusion

Transfusion-Associated Graft-versus-Host Disease

Transfusion-associated graft-versus-host disease is caused by engraftment of donor lymphocytes from transfused blood products, initiating an immune reaction against recipient tissues. Severely immunocompromised patients are at risk. Also, directed donations from first- or second-degree relatives are at risk because transfused lymphocytes with shared HLA haplotypes cannot be recognized and eliminated.[89] A generalized rash, leukopenia, and thrombocytopenia occur. Sepsis and death usually result. Irradiation of blood can prevent transfusion-associated graft-versus-host disease from occurring, although there is a report of one case occurring despite leukocyte filtering.[90]

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is now the leading cause of transfusion-related mortality (see Table 55-6), although it probably is underdiagnosed and underreported.[91-93] This injury manifests as noncardiogenic pulmonary edema. Clinically, symptoms and signs appear 1 to 2 hours after transfusion and are in force within 6 hours. Fever, dyspnea, fluid in the endotracheal tube, and severe hypoxia are typical. During anesthesia, a persistent decrease in blood oxygen saturation can be the presenting sign. Although the chest radiograph is characteristic of pulmonary edema, circulatory overload (i.e., left atrial hypertension) is not present. All blood components, especially FFP, are implicated as caustic factors. There is no specific therapy other than stopping the transfusion and instituting critical care supportive measures. However, the transfusion should be immediately stopped and the blood bank notified for a different donor and quarantining all units from that donor. All records should be re-examined and the results of the patient's HLA testing should be evaluated if possible. Most patients recover in 96 hours, although TRALI remains the leading cause of transfusion-related death.

Adverse Ocular Reaction

In 1997, 112 cases of bilateral conjunctival erythema were reported to have occurred within 24 hours of transfusion. The Centers for Disease Control and Prevention studied 49 other cases in 1997 and 1998 and concluded that they were toxic reactions to a chemical or material used in the blood collection filtration system, most likely a leukocyte-reducing filter system.[94]

Transfusion-Related Immunomodulation

Homologous (allogeneic) blood transfusion exerts a nonspecific immunosuppressive action on the recipient. More than 150 clinical studies have tried to relate allogeneic blood transfusions

Table 55-13 Comparison of Whole Blood and Packed Red Blood Cells

Value	Whole Blood	Packed Red Blood Cells
Volume (mL)	517	300
Erythrocyte mass (mL)	200	200
Hematocrit (%)	40	70
Albumin (g)	12.5	4

Total protein (g)	48.8	36
Plasma sodium (mEq)	45	15
Plasma potassium (mEq)	15	4
Plasma acid (citric-lactic)	80	25 (mEq)
Donor-to-recipient ratio	1 unit per patient	1 unit per 4-6 patients

From Landers DF, Hill GE, Wong KC, et al: Blood transfusion-induced immunomodulation. Anesth Analg 82:187, 1996.

to recurrence of resected cancers, postoperative infections, and virus activation, with the conclusion that adverse effects may be caused by transfusion-related immunomodulation. Although the conclusions of these studies are contradictory and inconclusive, universal leukocyte reduction of RBCs is moving forward (see "Leukoreduction of Red Blood Cell Transfusions").[95]

Leukoreduction of Red Blood Cell Transfusions

One of the most dramatic changes in transfusion medicine in the past 10 years has been the universal use of leukoreduced packed RBCs internationally, which includes Western Europe, the United Kingdom, and Canada. In the United States as of 2004, more than 50% of the packed RBCs given are leukoreduced. What is the logic on which the increased use of leukoreduced blood is based?

There are some clear indications for leukoreduced blood. The chances of a febrile reaction can be reduced, especially in patients who are already alloimmunized from pregnancy. The risk of HLA alloimmunization from blood transfusions can be reduced, which would be especially helpful in minimizing refractoriness to platelet transfusions, and the risk of CMV can be reduced by using leukoreduced blood.

Universal leukoreduction has been seriously considered or implemented because of some anticipated benefits, including decreased transmission of variant Creutzfeldt-Jakob disease, leukocyte-induced immunomodulation, and even decreased postoperative mortality. In 2001, the case for and against universal leukoreduction was debated.[96,97] As of 2004, these anticipated benefits were not confirmed, despite numerous studies attempting to do so.[98] As nicely summarized by Corwin and AuBuchon,[96] a "may help, won't hurt" approach has been used to justify universal leukoreduction. However, this approach can be expensive. Bacterial contamination of platelets, TRALI, and acute hemolytic reactions cause more morbidity and mortality that would not be significantly helped by leukoreduction (see Table 55-6). Nevertheless, universal leukoreduction is the direction in which transfusion medicine is going.

Blood Component Therapy

A major advance in the field of blood banking has been the development of blood component therapy. It is beyond the scope of this chapter to describe the various separation steps in detail, but a superficial outline of the scheme by which various blood components are derived is shown in Figure 55-10. The basic philosophy is based on the concept that patients are best treated by administration of the specific fraction of blood that they lack. This concept has presented problems to the surgical team, who often desire whole blood.

Packed Red Blood Cells

Packed RBCs contain the same amount of hemoglobin as whole blood, but much of the plasma has been removed. The hematocrit value is 40% in whole blood and 70% in packed erythrocytes (see Table 55-13). Philosophically, whole blood provides oxygen-carrying capacity and intravascular blood volume expansion. Other than severe hemorrhage, most indications for red blood cells can be effectively treated with packed RBCs, retaining the plasma and the components thereof for other patients (see Fig. 55-10). Many blood banks have conscientiously followed this principle, and whole blood cannot be obtained in the operating rooms except by special request. In essence, blood bankers are saying that except for a rare situation (e.g., hypovolemic shock), whole blood is not necessary.

Because of this trend, some hospitals do not have whole blood readily available.

The administration of packed RBCs is facilitated by reconstituting them with a crystalloid or colloid; however, not all crystalloids are suitable. If the solution contains calcium, clotting occurs. Lactated Ringer's solution is not recommended for use as a diluent for packed RBCs (Table 55-14). Conversely, using flow rates and clot formation, Cull and colleagues[99] found lactated Ringer's solution and normal saline to be equally acceptable. A more important factor may be whether the diluent is hypotonic with respect to plasma. If so, the RBCs will swell and eventually lyse. Solutions that cause hemolysis are listed in Table 55-14. Clinicians who fear that the crystalloid-reconstituted RBCs may cause low serum concentrations may be tempted to use a plasma derivative, such as Plasmanate. However, these solutions also can cause hemolysis. The osmolality of Plasmanate is only 180 mOsm/kg. Solutions recommended for reconstituted packed erythrocytes are 5% dextrose in 0.4% saline, 5% dextrose in 0.9% saline, 0.9% saline, and Normosol-R with a pH of 7.4.

Platelet Concentrates

Platelet concentrates are prepared by differential centrifugation from freshly drawn units of blood or from donors who specifically donate large amounts of platelets by plateletpheresis techniques. If platelets are stored at room temperature, they are satisfactory to use 7 days after collection with constant and gentle agitation. Platelet concentrates present unique "conflicts" in medicine. First, bacterial contamination, mainly from platelet

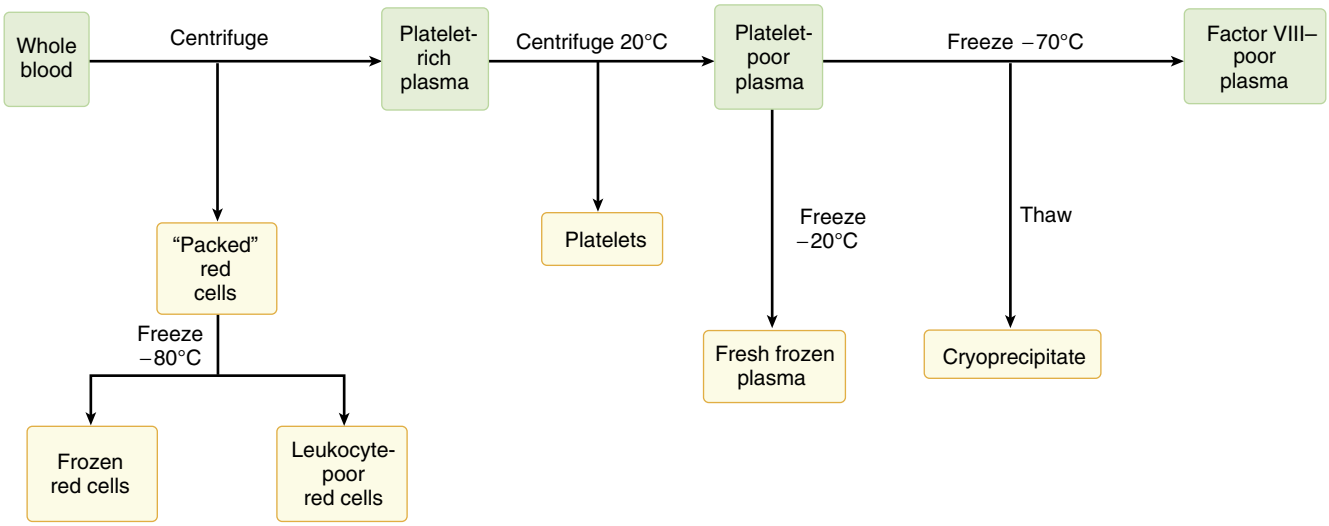

Figure 55-10 Scheme for separation of whole blood for component therapy.

concentrates, is the third leading cause of transfusion-related deaths (see Table 55-6). They are primarily effective at room temperature, which enhances bacterial growth. Furthermore, this has been a problem for more than 20 years. In the report of 10 septic platelet transfusions between 1982 and 1985, one half were platelets stored for 5 days or more. A prospective analysis from 1987 to 1990 resulted in seven cases of sepsis in patients receiving platelets for thrombocytopenia secondary to bone marrow failure.[100] Because use of multidonor platelet products stored for 5 days results in an incidence of sepsis five times higher than use of those stored for 4 days, shorter storage times are being emphasized. The incidence of platelet-related sepsis was about 1 case in 12,000 people.[101] The estimated incidence of bacterial contamination of platelets was about 1 case in 2,000.[102]

The increased risk of bacterial overgrowth is related to the storage temperature of 20°C to 24°C. For any patient who develops a fever within 6 hours after receiving platelets, sepsis from platelets should be considered. The evaluation of storing platelets for increased efficacy, but yet needing additional testing, actually makes the platelets available to the clinician for only about 3 days (Table 55-15). More recently, allowing platelets to be stored for 7 days minus 2 days for testing makes them available for 5 days, which enhances overall use of a valuable product and improved platelet inventory management. Presently, platelet concentrates are routinely tested for bacteria and are the only blood product that is stored at room temperature.[103] The rate of bacteria in platelets was 1/5000 before and 1/50,000 after routine bacteria culturing.[103] Data in 2007 indicated 186 positive cultures in 1,004,206 units, out of which 20 were septic reactions. Thirteen of these occurred 5 days after collection and resulted in three fatalities.[104]

Indications for the use of platelets are somewhat difficult to define. In the July 1989 *FDA Drug Bulletin* it was stated that platelets should not be given to patients with immune thrombocytopenic purpura (unless there is life-threatening bleeding), prophylactically with massive blood transfusion, or prophylactically after cardiopulmonary bypass. The American Society of Anesthesiologists (ASA) Task Force[4] provided the following recommendations:

Table 55-14 Compatibility of Blood with Intravenous Solutions

	Hemolysis at 30 Minutes	
Blood to Intravenous Solution (1 : 1 Ratio)	**Room Temperature**	**37°C**
5% Dextrose in water	1+	4+
Plasmanate*	1+	3+
5% Dextrose in 0.2% saline	0	3+
5% Dextrose in 0.4% saline	0	0
5% Dextrose in 0.9% saline	0	0
0.9% Saline	0	0
Normosol-R, pH 7.4†	0	0
Lactated Ringer's solution	0 (clotted)	0 (clotted)

§Bacterial detection implemented.

1. Prophylactic platelet transfusion is ineffective and rarely indicated when thrombocytopenia is due to increased platelet destruction (e.g., idiopathic thrombocytic purpura).
2. Prophylactic platelet transfusion is rarely indicated in surgical patients with thrombocytopenia due to decreased platelet production when the platelet count is greater than 100×10^9/L and is usually indicated when the platelet count is less than 50×10^9/L. The determination of whether patients with intermediate platelet counts (50 to 100×10^9/L) require therapy should be based on the patient's risk of bleeding.
3. Surgical and obstetric patients with microvascular bleeding usually require platelet transfusion if the platelet count is less than 50×10^9/L and rarely require therapy if it is greater than 100×10^9/L. With intermediate platelet counts (50 to 100×10^9/L), the determination should be based on the patient's risk for more significant bleeding.
4. Vaginal deliveries or operative procedures ordinarily associated with insignificant blood loss may be undertaken in patients with platelet counts less than 50×10^9/L.
5. Platelet transfusion may be indicated despite an apparently adequate platelet count if there is known platelet dysfunction and microvascular bleeding.

Patients with severe thrombocytopenia (<20,000 cells/mm^3) and clinical signs of bleeding usually require platelet transfusion. However, patients may have very low platelet counts (much less than 20,000 cells/mm^3) and not have any clinical bleeding. Patients such as these probably do not need platelet transfusions. Individuals who have undergone trauma or require surgery need higher platelet counts, probably 100,000 cells/mm^3, to maintain adequate hemostasis (see Table 55-5). Laboratory determinations and clinical evaluations must be taken into account before a decision to transfuse platelets is made.

When possible, ABO-compatible platelets should be used. The need to use them, however, is not well documented. Specific testing is difficult. Aggregation, the end point of RBC crossmatch, cannot be used because platelets cause clumping. The platelet membrane has immunoglobulins. Any additional deposit of recipient antibodies is difficult to detect. Despite the fact that platelets can be destroyed by antibodies directed against class I human leukocyte antigen proteins on their membranes and, to a lesser extent, by antibodies against ABO, platelets chosen for transfusion probably will continue to be chosen without regard to antigen systems.[102] ABO-incompatible platelets produce very adequate hemostasis.

The effectiveness of platelet transfusions is difficult to monitor. Under ideal circumstances, one platelet concentrate usually produces an increase of about 7000 to 10,000 platelets/mm^3 at 1 hour after transfusion to the 70-kg adult. Ten units of platelet concentrates are required to increase the platelet count by 100,000 cells/mm^3. However, many factors, including splenomegaly, previous sensitization, fever, sepsis, and active bleeding, may lead to decreased survivals and decreased recovery of transfused platelets.

Various different types of platelet concentrates have been proposed, including apheresis (i.e., collecting more platelets from one donor to avoid pooling of platelets from multiple donors), leukocyte-depleted platelets, and ultraviolet B–irradiated platelets. The use of these products is reviewed by Kruskall.[102]

Fresh Frozen Plasma

FFP is prepared at the time that blood is obtained from a donor. It contains all the plasma proteins, particularly factors V and VIII, which gradually decline during the storage of blood. The use of FFP carries with it certain inherent risks that are observed with the use of essentially any blood product. The major risk is transmission of infectious diseases, such as hepatitis B, hepatitis C, and AIDS. Other risks include sensitization to foreign proteins. To increase overall utilization of blood products, many variations on the production of FFP exist. For example, there is variation in how long FFP is viable after thawing from 24 hours to 5 days. Also, plasma frozen 24 hours after phlebotomy (FP24) is comparable to FFP except for an approximate 25% decrease in factor VIII.[105]

Despite all the problems associated with FFP, its use increased 10-fold between 1974 and 1984, when consumption had reached almost 2 million units annually. This alarming increase caused the National Institutes of Health to conduct a Consensus Development Conference on Fresh Frozen Plasma in September 1984, of which I was a member.[49] More recently, the ASA Task Force[4] recommended the administration of FFP with the following guidelines:

1. For urgent reversal of warfarin therapy
2. For correction of known coagulation factor deficiencies for which specific correlates are unavailable
3. For correction of microvascular bleeding in the presence of increased (>1.5 times normal) prothrombin time or partial thromboplastin time
4. For correction of microvascular bleeding secondary to coagulation factor deficiency in patients transfused with more than 1 blood volume and when prothrombin time and partial thromboplastin time cannot be obtained in a timely fashion
5. FFP should be given in doses calculated to achieve a minimum of 30% of plasma factor concentration (usually achieved with administration of 10 to 15 mL/kg of FFP), except for urgent reversal of warfarin anticoagulation, for which 5 to 8 mL/kg of FFP usually suffice. Four to five platelet concentrates, 1 unit of single-donor apheresis platelets, or 1 unit of whole blood provides a quantity of coagulation factors similar to that contained on 1 unit of

FFP (except for decreased, but still hemostatic, concentrations of factors V and VIII in whole blood).
6. FFP is contraindicated for augmentation of plasma volume or albumin concentration.

The ASA Task Force[4] concluded that there was little scientific evidence to support the increasing use of FFP in clinical medicine. Although FFP is a reliable solution for intravascular volume replacement in cases of acute blood loss, alternative therapies are equally satisfactory and considerably safer. There is no documentation that FFP has a beneficial effect when used as part of transfusion management of patients with massive hemorrhage.

The practice of administering packed RBCs and FFP to the same patient should be discouraged because this adds to the cost and doubles the infection exposure. When conditions are appropriate, whole blood should be given.

The only indications for FFP administration the ASA Task Force[3] agreed on were the following:

1. Replacement of isolated factor deficiencies (as documented by laboratory evidence)
2. Reversal of warfarin effect
3. In cases of antithrombin III deficiency
4. Treatment of immunodeficiencies
5. Treatment of thrombotic thrombocytopenia purpura
6. Massive blood transfusion (rarely and only when factors V and VIII are less than 25% of normal)
7. Requirements for indications 1 and 6 are prothrombin and partial thromboplastin times at least 1.5 times longer than normal.

As of 2004, our policy at the University of California, San Francisco, is that in patients with clinical bleeding or oozing or those with an invasive procedure (e.g., percutaneous liver biopsy), the use of FFP is appropriate with a prothrombin time of 17 seconds or longer if the platelet count is more than 50,000 cells/mm^3 and the blood fibrinogen concentration is more than 100 mg/dL. FFP may be indicated for dilutional coagulopathy in patients with a prothrombin time more than 17 seconds and in whom administration of more crystalloids is anticipated.

Cryoprecipitate

Cryoprecipitate is prepared in such a way that it contains significant levels of factor VIII and fibrinogen. It also contains von Willebrand factor and fibronectin. All other plasma proteins are present in only trace amounts in cryoprecipitate. The use of cryoprecipitate in the treatment of factor VIII deficiency or hemophilia A has been outlined by Brown and coworkers.[106] Cryoprecipitate contains factor VIII:C (i.e., procoagulant activity), factor VIII:vWF (i.e., von Willebrand factor), fibrinogen, factor XIII, and fibronectin, which is a glycoprotein that may play a role in reticuloendothelial clearance of foreign particles and bacteria from the blood. Cryoprecipitate can also be used in the treatment of fibrinogen deficiencies and is preferable to commercially prepared fibrinogen preparations, which have a very high incidence of hepatitis, whereas the risk of hepatitis in cryoprecipitate is no more frequent than that from a single unit of blood.

Cryoprecipitate is frequently administered as ABO compatible; however, this probably is not very important because the concentration of antibodies in cryoprecipitate is extremely low. Cryoprecipitate may contain RBC fragments, and cryoprecipitate prepared from Rh-positive individuals can possibly sensitize Rh-negative individuals to the Rh O antigen.

Cryoprecipitate should be administered through a filter and as rapidly as possible. The rate of administration should be at least 200 mL/hr, and infusion should be completed within 6 hours of thawing.

Commercial concentrates of factor VIII have been the standard therapy for hemophilia. Although heat inactivation of factor VIII concentrate reduces infectivity, such a risk is still present. Recombinant DNA techniques have been used to develop factor VIII, which is free of disease transmission.[107] Mild cases of hemophilia may be treated without blood products by administration of desmopressin. Appropriate therapy is difficult to ascertain for patients who have inhibitors (i.e., alloantibodies) to factor VIII.

Fibrin glue is used occasionally by surgeons to create local hemostasis. It is prepared in a manner similar to that of cryoprecipitate. When FFP is thawed, the precipitate contains large amounts of fibrinogen. When centrifuged, about 4 mL of concentrated precipitate results. With added thrombin, it is applied locally, the efficacy of which is difficult to determine.

Prothrombin Complex

Factor IX can be recovered from plasma or plasma fractions by absorption with ion exchanges or inorganic chemicals. These products are all complexes of factors II, VII, IX, and X. Two commercial preparations are Konyne (Cutter Laboratories, Berkeley, CA) and Proplex (Hyland Division of Travenol Laboratories, Costa Mesa, CA). Other products include Alpha Nine SD, BeneFix, Mononine, and Profilnine SD. Bebulin VH is a vapor-heated concentrate of vitamin K–dependent factors in a much smaller volume than is achievable with FFP.

The main indication for these products is treatment of factor IX deficiency, or hemophilia B (i.e., Christmas disease). This is a hemorrhagic disorder that is distinguishable from hemophilia A only by laboratory tests. Factor IX or prothrombin complex has also been used for the treatment of acquired hypoprothrombinemic bleeding disorders, principally sodium warfarin overdose; however, its use is limited because of the risk of hepatitis.

Single-Donor Plasma

Single-donor plasma is plasma that has been removed from stored blood without any effort being made to preserve coagulation factors. Single-donor plasma is very effective as a volume expander. All the precautions outlined for the administration of FFP should be followed when single-donor plasma is administered. It obviously cannot be used to correct deficiencies in coagulation factors.

Other Options to Reduce Infectivity

Solvent-Detergent

Plasma from multiple donors is pooled and subjected to a lipid-destroying mixture of a solvent (tri-n-butyl phosphate) and a detergent (Triton X-100) to inactivate lipid-enveloped infectious agents, including HIV, HTLV, hepatitis C virus, and hepatitis B virus.[108] It has several disadvantages, including the risk of contamination of nonenveloped agents. Recalls can occur after any fraction of a lot has been released. It can be much more expensive than other preparations.

Single-Donor Plasma, Donor Retested

A donation is made, and FFP is prepared. The unit (the first donation) is kept if all history and infectious diseases markers are negative. That unit is not released for use until the same donor donates a second unit at least 3 months after the first donation and again passes all donor-intake and serologic testing. At that time, the first unit is released. The second unit is not released until the donor returns more than 3 months later for a third donation and again passes all the testing. At that time, the second unit can be released for use. This approach has obvious advantages but is administratively complex.

Frequent-Donor Plasma

An inverse relationship exists between the number of donations a person has given and the chance that he or she will become seropositive for a disease. The relationship is independent of the time over which the donations were given. A maximum reduction of the incidence of seropositivity is reached at four or more donations. Predictions are that reduction in seropositivity (and therefore transmission) to one third to one half of the current figures is possible.

These options were presented at the University of California, San Francisco, Transfusion Committee meeting and indicate that clinicians will have many ways of ensuring safer plasma for patients. With the newer tests of infectivity, the previously described FFP approaches may not be necessary.

Albumin and Plasma Protein Preparations

Several commercial products containing albumin are available for use to increase intravascular volume. Albumin is available as a 5% or a 25% solution in isotonic saline. Plasma protein fractions containing albumin and α and β globulins are available. These solutions are prepared commercially from albumin fractions from large pools of plasma reconstituted in isotonic electrolyte solutions. Such solutions can be given without regard to ABO blood type and without crossmatch and should be used primarily as volume expanders. They are very expensive and in short supply. Bacterial sepsis has been associated with albumin administration.[109] For much of 1997, there was a shortage of 5% albumin because of the concern about contamination with variant Creutzfeldt-Jakob disease. If available, albumin should be administered within 4 hours of initiation of the infusion because of the potential for contamination after opening the bottle. In 2003, Vincent and associates[110] analyzed all adverse reports on the 10 major suppliers of human albumin worldwide from 1998 to 2000. Although cases were possibly underreported, the investigators concluded that adverse events were rare with human albumin administration. It appears to be quite safe, but the indications for its use are controversial.

Administration of the plasma protein fraction of 5% serum albumin solutions should be restricted for the treatment of documented hypoproteinemia or conditions such as burns and peritonitis, in which hypoproteinemia is likely. These solutions expand the vascular space for a longer period than balanced electrolyte solutions do. However, albumin's osmotic ability draws fluid into the vascular space from other extracellular fluid compartments. In most states of hypovolemia and dehydration, the entire extracellular fluid space already is depleted. Fluids such as 0.9% saline or lactated Ringer's solution, which expand the entire extracellular fluid space, should be given.

Synthetic Colloid Solution Therapy

The crystalloid versus colloid conflict has been debated for many years. The University Hospital Consortium developed guidelines for the use of albumin, nonprotein colloid, and colloid solutions.[111] Unfortunately, no anesthesiologists were represented in the Consensus exercise. Since 2000, Boldt's[112] analysis of the literature, including a Cochrane Group review in 2002, found no consistent difference between crystalloids (i.e., isotonic and hypertonic) and different types of colloids as a basis for intravascular volume replacement. There is no doubt that colloids expand intravascular volume more than crystalloids (i.e., a smaller amount of colloid is required for adequate intravascular resuscitation).[113] However, outcomes (e.g., mortality) do not provide convincing evidence that one fluid replacement strategy is better than others.

Synthetic Hydroxyethyl Starch

Between 2000 and 2003, Boldt[112] found 40 original studies with a total of 2454 subjects. The most commonly used preparation was 6% hydroxyethyl starch (HES, Hespan). Although an effective intravascular expander, it has not gained widespread popularity probably because of its effects on coagulation, particularly with regard to increased bleeding and platelet function. The molecular mass plays some role in the adverse coagulation effects (i.e., smaller molecular mass has less effect on coagulation). Two new HES preparations have been developed to decrease coagulation effects. Hextend has been studied extensively. It is 6% HES but also contains a physiologically balanced medium of electrolytes, glucose, and lactate. It has a similar pharmacokinetic and dynamic profile to other starch preparations with fewer effects on

coagulation.[114] Gelatin has also been used, but it has not been as widely studied as HES.[115]

Dextrans

Dextran 70 (Macrodex), with a molecular mass of about 70,000 daltons, is an effective volume expander. However, after infusion of more than 20 mL/kg in 24 hours, dextran 70 may interfere with normal blood clotting, causing a deficiency with crossmatching procedures and possibly a bleeding diathesis. These clotting defects reflect reduced platelet adhesiveness resulting from an antithrombin effect. The incidence of severe anaphylactoid or anaphylactic reactions is a concern. These reactions are mediated by dextran-reactive antibodies that are IgG immunoglobulins. Dextran-reactive antibodies are formed in response to dextran polysaccharides. This process can be prevented if the potentially reactive sites on the dextran-reactive antibody are blocked before the antibody is given. By prior administration of a hapten, a substance capable of combining with immunoglobulins but not producing a reaction, the reactive sites are occupied and unable to react to the antigen. Prior administration of dextran I (Promit, molecular mass of 1000 daltons) has proved effective as a hapten and decreases, but does not eliminate, the incidence of severe reactions.[116] Dextran 70 exerts a higher colloid osmotic pressure than blood. Dextran 70 and albumin may deplete the extracellular fluid space of water, as does albumin.

Dextran 40 (Rheomacrodex), with a molecular mass of 40,000 daltons, has been used primarily to reduce blood viscosity and cellular aggregation and to improve microcirculation during low-flow states. It is often given prophylactically to decrease the incidence of postoperative thromboembolism. Blood viscosity may be increased by trauma, blood loss, burns, and endotoxin shock. Although viscosity can be decreased by dextran 40, the presumed improvement in flow through the microcirculation has not been well documented.

Hypertonic Saline, Possibly with Dextran

The sodium concentration of hypertonic saline solutions is 250 to 1200 mEq/L. The theoretical advantage is that the greater the sodium concentration, the less total volume is required for adequate resuscitation. The lower infusion volume probably reflects the osmotically related movement of intracellular water into the extracellular space. Other mechanisms include a direct inotropic effect on the myocardium and a direct peripheral vasodilator effect. The main problem is severe hypernatremia, which can cause brain dehydration and can be fatal.

Various hyperosmotic-hyperoncotic solutions have been used for resuscitation of hypovolemic patients. The most common combination is hypertonic saline and 6% dextran 70. In animals, these fluids restore gut and kidney microcirculation more effectively than normal saline.[117,118] The addition of dextran increases the intravascular volume effect of hypertonic saline but does not extend the duration of effect in a clinically significant manner.[117] Clinical practice will be required to ascertain the ultimate role, if any, of these fluids.

Synthetic Oxygen-Carrying Substances

Other Than Human Red Blood Cells (Blood)

Other various substances that carry or facilitate the transport of oxygen have been made. Two concepts of synthetic blood have been attempted. The first approach uses linear binding kinetics, unlike the nonlinear binding of hemoglobin. The most notable is the perfluorochemical emulsion called Fluosol-DA. However, it had little use because it carries oxygen (i.e., a small amount) only when the Pao_2 is more than 300 mm Hg.[118] A newer perfluoro compound, perfluorooctyl bromide, carries three to four times more oxygen and has a longer half-life and presumably fewer problems than are associated with Fluosol-DA. Other related products are Oxygent (Alliance), Oxycyte (synthetic blood), and several other perfluorocarbon emulsions.

The remaining synthetic blood (a term this author uses but not one officially accepted by industry and the FDA) or oxygen therapeutics are labeled as hemoglobin-based oxygen carriers (HBOCs). These products modify the hemoglobin molecule from humans, animals, or recombinant technology. Original efforts required hemoglobin to be stroma free to prevent nephrotoxicity. The stroma-free hemoglobin needed to be modified to have a favorable oxygen affinity and to extend its relatively short intravascular half-life. Only three products have been undergoing clinical trials. Two products are from outdated human RBCs and the third from bovine RBCs. However, these solutions are not without complications. The most serious are kidney toxicity, an increase in affinity for oxygen (i.e., left shift in the oxygen dissociation curve), and arteriolar vasoconstriction from nitric oxide scavenged by the infused hemoglobin. As described at the end of this section, this vasoconstriction may prove to be their ultimate downfall. A variety of approaches are being used, including crosslinking, pyridoxylation and polymerization, and conjugation and encapsulation, to decrease oxygen affinity, to increase deposition in the reticuloendothelial system, and to increase half-life.
