In plastic surgery, surface temperature measurements are a useful and often important way of diagnosing burn depth (Cole et al 1991, Wyllie & Sutherland 1991), the deeper burn being colder than surrounding tissue (see Ch. 30). After transplantation of skin flaps, a change in temperature of a flap could indicate poor vascular supply, if lowered, or infection, if raised.

Electronic thermometers

Although the mercury-in-glass thermometer is a reliable method for body temperature measurement, electronic thermometers have improved both safety and speed of measurement and revolutionised temperature monitoring for nurses in the UK over the last 20 years. Thermometers such as the IVAC reduce the time taken to obtain an accurate measurement using the traditional clinical (mercury-in-glass) thermometer from approximately 9 min to 1 min. For a single 'spot' measurement, electronic thermometers are quick and simple to use.

Tempa-Dot thermometers

In 1999 a new 'generation' of single-use clinical thermometers became available. The 3M company introduced a single-use (disposable) clinical thermometer which was considered to be a more convenient and hygienic alternative to mercury-in-glass and electronic thermometers. This thermometer is also useful in frail older patients, as well as those patients with stroke, where keeping the electronic thermometer in the mouth can be difficult and uncomfortable. Each thermometer has a series, or matrix, of temperature-indicating dots at the tip. Within each dot, a different combination of chemicals melts, changing colour from beige to blue at intervals of 0.1°C. The temperature is read from the number of dots that have changed colour. The range of temperature which can be measured with the Tempa-Dot thermometer is 35.5–40.4°C.

Whilst Tempa-Dot thermometers have some advantages over other methods, nurses should be aware that temperatures below 35.5°C or above 40.4°C will not be detected. These thermometers are therefore not suitable for temperature measurement when hypo- or hyperthermia is suspected but are considered useful in paediatrics (Macqueen 2001), correctly identifying fever in children with a sensitivity of 92% (Morley et al 1998).

Taking temperatures

Recording an accurate body temperature depends not only on the reliability of the instrument, but also on the clinical skill of the nurse. Even the most accurate of instruments will give an incorrect reading if the nurse has a poor temperature-taking technique. Table 22.2 gives some useful tips to help nurses improve clinical practice.

Table 22.2 Sites for body temperature measurement: advantages and disadvantages

Site	Nursing practice	Advantages	Disadvantages
Axilla	Place in centre of armpit, hold arm against chest. Leave in position for 9 min	Ideal for temperature measurement in babies and toddlers	Less accurate than oral or rectal measurements but can be a reasonable indicator of core temperature if thermometer is left in situ for the required length of time. Since measurement is not taken in a body cavity, there is more chance of external influences affecting the result
Rectum	Insert rectal thermometer 4 cm into the anus (adults) or 2–3 cm in an infant. Leave in situ for 4 min	Suitable site for babies or for unconscious patients who need continuous temperature monitoring	Unacceptable for routine monitoring in some conscious patients, although seriously ill patients with fluctuating conscious levels may require rectal temperature monitoring. Rectal temperature may be higher than at other sites.
Ear (auditory canal) (e.g. using the Core Check thermometer, Ivac, Basingstoke, UK)	Ensure the 'lens' of the thermometer is clean (free from cerumen or ear wax). Apply lens cover. Gently hold the pinna and insert probe into the auditory canal. In small children it is important to pull the pinna gently backwards to straighten the ear canal (refer to manufacturer's instructions). Ensure lens is directed towards the tympanum and not to the skin inside the ear canal. After pressing the thermometer 'start' button, a bleep will be heard. It is advisable to repeat the measurement in the opposite ear to ensure parity of measurements in both ears. However, there is sometimes a difference between the temperature of the ears. This is particularly true in hospital where measurements are made on patients who have recently been lying on their side, with their ear on a pillow	Quick and easy to use, with little danger of ear perforation, even in babies. Always remember that thermometers must be calibrated regularly (6-monthly) by the hospital technical department	Unreliable measurements can occur if the ear is inadvertently cooled or warmed, either naturally or by recent local heating/cooling; e.g. if a tympanic temperature measurement is taken in patients who have recently been in a cold environment, or if patients are receiving body cooling treatment for a high temperature, especially where the scalp is involved. Where repeat measurements are made in the same ear, repeated placement of the thermometer in the same ear may cause the measurement to be lower each time it is made, because the instrument casing may slightly lower the temperature inside the ear canal

In the conscious patient, the options for deep body temperature measurement are limited to conventional sites such as the axillae, mouth and tympanum (auditory canal). However, when patients are critically ill, accurate temperature measurement becomes a priority. The patient's temperature may need to be measured at a site which allows the thermometer to remain in situ for many hours, i.e. for continuous monitoring. This is common in the intensive care unit. In such cases, body core temperature can be measured using indwelling thermometers (thermistors) placed in the rectum, oesophagus, nasopharynx or urinary bladder. Continuous temperature measurements are provided from bedside monitoring systems.

Special cases

In the brain-injured patient, a rise in temperature of 1–2°C above normal is linked to a poor neurological outcome (Natale et al 2000). Accurate measurement of brain temperature is therefore desirable. For many years this was not possible outside the laboratory but today, brain temperature monitoring can be performed at the bedside. Brain temperature can be measured within brain tissue (parenchyma) as well as in the ventricles and is usually undertaken in conjunction with routine monitoring of intracranial pressure (Childs et al 2005).

22.10 Ask a qualified nurse to help you with this exercise. With a patient's consent and cooperation, measure oral and axilla temperature at intervals of 1, 3, 5 and 9 min. Compare the results. Are there differences in the values recorded at the two sites?

22.11 If you have some experience of using an electronic thermometer, comment on the advantages (if any) of this technique of measuring deep body temperature compared with the mercury-in-glass thermometer.

22.12 Ask your mentor or the charge nurse on the ward where you are working to tell you about the cost of temperature taking and how much of the ward/unit budget is allocated to temperature measurement.

DISTURBANCES IN TEMPERATURE REGULATION

The aim of this section is to supplement the nurse's understanding of thermal physiology with examples of abnormal or disturbed thermoregulation.

Table 22.3 gives examples of clinical conditions associated with a rise in body temperature. The causes of increased body temperature can be divided into two categories:

- a rise due to fever
- an increase as a result of heat illness.

Table 22.3 Changes in body temperature

	Cause	Clinical examples	Appropriate treatment
Fever	Elevation of hypothalamic set-point by endogenous pyrogens such as cytokines, interleukin-1 and interleukin-6. Both are released from the patient's own white cells in response to bacterial or viral infection or to damage to skin and tissues	Infection: bronchitis, malaria, sepsis, meningitis Trauma: burn injury, minor and major surgery, myocardial infarction, thrombophlebitis	Antipyretic medications such as aspirin or paracetamol return altered set-point temperature to a lower level. Avoid external cooling as this may exacerbate the rising core temperature
Heat illness	Increased metabolic heat production, *or* Reduction in the rate of heat loss (by R, C and E) from the body surface (see Table 22.1)	Heat stroke resulting from high air temperature, overwrapping (children/older people) and excessive clothing, or due to increased exercise or work in hot conditions where dehydration and reduced sweating are common associated factors	External cooling: 1. Increase radiant and convective heat loss by removing clothing and helping 'stir' the air around the subject. Avoid cold draughts. Do not use ice packs, as these can increase vasoconstriction 2. Increase evaporative heat loss by applying a fine mist of warm water (40°C) over the body and exposing as much of the skin surface as possible to the air
Malignant hyperpyrexia	Largely unknown. Patients found to have an underlying inborn error of muscle metabolism, usually triggered by general anaesthesia	Hyperthermia occurs shortly, or immediately, after general anaesthetic, in apparently normal patients. Once body temperature starts to go up, it does so very rapidly, by as much as 1°C every 5 min. Temperatures as high as 46°C may be reached, with tachycardia, cyanosis and loss of consciousness	Active cooling, maintenance of cardiac output, correction of metabolic disturbances, e.g. hyperkalaemia, acidosis. Administration of dantrolene sodium

It is important to recognise the fundamental differences between these two main causes of raised body temperature as well as to appreciate their implications for treatment.

Fever

The high 'core' or deep body temperature associated with fever is due to an upward re-set in the central hypothalamic set-point temperature (see p. 814). If the set-point is shifted, for example from 37° to 39°C, thermoreceptors in the brain detect a discrepancy between the set-point temperature and the temperature of the blood circulating (37°C) through the hypothalamus. This is the error signal described on page 814. Since blood temperature is lower than the new, raised set-point temperature, heat gain mechanisms will be stimulated to achieve an increase in the temperature of the 'core'. This can be observed when the febrile patient complains of being cold and pulls on more bedclothes or turns the heating up. Patients do this even when their core temperature has started to rise. They complain that their hands and feet feel cold and this is due to the blood in the skin being diverted away from the 'shell' to the central 'core'. The patient may also start to shiver. Very vigorous shivering is called a rigor. The occurrence of febrile convulsions in young children and the related nursing care is discussed in Box 22.3.

As body temperature rises, heat loss mechanisms are inhibited or 'switched off'. These thermoregulatory changes help the temperature to reach the new set-point level. At this stage, the nurse should not try to lower the patient's temperature by cooling, either by tepid sponging or with electric fans, because by doing so the stimulated heat conservation mechanisms already in operation will be counteracted. However, once the temperature of the blood and core tissues are at the new 'set-point' level and sufficient heat has been stored within the body to sustain the new set-point temperature, the patient will become more comfortable despite the higher (febrile) temperature.

The set-point will not remain at the higher level. Eventually, the biological effects of the pyrogen (see below) will wear off and the thermoregulatory 'set-point' will abruptly return to normal. When this happens, the patient will feel uncomfortable and hot. Hands, face and feet will become red as peripheral vasodilatation replaces vasoconstriction. Vasodilatation allows skin blood flow to reach the most superficial layers of skin so that heat exchange from core tissues to the skin surface and from the skin to the air can take place. At this stage the patient should be put in the best position to allow dissipation of body heat naturally. Forcing heat loss by causing excessive draughts or allowing the temperature of the room to fall so low that the patient quickly becomes cold will make them uncomfortable and possibly induce peripheral vasoconstriction again. If this happens, heat loss by radiation and convection will be reduced. Patients often have a drenching sweat when their set-point returns to normal. It is, however, possible to encourage heat loss by evaporation by spraying the patient with a fine mist of warm water. The use of non-steroidal anti-inflammatory drugs (NSAIDs) in the treatment of fever is discussed in Box 22.4.

Box 22.3

What to do in the event of a febrile convulsion

Febrile convulsions occur in 40 out of 1000 children and it has been estimated that 30% of all convulsions in children occur during a febrile episode. Approximately 2–5% of all children have at least one convulsion in association with fever by the time they are 5–7 years of age.

Febrile convulsions generally occur in normal children between the ages of 6 months and 5 years. Simple febrile convulsions are probably not harmful. They are brief, lasting only seconds or a few minutes. They occur soon after the onset of fever and it is the height of the fever rather than the speed of the rise in temperature that is thought to be an important contributing factor. However, there are some situations in which a rapidly developing high fever (of 39–40°C) in infants and young children is not associated with convulsions (Childs 1988) and this raises questions about the precise contribution of level of fever and rapidity of onset to the development of a convulsion.

Certain infections, particularly those of the central nervous system, have a high incidence of associated seizures. Bacterial and viral meningitis have been associated with a high incidence of convulsions, but these conditions may well precipitate convulsions by virtue of the nature of the underlying disease rather than because of the fever *per se*.

Nurses play an important role in the acute management of the child with a febrile convulsion. Convulsions can cause fear and misunderstanding and, since they generally occur in very young children, the parents may feel particularly helpless. Nurses are often in a good position to explore these fears and misconceptions with parents and to provide them with information about what to do if their child experiences a febrile convulsion; this information will help to reduce anxiety and feelings of helplessness.

When a convulsion starts, the child needs to be protected from falling on to the floor or against furniture. If they are in a cot or bed, care should be taken to prevent them from falling out or hitting themselves against sharp corners which may be within reach. The airway should be cleared but nothing should be inserted into the mouth. A common misconception is that the use of spoons or gags is necessary to prevent the tongue from blocking the airway. This practice is dangerous and can harm the child. As long as the nurse puts the child in the recovery position (see Ch. 26), observes the airway and takes the necessary actions to maintain a clear airway by, for example, wiping away accumulated secretions, little more can be done. However, if the convulsion does not resolve after a period of 10–20 min, medications may be needed to control it. In such a case, medical help will be needed.

In addition to protecting the child from injury during the convulsion, the nurse should document its characteristics. Notes should be made relating to the child's temperature at the time of the convulsion or the last measurement made before it started, the type of movements made during the convulsion, where they started, how they developed and for how long they lasted. The clinical condition of the child should also be described.

Box 22.4

Non-steroidal anti-inflammatory drugs (NSAIDs)

In addition to their anti-inflammatory effects, NSAIDs are antipyretics. They act by inhibiting the production of prostaglandins from arachidonic acid in the cyclo-oxygenase pathway.

Since 1986, the NSAID aspirin (acetylsalicylic acid) has been withdrawn from general use in children under the age of 12 years because of the association between this drug and a serious condition called Reye's syndrome.* Paracetamol (acetaminophen) is now the most commonly used antipyretic in children. Although not an NSAID, its antipyretic properties are thought to lie in its ability to prevent the synthesis of prostaglandins, which are thought to affect the temperature set-point when released into the brain (see p. 814).

Antipyretic drugs are not effective in conditions where high core temperatures are caused by heat illness; neither are they effective in lowering normal body temperature.

*Reye's syndrome is a rare illness that occurs typically in children and teenagers. The onset is usually during a viral illness such as influenza or chickenpox. This is then followed by protracted vomiting and neurological changes at just about the time when the child is beginning to recover from the original illness (Ward 1997). The use of aspirin during the illness has been identified as a factor contributing to the very serious metabolic disorders associated with it, i.e. encephalopathy and fatty degeneration of organs. Unexpected vomiting and disturbed brain function after a viral illness are symptoms of Reye's syndrome in children and teenagers, but in infants the symptoms may be slightly different and include diarrhoea, breathing difficulties and fits. The number of cases reported has fallen in countries where aspirin has been withdrawn from use in children (Larsen 1997).

How fever develops

Fever is caused by the action of proinflammatory cytokines acting within the brain. Cytokines are peptide molecules released from a variety of cells, including those of the immune system (see Ch. 16). In health, cytokines are essential for cell–cell communication. During episodes of disease, such as inflammation and injury, they are responsible for many of the exaggerated inflammatory changes which can lead to sepsis and multiple organ failure. However, cytokines are not always harmful in disease, because these molecules also have beneficial effects for the host. The anti-inflammatory cytokines, such as interleukin-10 (IL-10) and transforming growth factor beta (TGFβ) for example, are important for healing and repair. Cytokines therefore have harmful as well as beneficial effects upon the patient.

For many years, the substances thought to be responsible for the fever associated with infection, tissue breakdown and necrosis, e.g. after traumatic injury or myocardial infarction, were a group of peptides called endogenous pyrogens (EPs). The endogenous pyrogens have now been shown to include specific molecules and are collectively called interleukins. Interleukin-1 (IL-1) is generally believed to be the pyrogen which acts in the brain to raise the set-point temperature to a higher level. IL-1 can be detected in the circulation in some but not all diseases. For example, after severe acute respiratory syndrome in children, patients have markedly elevated levels of IL-1 (Ng et al 2004). High levels of circulating IL-1 are also reported after acute myocardial infarction (Francis et al 2004).

Release of IL-1 into the circulation is probably stimulated by other interleukins produced outside the brain. Interleukin-6 (IL-6), for example, is a cytokine produced by a number of different cells such as activated macrophages, monocytes, keratinocytes, fibroblasts and others. It is thought that IL-6 released at the site of inflammation or injury triggers the production of IL-1 in the brain. In the brain, IL-1 probably stimulates production of a group of substances called prostaglandins. These substances are thought ultimately to be responsible for elevating the thermoregulatory set-point (Ranels & Griffin 2003).

Chills and rigors

A sudden onset of fever with a 'chill' or 'rigor' is characteristic of some diseases. For example, the rigors associated with malaria are diagnostic of the disease and are often portrayed in novels and films as a serious symptom of tropical disease. Repeated rigors are typical not only of pyrogenic infections and bacteraemia but are now also recognised as a symptom of viral as well as bacterial infections. Rigors and chills also occur in other febrile illnesses and can be demonstrated experimentally. For example, fever can be induced in human volunteers by safe, intravenous administration of a pyrogen called endotoxin. Endotoxin is a lipopolysaccharide molecule produced from Gram-negative bacteria. In human volunteer studies of thermoregulation and metabolism, endotoxin administration produces a 1–1.5°C rise in body temperature, accompanied by chills, shivering, myalgia and flu-like symptoms. These symptoms begin approximately 90 min after the endotoxin is administered. All the symptoms disappear after 5–6 h (Soop et al 2002).

A chill or rigor is accompanied by intense feelings of cold. The patient's skin will be white and cold and they will probably pull their bedclothes tightly around their body and curl up into a ball. Their teeth may chatter and they will feel very uncomfortable. Intense shivering and violent jerking movements will be uncontrollable.

Fever in myocardial infarction

Myocardial infarction is an example of a condition in which there is an acute rise in deep body temperature, probably due to release of proinflammatory cytokines from the injured myocardium (Francis et al 2004). Typically, body temperature rises after the first 24 h to 37.8–39.9°C and remains elevated for 2–3 days. Temperatures may be even higher. By day 5, however, deep body temperature returns to normal. It is thought that the pattern of elevated body temperature reflects necrosis of myocardial tissue (see Ch. 2). If fever persists after the fifth day, the nurse should consider infection, e.g. pneumonia, thrombophlebitis or a systemic infection, as a possible cause.

22.13 Each of the following illnesses and conditions may result in fever:

- otitis media
- meningitis
- blood transfusion
- acquired immune deficiency syndrome (AIDS).

Construct a table to give the cause of the fever and its appropriate nursing care. You will need to refer to Nursing Care Plan 22.1 as well as to other chapters in this book to complete the table. When you have done so, answer the following questions:

(a) What is the common cause of the raised deep body temperature in the above examples?
(b) Why would you expect your chosen methods of treatment to be effective in lowering deep body temperature in each case?

Fever or heat illness?

Confusion sometimes surrounds the use of the word 'fever' to describe an elevated body temperature. 'Fever' is often used to describe a 'generic' increase in temperature, but in fact it has specific characteristics. To add to the confusion, the words 'hyperthermia' (wrongly) and 'hyperpyrexia' (correctly) are also used to describe febrile illness. In caring for patients with an elevated deep body temperature, it is important to appreciate the distinction between the mechanisms of fever on the one hand, and of heat illness on the other. When planning to treat the patient, the nurse should consider: 'Does this patient have a high temperature because of an altered set-point or because of a problem with dissipating their body heat loss?'. If the former is the case, the patient is febrile; if the latter seems more likely, then hyperthermia and heat illness should be suspected. The problem is that, in many cases, it is difficult to be sure of the cause of high body temperature.

How heat illness develops Heat illness is a term which includes the following three clinical conditions:

- heat cramps
- heat exhaustion
- heat stroke.

An elevated body temperature is not a diagnostic criterion for heat illness, but it may occur in association with clinical symptoms secondary to environmental heat stress or to a disturbance in the body's ability to dissipate body heat.

CASE HISTORY 22.1
Mr G

While making the weekly call to the home of Mr G, an 81-year-old widower, the community nurse finds him in the garden sitting in his wheelchair in a state of collapse. A relative arrives shortly afterwards and explains that since it was a nice day she thought Mr G would benefit from some fresh air and sunshine whilst she did his shopping.

Mr G feels hot and his hands and feet are red and sunburned. His skin is dry (he is not sweating) and his lips are slightly cracked. His axilla temperature (measured when taken indoors) is 39.2°C.

After being taken indoors, Mr G is sponged with warm water and his clothing removed or loosened. Cool drinks are given and his temperature gradually returns to normal over the next 4 h.

The cause of heat illness is quite different from that of fever. Fever and the concept of an upward re-setting of the hypothalamic set-point have already been discussed. Heat illness can be a minor medical problem or so severe that it poses a threat to life. Its primary cause is not the production of pyrogenic cytokines (IL-1, IL-6) but a variety of other factors, e.g. drugs, extremely hot and humid conditions, excessive overwrapping and body insulation, and very intense work in a hot environment, which causes heat to be stored in the body and which cannot be dissipated quickly enough from the body surface. A mild form of heat illness leads to heat cramp, and the most severe leads to heat stroke (see Case History 22.1).

Table 22.4 presents some of the signs which may alert the nurse to the fact that a patient is becoming overheated.

Nursing care of a febrile patient

Fever may start abruptly with a shaking chill, or it can develop without the patient even being aware that their

Table 22.4 Clinical appearance and observations of an apyrexial patient who complains of feeling hot: evidence for behavioural and physiological thermoregulation

Observation	Response
The bedclothes have been pushed to the bottom of the bed by the patient	This is a behavioural response to the sensation of feeling too warm. Removal of bedclothes/clothing exposes a larger area of the body surface for heat exchange by radiation and convection. If bedclothes/clothing are removed then sweat can freely evaporate to the room and so facilitate evaporative heat loss
Close inspection of the patient shows that the skin of the hands and feet is red and the veins in these areas dilated	Under control of the sympathetic nervous system, veins of the feet and hands vasodilate due to a reduction in vasomotor tone. Blood is therefore directed to the skin surface, resulting in the core tissues extending to the shell (see p. 814) and the skin appearing flushed. The skin is now at a higher temperature, thus creating a wider temperature gradient between the body and the environment. The greater the temperature difference between the body surface and its surroundings, the greater the heat loss by dry routes
Small droplets of sweat appear on the forehead and trunk	Sweating is stimulated in response to either an increase in skin temperature or a rise in core temperature (note the exception to this described in Table 22.1). Sweating occurs first on the forehead, followed by the upper arms, hands, thighs, feet and, finally, the abdomen. Sweating has been shown to start when the average skin temperature is 34°C; as skin temperature increases so does the sweat rate

Nursing Care Plan 22.1 Care of a febrile patient

Time scale	Problem	Action	Rationale
08.00	When measured, the patient's oral temperature has risen to 37.5°C	• Measure patient's temperature every 10 min	During a chill, frequent measurements should be made to determine the pattern of temperature and the maximum values reached
09.00	Oral temperature continues to rise, and now does so rapidly and is accompanied by shivering. The trunk is hot but the limbs are cold	• Cover the patient's body with blankets and raise the air temperature slightly. Avoid exposing the patient to cold draughts	At this stage the temperature regulating system is disturbed. Mechanisms are initiated to raise body heat to meet the new, raised set-point temperature. Any attempt at this stage to cool the patient will worsen their chill and delay the time in which the new set-point temperature is reached
11.00	Oral temperature has reached a plateau of 39.5°C	• Once deep body temperature has settled and is no longer rising, temperature measurements can be made every 30 min	A patient's temperature can be considered to be stable when there are at least two consecutive readings of the same value over a period of 1 h. Once the temperature is stable, measurements can be made every 2–4 h but observations of the patient's general condition should continue
11.30	Pulse rate has increased to 100 beats/min and respiratory rate to 20/min	• Frequent observations of pulse and respiratory rate should be part of the overall assessment of the febrile patient	As body temperature goes up so does cellular activity, i.e. there is a rise in metabolic activity. There are direct effects upon the cardiovascular and pulmonary systems as a consequence of a rise in temperature and metabolic activity. Metabolic activity increases by 13% for every 1°C rise in core temperature. Because of the increased energy demands brought about by fever, persistent pyrexia represents a drain on energy stores. In addition, febrile patients become anorexic and are reluctant to eat and so their energy intake falls. A poor energy intake in conjunction with increased energy expenditure results in negative energy balance or weight loss
11.45	An antipyretic has been prescribed to lower core temperature	• Administer aspirin/paracetamol as indicated. Note the patient's temperature at the time of giving the medication. Monitor the patient's temperature regularly (every 15 min) and record the changes on the patient's temperature chart to determine the efficacy of the treatment given • Remove blankets and switch off any form of external heating	Antipyretics such as aspirin return the upwardly reset temperature to the original set-point level of approximately 37°C. Once this happens, the excess heat stored within the body represents an excessive heat load which must be dissipated. In addition to heat loss by the dry routes, radiation, convection and evaporative heat losses are switched on and patients may sweat profusely. Body temperature subsequently falls During the phase of heat dissipation the surface of the body needs to be exposed so that heat loss by all routes can be encouraged
13.00	The patient's mouth is dry. Patient is drenched in sweat and feels uncomfortable	• Frequent mouth care should be given if the patient cannot eat or drink, but whenever possible clear fluids should be encouraged. These can be refreshing and will provide glucose for energy	Some authors claim that as much as 3 L water can be lost each day in a febrile sweating person. An inadequate fluid intake is accompanied by excretion of a small amount of concentrated urine. An inadequate urine output indicates poor hydration and this is often accompanied by the development of sordes. Drenching sweats are uncomfortable, particularly if nightwear and sheets are wet. The patient can be made more comfortable by giving a bedbath and by sponging with warm water. Cold water should be avoided as this causes external cooling and worsens the feeling of discomfort

temperature has risen. When measured, core temperature may remain high or it may fluctuate (Edwards 1998). A fluctuating temperature with peaks and troughs can occur naturally, as discussed on page 816, but in hospital, a peak followed by a trough is more likely to be due to the effects of administration of an antipyretic, such as aspirin or paracetamol, or to vigorous use of surface cooling.

Nursing the patient with fever is a skill. It demands knowledge of the mechanisms of thermoregulatory disturbance as well as good clinical practice. The care that might be given to a febrile patient in the course of a few hours is described in Nursing Care Plan 22.1.

It is important for the nurse to appreciate the differences between managing the patient with fever compared to hyperthermia caused by heat stroke. In heat stress or heat stroke the primary problem is one of heat imbalance: too much heat stored, not enough body heat lost. This can occur after a marathon or after too much sunbathing. In both situations the problem for the person is the same. Antipyretics are ineffective because the set-point remains unchanged. The first line of treatment is to aid the dissipation of heat from the body and to rehydrate the person. Mild cases of 'sunstroke' can be corrected by moving out of the sun and to a cool environment so that heat can be lost from the body by radiation and convection: the dry heat loss routes. Cold drinks will also be helpful and comforting. In extreme situations, heat exhaustion may occur. The person is unable to lose heat by sweating because the sweat glands fail to produce sweat. The most effective treatment is to expose the body and spray the skin with warm (not cold) water to promote vaporisational heat loss, whilst taking care not to cause peripheral vasoconstriction. Heat exhaustion is a major risk for soldiers during combat in a hot climate.

Hypothermia

Hypothermia is a state in which the temperature of the body is lower than the thermoregulatory set-point. This situation can occur accidentally, i.e. spontaneous or accidental hypothermia, or it can be induced deliberately, i.e. therapeutic hypothermia. Nurses may encounter patients who have had a prolonged period of cold exposure due to an accident either inside or outside the home. In hospital, a subnormal temperature may occur in a patient who has undergone a prolonged surgical procedure. Nurses also now encounter therapy designed deliberately to lower the temperature of the body for therapeutic reasons (see Box 22.5).

The physiological mechanisms that lead to the development of hypothermia can be explained with reference to the hillwalker described in Case History 22.2. With nightfall, a drop in air temperature will stimulate a number of physiological responses to limit the rate of heat loss from the surface of Mr E's body. First of all, a fall in skin temperature, detected by skin thermoreceptors, will cause a reduction in blood flow to the skin at the extremities, i.e. nose, fingertips, toes and ears. Whilst peripheral vasoconstriction is extremely effective in maintaining body temperature with a moderate fall in air temperature, the conditions on the hillside will be more severe and eventually peripheral vasoconstriction will become maximal. When the vessels cannot constrict further, other mechanisms will be stimulated to prevent a further fall in deep body temperature. This will involve activation of the thermoregulatory mechanisms of heat production.

The first response to a modest reduction in air temperature which causes mild sensations of discomfort is an increase in non-shivering thermogenesis (NST; see p. 815). Shivering quickly follows NST as the major thermoregulatory mechanism to raise heat production. The main stimulus to shivering thermogenesis is a fall in skin temperature, but the intensity of shivering increases when core temperature falls as well. Shivering starts first in the muscles of the jaw and neck and progresses to all skeletal muscles. Although shivering increases heat production by approximately five times the basal rate, only about 40% of the heat produced is retained within the body. The rest is lost from the body

Box 22.5

Deliberate cooling — new treatments using therapeutic hypothermia

Although accidental hypothermia is undoubtedly harmful and can lead to death, deliberate cooling of the body may have beneficial effects in specific conditions. Refrigeration of human tissue has a long history (Fay & Smith 1941). In patients with neurological conditions, such as brain tumours, or in patients with cancer, early research undertaken in the middle of the last century claimed positive benefits in reducing the size of the brain tumour as well as helping patients with intractable pain.

In the last few years, interest in therapeutic hypothermia has grown. Cooling is reported to be helpful in limiting the size of brain lesions, for example after stroke (Reith et al 1996) and after severe head injury. However, the results of therapeutic hypothermia in patients with severe head injury were not as encouraging as expected. A multicentre randomised trial in the USA of patients with severe head injury (Clifton et al 2001) failed to show that mild body hypothermia (bladder temperature 32–33°C) had any benefit. Nevertheless, there is new evidence that whole body cooling, to a core temperature of 33°C, provides neurological benefit for those patients who survive a cardiac arrest out of hospital (Bernard et al 2002).

CASE HISTORY 22.2

Mr E

Mr E, a novice hillwalker, becomes separated from his fellow hikers and is lost for many hours in the mountains of the Lake District. As evening approaches, the air temperature falls and Mr E begins to feel tired, hungry and cold. After putting on an extra woollen jumper he sets off to find shelter. He is found early the next morning huddled under an outcropping of rock. The rescue team recognise that he is suffering from hypothermia and take him to hospital.

On his admission to hospital, his rectal temperature is found to be 33.8°C. Although mortality accompanying this degree of cold exposure is approximately 50% (Houdas & Ring 1982) and Mr E is confused and unable to speak clearly when found, he does in fact recover after successful rewarming and emergency treatment.

surface. Although shivering is not a very economical process, it is very important in humans to increase heat production and so prevent hypothermia.

Shivering is maximal when core temperature is approximately 35°C. It does not go on indefinitely in response to continued cold exposure but stops when deep body temperature falls to approximately 32°C. At this point, energy stores in skeletal muscle will be exhausted; the muscular contractions of shivering rapidly utilise these stores. The cold also prevents optimum contraction of muscle tissue. As the protective thermoregulatory mechanisms fail, core temperature falls further and body systems begin to fail. Although the hillwalker in Case History 22.2 initially took sensible steps to protect himself from the cold and exposure to the weather, he continued to lose body heat. Under less severe conditions, his normal thermoregulatory mechanisms would have been adequate to prevent a serious fall in deep body temperature but the prolonged exposure in Mr E's case was obviously of major importance in the development of hypothermia.

22.14 Why is it so important for Mr E (Case History 22.2) to find shelter on the hillside? Why would rain have made the hillwalker's problem of becoming cold worse?

Causes of accidental hypothermia

Although accidental hypothermia does occur in fit young people, it is more often seen in neonates shortly after birth or in older people living at home. The young and the old are the most vulnerable to the effects of cold, particularly during the winter months. Resistance to cold in the fit and healthy person depends upon an efficient thermoregulatory system (see Fig. 22.2). Some impairment of thermoregulation may play a role in the predisposition of older people to the adverse effects of cold. Perception of cold, for example, may be impaired and the individual may therefore not respond to falling temperatures appropriately, for example by putting on extra clothing. Many older people become confined to a chair or their bed, so it is difficult for them to get up for extra clothes even when they do begin to feel the cold. Those caring for older people at home can help by leaving extra warm clothing close at hand to be used when needed; even wearing a hat at home may be useful to reduce heat loss from the head. Ensuring they have warm drinks close by, perhaps in a flask, and encouraging them to take these, will help to warm the body (see Box 22.1, p. 819).

Older people do not have the same ability as young adults to generate heat within the body, and therefore NST and shivering thermogenesis may not be as efficient. Other factors which, if present, may reduce the ability of the body to produce heat when needed (see Box 22.6) include:

- malnutrition
- hypothyroidism
- hypoglycaemia, which may be a particular problem in the older diabetic patient, as it lowers the threshold for the onset of shivering (Passias et al 1996); this means that a much greater fall in body temperature can occur before a hypoglycaemic patient starts to shiver
- intoxication with alcohol, because it limits the availability of glucose; the resulting hypoglycaemia inhibits shivering thermogenesis.

Box 22.6

Hypothermia in malnourished older people

During the winter months we often hear of older people becoming hypothermic after an injury, usually a fall. Why do some injured older people have such a problem in maintaining their body temperature at or around 37°C? Do older people become hypothermic because they get cold as a result of the fall, e.g. outside in the snow, or is there another reason? Studies have shown that very thin older women are more prone to fracture of the femur. They do not, as popularly believed, fall outside the home — 80% of falls in one study occurred indoors (Allison 1997).

It seems that in thin, underweight patients the central thermoregulatory 'thermostat' does not respond in the usual way to the cold, and if the patient is injured the problem is worsened. Injury *per se* has its own effects on thermoregulation, resulting in an inability to produce heat by shivering when body temperature falls. Body temperature of injured patients can fall well below 35°C, at which shivering is maximal in healthy subjects exposed to cold, before shivering heat production begins.

In summary, very thin, undernourished older people have a problem maintaining their body temperature because they do not produce heat when they need it most, i.e. when core temperature falls. When people get cold, they become confused and muscles get stiff, so it is not surprising that frail and older people are most at risk of a fall, especially in winter. Whether in the community or in hospital, nursing care should be directed towards ensuring that older people maintain their body weight and are protected from the cold. By doing this, injury and hypothermia may be prevented.

In the UK, accidental hypothermia in older people is a real hazard (Ranhoff 2000). Sadly, each winter, there are newspaper reports of older people who have died of hypothermia — deaths which are preventable. The British media (BBC News Online 2001) report that the British government is being urged to end the health risks for millions of older people who live in a cold home and who cannot afford to pay their fuel bills. With an estimated 30 000 deaths each year in cold weather, schemes to improve home insulation could make a positive impact in reducing accidental hypothermia in the older population. Mortality rate from hypothermia is considered to be approximately 40% (Stoner & Randall 1990).

Donaldson et al (1998) have shown that even in the coldest regions of the earth, such as Eastern Siberia, mortality from hypothermia is not as high as it is during winter in regions where the climate is more temperate. This is thought to be because the population in extremely cold regions takes what are quite simple precautions to prevent themselves becoming cold. For example, they wear very warm clothing in several layers and stay indoors as much as possible in their houses, which they keep warm.

The importance of temperature measurements in older people at home

When the community nurse visits older people during the winter months, some assessment of their environment and

of their thermoregulatory system should be made. If the nurse thinks that the patient's house is too cold, assessment of the risk of hypothermia should be carried out. The nurse should ensure that the thermometer selected, e.g. tympanic thermometer or Tempa-Dot thermometer, is adequate for use with patients who may have a temperature well below normal, i.e. 33–34°C.

Rewarming the hypothermic patient

Safe rewarming of a person who has developed hypothermia must be undertaken with care because patients may die several hours after arriving in the Emergency Department, even following an apparently successful rescue. This phenomenon, which has become known as 'after-drop', first came to prominence during the First World War during sea rescues of servicemen and women. After prolonged immersion in cold water, victims, alive when rescued and taken on board ship, died shortly afterwards despite receiving emergency rewarming treatment. These 'late' deaths after apparently successful rescue were a real tragedy and for many years were unexplained. It is now known, however, that 'after–drop' is a consequence of inappropriate rewarming. As the patient is warmed, blood vessels at the extremities dilate and a large volume of very cold blood flows from the extremities to the heart. This results in severe cardiac complications, e.g. ventricular fibrillation, and death follows.

The most appropriate way to rewarm a hypothermic patient after immersion in cold water also applies to the person subjected to cold exposure. The first step is to stop any further heat loss from the body. Next, a shock blanket is used to retain body heat. This is called 'passive' rewarming and it allows core temperature to rise slowly by the gradual build-up of body heat resulting from natural heat production. Providing that all endogenously produced body heat is retained within the body, organ temperature will rise gradually. If core temperature is above 32°C, passive rewarming is the method of choice. If core temperature is below 32°C and the patient is a young adult who has become hypothermic as a result of immersion in cold water or from exposure, 'active' rewarming of core tissues is required. There are a number of methods available, including:

- gastric lavage with warmed saline
- the introduction of warmed humidified oxygen in air via a ventilator
- the administration of warmed intravenous fluids
- warm peritoneal lavage.

It remains to be determined whether active or passive rewarming procedures are better in the treatment of accidental hypothermia in patients receiving intensive care (Vassal et al 2001).

In older patients, careful active rewarming is recommended (Ranhoff 2000)

In all patients it is important to remember that if the skin surface is warmed first, blood flow to the extremities will be increased. For older people with pre-existing cardiovascular disease, this could precipitate a fall in blood pressure. With active rewarming, core temperature can rise from 0.6 to 1.9°C/h (Stoner & Randall 1990). As core temperature rises, shivering may start and will become maximal at about 35°C.

Box 22.7

The metabolic 'cost' of a polar expedition

In 1992, two explorers, Mike Stroud and Sir Ranulph Fiennes, completed the first unaided crossing of Antarctica. The 1700 km journey took 95 days. Throughout the journey the men conducted a series of medical experiments to assess the effect of the extreme climate and hard work on their bodies. In air temperatures of between –10 and –50°C and strong winds, the men dragged their sleighs for 10–12 h each day. The journey took these men to the limits of human endurance. Despite a high food intake, each man lost an extreme amount of weight (26% and 29%), all of their body fat as well as a proportion of lean tissue (muscle). As body fat, and therefore insulation was lost, the men felt even colder and weaker and they became extremely malnourished. The hard work, the extreme cold over such a long time, together with a number of injuries, resulted in an enormous demand for energy. The food they ate was not enough to stop them from breaking down their energy stores of fat, and as time went on they also began to break down their muscle to provide a source of energy. The results of the tests and measurements on their body composition illustrate how the human body adapts to the most extreme conditions and climate (see Stroud 1997, 1998).

Local cold injuries (see also Box 22.7)

Frostbite

When tissue freezes, ice crystals form and the substances in tissue fluid become concentrated. The ice crystals can be many times the size of the cell itself. The degree of cell death after freezing depends on the concentration of the solute. Tissue damage resulting from freezing very much resembles a burn injury.

The milder form of freezing injury is called 'frost nip'. The extremities, i.e. nose, ear lobes, cheeks, fingertips, hands and feet, can be affected, but treatment is by simple rewarming of the affected area. A more serious form of cold injury is frostbite. In this condition, blood vessels are damaged and blood circulation to the affected part stops. The congested blood causes agglutination of cells, resulting in thrombus formation. The severe conditions which result in frostbite can mean that the person is so cold that they neglect to care for the frostbitten tissues and that, if rewarming does occur because of improvements in weather conditions, the frostbitten areas become macerated.

Treatment for frostbitten limbs should aim to warm the core tissues first before treating the local damage. The affected limb can then be immersed in water at 10–15°C. The water temperature should then be raised every 5 min by 5°C to a maximum of 40°C.

Once the core and the affected extremities have been rewarmed, the patient should remain on bed rest. The affected limbs should be elevated and tetanus toxoid administered. Antibiotics may be necessary if there is any evidence of infection. Local treatment should consist of care of the wound together with early physiotherapy.

Raynaud's phenomenon

Raynaud's phenomenon develops most often in young women and is due to abnormal stimulation of vasoconstrictor nerves (see Ch. 2). The cause of this abnormal vasoconstriction is thought to be more complex than simply increased vasoconstriction on exposure to a change in air temperature and may involve microvascular changes in the endothelium (Gardner-Medwin et al 2001). Mainly affected are the fingers; spasm of the digital arteries causes sluggish circulation in the fingers, which then become cyanosed. The intense vasoconstriction causes the arteries to empty of blood and this leads to the typical 'dead' white appearance of the fingers. When the vasoconstrictor spasm has passed the circulation starts to flow again. At this stage the individual experiences tingling and throbbing followed by intense pain. In some individuals, vasoconstriction can be so severe and prolonged that the skin of the fingertips becomes ulcerated and necrosed, a condition known as 'Raynaud's disease'. Raynaud's phenomenon generally worsens in winter.

Nursing care of individuals with Raynaud's phenomenon should be directed towards helping them to avoid the stimuli which they know cause their fingers, and toes, to go 'dead'. For some people, simply wearing gloves may be sufficient precaution. Pocket handwarmers, often used by people involved in outdoor sports and pursuits, e.g. golfers and hillwalkers, are very useful in preventing attacks but they should be used before the person goes out into the cold, as once the hands have become cold a pocket handwarmer is unlikely to be sufficient to prevent vasoconstriction. In severe cases, vasodilator drugs or sympathectomy may be necessary.

22.15 Now try to apply the knowledge you have gained in reading this chapter to the following situations. In formulating your answers, refer to the relevant sections of this chapter as well as to the books and articles listed in the references and further reading.

22.16 85-year-old Mrs K was being cared for by her husband until his recent death. Now alone, Mrs K is visited daily by her daughter and the community nurse. Mrs K has become very depressed, her appetite is poor and she has lost weight. On one of your morning visits, you find Mrs K collapsed in the cold hallway of her home. You suspect she may have been on the floor for some hours. You notice that her skin is very cold. Her axilla temperature is 34°C.

(a) What is the rationale for the immediate management of this patient?
(b) What steps would you take to rewarm the patient at home and once admitted to hospital?
(c) What method of temperature measurement would be needed to record deep body temperature?
(d) What would you expect the method of rewarming to be in the Emergency Department?
(e) What advice would you give to the patient's family so that further episodes of hypothermia could be avoided?

22.17 In the following situations, what decisions would you consider appropriate in the management of a patient with a disturbance in body temperature? (Note: you may decide that no action is necessary in some cases; if so, give your reasons.)

(a) A patient admitted to hospital with abdominal pain has had a fluctuating oral temperature (between 36.5 and 37.5°C) for 2 days. When you last took her temperature it was 39°C and she was complaining of feeling cold. Her hands and feet were cold and she looked 'mottled' blue. The patient then started to shiver.
(b) A patient on his second postoperative day has had a raised axilla temperature for 6 h. Treatment with aspirin was given 30 min previously. The patient is flushed and droplets of sweat are present on his forehead.

INTRODUCTION

For most healthy individuals, the term 'wound' conjures up thoughts of a cut, a graze or even a surgical incision that heals rapidly without difficulty. For nurses, however, the management of wounds is a complex aspect of patient care, requiring much skill and expertise. A nurse may care for a patient with a wound in a variety of settings, ranging, for example, from patients with surgical incisions nursed in hospital, to patients with chronic leg ulcers nursed in their own homes, to patients with industrial injury or trauma treated in their workplace.

The impact of a wound on an individual can be considerable. Pain, fear and scarring are the most obvious, but individuals vary in their response to having a wound (see Ch. 26). For some, restriction in social activity, or the financial implications of not being able to work, should also be considered alongside the psychological effects of altered body image (Wilson 2000).

Tissue injury and the resulting wound problems have existed for as long as humans have walked the earth (Leaper 1998). For many centuries, trauma and war injury caused most wounds. A variety of readily available materials were used as wound coverings, the forefathers of today's dressing materials. Prehistoric humans had a wide range of salves, which were used to achieve haemostasis, and plant extracts, herbs, cold water, snow and clay were used to ease pain. Surprisingly, throughout human history, wound management has been well documented. One of the first records of wounds was found in cave paintings. Archaeologists have found skulls dating back to the New Stone Age that show evidence of healing following skull trephining. This demonstrates not only that this surgical procedure was performed then, but also that people survived it long enough to heal. Injuries that did not result in death were likely to have been lacerations, contusions (bruises) and fractures. First-aid priorities in these situations would have been to arrest bleeding, bring the tissue edges together, hold them in place and protect the damaged tissues with a covering.

Scandinavian folklore suggests that for thousands of years plant extracts have been applied to wounds for a variety of reasons (Leaper 1998). Of these 2500 agents, some were antimicrobial, others astringent and others used to effect healing. Towards the end of the Roman era, Galen, the famous Greek physician and anatomist, AD 129–200, developed his theory of laudable pus — pus bonum et laudabile. The basis of this theory was that, should a wound become infected, its temperature would increase and this localisation of infection should be allowed to continue. Galen wrote that, when infection localised and then discharged itself, the wound would go on to heal without problems. In the years that followed, medical practitioners became so keen

on this idea that they believed not only that pus was acceptable, but also that it was essential and desirable for good wound healing. Clean, uninfected wounds were inoculated with various noxious substances in order to stimulate pus formation. These practices continued from the 7th to the 14th century. It was not until the 19th century that Pasteur and Lister managed to persuade their medical colleagues that mortality rates could be reduced by using antiseptics and aseptic principles.

Throughout time, individual species have varied in the way in which their tissues are renewed. Primitive vertebrates such as reptiles and amphibians have retained the ability to regenerate lost tissue. However, in humans, only liver and epidermal tissue can regenerate. Where tissue loss in humans occurs, healing is achieved by tissue repair, and the body's ability to deal with injury quickly and effectively has been important throughout human evolution for survival of the species.

The healing process comprises a complex series of events that depends on a number of factors, and in order for it to proceed at its optimal rate the individual concerned should be in good health. In caring for patients with wounds nurses have an important role in promoting health. Their skills as health promoters and health educators are called upon to optimise the healing time.

As in other aspects of nursing, the issues of clinical effectiveness and the delivery of evidence-based care are key to wound management. As wound healing is a relatively new specialty, the evidence base and research strategies are still being developed (Cullum & Roe 1995, Harding 1998, Bale 2004).

Definition of a wound

A wound can be defined as a defect or breach in the continuity of the skin. This is an injury to the skin or underlying tissues/organs caused by surgery, a blow, a cut, chemicals, heat/cold, friction/shear force, pressure or as a result of disease, such as in leg ulcers and carcinomas.

Box 23.1 lists the terms that are used in wound healing.

Box 23.1

Terms used in wound healing

Aseptic technique. A precautionary method, using sterile equipment and a 'no-touch' technique to prevent infection.
Autolysis. The disintegration or breakdown of cells or tissues by endogenous enzymes.
Autolytic debridement. The natural process by which the body's own enzymes degrade devitalised tissue on a wound bed.
Chemotaxis. The process by which chemical attractants (kinins) stimulate polymorphs to move towards damaged cells.
Collagen. Fibrous protein strands which provide the strength and structure of granulation tissue.
Collagenase. An enzyme which breaks down collagen during remodelling.
Debridement. The removal of devitalised tissues from a wound.
Dehiscence. Bursting open of a wound.
Elastin. Fibres in connective tissue which provide elasticity.
Epithelium. The cells which form the epidermis.
Exudate. The extracellular fluid which bathes a wound and is rich in nutrients, phagocytes and antibodies.
Fibronectin. An adhesive protein that is a component of extracellular matrix.
Glycosaminoglycans. A polysaccharide that is a component of extracellular matrix.
Granulation. The process of healing by secondary intention.
Ground substance. A gel-like material in which connective tissue cells and fibres are embedded.
Necrotic tissue. Dead tissue, often black in colour.
Proteoglycans. A polysaccharide that is a component of extracellular matrix.
Pus. A protein-rich liquid consisting of exudate, dead macrophages and bacteria.
Slough. Devitalised white/yellow tissue — dead tissue that separates (and is 'sloughed' off) from healthy tissue after inflammation and infection.
Tensile. The ability to be stretched.
Wound abscess. A localised collection of pus, caused by invading microorganisms, which forms as a result of liquefaction of disintegrated tissue and an accumulation of polymorphs — the process of abscess development is in response to the defences of the body attempting to 'wall off' the damage.

Wound types and the classification of wounds

There is no clear-cut method of classifying wounds. Some practitioners refer to wounds by anatomical site, e.g. abdominal wall wounds, axillary wounds. Others classify wounds by their depth, e.g. epidermal loss, subcutaneous wounds. Another possible classification is by degree of tissue loss (Dealey 1999). In the first group, there are wounds with little or no tissue loss where the skin edges can be brought together and sutured. In the second, there has been substantial tissue loss and the skin edges cannot be brought together.

Epidemiology

The epidemiology of wounds is not clearly documented. Because patients with wounds can be found in almost every specialty, information relating specifically to wounds is not collected. However, although there are currently no centrally collected data on wounds, information is available for some wound types, for example leg ulcers.

Leg ulcers

Leg ulcers have been described as 'loss of skin below the knee on the leg or foot which takes more than 6 weeks to heal' (Morison & Moffatt 1997). Leg ulceration has affected humans over the centuries and is associated with venous disease of the lower limb in approximately 80% of cases (Cullum et al 1997). It is estimated that between 1 and 22% of those over 60 years of age have a lower limb ulcer (Sieggreen & Kline 2003). The largest survey of patients with leg ulcers, carried out in Scotland in 1985 (Callam et al 1987), found that the prevalence of ulceration increased with age

and that by 85 years, more than ten times more women than men experienced ulceration.

The social and economic burden of managing these patients is considerable. Estimates vary, but Cullum et al (1997) estimated the costs to be between £230 and £400m annually for the UK alone. The cost of home care has been estimated at a minimum of £400m and this figure is likely to increase with the rising numbers of older people in the population (Moffatt 1995). For the most part these patients are cared for by their GP and by nurses within the community setting. However, there is an increasing trend towards referral to a specialist leg ulcer service or centre.

The individual's lifestyle can be greatly affected by the presence of a leg ulcer. These wounds are difficult to manage, traditionally slow to heal and, even once healed, likely to recur (Dale & Gibson 1986).

Pressure ulcers

Throughout the history of nursing, the issue of patients developing pressure ulcers has been associated with guilt and failure (Dealey 1997). Indeed, it has been suggested that many if not all pressure ulcers are preventable (Dealey 1999). In long-term care facilities as well as in the acute hospital setting, incidence and/or prevalence of pressure ulcers are used as the key quality indicators in patient care (DH 1993a). There is a growing awareness that the problem of pressure ulcers in patient care is not only a nursing issue but also involves medical staff, management and government (Sussman & Bates-Jensen 1998, Pieper 2000, European Pressure Ulcer Advisory Panel 2003). Improvement in patient care needs a number of approaches, including the development of local prevention strategies and educational programmes for all health care professionals (Dealey 1997).

Pressure ulcers are among the most difficult wounds to manage. UK surveys have documented the prevalence rate as being between 10.3 and 18.6% (Clark & Cullum 1992, O'Dea 1993, Pieper 2000). Across Europe this figure is similar, reported to be 18.1% (Clark et al 2004).

The incidence of pressure ulcers within hospital ranges from 4.3 to 43% (Gebhardt 1992, Clark & Watts 1994) and within nursing homes ranges from 5 to 23% (Pieper 2000). However, in the most acute settings the incidence is reported to be as low as between 1.1 and 2.7% (Williams et al 2004). The variation in rates depends on the specialty in which the patients are being nursed; orthopaedic units and wards where patients are older, immobile, chronically ill and disabled have the higher rates.

The cost implications of a patient developing a pressure ulcer are high. Such patients need to spend longer in hospital and, even when discharged home, frequently require a district nurse to continue treatment. This financial cost is thought to be rising. In 1982 the estimate was £150m (Scales et al 1982), and it subsequently increased to £300m in 1988 (Waterlow 1988) and £755m in 1993 (DH 1993b). Given the rising numbers of older and debilitated people, the figure could be much higher today; the costs have been estimated to be a minimum of £250 000 a year in one community unit (Dealey 1999).

The personal costs to the individual of developing a pressure ulcer also need to be taken into account. Apart from the disappointment of having discharge from hospital postponed and return to normal function delayed, there is the pain and distress, all of which are difficult to measure (Dealey 1997).

Given the suggestion that many if not all pressure ulcers can be prevented (Dealey 1999), the extent of the challenge for practising nurses is clear (p. 849).

Table 23.1 Important cells in wound healing

Cell	Function
Endothelial cells	Help to achieve haemostasis
Polymorphs	Take part in the initial inflammatory response
Macrophages	Digest debris and stimulate other cells to function; orchestrate wound healing processes
Fibroblasts	Produce collagen
Myofibroblasts	Aid wound contraction by producing mature collagen

23.1 What are the mechanisms in your organisation for measuring the prevalence and incidence of pressure ulcers? How does this compare with national figures?

THE PHYSIOLOGY OF WOUND HEALING

A number of cell types are involved in the process of healing (see Table 23.1).

Tissue repair

The wound healing process comprises a complex series of events, whereby the continuity and strength of damaged tissues are restored by the formation of connective tissue and regrowth of epithelium. The process can be divided into four phases (see Fig. 23.1) but, since wound healing is a continuous biological process, there is some overlap between them (see Table 23.2).

Phase I — haemostasis

As soon as a wound occurs, it bleeds and blood initially fills the wound defect. Platelets aggregate and degranulate, resulting in clot formation and haemostasis (Witte & Barbul 1997). Haemostasis is the arrest of bleeding at the site of blood vessel damage, and is essential to preserve the integrity of the closed and high-pressure circulatory system in order to limit blood loss. A fibrinous clot forms as the blood coagulates, which now acts as a preliminary matrix or scaffold within the wound space into which cells can migrate.

Phase II — inflammation

The fibrin clot begins to degrade and the surrounding capillaries dilate and become permeable, allowing fluid into the wound site. This activates the complement system, which is composed of a series of interacting soluble proteins found in serum and extracellular fluid that induces lysis and destruction of target cells, such as bacteria. Cytokines and proteolytic fragments are also found in the wound space (Steed 1997), their accumulation initiating a massive

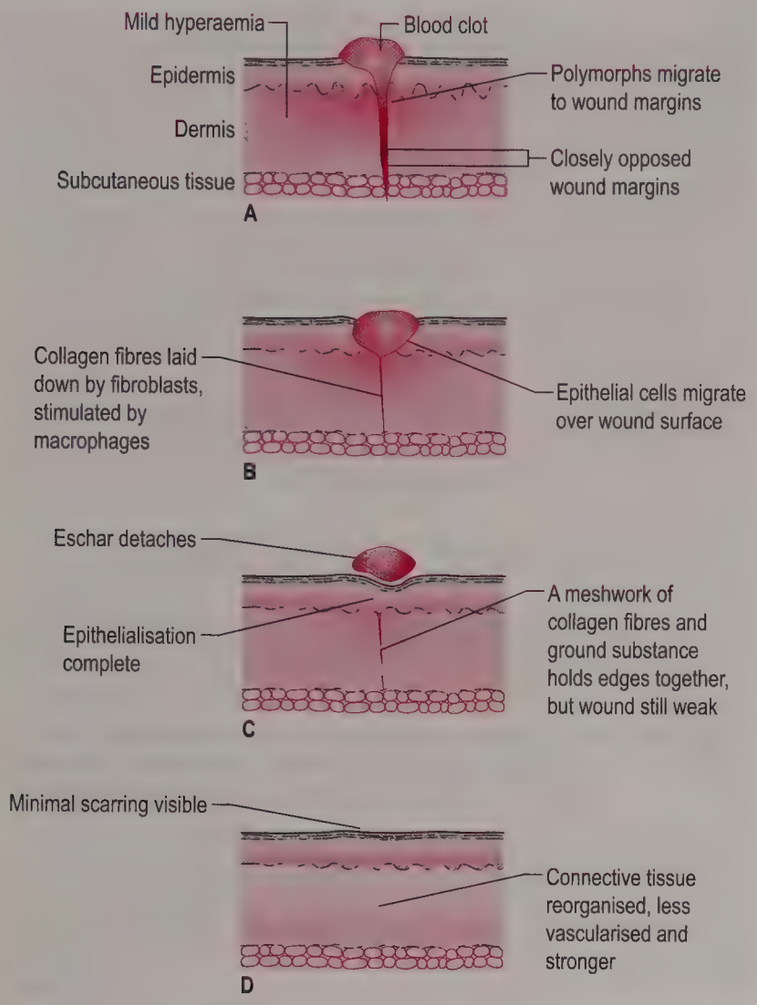

Fig. 23.1 Wound healing by primary intention. A: Haemostasis. B: Inflammation. C: Proliferation/reconstruction phase. D: Maturation phase.

Table 23.2 Phases of wound healing

Phase	Time after sustaining wound
Haemostasis	0–3 days
Inflammation	2–5 days
Proliferation	4–28 days or until defect is filled
Maturation	15 days–1 year

influx of other cells. The two main inflammatory cells are neutrophils and macrophages (Martin 1997).

- Neutrophils flood into the wound shortly after injury and reach their peak number within 24–48 h, their main function being to destroy bacteria through the process of phagocytosis. Neutrophils have a very short life span and their numbers reduce rapidly 3 days post injury, provided there is no infection.
- Tissue macrophages, like neutrophils, destroy bacteria and debris through phagocytosis. However, the macrophage is also a rich source of biological regulators, including cytokines and growth factors, bioactive lipid products, and proteolytic enzymes, elements essential for the normal healing process (Steed 1997, Slavin 1999).

This phase can be looked on as one of biological cleansing. It does, however, make a considerable metabolic demand on the body. Much heat and fluid can also be lost where a cavity wound exists. The shorter the duration of this phase, the better, because as it nears completion, proliferation or formation of new tissue can begin. Following the inflammation phase, the wound site is prepared for the repair process to begin.

Phase III — proliferation/reconstruction

Tissue repair takes place during this phase. It usually begins at around day three and lasts for some weeks. Proliferation is characterised by the formation of granulation tissue in the wound space. This new tissue consists of a matrix of fibrin, fibronectin, collagens, proteoglycans and glycosaminoglycans, and other glycoproteins (Hart 2002). Fibroblast cells move into the wound space and proliferate. Their function is to synthesise and deposit extracellular proteins, producing growth factors and angiogenic factors that regulate cell proliferation and angiogenesis (Stephens & Thomas 2002). Fibroblasts will multiply rapidly in the well-nourished individual and, to be most effective, need adequate amounts of vitamin C, iron, oxygen and nutrients. Accounting for 70–80% of the dry weight of dermis, collagen is the most abundant protein in human tissue (Wysocki 2000). Collagen is usually produced by fibroblasts and at least 19 genetically distinct collagens have been identified. Granulation tissue also contains elastin, providing the wound with elasticity and resilience (Wysocki 2000).

Angiogenesis is the formation of new blood vessels in the wound space and such vessels are essential for the delivery of oxygen and other nutrients. The key cells involved in angiogenesis are the vascular endothelial cells, which arise from the damaged end of vessels and capillaries (Neal 2001). New vessels sprout from existing small vessels at the wound edge, endothelial cells detaching from these small vessels and penetrating the wound space. These sprouts are then extended in length until they meet other capillaries, connecting together to form new vascular loops and networks.

Re-epithelialisation begins a few hours after injury and continues as the wound begins to fill with granulation tissue. At the wound edges, epithelial cells divide and, gradually, epithelium migrates from the edges towards the middle of the wound. Epithelialisation of larger areas is achieved not only by migration, but also by rapid division of epithelial cells near hair follicles, which might be present deep in the dermis. Islands of epithelium appear wherever a follicle is present. Cells migrate from these islands to meet each other, while cells from the edges of the wound grow inwards to cover the raw surface.

The final feature of proliferation is wound contraction, beginning around day five. Wound contraction is a dynamic process where cells reorganise the surrounding connective tissue, reducing the amount of granulation tissue. This effect is mostly due to the activity of fibroblasts and myofibroblasts which, under the influence of cytokines, contract to pull the wound edges together.

Phase IV — maturation

This phase usually begins around 7 days post injury and continues for many months or years, long after the wound appears to the naked eye to be closed or healed. The immature collagen laid down in phase II is gradually replaced by a mature collagen. The formation of new collagen and the lysis of immature collagen are balanced so that the amount of collagen present at any one time remains constant. The immature collagen is laid down in a random, haphazard fashion, its function being to fill the wound defect as quickly as possible. The remodelling process involves the balance between synthesis and degradation of collagen, where the cells producing the different types of collagen are subjected to apoptosis (programmed cell death) (Tjero-Trujeque 2001). Mature collagen is laid down following lines of tension within the wound, and at the same time it is cross-linked to give strength. Tensile strength at 14 days in sutured wounds is approximately 10% of the original strength of the skin. Within 3 weeks this increases to 20%, gradually reaching a maximum of 70–80% about 1 year later.

Healing by primary/first intention

When injury occurs, whether through accident or as a surgical necessity, the aim of treatment is to effect complete healing as quickly as possible with minimal scarring. To achieve this, the method of choice is healing by primary intention, which occurs when wound edges are in apposition (see Fig. 23.1). There is minimal formation of granulation tissue and once the wound has healed, only a thin seam remains. Healing by primary intention is only possible where there is adequate, mobile tissue and no complicating bacterial contamination. In situations where contamination is suspected, closure of the wound is accompanied by the use of prophylactic systemic antibiotics. For healing to take place by primary intention, the wound edges need to be closely approximated and held together until the wound has healed sufficiently. The skin may be closed by using tapes, clips, continuous or interrupted sutures, or glue. However, a Cochrane systematic review of tissue adhesives reports that it is unclear whether these are more or less effective than sutures or tapes (Coulthard et al 2004). The skill of the surgeon ensures that the sutures are not inserted too tightly and that the skin edges are closely apposed. The choice of suture material depends on the type of tissue being closed and on the particular function of the tissue (Leaper & Gottrup 1998).

Healing by secondary intention

Where there is significant tissue loss and/or bacterial contamination, wounds are usually left open to heal by secondary intention through the formation of granulation tissue and, later, wound contraction (see Fig. 23.2). Due to the amount of tissue excised or lost during injury, wound healing by secondary intention is a longer process, taking weeks or even months to complete. The healing process itself proceeds in much the same way as for healing by primary intention. The proliferative phase is much extended, as this is when granulation tissue forms and fills the wound defect. It was established many years ago (Marks et al 1983) that, for some wounds, the length of time taken to heal depends on the original size, i.e. small wounds heal more quickly than larger ones, and it is therefore possible in some wound types (pilonidal sinus, abdominal and axillary wounds) to predict when wounds of a given size that are free from infection will heal.

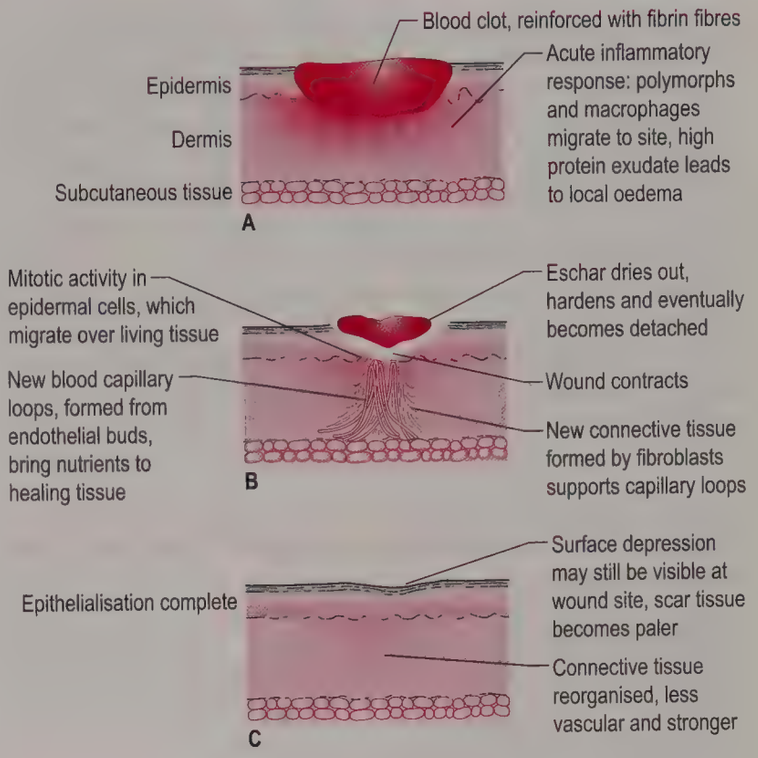

Fig. 23.2 Wound healing by secondary intention. A: Haemostasis/inflammation. B: Proliferation phase. C: Maturation phase.

For methods of wound closure and types of suture material, see Leaper & Gottrup (1998) and Coulthard et al (2004).

Scar tissue

A scar is the mark that may remain after a wound has healed. A scar consists of relatively avascular collagen fibres covered by a thin layer of epithelium.

Most scars fade with time (see Table 23.3) and the resultant cosmetic effect is generally acceptable, but abnormal scarring can lead to problems, as follows:

- *Stretching of scar tissue* — this can occur where sutures have been removed prematurely, especially over areas

Table 23.3 The maturation of scar tissue

Time after sustaining wound	Characteristics of scar
0–28 days	The scar is fragile and soft
28 days–3 months	The scar becomes denser, stronger and is red or purplish in colour
3 months onwards	Over time the colour fades to white and the tissues become softer and more elastic

that are under tension, e.g. the skin over the scapula and back are common sites where stretching occurs
- *Hypertrophic scar tissue* — here collagen lysis and collagen production are out of synchrony and excessive tissue lies within the boundaries of the scar
- *Keloid* — this is a protuberant, prominent scar that results from excessive collagen formation in the dermis during connective tissue repair.

Hypertrophic and keloidal scarring are examples of excessive scar formation. Such scarring is more common in young people, especially during pregnancy and puberty, and also in deeply pigmented skins, the peristernal area being particularly susceptible.

A number of factors influence scarring (see Table 23.4).

Why some wounds are sutured and others are left open

Wound closure, enabling wounds to heal by primary intention, is considered to be the method of choice whenever possible, as healing by primary intention is much quicker than healing by secondary intention.

Wound closure is undertaken where:

- the procedure will result in cosmetically acceptable scars; adhesive tapes and clips can be used to avoid undesirable suture marks
- sufficient mobile tissue exists to allow the edges of the wound to be brought together easily without tension or without causing trauma which could lead to subsequent wound breakdown
- the wound site is clean, e.g. when an operation is considered to be a clean procedure as in excision of lipoma, a benign tumour containing fatty tissue.

Secondary intention is chosen as the method of healing where:

- the final cosmetic effect is likely to be an improvement over either suturing or skin grafting
- there is insufficient tissue to allow the wound edges to be approximated, e.g. in some chronic open wounds such as leg ulcers (see p. 852) and pressure ulcers (see p. 849)
- the wound area is heavily contaminated or infected, e.g. in a contaminated injury or surgical procedure such as excision of an infected pilonidal sinus.

FACTORS THAT ADVERSELY AFFECT HEALING

23.2 Before considering factors that adversely affect wound healing, identify the requirements for optimal wound healing.

A number of factors can adversely affect the normal rate of healing, slowing it down and, in severe cases, impairing it altogether. These factors can be intrinsic or extrinsic.

Intrinsic factors

Advanced age (see Ch. 35). With advancing years the dermis gradually becomes thinner and the underlying structural support, collagen, diminishes at a rate of 1% per year (Hunter 1995). In addition, as fewer fibroblasts produce less collagen, skin loses its elasticity and its ability for elastic recoil, leading to creases and wrinkles. At the same time the amount of subcutaneous fat reduces, and there is less of a cushion for underlying bone. As individuals age, the natural moisture from sebum secretions lessens as sweat glands become smaller, leading to increasing dryness of the skin. The consequence of ageing is dry, thin, inelastic skin that is susceptible to damage, with a reduced metabolic rate and a prolonged healing period. These factors together with poor circulation associated with old age affect the tensile wound strength.

Malnutrition Malnutrition may result in delayed wound healing and the production of weak, poor quality scars (Pinchcofsky-Devin 1994). McLaren (1997) describes two types of malnutrition that affect healing: protein-energy malnutrition and nutrient deficiencies.

Protein-energy malnutrition (PEM) is caused by an absolute or relative deficiency of energy and protein that affects between 19 and 50% of hospitalised patients (McLaren 1997). Several factors contribute to PEM including a reduced intake of nutrients, reduced absorption and digestion of nutrients, and increased metabolic use. McWhirter and Pennington (1994) reported that 200 out of 500 patients admitted to hospital were undernourished, and just over 100 lost weight during their admission. Other research supports these findings. McLaren (1997) estimates that although 70% of patients admitted to hospital are malnourished prior to admission, the remaining 30% develop PEM during their hospital stay.

For a review of the literature related to complications experienced by patients admitted to hospital when they

Table 23.4 Factors influencing scarring

Cause of injury		Race	Age	Wound site
Burn/trauma	Surgery			
1. Over joints contractures can occur 2. Dirty injuries caused by gravel can cause pigmentation	1. The skill of the surgeon 2. The type of suture material used, i.e. non-absorbable sutures, alongside the wound	1. Extreme hypertrophic scarring is common in deeply pigmented races and rare in Caucasian races	1. In infancy and childhood, scars resolve quickly 2. In pregnant women, hypertrophic scarring is more common	1. Scars which follow the body's natural lines of skin tension do best 2. Scars which cross skin folds do less well 3. Scars on the shoulders, sternum and back produce unsightly scarring

are undernourished and starved during their stay, see Stotts (2000).

Malnutrition can adversely affect wound healing by reducing tensile strength, increasing wound dehiscence and increasing susceptibility to infections (Dickerson 1995) and to developing pressure ulcers (Meaume et al 1994).

Nutrient deficiency The European Pressure Ulcer Advisory Panel (2003) has produced nutrition guidelines that recommend a minimum daily intake of 30–35 g/kg body weight, with 1–1.5 g/kg/day of protein and 1 mL/kcal/day of fluid intake. These guidelines also recommend that nurses consider the quality of the food that patients are offered, along with removing the physical or social barriers to its consumption. For some patients it is not always easy to maintain adequate nutrition, e.g. an older person living alone may lose interest in cooking or a terminally ill patient may be unable to eat due to nausea. The importance of diet cannot be overemphasised, and wherever possible the nurse should ensure that the patient receives all the nutrients required for healing. The advice of a dietitian may be sought in an attempt to improve or supplement the nutritional status of vulnerable individuals (see Ch. 21).

Dehydration The normal metabolic processes of an individual require approximately 2500 mL of water every 24 h (see Ch. 20). A dehydrated individual will not be able to metabolise efficiently and this will adversely affect the healing process.

Disease processes The metabolic effects of a number of disease processes can delay healing. Anaemia, arteriosclerosis, cardiovascular disorders, diabetes mellitus, cancer, inflammatory disease, immune disease, rheumatoid arthritis and jaundice are included in this group, as is any other disease that impairs the body's immune response. It is important to remember that in some patients, particularly older people, several disease processes may be present at the same time.

Impaired blood supply to the area Where the blood supply to the wounded area is impaired, insufficient nutrients and oxygen are supplied and the healing period is prolonged. This happens, for example, in patients with peripheral vascular disease and lower limb ulcers.

Smoking adversely affects the healing process in a number of ways. Smoking and the absorption of nicotine has a vasoconstricting effect. After smoking one cigarette, peripheral blood flow has been shown to be reduced by 50% and to remain so for more than an hour (Siana et al 1992). The main influences of nicotine and carbon dioxide relate to the effects on peripheral tissues, with a reduction in oxygen tension in these tissues and the formation of thrombi. Nicotine has been demonstrated to inhibit epithelialisation (Waldrop & Doughty 2000) and the healing of abdominal wounds, the overall cosmetic effect of a scar being poorer in patients who were smokers (Siana et al 1992).

Extrinsic factors

Poor surgical technique Tissues handled excessively during surgery can be damaged, resulting in haematoma formation. This can lead to the development of infection as the haematoma is broken down. A dead space may also occur if tissues are not correctly approximated during surgery, again encouraging the development of infection. In addition, where sutures are inserted too tightly, the tissue becomes damaged and tissue death can occur.

Medication A whole range of medications can affect healing. Cytotoxic medication given during chemotherapy can destroy healthy as well as malignant cells. Ideally, their use is withheld until any wound healing is complete, usually a period of 4 weeks. Steroids also slow down, or prevent, healing taking place and their use is closely monitored in individuals with wounds.

Inappropriate wound management The healing process may be adversely affected by the use of poor dressing technique, the wrong dressing material or antiseptics where they are not needed (see p. 844). It is essential that the nurse is aware of what is required from a dressing material in order to ensure that each product is used cost-effectively.

Psychosocial factors There is a close association between psychological and physical well-being. Stress and anxiety can affect the immune system (Waldrop & Doughty 2000) through elevation of serum levels of corticosteroid, which impairs immune function (Kiecolt-Glaser 1995). Researchers have also studied the effects of stress on the sympathetic nervous system, where vasoactive substances (catecholamines) impair blood perfusion to the wound bed (Stotts & Wipke-Tevis 1996, Padgett et al 1998). Sleep disturbances are linked to being stressed and sleep is thought to be essential for healing and tissue repair (Dealey 1999).

Infection Of all the factors that can delay or prevent healing, infection is the most important (see Ch. 16).

WOUND INFECTION

All wounds are likely to be colonised by bacteria, though many of these do not delay or affect healing. It is pathogenic organisms, growing in large numbers, which usually produce wound infection (Leaper & Harding 2000). Established infection in a healing wound often delays healing and may even cause wound breakdown, herniation of the wound or complete wound dehiscence. The clinical signs and symptoms of a wound infection are summarised in Box 23.2. Despite all the technological advances that have been made in surgery and wound management, the problem of wound infection persists. This happens because the causes of wound infection are so varied and are often linked to the individual's general condition; both nutritional status and immune status are important factors in resistance to infection (Bale & Jones 1997, Williams & Leaper 1998).

The wound environment itself can encourage bacterial growth. Anaerobic organisms, for example, thrive in wounds with a poor oxygen supply. A wound bed or area that is free from haematoma and dead tissue and is clean reduces the risk of infection.

The way in which the wound is managed can also affect infection. Contamination by bacteria, through poor

Box 23.2

Clinical signs and symptoms of wound infection

The local effects of wound infection are:

- Pain — throbbing
- Redness — erythema
- Swelling — of the area surrounding the wound
- Discharge — haemoserous and/or purulent
- Loss of function — to protect the area
- Unhealthy appearance of the wound bed (p. 842).

Wound infection prolongs the inflammatory healing phase and delays healing by secondary intention. Systemic effects on the patient are:

- Raised temperature
- Increased metabolic rate
- General malaise
- Anorexia.

technique on the part of the nurse, poor hygiene or incontinence on the part of the patient, can all increase the risk of wound infection. The consequences of wound infection vary depending upon the condition of the patient and the environment in which they are being nursed: in hospital, a patient with a surgical wound infection poses a considerable risk to other patients with wounds on that ward; at home, that patient is less of a risk to the family and community, who are unlikely to be vulnerable.

Factors that predispose to wound infection

Factors associated with the patient

There are several factors that, in addition to delaying the healing process, can predispose a patient to wound infection. These can be identified on first assessment:

- Poor nutritional status — McLaren (1997) has described in detail the effects of deficiencies in nutrition on wound healing. Protein-energy malnutrition (PEM) has been linked to hospitalisation and impacts on all aspects of patient care, including developing pressure ulcers and influencing postoperative wound infection.
- Immunosuppression — suppression of the immune system, e.g. in diabetes mellitus or after steroid therapy, can lead to an increased rate of infection (Kindlen & Morison 1997).
- Excessive body weight.
- Advanced age.

Factors specifically related to the hospital environment

- Adverse spatial arrangements — when too many patients are nursed in close proximity to each other, especially in an open ward, the wound infection rate increases. An increase occurs when more than 25 patients are being nursed in an open ward (NHS Estates 2002).
- Length of preoperative stay — the wound infection rate is linked to the length of time a patient spends in hospital prior to operation. The longer this period, the more likelihood there is of the individual being colonised by the pathogenic bacteria found in hospitals.
- Inappropriate preoperative care — it is not usually necessary to shave the site preoperatively (Williams & Leaper 1998). Where shaving is required, it should occur immediately prior to surgery to reduce the risk of bacterial growth on newly shaved skin (see Ch. 26). These precautions should result in a wound infection rate of less than 1%.
- Prolonged operative procedure — since 1980, research has suggested that the longer the operation, the greater is the risk of infection in clean wounds (Cruse & Foord 1980, Williams & Leaper 1998).
- Surgical contamination — in elective surgery, e.g. excision of a benign breast lump, the rate of infection should be less than 5%, and with effective surveillance and control this can be reduced to less than 2% (Leaper & Harding 2000). In emergency operations where the area is contaminated, e.g. for perforated bowel, the rate soars to between 20 and 40% (Leaper & Harding 2000).
- Use of drains — these are used to close or minimise dead space in a wound or to evacuate haematomas or body fluids, with the intention of reducing the risk of infection (Bale & Leaper 2000). They should be used with caution, as all drains are foreign bodies and may cause tissue reactions.

As a wound infection develops, localisation of the infection leads to the formation of a wound abscess. This may drain through the suture line or into the wound in the case of cavities. Occasionally, if deep-seated, the abscess will need a surgical incision to drain it properly. Where partial wound breakdown occurs, extra caution is needed to explore and assess the wound as being suitable for healing by secondary intention (Bale & Jones 1997).

Sources of wound infection

Endogenous Organisms found on the patient's own skin are endogenous sources of wound infection. These organisms, usually *Staphylococcus aureus* or gut commensals, are either present under normal circumstances or are hospital pathogens that colonise the body after the patient is admitted to hospital. Shortening the time between admission and surgery reduces the possibility of skin contamination by hospital acquired bacteria (Williams & Leaper 1998, Dealey 1999).

S. aureus is found on the skin and sometimes in the upper respiratory tract. This organism does not normally affect the patient adversely, but when a wound has been created, *S. aureus* can invade the wound from adjacent skin or be breathed into the wound from the nose.

Exogenous Infections from exogenous sources are those that occur following contamination of the wound from a source external to the patient. This may happen in theatre or later in the ward when pathogens are allowed to fall onto the wound and penetrate it. Bacteria such as *Pseudomonas aeruginosa* can be found in wet areas or where moisture is present, i.e. in water, other fluids or ventilators. *P. aeruginosa* is also found in flower vases, sinks and drains.

Accidental injuries are highly likely to have been contaminated by bacteria. *Clostridium tetani* and *Clostridium welchii* are present in the soil and can be hazardous. People who receive minor injuries whilst gardening are at risk and, if they have not already had antitetanus immunoglobulin, should be immunised.

Bacteria

Bacteria consist of a variety of single-celled organisms that have a primitive nucleus with no nuclear membrane. Bacteria vary in size, but are larger than viruses and can be seen under a light microscope. They reproduce by simple binary fission, i.e. each bacterial cell divides into two, both of which can divide again. The rate of division of bacteria, and so multiplication, depends on their environment, and in suitable conditions they divide rapidly.

Many of the harmful effects of bacteria on humans are caused by products of the bacteria, namely toxins, when these are released into the bloodstream. Endotoxins are released when a bacterial cell dies and breaks up, whereas exotoxins are released continually by thriving bacteria.

Bacterial cell walls The cell wall of a bacterium can have a number of characteristics. These ultimately influence how capable a host will be at destroying that bacterium (see Box 23.3). It is the cell wall that the body's immune system penetrates in order to destroy it.

23.3 Identify the major microorganisms that cause wound infection. Can you identify their sources?

WOUND MANAGEMENT — A HOLISTIC APPROACH

Ideally, assessment and management of a patient with a wound utilises a systematic approach (Bale 2000). This begins with an initial assessment (see Box 23.4) of both the patient and the wound so that management can be planned. Following implementation, evaluation of that management is required to ensure that the needs of the patient have been met.

Box 23.3

Gram-positive versus Gram-negative bacteria

The differing characteristics of the bacterial cell wall can be determined by the staining reaction first used by Professor Hans Gram in the late 19th century. Gram, who developed the procedure quite accidentally, found that due to the properties of the cell wall, certain bacteria retain staining with crystal violet and resist any attempt to decolorise with ethanol. Other bacteria lose the stain, or respond to decolorisation and then respond to a pink counterstain: the former are described as Gram-positive bacteria and include such organisms as the cocci and clostridia; the latter are described as Gram-negative and include such organisms as *Escherichia coli* and *Pseudomonas aeruginosa*. This staining reaction is now considered a major classification distinction between bacteria.

Box 23.4

Assessment in wound care

1. Assess the patient:
   - Identify factors that might impede healing, such as intercurrent disease processes or certain medications (see p. 838)
   - Where disease processes are identified, attempt to ensure that they are corrected
   - Where they cannot be corrected, build an expected delay in healing into the nursing care plan.
2. Assess the wound:
   - Consider whether the wound is healthy for the stage of healing and free from infection
   - Assess the wound's physical characteristics
   - Where appropriate, measure and record wound size and shape.
3. Assess the environment in which the patient is being nursed.
4. Assess the appropriateness of wound agents and wound dressing materials.

This approach can be adapted to suit the environment in which the patient is being cared for, whether this is in the patient's own home or in the hospital setting.

Wound management is an aspect of nursing that is undergoing rapid change and expansion. Research has been undertaken using different study designs to answer a diverse range of clinical questions, and to explore the lived experiences of patients. Best available evidence is used not only to inform practice but also to develop clinical guidelines (National Institute for Clinical Excellence 2001, European Pressure Ulcer Advisory Panel 2003). Journals (paper and electronic), the internet, study days and conferences provide access to much of the research data. A wide range of educational opportunities at undergraduate and postgraduate levels is available for those wishing to further their knowledge regarding wound care.

Patient assessment

This should be patient-centred, comprehensive and should consider the physical and social environment.

Whether the patient is being cared for in hospital or in the home, or is young or old, assessment of the patient's general condition should be undertaken. This is done to identify any of the factors that might impair the wound-healing process (p. 838): for those factors seen as reversible, treatment should be sought; for those factors uncovered for which no treatment is possible, some degree of delay in healing should be anticipated and allowed for in the care plan.

The patient's social environment can affect the treatment options. For example, when caring for a frail older person living alone, the nurse may need to select a dressing that is waterproof, in order that carers who come in to bathe the person on days when the district nurse does not visit need not disturb the wound unnecessarily.

For further reading, see Bannon (1993). In this article, the author explains the importance of the holistic approach to wound care in the setting of an intensive care unit.

Assessment of the wound

In the assessment of the wound and surrounding skin, a range of wound criteria are considered which can help ensure that the patient receives the most appropriate care to suit their needs (Bale & Jones 1997).

Assessment of wounds that are healing by primary intention

Three questions should be addressed:

1. *What has caused this wound?* The answer may be surgical incision to perform an operation, or surgical excision of an abscess. Once the cause of the wound has been established, the expected prognosis for complete healing can be estimated. For example, a surgical incision in a fit, 20-year-old woman to remove a benign breast lump should result in a wound that will heal quickly and without complications. The expected healing potential in an older person who has had emergency bowel surgery for removal of colonic cancer is less good.
2. *Is the wound healthy for the stage of healing?* During the first 3 days of healing by primary intention, the area surrounding the wound will be red, swollen, indurated and often painful. This is normal during the inflammatory phase of healing. It would not be considered normal if the patient presented with the same symptoms 7–10 days postoperatively, and would indicate the presence of infection. Recognising what is normal throughout the healing process is essential. Only when this has been achieved can the abnormal be identified.
3. *What needs to be done in the days before the sutures or clips are removed?* Nothing; if the wound remains healthy during the early days, the original dressing, if unstained and intact, can be left in place until the wound closure material is removed.

Assessment of cavity wounds

If wound management materials are to be used effectively, the appropriate product must be applied to the wound throughout the stages of healing. During the assessment the following factors should be taken into consideration (Bale 2000).

Appearance of the wound bed In the pregranulation stage, cavity wounds often appear red and raw, and have the very uneven surface of adipose tissue. It is important to recognise that this is normal for this early stage of healing. Within 10–13 days the appearance of the wound will change as granulation tissue is formed. A healthy wound should be pale pink in colour, sometimes covered with a pale yellow membrane, pain-free and should not bleed easily if touched. If infection is present, the appearance of the wound will alter. The colour of the tissue may change to a dark red and the wound will show a tendency to bleed easily on light contact and become uncomfortable or painful. Superficial bridging of tissue can also be seen within the cavity (Bale 2000). As the presence of infection can delay healing, prompt treatment is needed in these situations. For deep-seated infection, a wound swab (see Box 23.5) followed by the appropriate course of antibiotics is generally indicated, but more superficial infections can sometimes be treated topically. Until the infection is cleared, no dressing material will be fully effective.

Box 23.5

Taking a wound swab

Points to remember:

- Use an aseptic technique
- Use a sterile, microbiological cotton wool swab
- This swab should be moistened in a transport medium before use
- If the wound is flat or shallow, gently rotate the swab across the middle of the wound bed. Care needs to be taken not to contaminate the swab with skin flora from the edges of the wound
- If the wound is deep, or has a recess, insert the swab into the depths of the wound. Bacteria present in the depths of a wound are different from and more likely to be pathogenic than bacteria on the surface of a wound
- Carefully replace the swab directly into its storage tube containing culture medium
- Deliver to the laboratory as soon as possible, but at the latest within 24 h
- Record antibiotic drugs being given, the site of the wound, together with any other information likely to be of help to the laboratory.

Wound size In general, the larger a wound, the longer it will take to heal; therefore the size of a wound provides a useful indication of the probable healing time. The healing rates of some wound types, such as pilonidal sinus excisions, axillary wounds and abdominal wall wounds, have been carefully measured, and so it is possible with these wound types to predict with some accuracy how long they will take to heal (Leaper & Gottrup 1998, Wilson 2000).

The size of a wound may also influence the choice of dressing. Whilst small cavities may be dressed with one of a number of products, it may not be practical to use some products on larger wounds where multiple pieces or packs would be required. In these situations, the choice of dressing material may be limited to products that provide the bulk with just one or two packs. This is an especially important consideration in the community where the available size range of modern dressing materials may be limited.

Wound measurement In order to assess the effectiveness of a particular treatment, it is necessary to monitor changes in the size of the wound. For the majority of wound situations this should be the way a wound progresses towards complete healing. Surgically created cavities are usually of even contour and depth; the length and breadth of such a wound can generally be determined fairly easily (Bale 2000). Weekly measurement is often sufficient and steady progress should be evident.

Wound volume is more difficult to assess and does not really offer any advantages over the measurement of linear dimensions.

Chronic wounds, such as pressure ulcers, are often more difficult to measure as these wounds can extend under

the skin edge. The simplest way of assessing the extent of these wounds is to measure by using a cotton wool bud or probe gently inserted into the wound, under the edge of the cavity, marking the boundary on the skin with an ink marker. This outline of the extent of the wound can then be traced onto paper and stored as a permanent record of wound progress.

For leg ulcers, the circumference of the wound can be traced onto clean acetate or plastic sheets and, again, can be stored as a permanent record.

Re-measurement of chronic wounds may only be necessary every 2–3 weeks, as healing is generally slower in these situations. Accurate measurement and record keeping avoids the need to depend upon clinical impression. More sophisticated and expensive methods of wound measurement are available, including structured light and computer imagery, which assess wound area and volume (Bale 2000). Photography, using instant Polaroid or a digital camera, is valuable in providing a permanent record of the appearance of the wound.

23.4 How are wounds measured in the areas in which you have worked? Devise a way of recording the wound dimensions in the care plan of one of your patients.

Wound shape and depth When managing cavity wounds, it is necessary to recognise the importance of wound shape. Ideally, cavities created surgically should be boat- or saucer-shaped, with evenly sloping sides. Where pockets, tracts or sinuses occur within a cavity, drainage of exudate may be inadequate, and this in turn may greatly delay healing. Poor wound shape also restricts the range of dressing materials that can be used. For example, a long narrow cavity will require a dressing material that is conformable enough to be inserted into the restricted space but which can be easily removed from the depth of the wound without leaving behind fibres and particles which could then become a focus for infection.

In a wound where the shape is so poor that progress towards healing is unacceptably slow, surgical revision may be required in order to create a wound with more regular contours. This is occasionally necessary when wounds that have undergone primary closure subsequently break down. Pressure ulcers are particularly prone to develop into poorly shaped wounds and, as surgical revision here is not always possible or advisable due to the poor health of the individual, careful choice of an appropriate dressing material is essential (Bale 2000).

Exudate production Cavities vary enormously in the amount of exudate they produce. New, surgically created wounds can exude heavily, whereas some deep pressure ulcers produce very little exudate. This variation will affect management, especially the choice of dressing material. Some products are highly absorbent and are able to deal with copious discharges, whereas others have a limited capacity for absorption. The inappropriate use of a dressing material can sometimes have serious consequences. If, for example, a dressing material is chosen that is unable to cope with heavy exudate production, the surrounding skin can quickly become macerated. Alternatively, a very hydrophilic dressing material applied to a lightly exuding wound may cause excessive drying of the wound surface, delaying healing and sometimes even causing pain.

Presence of slough or necrotic tissue When slough or necrotic tissue is present on the wound surface, healing will be delayed or, in some cases, prevented altogether. This material needs to be loosened and removed to allow wound healing to progress. This procedure is known as debridement and is a difficult task that requires intensive and skilled nursing intervention (see p. 845) (Bale 1996).

The location of care

This can affect patients' progress. Those nursed in hospital are in an environment where their dietary intake and fluid balance can be monitored and their general well-being assured. Nursing care is available continuously and, to a certain extent, the nurse 'controls' the environment in which the patient is being nursed. In the community, when patients are being cared for in their own homes, the nurse has far less influence over a patient's environment. As a guest, the district nurse is able to advise and recommend an adequate food and fluid intake but is unable to monitor this accurately, as each visit may only be for a comparatively short period once or twice a day.

Creating an environment for healing

Principles of moist wound healing

Healing proceeds at its optimal rate when the wound is enclosed in a warm, moist environment (see Fig. 23.3). Under these conditions, cellular activity is maximised; the benefits of such an environment have been recognised since the early 1960s (Winter 1962). This is true for the whole spectrum of wounds encountered, from superficial cuts and grazes to large, extensive granulating wounds. Exposure of a wound to the air precipitates drying out of the wound surface and scab formation. Nurses should consider the importance of providing a suitable environment for wound healing when choosing a wound management material. The term 'dressing' traditionally depicted some form of absorbent cotton/gauze-type material that was used to soak up excess wound secretions and protect the wound from trauma. By the 1990s a wide range of sophisticated materials had been developed to cater for the diversity of individual wound situations. Many of these materials interact with the wound surface (so-called interactive materials) and are designed to optimise the local conditions for wound healing (Bale 2000). Box 23.6 summarises the characteristics of an ideal wound dressing material.

As therapies continue to be developed, the use of growth factors, cultured human skin and synthetic substitutes are being introduced into patient care (Gentzknow et al 1996). Although such therapies are not appropriate for many patients whose wounds are healing rapidly, their use can be invaluable for wounds in life-threatening and other difficult situations such as burns and chronic and indolent ulcers.

Principles of cleansing

Why cleanse a wound? Sutured wounds rarely need cleansing unless leakage has occurred. In this situation

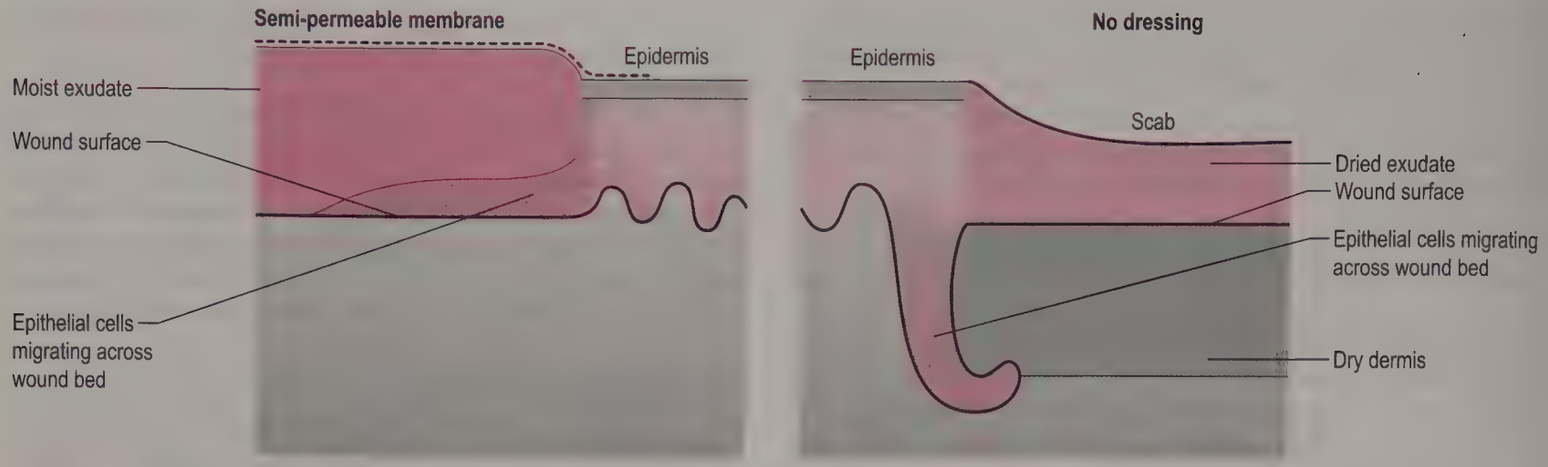

Fig. 23.3 Healing of skin wounds with and without a semi-permeable membrane dressing (Adapted from Winter 1962).

Box 23.6

Characteristics of an ideal dressing

- Non-adherent
- Impermeable to bacteria
- Capable of maintaining a high humidity at the wound site while removing excess exudate
- Thermally insulating
- Non-toxic and non-allergenic
- Comfortable and conformable
- Capable of protecting the wound from further trauma
- Requires infrequent dressing changes
- Cost-effective
- Long shelf-life
- Available both in hospital and in the community

Reproduced with permission from Morison et al (1997).

the suture line can be gently, aseptically cleansed with sterile normal saline. With open wounds, strict asepsis is not always required. The patient can use the bath or preferably the shower to irrigate the wound with warm water (Bale & Jones 1997). For patient comfort, fluids used for wound cleansing should be warmed to body temperature. The main reason for cleansing open cavity wounds is to remove any loose debris and excess wound secretions. A shower is particularly useful in achieving this. The gently flushing action of the spray will remove any particles that are loose, and flushing for 10–15 s is usually sufficient. If bathing, the wound should be flushed by splashing water into it. Wounds of the lower limb can be bathed in a bucket or bowl, gently splashing the wound to remove loose debris. A bucket can be lined with a commercial bin liner. This protects the bucket from contamination and makes cleaning of the bucket much easier and so reduces the potential risk of cross-infection.

For further reading on wound irrigation, see Cunliffe & Fawcett (2002).

The role of antiseptics and topical agents (see Table 23.5). The actions of the whole range of antiseptics and cleansing agents are generally poorly understood, though researchers have attempted to investigate their effects on healing tissue. Some antiseptics are reported to have adverse effects on healing (Williams & Leaper 1998), whilst others have a positive effect (Gilchrist 1997). The challenge for nurses is to match these results with the clinical situations they

Table 23.5 Topical cleansing agents

Agent	Action
Cetrimide	A detergent that cleanses the wound bed, useful for traumatic injuries that are contaminated or require debridement. Bacteriostatic against Gram-negative bacteria though rapidly deactivated on contact with organic material
Chlorhexidine	Aqueous version used for wound cleansing. Bacteriostatic against both Gram-positive and Gram-negative bacteria though rapidly deactivated on contact with organic material
Iodine preparations: povidone and cadexomer products	Have a broad action against both Gram-positive and Gram-negative bacteria
Isotonic saline 0.9% sodium chloride	Physiologically compatible with body fluids. Suitable for mechanical cleansing of excess or stale wound exudate and loose debris
Drinking and boiled water	Suitable for mechanical cleansing of excess or stale wound exudate and loose debris

encounter. All wounds become colonised from the surrounding skin by bacteria, which are particular to that individual and their presence rarely delays healing (Williams & Leaper 1998).

Bacterial studies on pilonidal sinus excisions, axillary wounds and abdominal wall wounds have shown that the vast majority of bacteria present in these wound types do not cause problems to the patient or, in fact, delay healing. Similarly, in a study of the bacteriology of leg ulcers, the presence of bacteria on the wound surface again did not delay healing (Gilchrist 1999). Patients with leg ulcers appeared to keep their initial bacterial flora irrespective of the type of treatment and its eventual outcome. The organisms here included *Staphylococcus aureus*, *Escherichia coli* and *Pseudomonas aeruginosa*.

Wound cleansing The purpose of cleansing a wound is to gently remove loose debris and other surface contaminants, so providing an optimal healing environment prior to applying a dressing. However, wound exudate bathes the surface of wounds and provides nutrients and cytokines essential for healing. Cleansing the surface of a wound removes exudate and in some cases this inhibits the healing process (Barone et al 1998). Nurses need to consider carefully why they are cleansing a wound and to balance the need to remove exudate because of harmful effects, against leaving it in place to enhance healing. Exudate needs to be removed if:

- it is causing maceration to the wound bed and/or surrounding tissues
- there are signs of infection
- foreign bodies are present
- devitalised tissue is present
- it has an unpleasant odour and is embarrassing and nauseating for the patient
- it is excessive and is oozing through dressings and onto clothing/bedding/furniture.

Where the wound is healthy with minimal amounts of exudate, routine wound cleansing is of little benefit (Davies 1999). Nurses should use a realistic approach when cleansing wounds. Many antiseptics have a short-lived action and so bacteria will quickly re-colonise the wound surface. If these organisms are not harmful, why seek to eradicate them?

Removal of devitalised tissue

Chemical debridement Before the advent of modern dressing materials, a range of chemicals was applied to sloughy and necrotic tissue in an attempt to soften and remove it (Bale 1996), but with varying degrees of success. These agents have difficulty penetrating the surface of leathery and hard necrotic tissue, so rendering them ineffective. Where healthy granulation tissue is present, damage can occur due to the toxicity of the chemicals.

Surgical or sharp debridement is the removal of devitalised tissue using a scalpel and scissors. It is sometimes possible for a surgeon to excise devitalised tissue with or without anaesthesia depending on the site and depth of the problem. Alternatively, experienced and specialist nurses can also perform this procedure. If general anaesthesia is not indicated then careful consideration is needed to ensure that the patient does not feel pain or discomfort, and that the area is not painful. The advantages of this method are that debridement is instant and a healthy cavity results. Where patients are being cared for in the community, access to a surgeon or specialist nurse may be limited and this is not always a practical alternative for many patients.

Autolytic debridement Autolysis is the lysis of devitalised tissue from the wound bed by white blood cells and proteolytic, fibrinolytic and collagenolytic enzymes (Ramundo & Wells 2000), which work best under moist conditions. Several types of wound dressing provide this moist environment that facilitates cleaving of the devitalised tissue from the wound bed. These dressings can effectively remove devitalised and necrotic tissue without damaging either the skin surrounding the wound or healthy tissue within the wound. Included in these are the hydrogels and hydrocolloids (see Table 23.6).

Excessive granulation

From time to time, re-epithelialisation fails to take place due to the presence of excessive granulation tissue or 'proud flesh'. Treatment is needed to flatten the granulation tissue so that it is level with the epithelial edge, as new epithelium cannot migrate up over this 'proud flesh'. An application of 75% silver nitrate stick will cauterise the tissue, but a less traumatic method is the use of a cream containing a corticosteroid, although this should be used under medical supervision. The need for careful assessment is paramount in the successful treatment of cavity wounds. When planning a wound care programme, consideration of these factors should provide the nurse with an accurate picture of the needs of each patient and also provide some assistance with the dressing selection process.

New wound healing therapies

The drive to develop therapies that accelerate wound healing continues. Such therapies are designed to interact with the wound and enhance the wound environment. These include growth factors, skin substitutes, antimicrobials, vacuum-assisted closure and wound warming.

Growth factors aim to regulate cellular activity, including:

- the movement of cells into a wound
- replacement of damaged epidermal and dermal cells
- formation of scar tissue
- remodelling of scar tissue (Schulz 2000).

One example of a product available for such use is recombinant growth factor, platelet derived growth factor (PDGF), which is used to stimulate the formation of extracellular matrix and granulation tissue. Other examples include basic fibroblast growth factor (bFGF), transforming growth factor, b family (TGFb), and the interleukin family of proteins. Research continues to determine which wounds are likely to benefit most from the application of such agents.

Tissue engineering A range of artificial skin, cultured skin and living skin equivalents has been developed, though

Table 23.6 Dressings and topical wound products

Material	Presentation	Action	Indications for use	Special considerations
Alginates (fibres of calcium or sodium alginate derived from seaweed)	Flat sheets, ropes and packing	Absorbent; gels in contact with exudate Non-adhesive, non-occlusive	Partial and full thickness wounds Moderate to heavily exuding wounds	Can be packed into cavities and sinuses Can be rinsed from wound bed, cavity or sinus Usually require a secondary dressing
Antimicrobial dressings (impregnated with iodines, silvers)	Flat sheets and packing	Have an antimicrobial effect on the wound bed	Heavily contaminated or infected partial and full thickness wounds Moderate to heavily exuding wounds as these products usually need exudate to activate the antimicrobial effect	Usually require a secondary dressing Silver products can cause staining of surrounding skin and clothing if not contained
Foams (hydrophilic polyurethane/ polymer)	Flat sheets and cavity dressings Some are adhesive, some are semi-occlusive	Absorbent; some can retain exudate in foam	Partial and full thickness wounds Moderate to heavily exuding wounds	Removed in one piece Some are reusable and can be disinfected
Films (polyurethane or co-polymers)	Adhesive sheets	Transparent dressing Maintain a moist environment Impermeable to fluids and microorganisms	Partial and full thickness wounds Moderate to heavily exuding wounds	Removed in one piece Can be used as a primary wound contact dressing or to hold other dressings in place (e.g. hydrogels)
Hydrocolloids (hydrophilic colloid particles derived from cellulose, gelatins and pectins bound to a polyurethane foam backing)	Adhesive flat sheets in different thicknesses Gels Powders	Maintain a moist environment Provide an environment for autolysis Impermeable to fluids and microorganisms	Partial and full thickness wounds Dry to moderately exuding wounds Often not recommended for heavily exuding wounds, tracts and sinuses	Usually leave a residue that can be malodorous
Hydrofibres (fibres of carboxymethyl-cellulose)	Flat sheets and packing	Absorbent product that gels on contact with exudate	Partial and full thickness wounds Moderately to heavily exuding wounds	Require a secondary dressing
Hydrogels (water- and glycerin-based crossed-linked hydrophilic polymers)	Sachets of gel Sheets available Packing available Some are a carrier for antibiotics	Maintain a moist environment Provide an environment for autolysis	Partial and full thickness wounds Dry to moderately exuding wounds Provide an environment for autolysis	Usually require a secondary dressing to hold gel in contact with wound bed May cause maceration of skin surrounding wound and so often not recommended for heavily exuding wounds
Hydropolymers (multilayered)	Adhesive sheets of different thicknesses	Absorbent, some can retain exudate in the layers of dressing	Partial and full thickness wounds Minimal to heavily exuding wounds	Adhesive dressing that has the ability to be peeled away and reapplied
Low adherent dressings (woven mesh or net of polyamide)	Sheets Often silicone coated	Wound contact layers that wick exudate onto a retention dressing	Partial and full thickness wounds Moderately to heavily exuding wounds	Used under compression bandaging systems and in situations where a secondary dressing absorbs exudate

Table 23.6 Dressings and topical wound products *(Continued)*

Material	Presentation	Action	Indications for use	Special considerations
Skin substitutes or equivalents (bioabsorbable matrix containing fibroblasts and/or keratinocytes)	Single or multilayers of living cells, transported on a mesh or medium	Replaces skin and provides wound coverage with cellular activity	Partial and full thickness wounds Usually indicated for chronic and slow or non-healing wounds such as diabetic foot ulcers and venous leg ulcers Have been used extensively in burns patients	Usually require specialist skills and facilities Require special transportation and storage as some products are provided frozen and others are incubated Some wound bed preparation is needed prior to application

NB: This table provides examples of the main groups of dressings and topical wound products. However, it is not an exhaustive list and other products are available as combinations or variations of these main groups.

these are expensive to produce. They are recommended for indolent wounds, burns and diabetic foot ulceration (Gentzknow et al 1996) and usually comprise a bioabsorbable matrix of collagen that has been inoculated with living fibroblasts or keratinocytes. This technology is unlikely to be widely available but could enhance the care of and improve outcomes for patients with the most difficult wound healing problems.

Dressing change techniques

Throughout the UK there are many different policies, procedures and protocols for dressing changes. However, there are fundamental principles that need to be adhered to when undertaking wound care procedures (Rolstad et al 2000), namely standard infection control precautions where clean, non-sterile gloves are used to remove a soiled dressing and these discarded and a new pair of gloves used for any further procedures (Stotts 1997). A dressing needs changed when:

- there is a specific purpose, e.g. to remove sutures
- clinical signs of infection are present
- wound discharge has leaked through the dressing
- cleansing of an open wound is necessary — this may be as frequently as twice a day or as infrequently as once a week (see Table 23.6 for different dressings)
- special treatments are needed, e.g. burns dressings.

Aseptic technique

In hospital When dressing changes are being performed within a hospital, the nurse must always take into consideration the possibility of transferring bacteria from one patient to another, due to the close proximity in which patients are cared for. This is more of a risk when several patients with wounds are being nursed in the same ward and by the same nurses. Once a wound has become contaminated, clinical infection can quickly develop (see Ch. 16). Aseptic technique aims to prevent pathogenic organisms from contaminating a wound (see Box 23.7). In hospital, dressings are generally changed using an aseptic technique. There may, however, be occasions when dressing changes require a technique that is socially clean without being fully aseptic. It is an individual nurse's responsibility to understand the principles of asepsis and standard infection control precautions and adapt knowledge to the situation being managed.

In the community In the hospital, equipment is provided which allows the nurse to manage safely all the wound management situations encountered. Maintaining asepsis may pose different problems in the patient's own home. The district nurse may have little control over the cleanliness of the area and needs to take extra care when changing dressings. It is just as important in the community to avoid cross-infection between households and contamination of

Box 23.7

Principles of aseptic technique

- Perform the procedure in an area which is closed, clean and well ventilated at least 1 h after periods of activity — bed making and ward cleaning, for example, increase the circulation of dust particles and airborne bacteria
- Use a clean trolley — this should be thoroughly cleaned daily and wiped with an alcoholic solution before and after use
- Wash hands (p. 666) before, after and at any point during the procedure should they become contaminated. The use of an alcoholic hand-rub can sometimes be substituted
- Wear a clean plastic apron to protect the patient from bacteria on the nurse's uniform
- Use sterile equipment for the procedure — be aware of how your health authority/board identifies equipment which is sterile and therefore safe to use
- Discard equipment which has broken or damaged packaging
- Use sterile fluids and dressing materials
- Prepare equipment before dressings are removed
- Use gloves to remove any dressings and dispose of both immediately
- Carry out the procedure using forceps or sterile gloves, discarding equipment as it becomes contaminated
- Dispose of used equipment in the appropriate bin

wounds. The district nurse in these situations has many opportunities for health education.

The use of a clean technique

For many dressing changes, the use of a clean technique (see Table 23.7) is safe and acceptable (Flanagan 1997). The types of wound suitable for this method include the majority of granulating wounds.

Involving the patient in wound care

Whether patients are being cared for at home or in hospital, there are many opportunities for the nurse to involve patients in wound management. This is important in giving the patient a sense of independence and will help promote return to normality. Patients with sutured wounds can be taught to monitor themselves for clinical signs of infection and to give good self-care in terms of nutrition, fluid intake, rest and avoidance of excessive movement of the affected area. Patients with open wounds can become much more involved. In addition to the self-care elements outlined above, they can be taught about the appearance of the wound surface and what can be expected to happen during the healing phase. In the community, patients and their relatives can be taught the basic dressing-change technique where asepsis is not necessary and the district nurse can assume a supervisory role. This obviously depends on individual circumstances and the patient's level of understanding, but certainly many patients with open wounds are able to play a major role in wound management. This is important as the patient begins to resume a more normal lifestyle and it also avoids the need for routine daily visits by the district nurse.

Patients with chronic wounds, such as leg ulcers and pressure ulcers, need special help, but it is very important to gain their cooperation. Patients with venous leg ulcers (see p. 852) require advice on leg elevation techniques and calf pump muscle exercises, which stimulate the circulation and aid drainage of the lower limb. Carers of patients with pressure ulcers (see p. 849) need advice and training on manual handling, i.e. turning and repositioning the patient. Carers also need to know how the pressure-relieving aids work, so that these are used correctly at all times and not just when the district nurse is in the home.

Nurse prescribing

In 1999 a *Review of Prescribing, Supply and Administration of Medicines* recommended that new forms of prescribing — 'supplementary prescribing' and 'independent prescribing' — be carried out by nurses and pharmacists as non-medical professionals (DH 2004). Since then programmes for the education, training and regulation of nurses and pharmacists have been developed. There are plans to extend some aspects of this patient service to include physiotherapists, radiographers, podiatrists, chiropodists and optometrists. In addition, patient group directives (PGDs) enable nurses to supply and administer prescription only medicines to patients under the direction of a doctor. It is envisaged that these PGDs will be on an individual, patient-specific basis.

23.5 Discuss with a community nurse some examples of nurse prescribing in relation to wound care.

Wound management policies and guidelines

Most health care providers in the UK have developed wound treatment and prevention policies to help guide their staff towards safe and standardised nursing care. Ideally, these are based on the best available evidence sourced from systematic reviews of the literature covering randomised, controlled trials (Cullum et al 1997). Given the rapid development of wound dressings and associated devices such as bandages and pressure-relieving equipment, and the wide range of therapies available to patients, such protocols and guidelines can enhance quality of care for patients by ensuring they receive treatment that is evidence based.

The transition from hospital to home

The transition from hospital to home for patients with wounds usually takes place without any problems. Liaison nurses are available to organise the discharge home and to arrange for any visits needed by the district nurse for the newly discharged patient. In emergency departments, a liaison service may also be available. It is important, however, that wherever patients receive treatment they have a point of contact so that they are well supported when discharged home (Bale & Jones 1997).

Table 23.7 Clean technique

Procedure	Rationale
1. Use non-sterile gloves to remove dressing. Change gloves	Protects both nurse and patient from cross-infection
2. Shower or bathe patient's wound	Mechanically removes loose wound debris (NB: ensure thorough cleansing of shower/bath whether at home or in hospital)
3. Use clean bowl/bucket with bin liner for patients with small wounds or foot/leg wounds in the home	Prevents contamination of equipment
4. Use clean paper or a clean towel to dry area surrounding wound	Prior to application of dressing, area needs to be dry
5. Encourage patient involvement in treatment	Increases patient compliance and encourages return to normal activity

Provision of materials in hospitals and in the community

Nurses may be unaware of the vast differences which exist in the provision of wound management materials to patients cared for in hospital compared with those cared for in the community. Although most hospitals impose some form of restriction on which materials are provided, generally all the main groups of manufactured materials are available. These are supplied not only to inpatients but also to outpatients who are under the care of a hospital consultant. All materials needed for inpatient treatment are provided without direct cost to the individual patient. It is the norm, then, for patients treated in hospital to have access to a comprehensive range of wound management materials for their wound care, and supplies of these continue as long as the patient remains in hospital.

Patients managed in the community are in a different position. Materials needed for their treatment are generally obtained from the general practitioner (GP), practice nurse or district nurse who writes a prescription for those items required. Unless the patient is exempt from paying, a charge is made for each item dispensed, though provision is made to enable patients to purchase a 'season ticket' lasting 4 months or 1 year. The products that can be prescribed are listed in the Drug Tariff that is controlled by the Department of Health. This list defines those dressing products that can be prescribed for use in the community and can be accessed on www.drugtariff.com.

23.6 Ask the pharmacist what products are available on FP10 and GP10 (NHS Scotland) to patients in the community. Look also at the sizes of prescribable products.

Expectations of outcome and effectiveness of treatment

Following individual patient and wound assessment, the nurse should have reasonable expectations regarding the prospects of achieving complete healing. In some wounds, complete healing is expected rapidly, as in primary wound closure following excision of a lipoma in a healthy young person. For others, the prognosis for healing is less good, e.g. an older woman with arthritis and a venous leg ulcer. The expected outcome affects the choice of treatment for individual patients. For patients with a poor prognosis for healing, treatment is often directed towards minimising symptoms and preventing further wound breakdown. This situation can arise in terminally ill patients with superficial pressure ulcers where the aim is to prevent penetration of the ulcer into deeper tissues. Patient comfort and convenience become the priorities and provide some measure of the effectiveness of the treatment. Where healing is expected, effectiveness means complete healing is achieved in the minimum number of days.

Cost-effectiveness

Efficacy is also measured in terms of the cost of treatments. Hospital doctors, GPs, practice nurses or district nurses and the pharmacists who supply materials for wound management can be misled into believing that, because the initial cost of a material is high then it follows that the total treatment costs will also be high. Modern wound dressing materials can be very expensive to buy per unit. However, these dressings can often be left on the wound for several days and, in some cases, for a full week.

It is important, when comparing the costs of dressing materials, to consider:

- how long the product can be left on the wound
- how much nursing time is needed to change and apply dressings
- the benefits of using a material which is interactive and so stimulates tissue growth to achieve rapid healing or stimulate healing in a chronic wound.

Clinical evidence for improvement in healing or other outcome measures

It is in the area of materials that there has been most benefit, especially in the community, where much of the chronic wound care is undertaken. Modern wound treatments are helping to control wound symptoms and to achieve healing in chronic wounds, thus enabling more efficient use of nurses' time. Discharging such patients after many months, if not years, of treatment also improves their quality of life.

SPECIFIC WOUND TYPES

Pressure ulcers

Definition A pressure ulcer is an area of localised damage to the skin caused by disruption of the blood supply to the area, usually caused by pressure, shear or friction, or a combination of any of these (Dealey 1999). Tissue damage can be restricted to superficial epidermal loss or may involve underlying structures, extending to involve muscle and bone (European Pressure Ulcer Advisory Panel 1998).

The prevention and management of pressure ulcers present major challenges for nurses. The pressure ulcer problem is widespread and persistent, affecting patients from all walks of life and with a range of illnesses. It causes diminished quality of life and distress to patients and carers and makes major financial demands on the health service. As a result, in many hospital and community trusts, nurses are now supported by a 'tissue viability service' (Dealey 1997). Particular difficulties arise in trying to identify patients who might develop a pressure ulcer, and when they are at risk of doing so.

It is a basic responsibility of nurses to:

- assess accurately the patients in their care for being 'at risk' of developing a pressure ulcer
- ensure that any predisposing factors are reduced
- ensure that patients are nursed on the most suitable surface, depending on their individual needs
- ensure that established pressure ulcers are efficiently managed
- undertake regular and ongoing reassessments of individual patients; a patient's needs vary from one day to the next, and in the very ill from one hour to the next.

Aetiology

Pressure ulcers result from areas of previously healthy tissue becoming devitalised, resulting in localised tissue death. Pressure ulcers develop in a number of ways:

- as a result of direct, unrelieved pressure of soft tissues against bone
- where friction occurs between the patient and the surface of a bed or chair; this can happen if the patient is moved and the skin is dragged over a sheet
- as a result of the shear forces that frequently accompany both direct pressure and friction; shear forces develop in tissues that are distorted and pulled, so that the blood supply is disrupted.

Classification

In order to assess the extent or degree of damage, grading systems have been developed (European Pressure Ulcer Advisory Panel 1998). The EPUAP system has four grades of tissue damage:

- *Grade 1* — non-blanchable erythema of intact skin. Discoloration of the skin, warmth, oedema, induration or hardness may also be used as indicators, particularly on individuals with darker skin.
- *Grade 2* — partial-thickness skin loss involving epidermis, dermis or both. The ulcer is superficial and presents clinically as an abrasion or blister.
- *Grade 3* — full-thickness skin loss involving damage to or necrosis of subcutaneous tissue that may extend down to, but not through, underlying fascia.
- *Grade 4* — extensive destruction, tissue necrosis or damage to muscle, bone or supporting structures with or without full thickness skin loss.

Assessment of risk

In an acute illness, even the most unlikely individual may become 'at risk' of developing a pressure ulcer; therefore, all patients should be assessed on admission either to a hospital ward or unit or onto a district nurse's caseload — 'The importance of assessing all patients (except perhaps some short-stay cases) cannot be overemphasised' (Dealey 1999). A combination of disease processes and/or drug therapies or surgery, for example, can quite suddenly put an individual into an 'at risk' category.

The following patients are at risk of developing pressure ulcers:

- older people
- the immobile, e.g. paraplegic or following certain types of orthopaedic surgery
- those with sensory loss, e.g. in a coma, or in the diabetic
- those with a range of systemic diseases, e.g. anaemia, peripheral vascular disease, carcinoma
- those having a range of medication, e.g. anti-inflammatory, cytotoxic or steroid medication
- those with impaired continence
- poorly nourished individuals
- the obese and those with below-average body weight.

Several scales and scoring systems have been devised for assessing risk; the most widely used in the UK is probably the Waterlow score (see Fig. 23.4). There are other risk assessment scores available, though only some — the Norton Scale, the Braden Scale and the Central Begeleidings Orgaan (CBO) — have undergone validity testing (Braden 1997, Schoonhaven et al 2002). National (National Institute for Clinical Excellence 2001) and international (European Pressure Ulcer Advisory Panel 1998) guidelines have been produced to guide nurses towards adopting an evidence-based approach to caring for patients. Many health care providers have adapted guidelines for local use to suit their own patients' needs and as part of a pressure ulcer prevention policy. Guidelines are designed to rationalise and standardise patient care so that all patients receive a reasonable level of care. Guidelines also help to ensure that the available pressure-relieving equipment is used most efficiently. However, all health care professionals have a responsibility for taking action once risk is identified (Dealey 1997).

As part of guideline recommendations, risk assessment tools are designed to support nurses' clinical judgement and not to replace it (Bates-Jensen 1997, Braden 1997, National Institute for Clinical Excellence 2001). They are useful only if used regularly — on admission and again each time the patient's condition changes. The scores need to be accurately documented and then used to determine the most appropriate pressure-relieving devices on which to nurse the patient.

23.7 What scoring system does your ward/area use? Where is the score documented and how often are patients reassessed?

For further information, see Dealey (1997).

Prevention of pressure ulcers

Once patients have been identified as being 'at risk', they should be nursed on the most appropriate surface. This includes not only the mattress on the bed but also any chairs in which they may sit during the day (Dealey 1999). Other areas worth considering are theatre operating tables and trolleys on which patients are transported around the hospital. Liaison with other professionals may be indicated, for example with the physiotherapist to assess the degree of mobility an individual has and where help and treatment can be given.

Attempts to reduce friction and shearing when nursing patients are essential. At home this is easier than in hospital where sheets may become hard when washed in very hot water and dried in very hot dryers. Where possible, patients should be nursed on soft sheets and covered with a duvet or soft blankets, as hard rigid surfaces increase friction.

Friction also increases with moisture. As increased skin moisture can result from incontinence and sweating, these should be avoided where possible. Nutrition and fluid balance also need attention. It has been estimated that dehydrated patients and patients in a negative nitrogen balance are more likely to experience tissue breakdown.

For further information, see the European Pressure Ulcer Advisory Panel website, www.epuap.org.

Management of patients with established pressure ulcers

In addition to providing a suitable surface on which to nurse the patient, and ensuring adequate nutrition and using

B

REMEMBER: TISSUE DAMAGE OFTEN STARTS PRIOR TO ADMISSION, IN CASUALTY.

ASSESSMENT: (see over) If the patient falls into any of the risk categories then preventive nursing is required.
A combination of good nursing techniques and preventive aids will definitely be necessary.

PREVENTION:

Preventive aids:

Special mattress/bed:
- 10+ Water mattresses, e.g. Dyson, Spenco, Vaperm, Topper.
- 15+ Large cell ripple, e.g. Huntleigh, Water beds.
- 20+ Pegasus Airwave, Clinitron, Mediscus

Chair: Correct for patient protection – side/seats, movement, e.g. Nestor, Roho, Jay.

Bed clothing:
- i) Cotton cellular blanket
- ii) Duvet
- iii) Vapour permeable mattress cover.
- iv) Pillows

Nursing care:
- Pain control
- Turning / 30° tilt
- Passive movements
- Nutrition – high protein, minerals, vitamins

Mechanical aids: Real sheepskins – sacral, heel/elbow pads, e.g. Pegasus Lamb Pads, Gel protection; Bed Cradle

Patient aids: Monkey Pole; Hand Lifts

Operating table/ Theatre trolley: e.g. 'Moulding Top'; e.g. Topper, Waffle

Skin care: General hygiene, NO rubbing; Prevent shearing force damage; e.g. correct lifting and positioning; Dress with inert covering e.g. Opsite

IF TREATMENT IS REQUIRED, FIRST REMOVE PRESSURE

WOUND CLASSIFICATION:

Blanching hyperaemia	STAGE I	Is wound RED?	NO → YES Semi-occlusive dressing; Bioclusive, Tegaderm.
Non-blanching hyperaemia	STAGE II	Is wound RED, clean but not healed?	NO → YES Granuflex, Lyofoam, Scherisorb, Sorbsan, Silastic Foam (deep)
Ulceration progresses	STAGE III	Is wound YELLOW/infected/inflamed?	NO → YES Sorbsan, Scherisorb, Debrisan, Granuflex
Ulceration extends	STAGE IV	Infected?	NO → YES Sorbsan packing, Isosorb, Actisorb, Flamazine (for pseudomonas), Debrisan
Infective necrosis	STAGE V	Is wound BLACK/necrotic?	NO → YES Debride – surgical excision; Granuflex, Scherisorb, Varidase

good handling techniques when moving a patient, local care of the pressure ulcer needs to be considered (Morison et al 1997).

Grade 1 Although no open ulcer is present, blood supply to tissues has been disrupted and will rapidly deteriorate if pressure is not relieved as a matter of urgency.

Grade 2 These superficial wounds usually need a dressing to assist tissue recovery and to protect the area. A common cause of Grade 2 ulcers is either friction or, more usually, a combination of friction and shear force. Elimination of the cause is needed to avoid further and more extensive damage. Several materials can be chosen as dressings that will provide a healing environment: semi-permeable films and thin hydrocolloids are all good examples (see Table 23.6). Where incontinence is a problem, these occlusive or semi-occlusive materials are invaluable.

Grades 3 and 4 These deeper wounds are much more difficult to manage. They often have an irregular contour with the wound extending under the skin edge. Assessment is needed of the full extent of the wound (see p. 842). Other challenges related to wound shape are sinus formation, which requires careful management, and packing and/or irrigation. This is a situation where surgical intervention may need to be considered.

Necrotic tissue and slough deep within these extensive wounds must be removed if healing is to proceed, and there are several ways of achieving this (Bale 1996) (see p. 845). Until most of the devitalised tissue has been removed, the full extent of the pressure ulcer cannot be assessed. The development of severe tissue damage is a serious and potentially hazardous situation for a patient. Ninety per cent of patients with deep necrotic pressure ulcers of the trunk die within 4 months (Bliss 1990).

Other nursing considerations

The management of patients with established pressure ulcers is costly in both economic and personal terms. Prevention of pressure ulcers is often far cheaper than management (Dealey 1997). Health service managers are able to cost the treatment of pressure ulcers more accurately and with the call for pressure ulcers to become a notifiable condition (Dealey 1997) more emphasis is being put on prevention.

Patient education

In the prevention and management of pressure ulcers, patients have an important role to play. All patients, including young, chronically disabled patients can be taught various methods of regularly relieving pressure by changing position (Colburn 1997). Patients who are not able to take such an active part in their own management can be taught the value of and need for the changes of position that nurses and other carers carry out for them. Concordance increases when patients understand why intervention is necessary.

Education leaflets can also be useful. An extract from a typical patient information leaflet demonstrates how the nurse and the patient share in the prevention of pressure ulcers (see Box 23.8).

Box 23.8

Extract from an education leaflet: preventing pressure ulcers

As most pressure ulcers are the result of staying in one position for too long, the answer is to:

Relieve the pressure by changing position
Ideally, you should get up out of bed or your chair at least once every 2 hours during the day and take a short walk. This activity also helps your blood circulation and stops your muscles getting lax.

If you are confined to a chair, you should lift your bottom off the seat for a few moments every half an hour by pushing up on the arms of the chair.

If you have to stay in bed, then your bed may be fitted with a 'monkey pole' or rope ladder — the nurse will show you how to use this to lift yourself off the bed.

If your pressure ulcer is extensive or deep, or your movement is very restricted, a special movement chart will be devised for you by the nursing staff to keep you off the ulcer as much as possible, and you may be given a special bed or mattress.

Reproduced with permission from Morison et al (1997).

Throughout the UK and mainland Europe guidelines for the prevention and treatment of pressure ulcers have been produced in different languages for professionals, carers and patients (European Pressure Ulcer Advisory Panel 1998).

Leg ulcers

Leg ulceration is a common clinical problem, affecting between 1 and 2% of the population (Doughty et al 2000). Essentially a community-based problem, the day-to-day care of patients with these wounds is usually undertaken in the community by district and practice nurses, supported by GPs. The major cause of leg ulceration in the UK is chronic venous insufficiency associated with venous hypertension (70–75%). Between 20 and 30% of patients with a leg ulcer have some degree of ischaemia, with diabetes, vasculitis and trauma accounting for other causes of leg ulceration (Collier 1999).

One of the most important stages in the assessment of these patients is to diagnose the aetiology of the ulcer, as this dictates the most appropriate method of management. Such diagnosis is achieved by conducting a lower limb assessment in conjunction with the use of a hand-held Doppler (Morison & Moffatt 1997, Doughty et al 2000) (see Box 23.9 and p. 853).

Venous stasis leg ulcers

This is the most commonly encountered group of leg ulcers, occurring frequently in older female patients. Damage to the veins deep in the calf causes incompetence of the perforators, the veins which link the deep and superficial veins in the calf (see Fig. 23.5).

Drainage of the skin in the lower leg is affected, leading to oedema, induration and pigmentation. Fibrin is laid

Box 23.9

How to take the ankle pressure index

- Lay the patient flat and allow the patient to rest quietly for 20 min. This is necessary to eliminate the effects of gravity on the legs
- Place the sphygmomanometer cuff on the upper arm, and apply gel over the brachial artery. Hold the Doppler probe at a 45° angle and measure the systolic pressure
- Place the sphygmomanometer cuff around the malleolus (should the ulcer be sited here, place the cuff above the ulcer). Apply gel around either the dorsalis pedis or posterior tibial pulse
- Locate the pulse and inflate the cuff until Doppler sound disappears. Gradually deflate the cuff and, when sound returns, record this as the ankle systolic pressure. The ankle pressure index is calculated by dividing the ankle pressure reading by the brachial pressure reading

Normal ankle pressure index ≥1
Abnormal ankle pressure index ≤1
If ankle pressure index is ≤0.8, the arterial impairment is likely to be significant

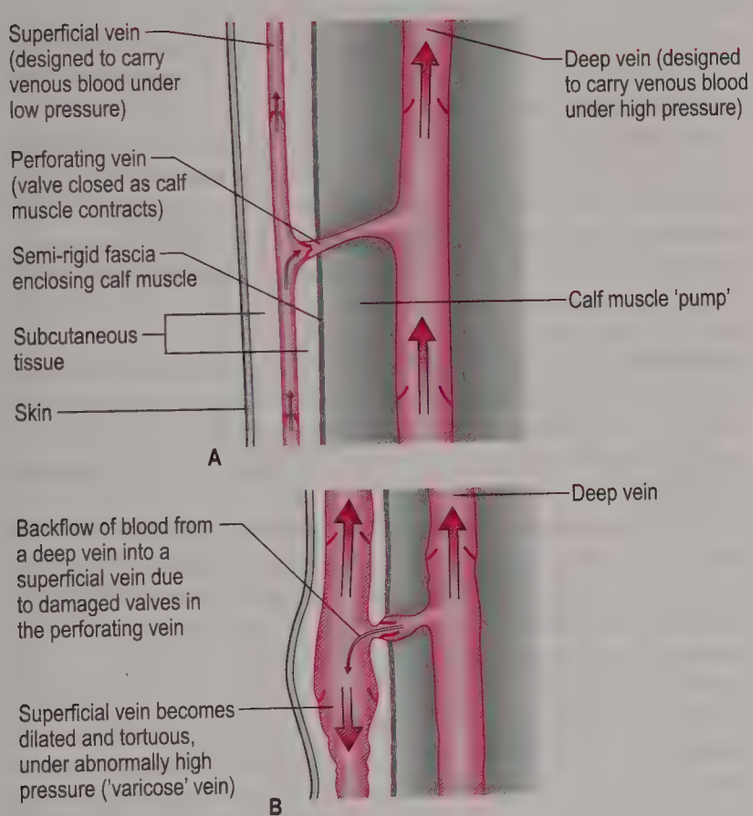

Fig. 23.5 A: Healthy, intact valves prevent backflow of blood from the deep to the superficial veins. B: An incompetent valve in a perforating vein allows backflow of blood from the deep to the superficial venous system.

down around the capillaries in this area, which interferes with oxygen diffusion into the tissues. Following this, any knock or minor injury to the lower leg leads rapidly to breakdown of the skin and ulceration. Most commonly, ulceration occurs around the medial malleolus; the ulcers are shallow and pain is not usually a factor. A typical past history reveals previous phlebitis, deep vein thrombosis (DVT), leg fracture or severe leg injury, or varicose veins.

It can take many months for venous ulcers to heal. Due to the poor condition of the tissues, ulceration can recur and these patients need to wear compression stockings, even after healing, to help maintain drainage of the affected limb.

For further reading, see the European Wound Management Association position document on understanding compression therapy (2003).

Assessment One of the primary aims of assessment in a patient with a leg ulcer is to determine the cause. This is frequently undertaken by both the nurse and doctor working together as part of the primary health care team. Assessment includes:

- taking a comprehensive medical history which might indicate the presence of venous disease, e.g. history of previous DVT, venous claudication, previous vein surgery or pelvic trauma
- undertaking a thorough clinical examination to support the medical history
- undertaking the appropriate investigations: a Doppler assessment will give the ankle pressure index (see Box 23.9) but other investigations may include haemoglobin to exclude anaemia, ESR to indicate the presence of infection, glucose levels to exclude diabetes mellitus, and wound swab where infection is suspected.

Management

Bandaging The most important component in the treatment of venous stasis ulcers is the control of oedema by compression bandages or support stockings (Morison & Moffatt 1997). Compression bandages are designed to give a graduated compression that provides more support at the ankle and less at the knee, to compensate for the failure of the perforators in the leg. The bandages need to be worn constantly during the day when the patient is walking and upright, to reduce oedema. It may be necessary to prescribe diuretics to assist drainage of oedema.

The principles of compression bandaging are to:

- bandage from toes to below the knee (see Fig. 23.6)
- apply graduated compression by applying even tension to a compression bandage; more pressure is applied to the ankle and less as the circumference of the leg increases to the knee — 30–40 mmHg of pressure may be required at the ankle, graduating to 15–20 mmHg below the knee (Morison & Moffatt 1997)
- maintain the level of compression
- ensure that the bandage/stocking does not slip, causing constriction of the limb (Morison & Moffatt 1997, European Wound Management Association 2003).

The pressure exerted by a bandaging system can be calculated using Laplace's law (see Box 23.10).

Selection of a bandage depends on the amount of compression required. Three grades of compression bandage are available:

- grade I provides very light compression or support for mild oedema

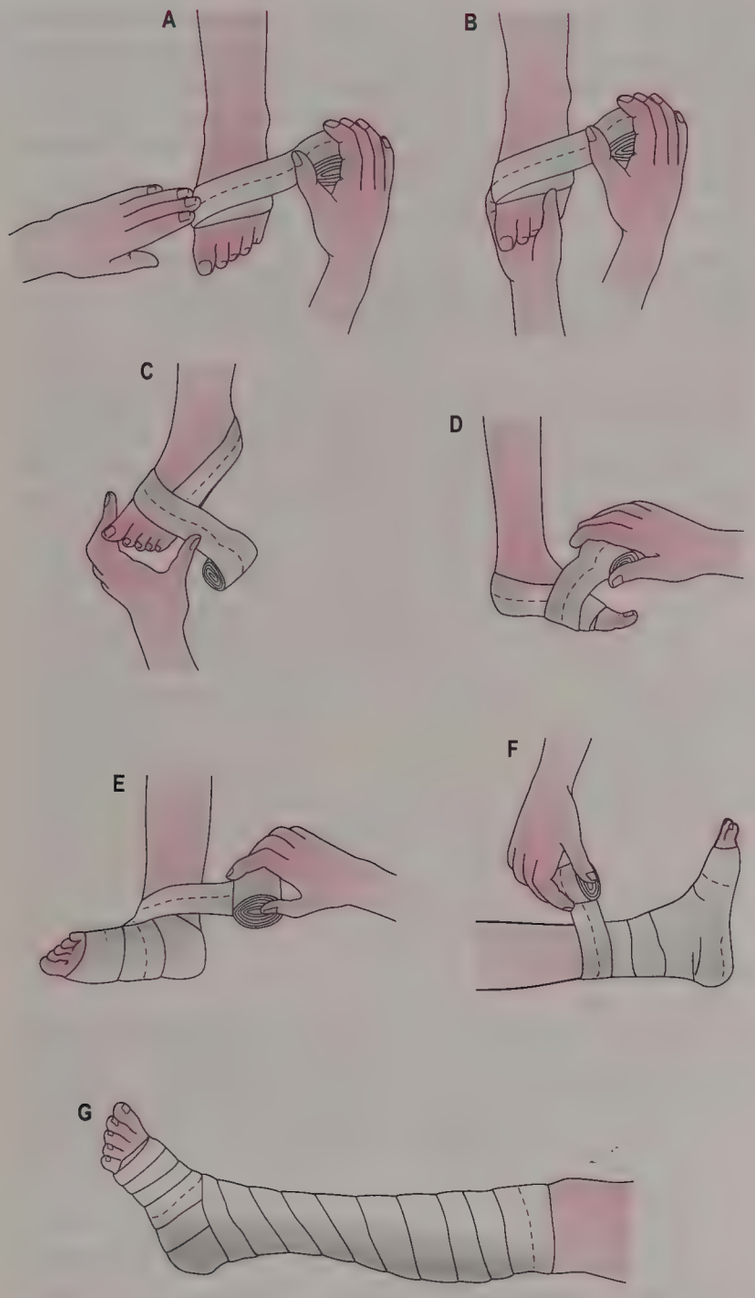

Fig. 23.6 Elastic web bandage. A: Start bandage on the inner side of the sole of the foot, with the lower edge of bandage at the root of the toes. Turn 1½ times round the foot. B: The thumb fixes the bandage for the start of the turn around the heel. C: View from the outer side of the foot. Thumb and finger hold bandage in place prior to completing turn around base of toes. D: View from the inner side of the foot. E: View from the outer side of the foot. Continuation of the bandaging, keeping lower edge of the bandage along red or blue line of the previous turn. F: View from the outer side of the foot. Tension used is about half the full stretch of the bandage. G: View from the outer side of the leg. Note the position of the final turn of bandage immediately below the knee. (Reproduced with permission from Ryan 1991.)

- grade II provides moderate compression at the ankle of between 18 and 24 mmHg
- grade III provides strong compression, giving between 25 and 35 mmHg at the ankle.

Control of infection Where pain, cellulitis, erythema, enlarging of the ulcer and purulent discharge occur, antibiotics may be necessary to control the infection. These should be administered systemically. Superficial infection can sometimes be controlled by the topical application of an antiseptic.

Box 23.10

Formula for calculating the pressure exerted by a bandaging system

$$P = \frac{T \times N \times \text{constant}}{C \times W}$$

P = sub-bandage pressure
T = tension
N = number of layers
C = limb circumference
W = width of bandage

Reproduced with permission from Morison & Moffatt (1997).

Physiotherapy Exercises to stimulate the calf muscle pump, which assists venous return, can be taught to each patient, and these are encouraged regularly throughout the day to stimulate circulation and aid drainage of the lower legs. Some period of leg elevation should also be encouraged around the middle of the day, again to allow drainage of the lower legs.

Dressings Dressing management should be carefully considered once the factors outlined above have been successfully tackled. The ulcer should be assessed as for wounds (p. 842) and the appropriate material then selected (p. 846). Caution should be exercised with dressings and lotions as these patients quickly develop sensitivities to many of the commonly used products. The simplest treatments should be used first: non- or low adherent textile dressings, with hydrocolloid, alginate, impregnated textile dressings and foam dressings having a useful role when used in combination with an appropriate compression bandage.

A comprehensive patient assessment should aim to result in a complete treatment package. A suitable wound contact dressing and skin care combined with adequate compression therapy, physiotherapy and education are likely to produce the best patient outcomes.

Arterial ulcers

These are often the result of arteriosclerosis (Doughty et al 2000) of the lower leg and the underlying disease processes are different from venous disease (see Table 23.8). Arteriosclerosis may occur anywhere throughout the arterial circulation, causing narrowing and occlusion due to calcification of the artery wall. Damage to the arteries supplying the leg can be caused by vascular disease and this gradually occludes and blocks them. Additionally, infarction of smaller arteries is caused by embolus formation, which causes ischaemia in the area of skin normally supplied by that artery. What follows is a very rapid breakdown of the skin.

The characteristics of these ulcers are a history of intermittent claudication and rapid onset of a deep ulcer that is often extremely painful. Relief is gained by lowering the

Table 23.8 Characteristics of venous and arterial disease of the lower limb

Characteristic	Venous disease	Arterial disease
Site of ulcer	Around the 'garter' area, commonly above the medial malleolus	Anywhere on the lower limb including the foot, but commonly affecting the toes
Depth of ulcer	Shallow and spreading	Deep, with a punched-out appearance
Presence of oedema	Common, due to poor venous return	Often not detected
Onset	Gradual, unless precipitated by trauma	Rapid
Pain	Often uncomfortable, nagging in character	Pain on elevation of limb relieved by lowering it (the blood flow is increased when the limb is in the dependent position). The pain of ischaemia can be unremitting
Temperature of foot	Warm and well perfused	Cool or cold and poorly perfused
Condition of the skin surrounding the ulcer	Lipodermatosclerosis present Varicose eczema	
Ankle pressure index	>0.8	<0.8

affected limb and hanging it over the edge of the bed or chair. These patients rarely go to bed to sleep, or if they do, they have to get up in the night because of the pain. They tend to sleep in a chair, which allows the affected limb to hang down, thus optimising the blood supply.

These ulcers can occur anywhere on the lower leg, but usually present on the foot and lateral aspect of the lower leg. Foot pulses are often absent or very difficult to palpate. Doppler assessment reveals a pressure index of below 0.8. The patient may also have a history of cardiovascular disease, typically hypertension, myocardial infarction, strokes or transient ischaemic attacks.

Management Surgical intervention may be necessary to improve the circulation through reconstruction of vessels or to debride dead tissue within the ulcer, and skin grafting may be considered. Light bandaging only is applied to keep a dressing in place; compression is to be avoided at all costs as this would further impede an already poor blood supply to the area.

Healing of these wounds is slow and the prognosis for eventual healing often poor. Treatment aims to keep the patient as comfortable as possible and to achieve debridement and cleansing where necessary. Useful dressings include alginate sheets, medicated dressings and hydrogel sheets.

Mixed aetiology ulcers

Around 20% of venous ulcers also have a significant arterial blood supply deficiency (Morison & Moffatt 1997). This further complicates management, as control of oedema is needed but without restricting the already poor blood supply.

Diagnosis Accurate diagnosis is fundamental to successful treatment. Those giving care should be absolutely certain of exactly what the aetiology of the ulcer is before any type of treatment begins. Lower limb assessment together with Doppler assessment (p. 853) will assist diagnosis (Doughty et al 2000). Clearly, if arterial problems are allowed to go unrecognised and strong compression bandaging applied, treatment will not only be ineffective but could also cause the patient harm. Information on other types of leg ulcer is summarised in Box 23.11.

Patient education

Individual education regarding wound management can have a dramatic effect on progress. This aspect of care is particularly appropriate in patients with leg ulcers, especially venous leg ulcers, as unless these patients know the cause of their ulcer, they may not comply with treatment. Leg exercises, leg elevation and the need for adequate

Box 23.11

Other types of leg ulcer accounting for between 2 and 5% of lower limb ulcers

- *Vasculitic ulcers* — these are due to connective tissue disease, e.g. rheumatoid arthritis, scleroderma, and also occur on the lower leg. They are unusual and extremely difficult to manage due to the underlying disease process and the medication that these patients require.
- *Diabetic ulcers* — these occur most commonly on the foot. Again, due to the general condition of the patient, they heal slowly. It is worth noting that people with diabetes mellitus may give a falsely high reading on Doppler assessment due to peripheral hypertension. The management of rheumatoid and diabetic ulcers is generally under specialist care and treatment is prescribed by the individual consultant.
- *Traumatic ulcers*
- *Miscellaneous causes* — neoplastic and tropical ulcers are examples in this category.

Based on data from Morison & Moffatt (1997) and Doughty et al (2000).

compression are the key factors to success. Without this education the patient is not fully equipped to participate in management of the ulcer. Patient education can be helped by providing patients with leaflets that can be read at home (see Box 23.12).

Box 23.12

An education leaflet for patients with venous ulcers and their carers: how to care for your legs

How long must I keep the dressing and bandage (or stocking) in place?
Wear the support bandages or elastic support stockings as advised by the doctor and nurse. They will make arrangements for your next dressing change.

Do not be tempted to look under the bandage or disturb the dressing in the meantime, as this may delay healing. It is particularly important not to scratch the skin around the ulcer as this skin is easily damaged.

Ask for help AT ONCE if:

- your leg itches excessively, is hot, or more painful than usual
- you feel that the bandage is too tight anywhere
- you lose sensation in your toes, or they turn cold or blue
- you need any other advice.

Contact person:
Contact telephone number:

Can I exercise?
Yes. Exercise is good for your circulation and your general health. If possible, take a gentle walk every day. Even indoors, you can bend and stretch your toes while sitting, and bend, flex and circle your ankles to prevent them from becoming stiff. It is important not to stand still for too long. It is a good idea to do the dishes and the ironing sitting down, if you can obtain a chair of the correct height.

Should I sit with my legs up?
Yes. Sitting with your legs hanging down is almost as bad as standing in one place for too long. You should sit with your legs supported on a stool, on a cushion or pillow, i.e. above the level of your hips. It is also helpful to raise the foot of your bed 9 inches (23 cm) as this aids return of blood from the legs to the heart overnight.

Do I need a special diet?
You do not need a special diet, but try to eat a balanced one that includes protein (meat, fish, eggs), fresh fruit and vegetables. Being overweight does not help the circulation in your legs. Ask the doctor for advice on weight loss if this is a problem for you.

Are there any other ways I can help my legs?
Yes.

- Avoid knocks to your legs, as this could lead to another ulcer.
- Keep your legs warm, but do not sit too close to the fire as this can damage the skin.
- Do not wear anything tight around the tops of your legs, such as garters or girdles, as your circulation will be hindered.
- Stop smoking.

Reproduced with permission from Morison & Moffatt (1997).

Sutured wounds

Although the vast majority of sutured wounds heal without complication, there is a need for careful observation of both the patient and the wound site:

- Observe the patient for changes in vital signs, pulse, temperature, or malaise that could indicate the presence of infection, especially wound infection. Surgical wound infection accounts for 10.7% of all hospital acquired infections (Emmerson et al 1996) and is a major cause of postoperative morbidity.
- Observe the wound area for signs of infection after the initial inflammatory response has passed, i.e. redness, swelling, pain, discharge, heat.

When are the sutures removed? The best time for removal of suture material depends upon a number of factors:

- *The site of the wound* — wounds on the head and neck usually heal within 2 days due to the rich blood supply to the area, whereas wounds on the back may take 10–14 days to heal. The skin here is thicker and less well supplied with blood.
- *Patient variation* — if, during suture removal, the wound begins to gape then the nurse should stop and refer to the surgeon or a nurse specialist for advice. The skin edges can be pulled back together and held for a few more days with paper sutures.
- *Cosmetic considerations* — it should also be noted that leaving sutures in for too long can cause excessive scarring.

In general, the principles for managing sutured wounds are to leave the wound undisturbed and the theatre dressing intact unless either the patient or the wound area begins to develop signs which indicate the presence of infection (Bale & Jones 1997). Disturbing dressings unnecessarily can lead to the entry of bacteria into the wound itself or disturb the newly forming epithelium. Local wound infection can slow down the rate of healing and also increase the amount of scar tissue produced. Careful postoperative observation is important. Ultimately a severe wound infection can spread into the tissues and also the bloodstream, causing septicaemia which could be life threatening (Williams & Leaper 1998).

Traumatic wounds

Patients who present to the emergency department with traumatic wounds need special consideration. These patients may be shocked or have other injuries and their wounds are often contaminated due to the nature of the trauma (see Ch. 27).

These wounds are frequently an irregular shape, with varying degrees of tissue loss (Whiteside & Moorehead 1999). Due to contamination, wound closure is often not attempted (Bale & Leaper 2000). Mechanical cleansing of the wound is undertaken to remove debris such as glass, wood or tarmac. Where wound closure is attempted, antibiotic cover is given to prevent infection, and the patient also needs to be given prophylactic tetanus protection if they are not already covered (Whiteside & Moorehead 1999).

Patients with extensive injuries are admitted for inpatient treatment. However, the majority of patients with wounds are discharged home to be cared for in the community. They may be instructed to care for the wound themselves or asked to return to the emergency department for any dressing changes, or the community nurse may be asked to take over the wound management.

For further information, see Bale & Jones (1997), part 2: intervention.

Malignant wounds

This is one group of wounds where healing is not always the expected outcome of wound management. Carcinomas and sarcomas are most likely to result in ulceration and fungation in the latter stages of the disease (Bale & Harding 2000, Goldberg & McGinn-Byer 2000). Such lesions include fungating carcinoma of the breast, fungating lesions of malignant melanoma and a variety of other non-healing, extending or fungating wounds. Mortimer (1993) has defined the term 'fungating' as describing a malignancy that has ulcerated and infiltrated through the epithelium. Fungating wounds can result either in a protruding growth or in an ulcerating cavity (Carville 1994). These patients are generally managed by a combination of hospital and home care and over a period of time become well known to both agencies.

The growth of tumours is a complex process that controls blood flow and tissue oxygenation (Grocott 1995). Bridel-Nixon (1997) describes the process of fungation as a mixture of concurrent and progressive disease that affects haemostasis, lymph, interstitial and cellular environments. Hypoxia of the tissues causes tissue breakdown and encourages anaerobic and aerobic bacterial growth, producing malodour.

Problems encountered with malignant wounds (see Ch. 31) are as follows:

- *Wound site* — often these wounds are present in an area which is extremely difficult to dress in terms of keeping the dressing in place, e.g. on the chest wall, in the groin and on the lower limb.
- *Exudate production* — the exudate tends to be thick and sticky. Many dressings that do not adhere to other wound types will do so in the presence of this particularly viscous exudate. Hydrogel sheets and gel are very useful dressings for these wounds.
- *Pain* — where nerve endings are exposed, changing dressings and rubbing of dressings can be painful. Keeping the wound covered reduces the irritation to the nerve endings, and using gel dressings reduces pain at dressing changes.

Where healing is not the ultimate aim, wound management should maximise convenience and minimise distress.

For further reading, see Morison et al (1997), Chapter 11.

Burns

The management of burns is a specialised area (see Ch. 30). The treatment given depends on the individual burns unit. However, all follow the same basic principles for management. Treatment will depend on the physical well-being and age of the individual, the area burnt and the depth and extent of the burn.

Psychosocial factors

The presence of a wound will inevitably have some effect on well-being. There may be no difficulty when a wound is small and heals rapidly, but for many patients some degree of anxiety is felt relating to the wound. This can disrupt sleep patterns, increase the perception of pain and even suppress the immune system. In more serious wounds, a disturbance of body image may also cause lasting distress, particularly if the patient is unprepared for this (Wilson 2000).

23.8 How would you help the following patients to overcome their fears and worries?

- An older lady living alone has a chronic venous ulcer requiring frequent dressing by the community nurse. She is increasingly confined to the house.
- A small girl recovering from a hernia repair fears that when the sutures are removed her wound will break open.
- A young woman has been mugged on her way home from work. The knife wound to her face required suturing in the Emergency Department. She has had no opportunity to see the wound and is fearing the worst.

CONCLUSION

The effective management of patients with wounds requires an understanding of the healing process in conjunction with a systematic approach to both assessment and management, and includes:

- assessment of the individual's overall health, taking into account factors which might impair healing
- assessment of the wound
- planning the management of the individual and the wound, taking into account the social and physical environment, and using the most appropriate dressing materials available
- involving the patient, where possible, in wound care
- evaluation and reassessment of the individual until the wound heals or the needs of the patient change.

23.9 Which types of dressing material are available in your hospital/community?

Estimate the cost of dressings needed to manage four different patients for 1 week. Include dressing packs, surgical tapes and lotions as well as the dressing materials themselves.

How much variation is there between the four? Which patient is the most expensive to manage?

23.10 Go to the operating theatre and find out how pressure ulcers are prevented in theatre.

23.11 Go to the hospital pharmacy/chemist's shop to find out how dressing materials are ordered and dispensed. Who decides which products are made available in the hospital?

INTRODUCTION

Having control over urinary and faecal elimination is an expected norm within every society. In all but the very young, incontinence is generally not viewed with sympathy, and the real suffering it causes to individuals and their carers has not received the attention it deserves. Epidemiological research has shown that the number of people suffering from incontinence in some form or other far exceeds the number of cases reported to health professionals. An underlying theme of this chapter is the need to acknowledge the extent of the problem and to promote continence by improving screening practices and raising public and professional awareness of preventive measures against incontinence and of the range of treatments available.

Incontinence is a symptom that is often wrongly labelled as a disease. This chapter describes the underlying conditions that can prevent the acquisition of continence or provoke its loss. It is argued that a sound understanding of the causes and types of incontinence is essential for its proper investigation, treatment and management and that diagnostic assessment must recognise the individuality of each patient. Similarly, where incontinence is intractable, assessment for aids and equipment must be sensitive to the values, needs and priorities of each patient in order to ensure that an optimum quality of life is achieved.

Throughout the chapter the nurse is encouraged to take a positive, problem-solving approach towards this often hidden problem, to assess personal attitudes towards the subject of incontinence, and to base nursing decisions and actions on up-to-date, research-based knowledge.

URINARY CONTINENCE

The acquisition of continence in early childhood is a much valued developmental milestone. In the adult, the ability to control urinary and faecal elimination is largely taken for granted, and a loss of continence will have profound implications for the individual's ability to participate fully within society. While it may be deemed acceptable for a child to have an occasional 'accident', this is not generally the case for adults. The subject of incontinence is one which many people find difficult to discuss openly, and one which is poorly understood.

The onus is on health professionals to foster a change in social attitudes by acquiring a clear understanding of how continence is attained and how incontinence can develop. Nurses can make an important contribution to the promotion of continence among particularly vulnerable groups.

Defining continence

Continence may be defined in terms of the actions and abilities necessary for the appropriate management of urinary and faecal elimination. These include:

- recognising the need to pass urine or faeces
- identifying the correct place to pass urine or faeces
- delaying elimination until the appropriate place is reached
- reaching the correct place
- passing urine or faeces appropriately once a suitable place is reached.

Acquiring continence

Urinary continence cannot be acquired until the physiological systems necessary for micturition have matured. Once the prerequisite physical development has taken place, becoming continent is a matter of imitation, skill attainment and social conditioning.

The anatomy of the bladder is detailed in Chapter 8. The bladder is a simple organ which has a dual function: it acts as a reservoir for urine and it expels urine at the volition of the individual. Urine remains in the bladder as long as the intravesical pressure does not exceed the urethral resistance.

In normal micturition, the contraction of the detrusor muscle of the bladder induces the bladder neck to open while the pelvic floor muscles and the external sphincter relax. For a child to obtain continence they must acquire control of the mechanisms which prevent the bladder from automatically emptying when it is full; this is usually achieved by the age of 3 years.

The neurological control of the bladder at birth involves a simple sacral reflex arc whereby automatic filling and emptying of the bladder are under the control of sacral segments 3 and 4 of the spinal cord. Nerve endings in the bladder wall are activated by urine accumulation. These relay impulses with increasing frequency through the parasympathetic nerves to the spinal cord until the motor parasympathetic nerves react by causing the bladder muscles to contract and the urethral sphincter to open, whereupon reflex emptying occurs.

In order to achieve continence, a child needs to become aware of the sensation of the bladder becoming full and through trial and error attempt to overcome the reflex emptying mechanism by using the pelvic floor to keep the urethral sphincter closed. The sensory tracts of the spinal cord involve the cerebral cortex in the brain to overcome or inhibit the contractions; this requires practice as well as maturation of the central nervous system (see Fig. 24.1).

Continence thus involves the active inhibition of nerve impulses. When micturition is initiated, the brain ceases to send out inhibitory impulses, allowing the spinal reflex arc to be completed. Figure 24.2 illustrates the innervation of the bladder.

'Normal' patterns of micturition can vary markedly from one individual to another. Most people empty their bladder four to six times a day and have a bladder capacity of up to 600 mL; this may be altered, however, by age, fluid intake, medication, perspiration, body temperature, activity and stress. People in a state of anxiety generally feel the need to empty their bladders more often; in the event of acute emotional distress or sudden shock, it is possible for incontinence to occur.

ATTITUDES TOWARDS INCONTINENCE

In modern British society, attitudes towards many previously taboo subjects are rapidly changing. This is particularly evident in the topics that are now permissible within 'polite' conversation, e.g. intercourse, AIDS and homosexuality. Incontinence is also gradually becoming an acceptable subject for open discussion and began to be addressed openly in newspaper and magazine articles, and radio and television programmes from 1985 onwards (Glew 1985, Horsfield 1986, Walker 1987). Indeed today, advertisements for absorbent products fill many magazine pages and television commercials. Nevertheless, certain myths still persist, such as the notion that incontinence is an inevitable consequence of old age, or that wearing pads is the only solution. Such mistaken ideas must be dispelled in favour of seeking the underlying cause of incontinence in each individual case.

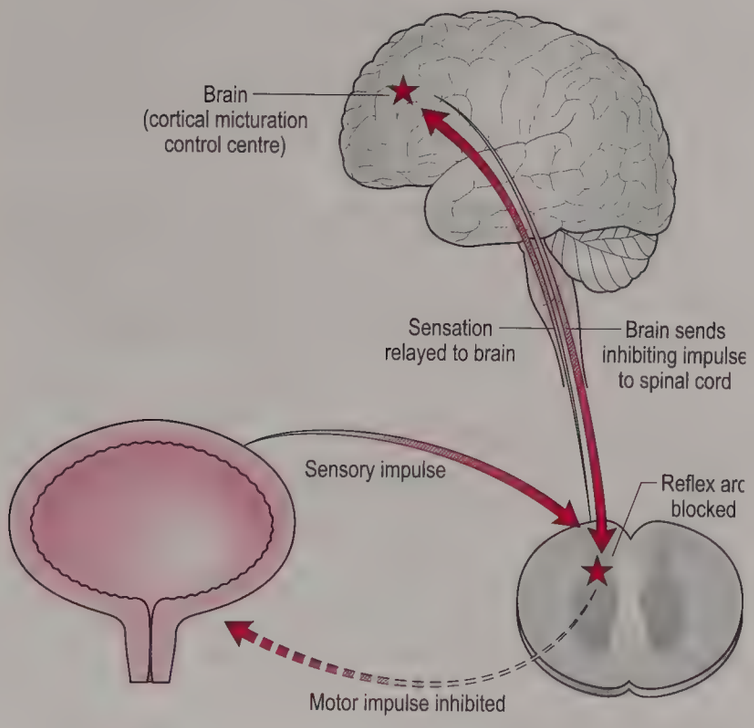

Fig. 24.1 Bladder-filling phase. The brain inhibits the spinal reflex arc. (Reproduced with kind permission from Coloplast.)

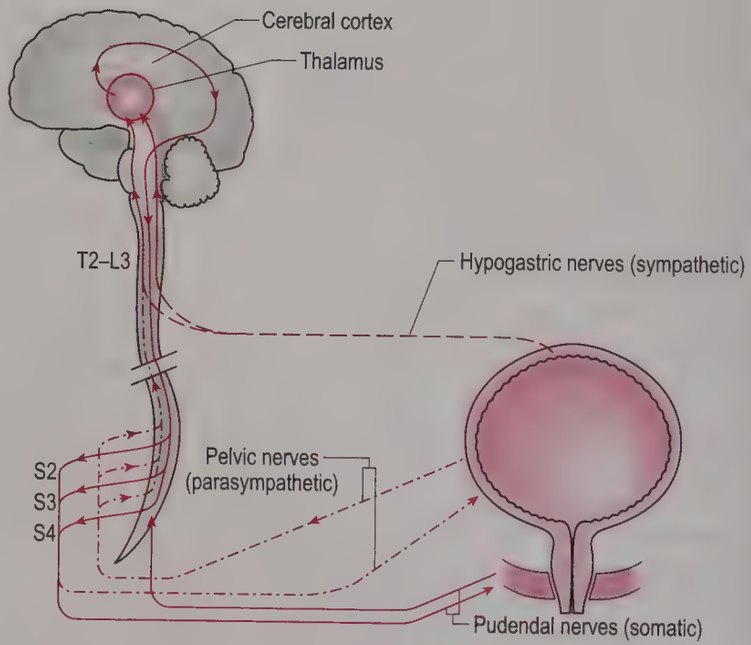

Fig. 24.2 Nerve pathways between the bladder, spine and micturition control centre. NB: nerves supplying the urethra have been omitted for clarity. (Reproduced with kind permission from Coloplast.)

For the nurse, perhaps the best starting point in this process of re-education is an examination of personal attitude to patients' toilet requirements, and what they can do to prevent the onset of incontinence. It has been found that some nurses consider routine or service requirements to be more important than assisting patients to use the toilet (Willis 2000, Morrow 2002, Nazarko 2003a).

Types of incontinence

The International Continence Society (ICS), which has coordinated the publication of a consensus document defining the terminology associated with the lower urinary tract, defines urinary incontinence as 'a condition in which involuntary loss of urine is a social or hygienic problem' (ICS 2002).

Urinary incontinence may take a variety of forms:

- stress incontinence
- urge incontinence
- overflow incontinence
- reflex incontinence
- nocturnal enuresis
- functional incontinence.

It is only when the specific type and cause of an individual's incontinence are known that appropriate treatment can be offered.

Stress incontinence results from a failure of the urethral sphincter to remain closed when a sudden increase in abdominal pressure on the bladder occurs, e.g. during coughing, sneezing or laughing. The weak pelvic floor allows the urethra to descend and the sphincter to open, releasing urine.

Urge incontinence results from the contraction of the detrusor muscle of the bladder as if to void, although the bladder may not be full. This may be caused by overactive detrusor function (motor urgency) or by hypersensitivity (sensory urgency).

Overflow incontinence occurs as a consequence of urinary retention, which may in turn result from:

- an obstruction, e.g. that caused by a tumour, faecal impaction or an enlarged prostate gland
- an underactive detrusor muscle, resulting in a flaccid bladder and thus failure to generate enough pressure to open the urethra
- failure of the urethra to open.

Reflex incontinence may occur as a result of damage to the spinal cord and loss of sensation associated with the desire to micturate, leading to failure to inhibit the simple reflex arc.

Enuresis refers to any involuntary loss of urine. Nocturnal enuresis is the term for urinary incontinence which occurs during sleep, in the absence of any organic disease or infection. Nocturia refers to being woken at night by the urge to pass urine.

Functional incontinence The individual with this type of incontinence would, in favourable circumstances, be able to remain continent but is prevented by pre-existing disease or disability from gaining access to an appropriate place at an appropriate time to pass urine. Diseases which may affect mobility and dexterity, and therefore continence, include multiple sclerosis, spina bifida, arthritis and spinal cord injury. In addition, conditions associated with ageing, such as slowness of movement, pain, joint stiffness, inability to climb stairs or difficulty in manipulating fastenings, may all contribute to incontinence.

EPIDEMIOLOGY

In conducting their seminal research into the prevalence of incontinence, Thomas et al (1980) used the following definition to identify all those in two London health districts over the age of 5 years who were incontinent: 'involuntary excretion or leakage of urine and/or faeces in inappropriate places or at inappropriate times, and production of two or more "accidents" a month or continuous leakage of urine'. This categorisation included individuals with 'long term catheters and urinary diversions'.

In the early stages of the study, this definition was applied to known patients who were already in touch with health and social services agencies. These individuals were monitored over a 1-year period, and the following information was obtained:

Age (years)	*Percentage of incontinence in this sample*
15–64	0.2% in women
	0.1% in men
65+	2.5% in women
	1.3% in men

In an extension of the study, a postal questionnaire was sent to all individuals over the age of 15 on the lists of 12 general practitioners (n = 22 430 patients) and an 89% return was obtained. The results, when compared with those of the first stage of the study, were illuminating, as they revealed a markedly higher incidence of incontinence, as follows:

Age (years)	*Percentage of incontinence in this sample*
15–64	8.5% in women
	1.6% in men
65+	11.6% in women
	6.9% in men

While incontinence was most prevalent among older women, its occurrence was significant across all age groups. Stress incontinence was reported less often by nulliparous than by parous women of all ages, and was especially prevalent among those who had borne four or more children. Urge incontinence also occurred more commonly among parous than nulliparous women. No significant class differences were found among men or women, but individuals of Afro-Caribbean or part Afro-Caribbean descent were more likely to have some form of incontinence than those with an Asian background. Differences have also been found within groups of Asiatic women working in the east end of London (Haggar 1995).

The most important finding of the study, however, was the 1:10 ratio of known to unknown cases of incontinence. This suggests that for every incontinent person who is

known to health or social services professionals, there are 10 others who are unidentified. As further in-depth interviews revealed, many people try to 'cope' with moderate to severe problems of incontinence without professional support. These findings identify the need for health care workers to take advantage of all appropriate opportunities in hospital or community care settings to identify those who require assessment and treatment for incontinence.

Brocklehurst (1993), in an analysis of a MORI poll, suggested that there has been some improvement in the number of people coming forward for help. Annual national awareness campaigns coordinated by the Department of Health and the Continence Foundation since 1994, the Continence Foundation helpline in London and the Continence Resource Centre in Glasgow all help to direct people to the professional services that they need by helping to remove the stigma in talking about the problem (Association for Continence Advice 2000).

Data presented by the Royal College of Physicians (1995) showed an increase in the number of people with incontinence, but this may be evidence of more people coming forward for help or admitting to the problem.

Surveys of health care institutions and social services homes between 1964 and 1986 showed a high prevalence of incontinence; however, it has been suggested that this was to some extent a consequence of the quality of care given. A high failure rate in addressing the problems of incontinence was apparent and this was attributed to insufficient knowledge (Townsend 1964, Egan et al 1983, Edginton et al 1986). In 1995, Peet et al found that 44% of residents in long-term care were incontinent, which suggests that despite the evidence gathered over several decades there had been little improvement in practice. The Audit Commission (1999), when auditing first assessments by community nurses, found that district nurses were primarily assessing incontinent patients for absorbent products rather than assessing their incontinence with a view to improved management or regaining continence.

The implication of these research findings is that there is a need not only to identify patients who are incontinent, but also to improve public and professional understanding of incontinence, to evaluate services available for those requiring assessment and to improve methods of treatment and management (Scottish Intercollegiate Guidelines Network (SIGN) 2004).

Continence care is an area which lends itself to nursing initiatives and there are some excellent nurse-led projects being established throughout the country. In 2002, the *Nursing Times* award in the privacy and dignity category was awarded to a nurse-led, community continence assessment clinic (Armstrong 2003).

24.1 Determine how many patients in your ward or on your community caseload are incontinent.

24.2 What percentage of your caseload does this represent?

24.3 To the best of your knowledge, how many of those who are incontinent have been fully investigated?

24.4 From what you have been told, try to identify the type of incontinence suffered by each person.

24.5 Compare your findings with the prevalence figures quoted in Peet et al (1995) or the Royal College of Physicians (1995).

24.6 Discuss your findings with a senior member of staff in your working area.

Sociological factors in underreporting of incontinence

The fact that incontinence remains to such a large extent a hidden problem among the general population can be attributed in part to the embarrassment felt by many people, leading to reluctance to admit to their incontinence and seek treatment (Mason et al 2001). Several authors agree that the more severe the incontinence, the more likely a patient is to seek medical help (Roe et al 1999, Shaw 2001). However the severity of the symptoms is only one factor which influences the patient in their choice to seek help or to hide their condition. Shaw (2001) identifies other factors which influence this decision:

- Lack of knowledge of causes, not considering incontinence to be a medical problem.
- Lack of knowledge of treatment options, not aware that the condition is amenable to cure.
- Belief that incontinence is a long-term condition related to age and parity.
- Previous experience or experience of friends/family.
- Variation of approach due to ethnic background and different attitudes to discussing such intimate problems.
- Personality of the individual and their relationship with individuals in their health care team.

The fact that it is 'comparatively rare for someone to decide in favour of or against a visit to the surgery without discussing his or her symptoms with others' — Freidson (1970) refers to this as 'a lay referral system' — may go some way towards explaining why incontinence is underreported. Many people prefer not to mention their incontinence to others; indeed Roe et al (1999) found that only 25% of one sample had discussed their incontinence with a friend, and so the opportunity for friends to encourage them to seek advice did not arise. Moreover, it may also be true that, in the case of women, the private and, to some degree, secretive management of menstruation gives an easily transferable model of management to follow should incontinence develop. Many women conceal the leakage of urine as they have concealed menstruation previously.

For many people, incontinence is a source of embarrassment or shame rather than a signal to them that they should seek medical help. The dysfunction is seen mainly in terms of its social consequences rather than as a symptom of a possible underlying illness or disease process.

Personal and social attitudes towards incontinence are not, however, the only factors that account for the underreporting of this widespread health problem. The way that particular health services are marketed or presented can also influence an individual's decision whether to seek help or cope on their own. In the words of one patient, 'I would find it too embarrassing to go to a special clinic ... perhaps a home visitor would be more helpful' (Association for Continence Advice 2000).

It is therefore important that available services reflect positive approaches to the promotion of continence, and progress on this is demonstrated in the setting of standards by nurses and monitoring of services and treatment.

In England and Wales, the Department of Health issued guidance to the NHS called *Good Practice in Continence Services* (DH 2000). This guidance included targets for health authorities for both inpatient and community care. The guidance has also influenced the content of the National Service Frameworks for Older People (see Ch. 35).

In Scotland, NHS Quality Improvement Scotland (NHSQIS) took a different approach in developing *Best Practice Statements for Adults with Urinary Dysfunction* (Nursing and Midwifery Practice Development Unit (NMPDU) 2002) and *Urinary Catheterization and Catheter Care* (NHSQIS 2004). NHSQIS has also published an evidence-based guideline on the *Management of Urinary Incontinence in Primary Care* (SIGN 2004). These publications have been widely disseminated through practice development initiatives to the NHS, general practice and the private care home sector. All these publications are available on the NHSQIS website (see 'Useful websites and addresses', p. 882).

In line with patient charter initiatives, a *Charter for Continence* was developed by a group of professional organisations in 1995 (see Box 24.1). This approach to involving patients has been strengthened by including patients on all the working parties for national continence publications, and including sections on patient information in those publications.

Box 24.1

Charter for Continence*

The Charter for Continence presents the specific needs and rights of people with bladder or bowel problems. It outlines the resources available and the standards of care that can be expected.

As a person with bladder or bowel problems you have the right to:

- Be treated with sensitivity and understanding
- Become continent if achievable
- Receive a thorough individual assessment of your condition by a doctor or nurse knowledgeable in this aspect of care
- Request specialist advice about continence care
- Be provided with a clear explanation of your diagnosis
- Participate in a full discussion of treatment options, their advantages and disadvantages
- Be provided with full, impartial information on the range of products which are available and how to obtain them
- Expect products to have clear instructions for use
- Receive regular reviews of treatment and be given the opportunity to change treatments if your condition has changed
- Be made aware of any treatments or products as they become available
- Be provided with a personal contact point able to give you ongoing advice and support.

*Developed by The Continence Foundation, InconTact, Association for Continence Advice (ACA), the RCN Continence Care Forum, Education and Resources for Improving Childhood Continence (ERIC), the Spinal Injuries Association and the Multiple Sclerosis Society. (Produced by an educational grant from Bard Ltd, March 1995.)

The Cochrane Urinary and Faecal Incontinence Review Group (CURE), based at the University of Aberdeen, maintains and disseminates systematic reviews of the effectiveness of the interventions for incontinence, including prevention, treatment and rehabilitation, concentrating on randomised controlled trials. Publications developed by this group can be accessed via the NHS Scotland e-library (see 'Useful websites and addresses', p. 882).

Care pathways, a process approach to managing integrated patient-focused care, have been designed to improve quality and standards of care for all incontinent people (Bayliss et al 1998, Cherry 2000).

An audit package, *Promoting Continence*, has been developed by the Royal College of Physicians (1998) which can be used for assessing continence care in relation to a single patient, multiple patients or for a facility audit. It covers urinary incontinence, faecal incontinence and urethral catheter management, and is intended to encourage staff to reflect on their management of incontinence and to consider areas where standards of care could be improved.

Identifying patients

Most people who are incontinent do not regard themselves as ill. It is therefore incumbent upon nurses and other professionals working in hospitals and the community to take advantage of every opportunity to identify those who are suffering in silence. Table 24.1 outlines potential opportunities for professionals to identify patients with continence problems and demonstrates that it is not always medical professionals who have the greatest opportunity to help these individuals. This supports the view that non-medical professionals and others should become better informed about this aspect of health. Pharmacists and home carers, to choose two very different examples, are well placed to provide information and foster positive attitudes towards treatment and should therefore be included in educational initiatives to promote continence.

PRIMARY REASONS FOR INCONTINENCE

Delay in achieving continence

In childhood, the acquisition of the skills necessary to achieve continence may be delayed. Nocturnal enuresis may present as a primary or secondary feature; its cause is not known. Although for many sufferers it often spontaneously resolves, it is sometimes not resolved during childhood. In such cases, if it remains untreated, it may be a problem throughout life (Butler 1994, Hjalmas et al 2004). The NHS Centre for Reviews and Dissemination (1997) published a systematic review of the effectiveness of interventions for managing childhood enuresis. Its impact on both individual and family has been researched by Morrison et al (2000).

Sometimes learning difficulties will prevent a person from attaining continence. Professionals working with individuals with learning difficulties, however, should base their interventions on the assumption that, although the process of toilet training may be slow, continence will eventually be achieved provided interventions are tailored to the individual and their family's requirements (Rogers 1998). Physical difficulties can also hinder the acquisition

Table 24.1 Lifespan opportunities for helping people who are incontinent

Lifespan stage	Potential problem areas	Sources of help: Nurses	Sources of help: Others
Childhood	Toilet training Enuresis Urinary control Learning disability Ureteric reflux	Health visitor, practice nurse, school nurse, community learning disability nurse, nursery nurse, community paediatric nurse	Doctor, consultant, dietitian, social worker, teachers
Teenager	Enuresis Sex education Cystitis	Health visitor, school nurse/matron, family planning nurse	Teachers, health educator
Pregnancy, childbirth	Antenatal frequency Difficult birth — tissue/nerve injuries, postnatal stress incontinence	Health visitor, midwife, district nurse	GP, physiotherapist, gynaecologist, obstetrician, self-help groups, pharmacist
Adulthood and hormone changes	Symptoms of incontinence from urological, gynaecological, neurological, psychological conditions	Continence advisor, practice nurse, clinic nurse, district nurse, health visitor, outpatients/occupational health nurse, specialist ward or urodynamics nurse	Urologist, neurologist, psychologist, physiotherapist, occupational therapist, dietitian, GP
Old age	As above, combined with the ageing process, prostatic enlargement and disability	District nurse, health visitor, practice nurse, day/ward nurse, older people's nurse	Home help, home carers, social workers and aides, GP, senior citizens advisors, consultant in medicine for older people

Reproduced with kind permission from the Continence Foundation.

of continence. Some children are incapable of acquiring continence, without medical intervention, because of spinal lesions, as in spina bifida, or other congenital conditions. A baby who is continuously wet should always be investigated for either congenital fistula or failure to empty the bladder. Such symptoms should be taken seriously. Ureteric reflux caused by failure of the bladder to empty will put pressure on the kidneys and may ultimately lead to renal failure.

Problems in maintaining continence

Childbirth Giving birth can cause damage to the mother's pudendal nerve, preventing the tone of the pelvic floor muscles from returning to normal. Van Kessel et al (2001) suggest that prolonged second-stage labour and the use of forceps put mothers at particular risk of incontinence.

Chronic disorders Cerebral, nerve or muscle damage can have varying effects on continence, as can trauma and damage resulting from injury or accident (see Fig. 24.3). Tumours or growths in the area of the bladder or cauda equina are also contributory factors, as is constipation.

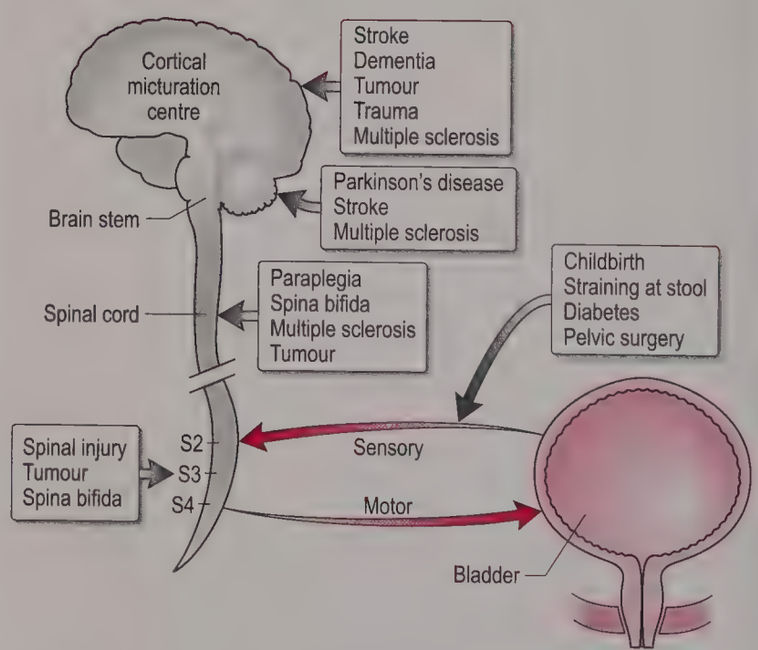

Fig. 24.3 Possible neurogenic causes of incontinence. (Reproduced with kind permission from Coloplast.)

Medications Many medications, especially diuretics, can have an effect on the bladder and its function. They may cause incontinence because of the sheer volume of output that they induce, and because of the demands they place on individuals with limited mobility in reaching an appropriate place where they can pass urine in time.

The sedative and diuretic effects of alcohol can contribute to incontinence. Sedatives and hypnotics make people less responsive to signals from the bladder. Antimuscarinic medications and others with some antimuscarinic action, such as phenothiazines and antidepressants, can cause retention in people with previously normal bladder function. Beta-blockers generate a variety of urinary dysfunctions.

For further information, see Greenstein & Gould (2004).

The effects of ageing Age can affect an individual's ability to maintain continence. It should be emphasised, however, that while incontinence is more prevalent among older people (especially women), it is not an inevitable consequence of ageing (Heath & Schofield 1999). The prevalence rates previously discussed cite the prevalence of incontinence in care home residents as 44% (Peet at al 1995) so even in this frail older population more than 50% remain continent. With age comes an increasing degeneration of the glomeruli in the kidneys; their function is reduced by up to 50% by the age of 80, thus impairing the ability of the kidney to concentrate urine. This consequence of ageing occurs alongside a decrease in the bladder's urine-storing capacity (Hald & Horn 1998).

The failure of ageing kidneys to eliminate sufficient waste products from the body during the day means that at night they remain very active. This results in an increased nocturnal output of urine leading to a change in the individual's pattern of micturition.

Ageing may also have some effect on the cerebral control of micturition, through the diminishing of cell function.

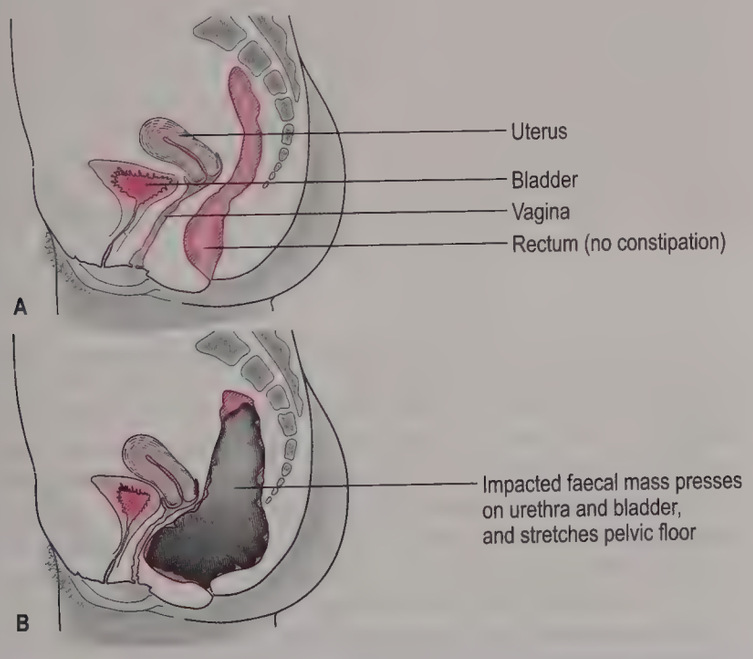

Fig. 24.4 How constipation can cause incontinence. Female, side view. (A): Normal. (B): Impacted. (Reproduced with kind permission from Coloplast.)

Ageing of the cerebral cortical neurones can reduce their effectiveness in inhibiting the sacral reflex arc, so that involuntary emptying of the bladder occurs.

In older women, vaginal dryness, soreness and atrophic changes may give a number of clues as to why incontinence has developed. Glycosuria or atrophic changes in the vulva may lead to vaginitis and urethritis (note that the lining of the vagina is continuous with that of the urethra). After the menopause, hormonal changes resulting in a decrease of oestrogen can cause dryness in the vagina and urethra. This may interfere with functioning of the moist seal of the urethral sphincter, thus allowing urine to leak through (International Continence Society 2002).

Constipation can also lead to urinary incontinence. Because of the anatomical proximity of the rectum and the urethra, it is possible for the urethra to be closed off by a faecal mass (see Fig. 24.4). This can result in incomplete voiding and thus stasis of urine, which in turn can encourage growth of bacteria in the bladder. A full rectum and patulous anus are signs of constipation.

PROMOTING CONTINENCE: A PROBLEM-SOLVING APPROACH

The problem-solving approach to nursing intervention consists of four stages:

1. Identifying the problem through assessment
2. Setting goals
3. Implementing care or treatment
4. Evaluating outcomes to ascertain that the goals have been achieved.

Involvement of the patient in all aspects of the nursing process will help to improve motivation and willingness to agree to treatment and will enhance the patient's feeling of independence and self-esteem.

Assessment

Assessment should be carried out in a manner which respects the patient's privacy and dignity (Armstrong 2003) with reference to a professionally agreed protocol and be tailored to the individual (SIGN 2004). It is vital that this assessment is conducted with a view to ascertaining the cause of any incontinence, for only then can the correct type of treatment be instigated (NMPDU 2002). In collecting information from patients, the nurse must have a clear understanding of the rationale behind the questions asked and of the implications for diagnosis and treatment of the patient's responses (see Table 24.2).

A full assessment should include:

- the patient's own account of the problem
- a detailed history, using closed and open-ended questions
- recording of micturition and incontinence over a few days
- physical examination by a competent professional
- urine testing
- further investigations as required.

Assessment should take place in a private setting and allow adequate time for the patient to air concerns and ask questions.

Table 24.2 Incontinence assessment questions

Question	Rationale
How long have these symptoms been present?	The symptoms may have begun at a life crisis or on taking a new medication, or they may have been a long-standing problem, but some new development has prompted the patient to ask for help
Are you wet every time?	It is important to establish the degree and frequency of wetting
How many times do you pass water each day?	A baseline needs to be established in order for progress to be charted
Are you wet at night as well as by day?	This gives an indication of the degree of the problem as well as the type of incontinence
Are you aware of the need to go to the toilet before you are wet?	This will determine whether signals are normal or absent
Do you have feelings of urgency to go to the toilet?	This indicates whether signals are present and their degree of urgency
Do you lose urine if you laugh, cough, jump or run?	A positive response often indicates genuine stress incontinence
Do you pass small amounts of urine?	Passing small amounts of urine may be due to urge, stress or overflow incontinence. It may also be indicative of reduced fluid intake
Do you pass a full stream?	Passing a full stream suggests the bladder capacity is normal
Is the stream of urine poor?	The flow rate may indicate a degree of obstruction or the bladder's inability to contract
Does passing urine sting?	Stinging urine usually indicates infection or a sore or broken area
Does the urine have a strong smell?	Urine invaded with bacteria or concentrated often has a strong smell
Do you have difficulty in starting to pass urine?	Hesitancy may be caused by an obstruction, e.g. prostatic enlargement
Do you dribble urine before or after going to the toilet?	Dribbling before suggests overflow; dribbling after suggests a failure to completely empty the bladder or an incompetent sphincter
Do you need to use pads or other aids, and if so how many and how often?	The answer may indicate the degree of urine loss
Are you constipated?	Constipation is the most common cause of urinary incontinence
Have you had any operations 'down below' (lower abdomen)?	Surgical trauma may be significant
Have you difficulty in getting to the toilet, problems with undoing clothes or any sight problems?	If the patient has problems with mobility or dexterity, clothes may need to be adapted and toilet seats raised. Supports to steady patients and aids to help them locate the toilet may be required
Are you taking any medication?	Many medications can affect the functioning of the urinary tract
Is the patient mentally aware?	Dementia may be the cause of incontinence due to a failure to remember the routines of the day

Questioning the patient

In order to establish a good rapport with patients, it is important to meet their own agenda when discussing the potentially embarrassing topic of incontinence. Open-ended questions such as 'Tell me about the problems with wetting that you have been having' or 'Could you describe what happens when wetting occurs' will give the patient a greater opportunity to relate the problem in detail than will questions that require a simple 'yes' or 'no' response. Open-ended questions will allow them to set out their own agenda for the interview. However, yes/no questions are useful with patients who are acutely embarrassed and have trouble finding a comfortable vocabulary to describe their problems.

The nurse's choice of language and sensitivity to the patient's preferred terminology will be important to the patient's comfort during the assessment interview. Patients generally use terms such as 'passing water', 'peeing' or 'making water' rather than medical terms such as 'micturition' or 'voiding' and many find words such as 'accidents', 'wetting' or 'leaking' more acceptable than the term 'incontinence'. Where the patient uses a euphemism or is vague, the nurse should seek clarification if there is any danger of misunderstanding, e.g. by asking 'When you said "at it" did you mean "having sex"?' or 'What do you mean by "a little"?'.

More specific questions may be indicated when the patient has a pre-existing illness, e.g. multiple sclerosis, or

where bleeding, pain or discharge has occurred. Obviously, some questions, such as those concerning childbirth or prostate problems, will be gender-specific. Supplementary questions can be asked by means of a written assessment form.

Table 24.2 provides a checklist of questions that can be used during the assessment interview, together with a rationale for each item of information requested. These questions should be posed only after the patient has described their symptoms and has been given the opportunity to articulate their own agenda of concerns.

Charting information

The patient's history may yield enough information to determine the probable type and cause of the incontinence. A baseline chart, recorded over a few days, can confirm the accuracy of the history by supplying information indicating frequency of micturition and incontinence and, where required, the volume of urine passed. Charting such information again at intervals of a few weeks or at the end of treatment will produce a means of evaluating the treatment implemented. Any chart provided should be straightforward and easily understood so that patients are encouraged to use it, as the success of any future treatment will depend upon the patient's motivation. A sample chart which can be photocopied for use is available in the SIGN guideline (2004).

After careful explanation, the patient should be given the chart to fill in for a few days. Discussion concerning keeping the chart easily accessible to the bathroom, but bearing in mind the need for discretion, will help the patient to identify what will work best for them. The times of voiding and times of wetting are the most important pieces of information. Ticking or a range of ++++ may be sufficient to quantify volumes of urine lost. Although cumbersome, before and after weighing of pads is possible if objective testing is required (Groutz et al 2000). The amount of detail requested should be tailored to each patient, to balance the need for as detailed a clinical picture as possible with the patient's ability to understand and complete the chart.

The above approach is advocated for most patients, whether in the hospital or the community. Many specialists in the field of continence care suggest that admission to hospital for a barrage of invasive tests to diagnose the type of incontinence is not required for the majority of patients (SIGN 2004). For many patients, thorough assessment will indicate the likely type, or cause, of the incontinence and a care/treatment plan can be devised.

Physical examination

Women In women, a physical examination can determine whether atrophic vaginal changes, vaginitis or painful excoriation are features, and whether prolapse(s) or constipation is present. In the case of genuine stress incontinence, provocative testing such as asking the patient to cough while they are in a semi-recumbent position may demonstrate leakage. Assessing the ability of the pelvic floor to contract should be undertaken before initiating a pelvic floor muscle re-education programme. Such an assessment should be performed by professionals who have developed the appropriate knowledge and expertise (SIGN 2004).

Men
should be examined for prostate enlargement and to determine whether the bladder is palpable. If the bladder is palpable or the history suggests inability to empty the bladder completely, it may be necessary to ask the patient to pass urine, after which an intermittent catheter can be introduced, or a portable bladder scanner used to assess the residual volume of urine.

Urine testing
A cloudy appearance of the urine and a strong odour are indications of a urinary tract infection. A urine sample should be obtained and tested for further indications of infection, proteinuria, leucocytes or blood. If indicated, a midstream sample should be sent for culture and sensitivity analysis. Routine testing of urine can identify problems which may contribute to incontinence; haematuria, for example, may be an indication of infection, stones in the bladder or tumour. Poorly controlled diabetes mellitus, evidenced by glycosuria, is associated with continence difficulties for a number of reasons:

- Glycosuria itself can irritate the bladder causing bladder spasm.
- The intense thirst which leads diabetic patients to drink excessive amounts of fluid results in the production of large volumes of urine which can overwhelm the bladder's storage ability.
- In the longer term, peripheral neuropathy may result in damage to the nerve endings in the bladder, leading to reduced sensation of bladder filling and reduced ability to block reflex emptying.

Further investigations

Once the type of incontinence has been diagnosed, goals can be set for the patient's achievement or recovery of continence. If the incontinence is of an intractable nature, requiring long-term management rather than cure, further assessment for toileting programmes, aids or equipment will be required. It may be the case that further investigation into the cause of the incontinence is needed and that referral is indicated.

Urodynamics Where the probable cause of incontinence is difficult to establish, or where surgery is being considered, patients are often referred for urodynamic testing. Depending on local protocols, this may be undertaken by a clinical nurse specialist, a urologist or a urogynaecologist.

Urodynamic tests measure the pressure and flow relationships in the bladder and urethra. They can aid diagnosis of the type of incontinence by showing sphincter incompetence, detrusor instability, urethral instability and problems with voiding due to obstruction or an underactive detrusor. The procedures are invasive, unpleasant, potentially very embarrassing, but generally not painful. Clear explanations and psychological support must be given to the patient throughout. Table 24.3 outlines the most common urodynamic investigations; further details can be found on the International Continence Society website (see 'Useful websites and addresses', p. 882).

Radiography Radiographs can reveal signs of stones or large tumours in the bladder and may be required to assess

Table 24.3 Urodynamic investigations

Test	To establish:	Indications
Post void residual urine (PVR)	the volume of urine remaining in the bladder after voiding	Should be done in all patients to exclude incomplete emptying and consequent recurrent infections, or damage to the upper urinary tract
Uroflowmetry	the rate of urine flow via the urethra	Advised for all patients to exclude voiding difficulties
Pressure/flow studies	voiding pressures (related to voiding, not incontinence)	Follow-up from abnormal PVR or uroflowmetry, to distinguish between possible causes, e.g. poor bladder contraction or urethral obstruction
Cystometry	the pressure/volume relationship within the bladder, detrusor activity, bladder capacity and bladder compliance	Basic urodynamic evaluation for patients experiencing incontinence to assess bladder function, especially prior to considering surgery
Urethral pressure profile	the closure pressure within the urethra available to counteract increase in bladder pressure	Suggested, though not proven, for individuals in whom urethral dysfunction is suspected
Leak point pressure	the bladder pressure at which involuntary leakage of urine from the urethra is observed (the rise in bladder pressure may be from detrusor contraction or increased abdominal pressure)	Detrusor leak point pressure estimations allow assessment of risk to the upper urinary tract Abdominal leak point pressure assesses the increase in abdominal pressure which causes stress incontinence, and thus assesses the urethral contribution to continence
Surface electromyography	the efficiency of the pelvic floor muscles during the filling and voiding phases	Limited value in routine urodynamics
Videourodynamics	the simultaneous measurement of pressure and visualisation of anatomy	Useful in patients with a complex history, for example individuals with neurological disease
Ambulatory urodynamic monitoring	leakage, flow rates and bladder and abdominal pressure while the individual is ambulant	Useful to assess therapeutic effects of medication or to establish patterns which can not be exhibited in a clinic

the extent of faecal impaction in the colon and to show any narrowing or obstruction.

Cystoscopy A cystoscope is an instrument fitted with a fine telescope which is introduced via the urethra into the bladder. Modern types of cystoscope are quite flexible and allow the procedure to be carried out with only a local anaesthetic. Cystoscopy allows the urologist the opportunity to inspect the bladder and urethra, observing for tumours, stones, strictures and the condition of the mucosa. Further information on this procedure is given in Chapter 8.

Planning and implementing care

Effective treatment can be implemented only when the type of incontinence has been correctly diagnosed. This may seem obvious, but patients report instances where their incontinence has been dismissed as trivial, something they have to live with rather than a symptom to be thoroughly investigated (Association for Continence Advice 2000).

Treatments for incontinence include advice on diet, fluid and caffeine intake, pelvic floor muscle exercises, bladder retraining, the administration of antimuscarinic medication, clean intermittent self-catheterisation, relieving underlying medical conditions and surgical intervention. These forms of treatment, together with their application in different forms of incontinence, are described below.

Advice on diet, fluid and caffeine intake

Diet should be reviewed in relation to establishing and maintaining a regular bowel habit. The avoidance of constipation will benefit urinary continence as an overfull bowel can distort the anatomical position of both the bladder and the pelvic floor. Many patients are unclear about what constitutes appropriate fluid intake. Some will restrict fluids in the hope of minimising incontinent episodes, others continually top up their cup or glass, generating such large volumes of urine that the bladder is unable to cope. Six to eight cups or glasses of fluid (approximately 250 mL each) in 24 h is appropriate for most people. There is evidence that caffeine increases the number of episodes of incontinence in those with a diagnosis of urge incontinence (Arya et al 2000, Bryant et al 2002).

Pelvic floor muscle exercises

These exercises are primarily intended to increase the strength of the levator ani muscles and to evoke their contraction to support the bladder during an increase in intra-abdominal pressure. In women, assessment of the ability to 'squeeze' the muscles around the vagina and, where appropriate, teaching them how to exercise to improve their muscle tone can counteract any descent of the pelvic floor and help restore the normal anatomical relationships and sphincter function. Figure 24.5 illustrates the anatomy of the muscles of the pelvic floor in women (Sapsford et al 1997).

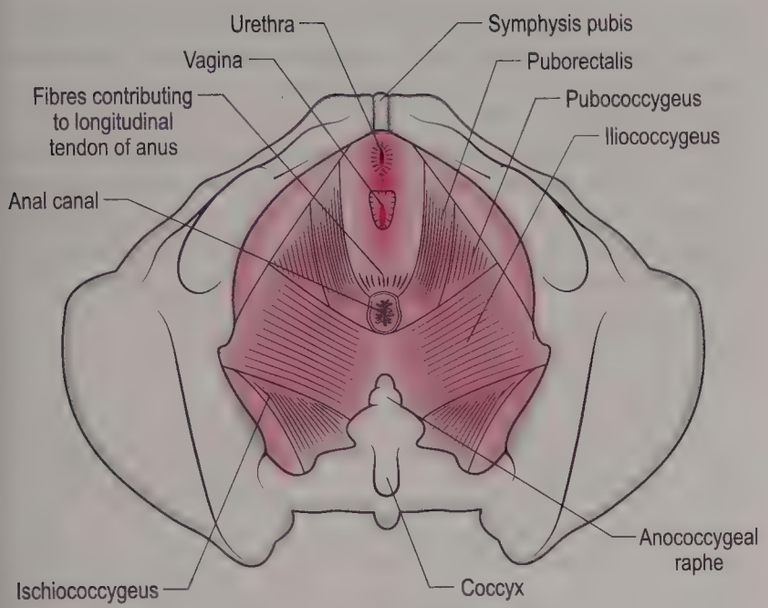

Fig. 24.5 Levator ani, perineal aspect.

Genuine stress incontinence in men or women (see p. 863) is the main problem for which pelvic floor muscle exercises may be used. This type of incontinence occurs when the pelvic floor is unable to counteract a sudden rise in abdominal pressure and allows the urethral sphincter to open, i.e. the intravesical pressure overcomes the intraurethral pressure.

Pelvic floor muscle exercises can also be useful for patients with frequency and urge incontinence. Sitting down when strong 'signals' occur and carrying out pelvic floor muscle contraction can help the patient to overcome the feeling of urgency and encourage the bladder to fill a little more before being emptied in a controlled way.

Pelvic floor muscle exercises are also useful following prostatectomy to stop postmicturition dribble and should be taught preoperatively.

Identifying the pelvic floor muscles Before patients can perform pelvic floor muscle exercises they must be able to identify two specific contractions:

- *the levator ani*, formed of the iliococcygeus, the ischiococcygeus and the pubococcygeus, can be located by imagining the onset of an episode of diarrhoea and the need to tighten the back passage muscle in order to get to the toilet without an accident
- *the pubococcygeus*, the anterior portion of the levator ani (see Fig. 24.5), can be located when passing urine. While in full stream, patients should try to stop, or at least slow, the flow and then try to remember which muscle was used in order to do this. This is only used once to locate the muscle and should not be performed as part of the exercise regimen. Female patients can check their ability to tighten the pelvic floor muscles by placing two fingers in the vagina and squeezing the muscles.

It is essential that patients identify contraction of the correct muscles; bearing down with the pelvic floor will not be of benefit, and may produce adverse results by causing further descent of the pelvic floor.

Motivation and practice In order to encourage compliance, the nurse must ensure that the patient has understood the instructions on performing the exercises and is motivated to practise them. An individual exercise regimen, identifying length of contractions and frequency of repetition, should be developed related to the individual's current muscle strength and opportunities to practise. An unrealistic regimen will be demotivating. Pelvic floor muscle exercises should be performed daily to increase muscle strength and should be performed three to four times weekly in the long term to maintain muscle strength (Laycock et al 2001).

Supplementary techniques Physiotherapists employ a range of equipment and techniques to help patients to overcome stress incontinence. These are detailed in the Chartered Society of Physiotherapy clinical guidelines (Laycock et al 2001).

There are a variety of methods by which the patient can be provided with biofeedback, e.g. digital palpation, manometry or electromyography, which will demonstrate evidence of muscle strength and illustrate any improvement, providing positive reinforcement of the benefit of the exercise regimen.

The use of cones of various weights, which are carried in the vagina, can support the patient in performing pelvic floor muscle exercises. There is no evidence that the use of vaginal cones is more beneficial than pelvic floor muscle exercises alone (SIGN 2004).

Neuromuscular electrical stimulation can be used to initiate muscle contractions, in the absence of a nerve impulse, by stimulating the muscle with a mild electric current. This is beneficial where a patient is unable to perform a voluntary muscle contraction.

Evaluation The success of these conservative approaches to achieving continence may be measured objectively by recording the weight of pads to calculate urine loss, if this is acceptable to the patient, and subjectively by the patient's reports on the perceived improvement in continence or the number of pad changes required per day. The long-term effectiveness of simple interventions such as pelvic floor muscle exercises or bladder retraining was demonstrated by O'Brien and Long (1995) and that of devices by Nygaard (1995).

24.7 While discussing the rehabilitation of her mother following a mild stroke, Mrs M confides to you that she is occasionally wet after lifting her mother. What is your role here and what advice may be given as to treatment?

Bladder retraining

For the patient with urge incontinence, bladder retraining, in conjunction with antimuscarinic medication, is the main treatment. The aim of this form of treatment is for the bladder to 'learn' to increase its capacity and for the urethral sphincter to maintain its ability to remain closed as the bladder fills, thereby lengthening the intervals between voiding.

Method The treatment begins with a baseline measurement of working bladder capacity, i.e. the amount of urine passed, and frequency of voiding at the time of assessment.

In stages, the patient then learns to hold on for a few minutes more between the bladder signal and going to the toilet. As each lengthened interval is achieved and maintained, new objectives are set for the next few days.

Antimuscarinic medication is a useful adjunct to bladder retraining, as it reduces the initial urge to void and thereby helps to increase bladder capacity. When the patient achieves an acceptable social interval between toilet visits, and an adequate bladder capacity, the medication is then reduced and eventually discontinued. Attempts by the patient to maintain the same regimen as when taking the medication are instigated. If the same interval between passing urine is maintained, the treatment is seen as successful.

Antimuscarinic medication is contraindicated in patients with glaucoma (see Ch. 13). The normal side-effect of a dry mouth should be explained to patients using this medication.

Evaluation Whatever the degree of success of the treatment, toileting regimens will remain individual to each patient. In order to evaluate progress, a further continence chart should be completed after a few weeks' treatment and again towards the end of treatment. Comparison of the charts, showing both voiding intervals and quantities, will allow an objective evaluation to be made as to the success of the treatment.

24.8 Mrs C needs to pass urine frequently. She tells you that she has had a 'poor' bladder for about 10 years which often wakes her at night, as well as 'keeping her on the run' during the day. After referral for urodynamics and further investigations, it is confirmed that she has urge incontinence. You are requested to instigate her treatment of a course of antimuscarinic medication and bladder training. What plan of action would you implement?

Clean intermittent self-catheterisation

This technique is employed by patients with voiding difficulties caused by conditions such as an atonic bladder or detrusor–sphincter dyssynergia, in which bladder contraction does not synchronise with opening of the urethral sphincter. It has also been used in conjunction with the passing of 'sounds' for treatment of urethral adhesion or prostate enlargement. Adhesions are often due to healing following infections and an enlarged prostate may restrict the diameter of the urethra. Clean intermittent self-catheterisation has also been of particular benefit to individuals with multiple sclerosis, spina bifida (Bardsley 2000), paraplegia and urinary retention due to prostate enlargement.

Intermittent self-catheterisation is a relatively simple treatment for incontinence, or incomplete bladder emptying, which is known to have been used in ancient times. The ancient Egyptians used reeds as catheters and the ancient Chinese, onion stems. The Roman encyclopaedist, Celsus, mentions the use of catheters in his writings (c. 30 BC) and throughout history catheters of a variety of materials are known to have been in use (Stewart 2001).

Assessment of the suitability of intermittent self-catheterisation for a particular patient must include identification of the specific type of incontinence and an evaluation of the manual dexterity, mental ability and motivation of the individual. Children as well as adults have been successful in learning the technique. In some cases it may be appropriate for partners or family members to be taught to carry out the catheterisation.

The procedure of self-catheterisation simulates normal voiding: the bladder is allowed to fill, the clean catheter is introduced and the bladder is then completely emptied. This prevents the build-up of residual urine in the bladder, which otherwise may cause:

- proliferation of bacteria in the bladder
- damage to the nerve endings
- overflow incontinence
- reflux of urine into the ureters and kidneys which may contribute to ascending infection or increase pressure within the upper urinary tract causing renal damage.

Unlike long-term catheterisation, in which aseptic technique is of paramount importance, intermittent catheterisation may seem unhygienic. However, the clean technique is not associated with bladder infection, as the bladder is completely emptied each time a catheter is passed (NHSQIS 2004).

The clean intermittent self-catheterisation technique requires the patient to be able to identify the urethra. A small catheter without a balloon, a nelaton catheter, is introduced into the bladder several times a day, dependent on individual requirements for assisted bladder emptying. There are two types of nelaton catheter available: prelubricated and non-lubricated.

- The prelubricated catheter often requires the patient to soak it in water for 30 s to activate the lubrication. Prelubricated catheters are for single use only.
- The non-lubricated catheter can be used with or without separate lubrication depending on patient preference. Non-lubricated catheters can be rinsed and reused, for a single patient, for up to a week.

Evaluation Most patients find that inserting the catheter becomes easier with each attempt. The success of the treatment can be measured in terms of the improved quality of life it offers to patients who previously were continually wet or who had to visit hospital emergency departments to seek relief from pain caused by failure to empty their bladder.

24.9 Mrs F, who is 42 years old, has multiple sclerosis. Although she has had symptoms of urge incontinence and frequent bouts of infection, she has now passed into a dyssynergia phase in which large residual volumes of urine occur and clean self-catheterisation is required. She has fairly good manual dexterity. Outline a plan for teaching her self-catheterisation.

Managing symptoms related to underlying medical disorders

Some types of incontinence can be reduced by treating the underlying medical disorder such as constipation, anal fissure and vaginitis.

Relieving constipation Constipation as a causative factor in urinary retention and subsequent incontinence is described on page 879. An investigation of the cause of the constipation must be undertaken, including a review of

medication and concurrent conditions. Diet and exercise/mobility should also be assessed.

Preventing constipation Patients who are prone to constipation should be encouraged to be as active as possible. Requests by older patients to go to the toilet should always be responded to as quickly as possible, in order to ensure that the gastrocolic reflex is never ignored. Once on the toilet the patient should be encouraged to sit for as long as is required. In the patient's home, it may be necessary to undertake structural adaptations to make the toilet more accessible or to install a chemical toilet or commode convenient to the patient's bedroom or sitting room.

A lack of privacy, time or comfort in an institutional care setting can easily interfere with the maintenance of good bowel habits. Where patients share facilities, nurses and carers must apply standards that allow patients to retain dignity and privacy.

Constipation can be prevented by the introduction of adequate fibre or roughage into the diet, in conjunction with an intake of approximately 8 cups of fluid a day. A dental check-up may be necessary to ensure that patients will be able to manage the raw or chewy food typical of a high-fibre diet. Individuals who are forced by dental problems to eat only soft foods will be susceptible to constipation, and therefore particular attention should be paid to their fibre intake, with fibre being added to their diet as required (see Ch. 21).

Confusional states For patients with senile dementia or other confusional states, adherence to a regular routine will help to reinforce the need to go to the toilet at particular times during the day. If a high-roughage diet is encouraged and usual patterns of defaecation maintained, usually 30 min after breakfast, a hot drink or other meals, it should be possible to prevent constipation. Spurious diarrhoea can occur in constipated individuals when the mass of faeces breaks down and mucus and faeces flow away, causing faecal incontinence associated with a characteristic, penetrating smell. It is preferable for patients with dementia to be assisted to the toilet at normal intervals rather than to be asked to adapt to new regimens such as using a commode.

24.10 Mr G has been drawn to your attention because of increasing agitation, exacerbated by what appears as diarrhoea and incontinence of faeces. What aspects of his regimen would be considered in his assessment and what therapies would you implement with his carer to promote continence?

Problems related to bowel evacuation Anal fissures and haemorrhoids need to be soothed and healed in order that constipation caused through pain and avoidance can be prevented. Codeine-based analgesic medication taken over a long period should always be accompanied by a regular laxative to prevent constipation from developing.

Vaginal dryness or vaginitis may be treated with oestrogen creams or oral supplements. Patients should be referred to a doctor if vaginal prolapse or procidentia is evident. For women who are not sexually active and prefer not to have surgery, a ring pessary may be used to correct the uterine displacement. This appliance will need to be changed at intervals of 3–6 months.

Referring patients

It is the responsibility of the nurse to investigate the causes of a patient's incontinence by careful history taking. Nurses in all areas of practice should take responsibility for their patients' continence assessments, as part of a holistic care plan (NMPDU 2002). The findings of the history can then be supplemented with a baseline chart (see p. 867) which records the times that the patient passes urine and/or faeces. Having fully assessed the patient's continence problem, the nurse should be in a position to initiate a plan of care aimed at restoration of continence.

For the nurse who is inexperienced in dealing with the problems of incontinence, a continence advisor or nurse with a specialist interest in continence is a useful resource, and can help the nurse gain confidence to interpret the data obtained from the patient history and the baseline bladder chart.

Should the patient present with a complex history or be unresponsive to the treatment plan, the nurse should arrange referral for specialist assessment from the appropriate professional. This may be a continence advisor, specialist nurse, gynaecologist, urologist, consultant in medicine for older people, physiotherapist, neurologist or psychiatrist.

In a busy surgery or hospital situation, the significance of a patient's incontinence may not be fully appreciated. The nurse, as patient's advocate, should make a case for further investigation, as the individual often feels embarrassed by the problem and is unable to convince the doctor of its impact on their quality of life.

Surgical intervention

Surgery for stress incontinence Although in most cases conservative measures of treatment are used initially, some cases of stress incontinence in women can only be treated by means of surgical intervention. Historically, operations for genuine stress incontinence were carried out under general anaesthetic by the vaginal or suprapubic route, the operation of choice being colposuspension. Work on the insertion of tension-free vaginal tape (TVT) under local anaesthetic has shown that this procedure has a success rate similar to that of the more traditional colposuspension (Ward & Hilton 2002).

Intervention for prostatic enlargement Where the prostate gland partially or completely obstructs the urethra, the bladder will not empty completely and the patient may also experience overflow incontinence. It is essential to assess the patient accurately prior to instigating treatment (Naderi et al 2004). Transurethral resection of the prostate (TURP) is the most common surgical intervention performed for an enlarged prostate. This operation is described in Chapter 9.

Whilst patients with an enlarged prostate gland may have experienced overflow incontinence preoperatively, if damage occurs to the sphincter during the operation, dribbling incontinence may develop postoperatively and

in some cases may be permanent. Gentle pressure behind the scrotum on the perineum or bulbospongiosum to drain the urethra following voiding can help to prevent post-micturition dribbling. There is also evidence to support the use of pelvic floor muscle exercises in men (Paterson et al 1997, Theofrastous et al 2002). Absorbent products such as dribble pouches and Y-front pants with a waterproof-backed gusset should be available in hospitals and in the community.

Incontinence within the institutional setting

In all care settings, the nurse should consider the potential impact which their approach to patient care may have on a patient's continence, particularly in settings where older people are cared for (NMPDU 2002). Such care settings tend to have a reputation for poor continence management, although there is evidence that, for example in the acute care sector, incontinent episodes may be seen simply as an inconvenience which interrupts the patient's care (Vinsnes et al 2001, Nazarko 2003a). When this attitude prevails, the patient or care home resident is more likely to be issued with pads or have a catheter inserted, rather than have a detailed assessment of their incontinence carried out, from which an individualised care plan can be developed and rehabilitation planned (Willis 2000).

Heavner (1998), in a review of urinary incontinence in extended care facilities, found that prompted voiding programmes for individual patients could maintain an individual's social continence even where there was a loss of cognitive function. Waters and Easton (1999) identified that whilst nursing staff felt they gave individualised care because they knew what was needed, observations of nurses at work showed a dependency on routine and little choice offered to patients. It was also observed that patients were often left without access to the nurse call system. Under these circumstances it is difficult for patients to continue with their own toilet regimen.

Examples of nursing where continence can be compromised are many and varied: for example, attention to the pelvic floor during labour and delivery, initial care of orthopaedic patients and providing accessible toilets for all patients in outpatient clinics.

Evaluation

The last stage of the problem-solving approach to nursing is to evaluate the care given and assess whether the goals set have been achieved. At this point new problems may come to light, in which case the nursing process will begin again with an assessment for this new problem.

24.11 Fully assess the next patient suffering from incontinence who is admitted to your ward or who you meet in the community. Outline your strategy for care resulting from this assessment.

Continence advisory services

NHS services

Nurses may find that, within their own health area, there is a well-established continence advisory service which offers support in the promotion of continence in the community and in the hospital setting. Each region in Scotland benefits from at least one continence advisor.

A review of continence services by the Department of Health resulted in a report which recommended models of good continence services and targets for health care teams (DH 2000). These included:

- The development of integrated continence services to provide continence assessment, care planning and evaluation for all individuals with continence problems.
- Specialist continence advice for individuals with complex continence problems.
- The development of protocols and care pathways for the integrated continence service.
- A system to evaluate the care given, including service user involvement.

The targets specified that continence care should be provided to all patients, including children and those with learning difficulties, and cover all care settings, community, care home and acute sector.

Continence advisors

The post of continence advisor has been of key importance in the struggle to improve care for individuals suffering from incontinence. In addition to carrying a small caseload of their own, continence advisors usually work at a strategic level developing continence services across a health board area (Nazarko 2003b). In the larger health board areas in Scotland there are teams of continence nurses with different geographical areas of responsibility or professional areas of expertise. In addition to individual patient care, the teams work to develop the overall standard of continence care by providing education to staff at all levels, in both the NHS and the care home sector. The continence teams also work on public awareness in national campaigns and local initiatives.

Networks have been set up to facilitate communication among, and to give support to, professionals working in the area of continence care. The Association for Continence Advisors (ACA) was formed in 1980. The association, which changed its name in 1990 to The Association for Continence Advice, is multidisciplinary and has over 750 members, including international members and representatives from appropriate manufacturers.

In order to expand the knowledge base of continence advisors and to provide peer support, the ACA organises branch meetings, holds annual conferences and issues four newsletters a year.

The setting up of local networks in some regions has helped continence advisors to disseminate information to nurses at all levels, and across authorities. The aim is to encourage sharing of best practice and to motivate and support nurses who are trying to improve their own knowledge and practice in the field of continence care (Ballantyne 2003).

MANAGING INTRACTABLE INCONTINENCE

For some patients, incontinence will unfortunately be intractable. The key to successful management of these patients' requirements for toileting programmes, aids and

equipment is, as always, to determine individual needs and priorities with a view to improving quality of life. The problem-solving approach should again be applied, taking into account:

- personal preference
- lifestyle
- home conditions
- the degree and frequency of micturition or defaecation
- financial considerations.

Aids and equipment

Aids and equipment are formally submitted to evaluation by product trials (Medical Devices Agency 1996a,b, 1997, 1998a,b, Fader et al 2001).

The type of aid that should be recommended for an individual will depend upon the specific type of incontinence experienced. The assessment of a patient's requirements for aids or equipment must be informed by an understanding of the cause of the incontinence.

Aids to enhance mobility and stability, raised toilet seats, portable bidets or commodes and clothes that have been chosen or adapted for ease of access may be helpful to many individuals. Aids to personal cleansing can also be made available to help the patient maintain independence and dignity.

Urinals for women

For women who are, for example, confined to a wheelchair, have arthritis or are taking diuretics, incontinence may result from an inability to get to the toilet in time, and the woman may benefit from using a female urinal. These are listed in the continence products directory (Continence Foundation 2000). Cottenden et al (1999) provide a review of the products in use.

Pads and pants

For men and women who cannot achieve urinary control, a wide range of appliances, pads and pants is available. For up-to-date details on these, the reader is again directed to the Continence Products Directory (Continence Foundation 2000), to PromoCon (see 'Useful websites and addresses', p. 882) or to the nearest NHS continence service, which will be able to provide information on the availability of containment products in their locality. A range of absorbent products are provided through local health services. The availability of aids and the process of collection or delivery vary for each area (Anthony 1997, Morrow 2003).

The type of absorbent product that is appropriate for an individual will be influenced by the laundry facilities available and the role and time available of any carer involved with the patient. During assessment for such aids, the nurse should balance the patient's wishes and the availability of laundry facilities, such as a washing machine, home help or laundry service, with the problems of disposing of soiled waste, for example no outside bin or limited weekly volume of waste allowed for uplift.

The pads available fall into the following categories:

Light incontinence To absorb minimal volumes of urine, small adhesive pads worn with the patient's own underwear or with stretch net pants, or cotton pants with a protective waterproof gusset, can be used.

Medium and heavy incontinence For medium and heavy incontinence, larger waterproof-backed pads can be used with stretch net pants. Where hygiene is a concern or where large amounts of reflex emptying occur, all-in-one adult diapers or nappy-style pads may be appropriate. Waterproof mattress covers are also available to prevent soiling. Reusable bed pads may be appropriate for those who have the necessary laundry facilities to cope with laundering and drying.

Procedure pads are used as an extra protection for furniture during a clinical procedure, e.g. administration of an enema or insertion of a catheter, and should not be used as a containment product for urinary incontinence.

Products for men

Additional equipment designed to enable men to contain urinary incontinence is available on prescription. Sheaths (urodomes) with varying types of adhesive fixings and drainage systems are continually being modified and the range available increased, to allow a more individual approach (Fader et al 2001).

Urethral occlusive devices are available but should be used with caution.

Y-front pants with a padded, waterproof-backed gusset are particularly useful for men with a retracted penis and dribbling problems.

Obtaining further information

Many other aids are available in addition to those mentioned above which may prove helpful to particular patients. During assessment for aids and equipment, it may be advisable to consult an occupational therapist, physiotherapist or continence advisor on the range of supplies available in a particular health area. The patient may wish to investigate aids to daily living on view in regional centres or in specialist outlets.

Financial support and advisory service

Individuals who are incontinent or who care for an incontinent person may be eligible for a number of benefits such as Disability Living Allowance, Attendance Allowance, Invalid Care Allowance or other financial support. Further information can be obtained from local social security offices and post offices and from the website (see 'Useful websites and addresses', p. 882).

A number of voluntary agencies may also be able to offer practical support. For children, the Family Fund can give help with washing machines, tumble driers and bedding. Services such as 'Crossroads' may be available to provide respite care so that carers can have a break from their responsibilities, and in some areas day centres are available for patients to attend.

24.12 When you are in your local post office or library, take note of any free literature or available benefits. Jot down the reference numbers of leaflets that may be relevant to your patients or build up a collection to refer to as particular questions on benefits arise.

Long-term catheter care

Long-term indwelling catheterisation is used in the management of incontinence only after all other treatment possibilities have been eliminated. It should not be undertaken without due consideration of the patient's lifestyle, preferences and likely level of compliance. The potential effect of long-term catheterisation on sexual relationships should also be considered (Getliffe 2003). Insertion of a suprapubic catheter may be preferable for some patients. The patient should be made aware of what catheter management will entail before the procedure is carried out (NHSQIS 2004).

Catheter care is an important part of the nurse's role in both the hospital and community; an understanding of the principles of catheter selection and drainage system management, together with skill in patient education, are prerequisites for this. The anatomy and physiology of the lower urinary tract system and the selection and management of catheters are outlined in Chapter 8. The following exercise will help readers to review their knowledge.

24.13 Mr A, who is 69 years old, has been sent home from hospital with a Foley catheter in place. He will need advice and information. Ascertain whether your knowledge base will be adequate to give good management care of his catheter and drainage system by considering the following questions.

(a) State four situations in which catheterisation would be justified.
(b) Define what is meant by a Foley catheter.
(c) When is a large balloon catheter (30 mL) used?
(d) When is a small balloon catheter (10 mL) used?
(e) State four other features which should be considered in the selection of a catheter.
(f) What materials can be used to make catheters?
(g) Can air, saline or other substances be used to fill the balloon of a Foley catheter? Justify your answer.
(h) List five features of drainage bags that are important to patients in selecting the appropriate system.
(i) Describe the options available to a female patient who wishes to have the choice of wearing short skirts or tight trousers over her catheter drainage system.
(j) What conditions are correct for the storage of catheters? What conditions should be avoided?

Preventing urinary tract infection

Urinary tract infection is the most common of all infections acquired in hospital, accounting for 30–40% of the total (Emmerson et al 1996). However, infection in the catheterised patient is not inevitable and can be prevented when the potential entry points of infection are properly managed.

24.14 In Figure 24.6, can you identify the potential entry points for infection? What techniques can be used to prevent infection at each of these entry points?

Considerable and ongoing research is being carried out on catheter management and, in keeping with the Nursing and Midwifery Council *Code of Professional Conduct* (NMC 2004), all nurses involved in catheter care should keep abreast of new research findings in this area.

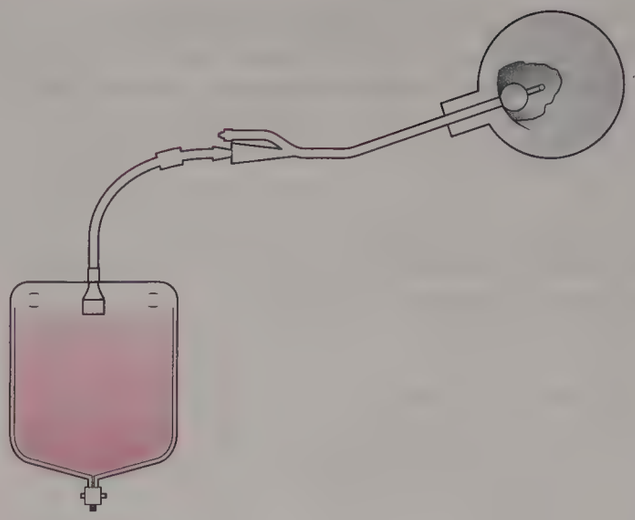

Fig. 24.6 Schematic of urethral catheter (see Stop-Think' 24.14).

Bladder lavage or catheter maintenance solution

Nurses should be clear that there is a difference between bladder irrigation and catheter maintenance or washout. Strictly speaking, irrigation refers to the continuous washing out of the bladder (see Ch. 8). Catheter maintenance solutions are available on prescription as a means of reducing catheter encrustation and debris and are often cited as a way of prolonging the 'life' of a catheter. There is disagreement as to whether these procedures should be carried out at all, as they disrupt the 'closed system' approach to management and cause shedding of cells from the bladder mucosa (Getliffe et al 2000). Research has shown that there may be a role for acidic catheter maintenance solutions in dissolving struvite crystals which encrust catheters (Getliffe et al 2000). However, these must be administered according to an individual treatment plan reflecting the patient's specific urinary pH fluctuations.

Nursing Care Plan 24.1 demonstrates the use of a problem-solving approach in identifying a patient's problems in caring for his catheter. It proceeds from identification of problems to setting goals with the patient and his relatives and then breaking down nursing interventions into their smallest components so that they can be carefully monitored and evaluated.

Supplying catheter equipment

Following the introduction of nurse prescribing (Royal College of Nursing 2000), certain qualified nurses working within the community can now order the supplies required by patients who have a catheter in situ. Patients should be given a list of all of their equipment, including sizes, types and capacity, as well as the name of a reliable pharmacist, retailer or mail order supplier. Appropriate details may be obtained by referring to the *Continence Products Directory* (Continence Foundation 2000) and the *Nurse Prescribers' Formulary* (Royal College of Nursing 2000), which is updated biannually. As noted on page 875, assessment of products is now being undertaken by the Medical Devices Agency (MDA 1996a,b, 1997, 1998a,b, Fader et al 2001).

Emergency help and contact numbers All catheterised patients in the community should be given a 24-h contact

Nursing Care Plan 24.1 Management of an indwelling catheter

Problem	Goal	Nursing action	Evaluation
Day 1 Unable to manage catheter and urine bag due to lack of knowledge and lack of manual dexterity	Day 1 To successfully and confidently manage care of the catheter and urine bags in as safe a manner as possible, by the time of discharge: Day 10	Day 1 Assess patient's ability to cope with buttons and zips	Day 1 While dressing today, patient was able to manage zip, but was slow with buttons
		Day 2 Change leg bag today and explain equipment and procedure	Day 2 Took a great deal of interest in management and asked how the catheter stayed in
		Day 3 Discuss with patient and daughter the general management of the catheter	Day 3 Married daughter visited; says she can visit him every day at home and phone him She thinks he could cope if instruction was given
		Day 3 Arrange a plan of teaching with patient and carer	Day 3 Married daughter coming on Day 4 at 10.00 h for a teaching session
		Day 4 Display of equipment and information session Provide written information	Day 4 Patient and daughter took interest and a number of queries were raised
		Day 4 Extra leg bag change Patient to change leg bag and put on night 'add-on' bag with supervision	Day 4 Managed leg bag Night-time bag put on correctly but forgot to open valve
		Day 5 Night nurse to supervise night-time add-on bag application	Day 5 With prompting, remembered to open valve
		Day 6 Night nurse to supervise removal of night-time bag	Day 6 Remembered to close valve Successful in removal, drainage and disposal
		Day 6 Liaison with district nurse for supervision at home	Day 6 Contacted Sr G. Discussed patient's progress. Will visit Day 7 p.m.
		Day 8 Supply patient with all equipment, written instructions and phone numbers for emergencies	Day 8 Patient read all the information and was able to identify each piece of equipment and how used Given DN's number and info on visit

Nursing Care Plan 24.1 Management of an indwelling catheter *(Continued)*

Problem	Goal	Nursing action	Evaluation
		Day 9 Discussion with patient and daughter on diet, emergencies, care and storage of equipment	Day 9 Daughter and patient happy about discharge on Day 10 Able to change add-on bag successfully this morning
		Day 10 Discharge 10.00 h	Day 10 Patient discharged, confident about catheter management Has 2 weeks' supply Daughter thanked staff for teaching session

number through which to gain help in an emergency. Practical advice on what constitutes a real problem and on what to do in certain emergencies should be given in writing to patients and carers (Getliffe 2003).

Sexuality

The impact of incontinence on self-esteem and the fear of wetting or soiling during intercourse can understandably have a negative effect on an individual's sex life (White & Getliffe 2003). MacKay and Hemmet (2001), in researching patient perceptions of incontinence, found that 16% of the respondents who considered their incontinence to be a significant problem had told no-one about their symptoms. This reluctance to discuss continence problems coupled with an avoidance of intimacy for fear of urinary leakage will inevitably lead to relationship difficulties.

Although many professionals may not see this aspect of their patient's well-being as a priority, patients who have been sexually active and are suddenly faced with incontinence caused by injury, childbirth or disease, or those who are facing progressive incontinence as a result of chronic disease, will have to make a difficult adjustment to changes in their sexual life. Problems of sexuality and incontinence affect both genders regardless of age (Cassels at al 2003).

The nurse's attitude

Following a review of the nursing literature on human sexuality, as early as 1979 Brower and Tanner concluded that most nursing authors were not concerned with the sexuality of their patients and its implications for nursing care. Booth (1990) confirmed that this is especially the case with respect to older people.

These findings serve to remind us that nurses involved in counselling must examine their own attitudes and feelings relating to the subject of sexuality. Counselling with regard to the implications of incontinence for the individual's sexuality should be initiated only when the patient signals that they are ready to address the issue. However, the nurse may need to introduce the subject and thereby give the patient 'permission' to voice any concerns. Reluctance to discuss questions of sexuality with patients may be due to the nurse's own inexperience or lack of self-awareness (Katz 2003, Wallace 2003). Gregory (2000) warns that there is no justification in encouraging a patient to divulge such personal and sensitive information if the nurse is not able to offer help or direct the patient to the appropriate specialist.

The reader is referred to Katz (2003) or Wallace (2003) for discussion of the issues relating to sexuality. Patient information leaflets discussing incontinence and sexual intercourse are available from Outsiders (see 'Useful websites and addresses', p. 882).

Practical problems and solutions

Certain issues concerning sexuality and incontinence may be dealt with in a practical manner, as outlined in the following.

Nocturnal enuresis is likely to inhibit both social and sexual intercourse and should be treated. The numbers of adults afflicted with nocturnal enuresis is uncertain, due to the hidden nature of the problem, although Hjalmas et al (2004) quote the prevalence of enuresis as 0.5% in otherwise healthy adults aged 18–64.

It is important to chart the patient's pattern of enuresis before treatment is commenced. Again, identifying the underlying cause can direct appropriate treatment. There are three conditions which underlie the diagnosis of enuresis, with patients often having a combination of these:

- a reduced bladder capacity
- an inability to concentrate urine at night
- difficulty in waking when the bladder is full.

Often a form of bladder training is tried initially, whereby the patient learns to hold onto urine longer during the day, thus leading to an increased bladder capacity and increased ability to hold urine at night.

The prescription of desmopressin, a form of the anti-diuretic hormone vasopressin, is helpful in reducing urine production at night, but does not cure the problem. This

medication is available as a spray. A single intranasal dose taken at night lasts for 10–12 h; this affords control of enuresis without affecting daytime urine production. Prolonged use is not recommended as adverse effects on the nose have been reported as well as water intoxication (NHS Centre for Reviews and Dissemination 1997).

The main treatment for nocturnal enuresis in the teenager and adult is to introduce the use of a personal alarm system to assist with learning to wake in time to void. A small electrode attached to a battery alarm system about the size of a matchbox is pinned to the patient's nightwear. When the first drop of urine touches the electrode, a signal is activated and wakes the patient.

Some patients may benefit from a combination of an alarm and medication to begin the treatment programme and then gradually withdraw both as control is established.

An excellent resource centre dealing with all aspects of enuresis is the Education and Resources for Improving Childhood Continence (ERIC; see 'Useful websites and addresses', p. 882). Many helpful pamphlets are available from the centre for adults as well as for children.

Cystitis involves either an infection or an inflammation of the bladder. The causal bacteria is usually *Escherichia coli*. It occurs most commonly in women, because of the anatomical proximity of the urethra, vagina and anus, and in some women may be linked to sexual intercourse. Incontinence rarely develops, but frequency and pain are present. When this occurs, many couples curtail their sexual activity, which may lead to tension in the relationship.

Careful hygiene, wiping the vulval area from front to back following defaecation and avoiding contact by the penis or fingers with the anus during intercourse may prevent problems. Passing urine before and after intercourse has been found to be helpful. Drinking copious amounts of water to flush the bladder can help when an attack of cystitis occurs. Management of cystitis can also involve antibiotic therapy or self-help techniques (Fihn 2003).

Preparation for intercourse

For many women who are incontinent, orgasm produces further episodes of urine loss. Passing urine before sexual intercourse may help. Protecting the bed and discussing the problem with one's partner can help to make the wetting less of an issue.

Catheterised patients need not avoid intercourse. For men, the catheter may be strapped to the underside of the penis and, in some individuals with a degree of impotence, may also help with rigidity. In women, the catheter may be strapped to the inner thigh or up onto the abdomen (Winson 2001). If clinically appropriate, sexually active patients may opt for a urinary catheter which is inserted suprapubically.

Counselling Open and reflective counselling will help to reveal the extent of any sexual problems experienced by the incontinent patient. If the patient's difficulties are not easily resolved, referral should be made to experts in sexual counselling who are available either in the hospital or in the community, or to other appropriate agencies such as Relate and Outsiders (see 'Useful websites and addresses', p. 882). The nurse should be prepared to furnish information on these organisations and details of how to contact them.

FAECAL INCONTINENCE

While urinary incontinence is more prevalent in the population than faecal incontinence, the latter is the more distressing problem. Faecal incontinence is socially even less acceptable than urinary incontinence and raises strong emotions among carers who have to deal with it. It is a source of discomfort and acute embarrassment for the sufferer, and contributes to feelings of helplessness and a loss of self-esteem.

Perry et al, in their 2002 study, found that approximately 6% of adults living at home aged over 40 had experienced faecal incontinence in the preceding year, although only 0.7% of those classed the faecal incontinence as disabling. It is especially prevalent among older people (Johanson & Lafferty 1996) and those requiring long-term care (Brocklehurst et al 1999). However, cohort research studies are discovering a number of women with damaged levator ani function following vaginal delivery (MacArthur et al 1997).

Faecal incontinence, like urinary incontinence, is a symptom of an underlying pathology and with appropriate assessment and treatment many individuals can be cured (Kenefick 2004).

Normal defaecation

Defaecation is the expulsion of faecal matter from the rectum with the aid of peristaltic movements of the muscular walls of the intestine (see Ch. 4). The rectum is stimulated to empty from impulses received from mass peristalsis, often starting from the gastrocolic reflex. The need for defaecation is felt as a response to distension of the sigmoid colon and the stimulation of the receptors. Further information on normal bowel function can be found in Chapter 4.

Anxiety can produce an urge to defaecate more often and in situations of extreme crisis faecal control can be temporarily lost.

The causes of faecal incontinence must be determined before treatment is instigated. Other than simple constipation, impaction and overflow diarrhoea, the main cause of faecal incontinence is usually damage to the pelvic floor and anal sphincters, resulting in an inability to recognise that the rectum is full or to distinguish between flatus and faeces.

Constipation

The constipated patient may complain of headache, general malaise and lack of appetite. Abdominal discomfort, rectal fullness and cramps may also be reported. During physical examination, the abdomen can be measured for signs of increasing distension (Harari 2004).

In people with a normal bowel, constipation may be caused by any of the following:

- a low-fibre diet
- low fluid intake
- inactivity
- ignoring the signals to defaecate
- pain in the anorectal region from haemorrhoids or fissures, an inability to position oneself comfortably in the necessary position, leading to avoidance of defaecation

- mouth pain or dental problems, leading to intake of soft foods only
- the use of pads for urinary incontinence, leading to neglect of toilet requirements by patient or staff where assistance is required
- intake of opioid analgesics, sedatives or hypnotic medication
- unacceptable toilet conditions
- unfamiliar surroundings or circumstances, leading to loss of habit
- inability to recognise social expectations, as in some cases of learning difficulties, dementia or excessive consumption of alcohol.

Where no obvious cause is found for the constipation, the problem may be due to damage to the pelvic floor and anal sphincter or to some other pathology, such as loss of rectal sensation as a result of surgery, injury or tumour. Other contributing conditions include dehydration resulting from endocrine or metabolic disorders and neurological damage.

Some individuals are prone to diarrhoea. Common causes are infection, inflammation in the bowel or rectum, excessive use of laxatives and the ingestion of certain foods or medicines. Parasitic infection can also cause diarrhoea.

Abnormalities resulting in faecal incontinence

The most common cause of faecal incontinence is damage to the puborectalis muscle and nerves, resulting in a failure of the valve at the anorectal flap or angle and associated lack of control and sensation. This may have been caused by trauma in childbirth (MacArthur et al 1997, Sultan & Kamm 1997), congenital abnormalities or damage sustained during surgery (Norton & Chelvanayagam 2004). Atonic muscles may also preclude adequate pushing to expel the faeces.

In the assessment of faecal incontinence, a history of the complaint and an explanation of what previously constituted a normal habit should be obtained in order to establish the specific type of incontinence. Bleeding, loss of sensation and the presence of mucus are all symptoms that should be investigated. A full description of the incontinence and its frequency are also important to the diagnosis. Liquid leakage is quite different from true diarrhoea.

Following a rectal examination, referral for a plain X-ray, proctoscopy, barium enema and stool culture may be necessary (see Ch. 4).

Interventions may be conservative, involving such measures as changing the diet and making toilets more accessible. Nurse-led clinics providing treatment for faecal incontinence using electrical stimulation have been very successful (Norton & Chelvanayagam 2004). In some cases, however, surgery will be indicated.

Gastrointestinal management of diarrhoea is fully described in Chapters 4, 20 and 21.

For a full account of the treatment available for rectal conditions, see Norton & Chelvanayagam (2004).

INTRODUCTION

Sleep is a fundamental element of life. We know that everybody needs sleep and yet people find it difficult to describe exactly what sleep is. We are all intrigued, for instance, by what happens when we fall asleep, why we dream and why our sleep patterns alter. However, despite centuries of observing sleep, extensive and systematic research, and the creation of both physiological and behavioural theories to explain sleep, the mechanisms and functions of sleep still elude us. The aim of this chapter is to enable nurses to understand more about sleep by considering what is meant by sleep, to identify factors that impact on the ability to sleep and to think about the ways in which they can assess a patient's sleeping patterns. Reading this chapter should help nurses feel more confident in providing nursing care that helps patients to overcome some of the problems associated with sleeplessness.

Before reading on, imagine the two scenarios detailed in Box 25.1. In the first, you are lying awake at home at 3 a.m. and in the second, you are awake in hospital. These two scenarios emphasise the importance that we attach to sleep. They also show how, in different situations, sleep means different things to different individuals and is affected by different environmental circumstances, the way we feel and our ability to control how we help ourselves to sleep.

WHAT IS SLEEP?

We spend so much of our lives asleep that one would expect it should be easy to define sleep but, paradoxically, once we are asleep, we remember little about it. One on-line dictionary definition (www.answers.com/topic/sleep) suggests that sleep can be defined as

> *A natural periodic state of rest for the mind and body, in which the eyes usually close and consciousness is completely or partially lost, so that there is a decrease in bodily movement and responsiveness to external stimuli. During sleep the brain in humans and other mammals undergoes a characteristic cycle of brain-wave activity that includes intervals of dreaming.*

This definition seems to reflect what many of us remember from our own experiences of going to or waking from sleep and also our observations of others as they sleep. For the most part, modern scientific researchers have tended to use objective criteria to describe sleep, usually in terms of physiological events occurring during specific stages of sleep. These include changes in the electrical activity of the brain and fluctuations in the secretion of various hormones. However, it is important to bear in mind that it is the individual's subjective experience of sleep that is of greatest importance in an assessment of the quality of sleep. Even when an electroencephalograph (EEG) indicates that sleep

Box 25.1

Thinking about sleep

Scenario one

Imagine you are at home. You went to bed as usual at 11 p.m. but it is now 3 a.m. and you are still awake. There is nothing stopping you sleeping except the gentle workings of your mind: you are warm and comfortable, there is no noise to disturb you and you don't have anything to worry about ... yet you still can't sleep. You know you need to, because you have to get up in the morning and go to work, be level headed and awake ... you toss and turn with frustration then decide to get up and make a drink. You return to bed to sip it and slowly, very slowly, feel the drowsy sleepiness that you've been hoping for wash over you.

Scenario two

Imagine that you are awake during the night in hospital. You are too warm and your bed is unfamiliar. You can hear the constant breathing of the three other people in your bay, the light footsteps of the nurses as they walk past the entrance to the bay and the intermittent ring of the telephone at the nurses' station, all of which keep interrupting the attempts to sleep. You are anxious about the results of the tests that have been taken and are due tomorrow. It seems as if everything is stacked against your sleeping: there is nothing that will help you to sleep without disturbing someone else or ringing for a sleeping pill and it is almost too late in the night to do that. You stare into the darkness willing sleep to overtake you, but it does not.

25.1

(a) If you have had sleepless nights, or had difficulty getting off to sleep, in what ways have you tried to deal with your sleeplessness? Try listing these, and then think how successful or otherwise your strategies were.

(b) Consider how patients you have nursed might deal with sleeplessness, and the various factors that might influence their ability to sleep — even the simple options you listed for yourself might be difficult for them to achieve.

For one nursing team's innovative approach to sleep promotion in hospital, see Cmiel et al (2004).

has been long and continuous, if the individual complains of sleeping badly, this cannot be contradicted. Conversely, if an individual habitually sleeps for only 2 h during the night, but feels that this amount is adequate, leaving them rested and refreshed, then there is nothing wrong with their sleep. The most important element of any nursing assessment of sleep is therefore to find out and to respect the patient's experiences and interpretations of their own sleep/waking patterns.

In order to help us to understand patients' sleep difficulties and the implications of these in planning care, some basic knowledge about the structure and function of sleep is useful. A summary of the two distinct types of sleep — non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep — and their function is given below (see also Fig. 25.1).

Non-rapid eye movement (NREM) sleep

NREM sleep comprises four stages, first described by Rechtschaffen and Kales (1968) in their seminal work on sleep staging. Each stage is associated with differing electrical activity of the brain.

- *Stage 0 or wakefulness* — the subject is awake with their eyes closed and an EEG would be characterised by generally low-voltage activity.
- *Stage 1 or drowsing* — this is the lightest stage of sleep during which the pupils constrict and dilate at intervals of approximately 1–3 s and the EEG shows mostly low-voltage, mixed-frequency activity. If asked, the subject may report feeling drowsy, but be awake. Even though the subject may feel fully alert, it is likely that observers will note reduced attentiveness. Some simple perceptual distortions, i.e. daydreams, may occur.
- *Stage 2 or light sleep* — this phase of altered consciousness is such that, if awakened, most people recognise that they have been asleep. Body movements begin to diminish and dreams involving a storyline first appear. Dream recall on waking, however, is far less vivid than for the second type of sleep, REM sleep.
- *Stage 3 or slow wave sleep* — when the amplitude of the EEG increases and body movements continue to diminish.
- *Stage 4 or slow wave sleep* — this phase is associated with a high degree of immobility and intense external stimuli are required to rouse a person in this stage of sleep. Large increases in the secretion of growth hormone occur during stage 4.

Note: Stages 3 and 4 are often considered together and termed slow wave sleep (SWS).

Rapid eye movement (REM) sleep

REM sleep, or paradoxical sleep, is characterised by dreaming, muscular relaxation and high levels of physiological arousal. During REM sleep, muscle tone is lower than in any other sleep stage. Blood pressure fluctuates, pulse and respiration rates increase and may become irregular, oxygen consumption increases, premature ventricular contractions may occur and there is penile tumescence in men and increased vaginal secretion in women.

The eye movement which occurs in REM sleep usually consists of rapid darting movements of the eyes under closed lids, occurring in bursts of 3–10 s at intervals of 30–40 s. These do not always occur, and if they are absent this is most likely to be during the first REM period of the night. If subjects are woken up, they often report that they have been dreaming; consequently, REM sleep is frequently referred to as dreaming sleep. In order to identify this phase of sleep, electrodes can be applied to the face to detect electrical activity due to eye movement, and below the chin to detect muscle tone. If all these electrical signals are recorded overnight, the result is a complex series of parallel traces known as a polysomnogram. From this, the

Fig. 25.1 Progressive changes in the EEG following the onset of sleep. (From SLEEP, by J. Allan Hobson. Copyright, 1995 by J. Allan Hobson. Reprinted by permission of W.H. Freeman and Company.)

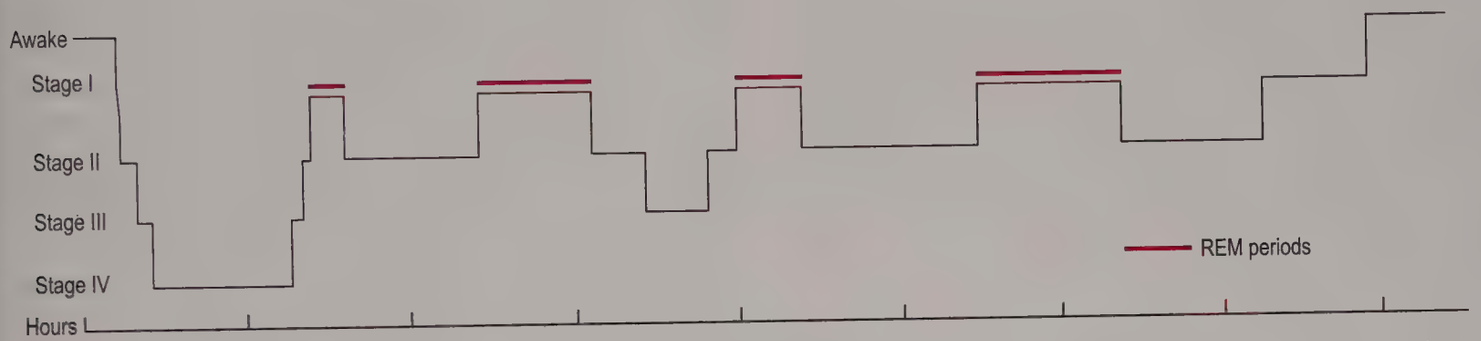

Fig. 25.2 Sleep architecture showing one night's progression of sleep cycles. (From SLEEP, by J. Allan Hobson. Copyright, 1995 by J. Allan Hobson. Reprinted by permission of W.H. Freeman and Company.)

most reliable indicator of REM, i.e. the disappearance of skeletal muscle tone, can be seen.

During a night's sleep both REM sleep and all four NREM stages may occur many times, usually in a cyclical fashion (see Figs 25.1 and 25.2). Sleep usually begins with stage 1 (drowsing) and progresses through stage 2 to slow wave sleep (SWS). This 'deep' sleep is frequently followed by a brief return to stage 2 before an episode of REM. The pattern then repeats, usually starting from stage 2. The duration of this cycle may vary considerably according to age and other factors, but in young healthy adults it lasts approximately 100 min. The first part of the night tends to contain more SWS, while the latter part of the night contains a higher proportion of REM. Interestingly, even during the day, people have been seen to undergo 100-min cycles of alertness and drowsiness, although they are usually unaware of these. During sleep, shifts from stage to stage tend to accompany body movements, with shifts to light sleep tending to occur suddenly, whereas shifts to deep sleep tend to be more gradual.

PHYSIOLOGICAL CONTROL OF SLEEP

Precisely how and why people sleep remains the subject of much research. At present it appears that the brain has several interlinked sleep centres: some relate to the onset and timing of sleep, some to REM sleep, others to NREM sleep and others to wakefulness. In addition, there are several putative, naturally occurring sleep substances, e.g. interleukin-1 and sleep promoting substance (SPS), that seem to be diffused throughout the brain.

Neurological control

The neurological control of sleep is complex and is not yet completely understood. Espana and Scammell (2003), in a useful clinical summary on sleep neurobiology, note that many neurochemically distinct systems interact to regulate wakefulness and sleep. The medulla, pons and midbrain comprise the brain stem (see Ch. 9) and accommodate many of the anatomical structures that govern sleep and wakefulness. It is also suggested that wakefulness is promoted by brain stem and hypothalamic neurones producing neurotransmitters such as acetylcholine, noradrenaline and 5-hydroxytryptamine (5-HT, also called serotonin) as well as dopamine, histamine and orexin/hypocretin. Each of these is capable of increasing wakefulness. In addition, neurones in the pons and preoptic area control both REM and NREM sleep.

Neurotransmitters

The main neurotransmitters implicated in the regulation of sleep and wakefulness are noradrenaline, acetylcholine

and 5-HT. Noradrenergic neurones are responsible for the arousal of the cortex observed during wakefulness and REM sleep. Cholinergic cells, i.e. those producing acetylcholine, facilitate REM sleep, while cells producing 5-HT appear to be responsible for the maintenance of NREM sleep and play an important role in the regulation of REM sleep.

Sleep substances

Theories claiming the existence of sleep substances have gained in popularity from the beginning of the 20th century. These are claimed to be naturally occurring substances that accumulate in the central nervous system (CNS) and cause sleep. Several sleep substances have been isolated, but it is not known whether they are central to the regulation of sleep or part of a larger and more complex system.

FUNCTIONS OF SLEEP

Despite enormous research efforts, the only universally agreed reason for sleeping is to avoid being sleepy! Interpretations of research findings vary, but it is generally considered that sleep appears to have a major role in the maintenance and/or restoration of physical and cerebral functioning (Moorcroft 1995). This may include:

- the resetting of physiological systems
- growth
- energy conservation
- modulation of immune functions
- homeostatic restoration of brain function
- maintenance of inherited behaviours and creativity.

It has also been suggested, however, that sleep may be simply an instinctual behaviour, a genetic remnant of earlier days when immobility at night increased our chances of survival.

For comment on the considerable number of hypothetical functions of sleep, see Benington (2001).

SWS and restorative processes

The direct study of sleep and tissue restitution in human subjects presents practical and ethical difficulties. Although it is possible to study people's sleep patterns in sleep laboratories, clearly it would be unacceptable to induce sleep deprivation in people who have sustained injury in order to study the effects of sleep on healing. In these circumstances, it is possible through a rather less direct route to investigate body restoration through the study of circadian variations in the levels of anabolic and catabolic hormones. These regular fluctuations suggest that anabolic processes occur during the sleep period.

In humans, protein synthesis is inhibited by hormones such as cortisol, glucagon and catecholamines, which result in wakefulness and reach their highest levels during the day. During sleep, energy expenditure in the tissues falls and the energy stored within the cells as adenosine triphosphate (ATP) rises to levels which become sufficiently high for protein synthesis to occur. The first episode of night-time SWS has been noted to coincide with peak levels of secretion of human growth hormone (HGH), which stimulates protein and RNA synthesis and amino acid uptake. Consequently, as one seminal overview of research into the functions of sleep suggested, peak tissue-building processes are associated with SWS (Shapiro & Flanigan 1993).

The onset of SWS is also associated with increased immunological activity. Further, SWS is the sleep state which has the highest positive correlation with the length of prior wakefulness and therefore appears to be associated with restorative properties. The evidence from Shapiro and Flannigan (1993) supports the assertion that sleep, and in particular SWS, is essential for tissue restoration.

For further information on sleep and circadian rhythm disorders, together with views on the need to include these subjects within nurse education curricula, see Lee et al (2004).

Functions of REM sleep

The functions of REM sleep are more difficult to explain. Babies have large amounts of REM sleep, whereas older people with chronic brain degeneration have a reduced duration of REM sleep. This implies that REM sleep has a possible role in brain metabolism. Human studies of REM sleep deprivation have not yet produced a clear picture of its effects. There have been tentative suggestions that REM sleep is involved in the integration of emotional experiences and new material into our existing worldviews. It also seems possible that REM sleep is involved in learning and memory, but research has so far failed to provide convincing evidence to support these ideas.

NORMAL SLEEP

No matter what objective recordings of sleep might indicate about its duration, continuity or 'architecture', if the sleeper is satisfied with their sleep, then it may be considered to be normal. A good, restful night's sleep and a good day's refreshed and efficient wakefulness are, of course, interrelated. Even though their relationship is not one of simple cause and effect, each depends on the quality of the other.

Individual requirements for sleep vary enormously. Russo (2005) highlights the differences in sleep required through the life course. For example, adults tend to need an average of 8 h sleep each night, whereas older people generally seem to need less than this, with children and young infants needing more. Some people habitually take a nap during the day. Some are early risers, while others are more active in the evening and tend to go to bed late. Horne and Ostberg (1976), who seminally described such people as 'larks' and 'owls', reported the tendency of individuals to 'morningness' or 'eveningness'. Hospital routines, for instance early or late medication rounds and/or the taking of regular observations, tend to override these individual variations in behaviour, with a possible outcome of disturbed sleep patterns for some (Jarman et al 2002, Cmiel et al 2004).

Factors affecting normal sleep

There are many factors that may naturally affect and may disturb normal sleep, several of which are described below. These include, for example, age and gender, diet, noise,

ambient temperature and pain. Each of these influences should be taken into account in nursing assessments of each patient's sleep, since the normal habits and needs of one person may vary from those of another.

Age

Changes in sleep patterns associated with age have been well documented, with neonates usually spending around 18 h asleep in every 24, young adults sleeping for an average of 8 h each night, and older people sleeping for 6 h. Older people tend to sleep less, spend more time in bed, have comparatively less stage 4 and REM sleep, and have more shifts between sleep stages than younger people (Rush & Schofield 1999).

For further information on age-related changes in sleep patterns, see Rush & Schofield (1999).

Problems such as getting to sleep or staying asleep also tend to be more common in older people (Rush & Schofield 1999); however, research reported by Klerman et al (2003) showed that although older people wake up more frequently than younger people, they do fall back to sleep at the same rate as their younger counterparts. These changes have been attributed to age-related loss of neurones and progressive fragmentation of circadian rhythmicity (Hood et al 2004). Older people also have increased amounts of wakefulness after sleep onset. Ancoli-Israel et al (1989) found that 41% of a sample of patients in a nursing home woke frequently due to apnoeic disturbances and leg jerks. Webb and Swinburne (1971) and Ersser et al (1999) attributed a high proportion of night-time awakenings among older people to pain and physical discomforts such as bladder distension and urinary urgency. Awareness of such problems should prompt nurses to alleviate discomfort as far as possible, to encourage regular bowel and bladder habits and ensure that optimum fluid intake is achieved by approximately 6 p.m. For those who enjoy tea or coffee, decaffeinated options should be encouraged for later in the day and evening.

For further information on the effectiveness of strategies to manage sleep in residents of aged care facilities, see Centre for Reviews and Dissemination (2005a).

Older people sustain an absolute and a relative reduction in time spent in stage 4 sleep, which may even disappear in a quarter of those in their sixties. Concurrently, they have an increased total duration of stage 1 sleep and an increase in the number of shifts into stage 1. The total sleep time (TST) is either reduced or unchanged in older people as compared with younger groups, although the time in bed tends to increase. This appears to be because older people spend more time lying in bed at night without attempting to sleep or while unsuccessfully trying to sleep, and lying in bed resting or napping during the day. Obviously, these sleep patterns could be considered abnormal in a younger age group, but should cause less concern amongst older people who are sick in hospital: wards with a large percentage of older patients should consequently adjust their routines to enable older people to continue such sleep habits (Humm 2001).

Maher (2001) discusses ways of assessing and improving disrupted sleep in older people.

For older people and their carers, the knowledge that changes in sleep patterns are commonly experienced and are therefore not necessarily pathological will be reassuring. Although some caution should be exercised, lest treatable problems relating to sleep are overlooked, nurses have an important role to play in educating patients and their carers about the predictable changes that occur in sleep habits with advancing age.

For further information, see Foley et al (1995) and Maher (2004).

25.2 Discuss with your mentor any changes in sleep patterns that have been experienced by older patients in your care. Consider which may be due to inevitable age-related physiological changes and whether any adverse consequences are likely.

Gender

Research has shown that there are some interesting differences between men and women in terms of their satisfaction with sleep. Men have more disturbances in sleep than women from early adulthood onward (Webb 1982), frequently due to nocturnal penile tumescence occurring during REM sleep. Wever (1984) found that women sleep significantly longer than men, although it is well recognised that women complain of problems with sleeping more than men and that they consume more sleep-inducing drugs. While this difference is evident from early adulthood, it becomes more clearly marked in middle age.

Heredity

Sleep quality and length appear to be influenced by genetic factors. This was demonstrated by Partinen et al's seminal work (1983) in which the sleep of 2238 monozygotic and 4545 dizygotic twin pairs were studied. De Castro (2002), in a study of self-reported sleep patterns in identical and fraternal twins, demonstrated significant genetic influences on the time individuals went to sleep and woke up, how often they woke up during the night, the duration of their sleep and wakefulness and their feelings of alertness both upon waking up and during the day. Familial clustering of narcolepsy (see p. 892) and idiopathic insomnia has also been observed. It is therefore worth noting in a nursing assessment whether there is a family history of sleep difficulties. It may not, however, always be possible to remedy inherited sleep problems by means of nursing interventions.

Body weight

Weight gain is associated with an increased duration of sleep, while weight loss is often associated with shorter sleep. This has been confirmed by several studies of people with anorexia, including one suggesting that anorexia and bulimia were both linked to sleep disorders (Della Marca et al 2004). As body weight falls, so does total sleep, which also becomes more broken and is interrupted by earlier waking. A study of 36 people (Adam 1987) confirmed that both total and percentage REM sleep correlated with body weight, although the reasons for this were not clear.

Exercise

The effect of exercise on normal sleep is not straightforward and research studies have produced conflicting evidence:

some have shown that exercise increases the duration of SWS, whereas some have found no effect and others a negative effect on sleep. Youngstedt et al's (1997) meta-analysis of 38 studies showed that exercise had different effects on different stages of sleep. The changes were somewhat modest, the greatest being an increase of 10 min on SWS. However, most of this research has focused on good sleepers. A randomised controlled trial of depressed older people showed that exercise had a more profound effect on poor than on good sleepers (Singh et al 1997).

Li et al (2004), also in a randomised controlled trial, studied the effectiveness of tai chi in improving sleep quality in older people who had disturbed sleep. Results demonstrated that older people who took part in the 6 month low to moderate intensity tai chi programme reported significantly improved sleep quality on a number of measures, including shorter time to sleep onset and longer sleep duration.

A Cochrane Review of interventions for sleep problems in older age cites one study (Montgomery & Dennis 2005) which found that sleep quality improved after a short (16 week) exercise programme consisting of 30–40 min of walking or low impact aerobics four times a week when compared with no treatment.

It appears that, overall, exercise has a small sleep-promoting effect for many people, provided that it is not taken late in the evening.

Anxiety and depression

Anxiety and depression frequently interfere with sleep. Most people experience these at some time in their lives, associated with, for example, occupational stress, family tension, bereavement, illness or other traumatic event (Lavie 2001). Admission to hospital may be a major cause of anxiety, with all the accompanying worries with regard to illness, investigations or surgery.

For further information on sleep disturbances in people diagnosed with cancer, see Vena et al (2004) and Clark et al (2004); for sleep problems experienced by caregivers of patients with advanced cancer, see Carter (2003).

The increased activity of the sympathetic nervous system due to anxiety results in an increase in plasma noradrenaline levels. This in turn results in sleep changes similar to those seen in older people, who have less stage 4 and REM sleep, and more stage shifts and awakenings, along with elevations of daytime and night-time plasma noradrenaline.

Insomnia due to depression has been associated with raised levels of monoamine oxidase, which catabolises the neurotransmitters noradrenaline and 5-HT, each of which is involved in sleep onset and maintenance. Depressed patients therefore tend to experience difficulty falling asleep, an increased number of awakenings during the night and early morning waking. Nursing staff should encourage depressed and anxious patients to discuss their feelings and, if possible, assist them to deal with underlying difficulties. Alerting medical staff to the apparent existence of anxiety and depression should ensure that the patient receives appropriate medical or psychological treatment.

25.3 Mr B is a 47-year-old man who had an appendicectomy 3 days ago. His physical recovery has been straightforward, but he is feeling very tired and depressed because he has been finding it difficult to sleep at night. Consequently, he has been reluctant to get up and walk and has been taking short naps throughout the day. Construct a plan of care, giving possible reasons for Mr B's inadequate sleep, suggesting practical nursing interventions and stating the expected outcome of these.

Physical illness

Cardiac and pulmonary diseases often worsen during the night (Redeker & Hedges 2002, Sutherland et al 2003, Redeker et al 2004). For example, the incidence of asthma attacks increases during the latter half of the night, while angina, cardiac dysrhythmias and nocturnal dyspnoea are all likely to worsen during sleep (see Chs 2 and 3). Metabolic disorders such as Cushing's disease, Addison's disease, hyper/hypothyroidism and diabetes mellitus may disrupt normal sleep patterns (see Ch. 5). Diseases that mobilise the immune system, whether viral, bacterial or fungal, may be associated with increased sleepiness (see Ch. 16).

Since many areas of the brain are implicated in sleep regulation, any pathology impinging on these sites can cause problems (see Chs 9 and 28). A rise in intracranial pressure, regardless of cause, increases sleepiness, which in some cases leads to coma and death. Interference with the brain stem or hypothalamus may affect the onset and maintenance of sleep.

Pain

People who live with chronic pain commonly experience sleep problems (see Ch. 19). Pain due to arthritis, cancer and low back injury is often described as intractable. Some types of chronic pain, such as that from peptic ulcers or reflux dyspepsia, have a circadian rhythm of increasing intensity at night. GPs tend to manage such pain by using medication, sometimes by aiming to relieve the cause, but more often providing symptomatic relief by means of analgesics or antacids. Sometimes the use of antidepressants, as adjuvant analgesics, is successful in promoting sleep, since some chronic pain syndromes can be associated with depression.

Nurses are closely involved in giving pain-relieving agents in hospital because of their 24-h, 7 days a week contact with patients. As long ago as 1979, Jones et al studied intensive care patients and found that pain was ranked second in contributing to sleep loss. Pain has been shown to be a major cause of sleep loss in the postoperative period (see Research Abstract 25.1) (Closs 1992, Southwell & Wistow 1995, Closs & Briggs 1997). Postoperative patients have strong views about sleep and pain (Closs 1991; see Box 25.2). If nurses are to be able to help patients cope with pain, they must perform an accurate nursing assessment of quality of sleep and be able to provide suitable interventions (see 'Methods of assessing sleep', p. 892, and Ch. 19).

For further information on the sleep experience of medical and surgical patients, see Tranmer et al (2003).

25.4 Discuss with your lecturer and your mentor how you can give effective pain relief whilst still ensuring that your patient is not unduly disturbed and gets enough rest. Think about how your care may differ during the day and the night.

RESEARCH ABSTRACT 25.1

A study of patients' and nurses' assessments of sleep in hospital

In this study by Southwell and Wistow (1995), 454 hospital patients completed questionnaires about their sleep. This included patients on medical, surgical, care of older people and acute psychiatric wards. Questionnaires were also distributed to 129 nurses working on those wards. Patients and nurses then answered questions concerning the same nights in hospital.

Half of the patients reported that they could not sleep through the night and were consequently sleep deprived. The main factors which patients reported as disturbing their sleep were discomfort (including beds and pillows and particularly the use of plastic covers on these), pain, noise, being too warm and worries. Half were dissatisfied with both settling and waking times.

There were differences in emphasis between patients' and nurses' views of environmental factors disruptive to sleep. More patients than nurses reported noise outwith the ward, emergencies, patients making a noise, nurses' shoes and nurses talking to one another. More nurses than patients reported treatments, commodes/bedpans, toilets flushing and nurses talking with patients. Nurses were more aware of noise generated by their own work and were largely unaware of the noise they caused by chatting to each other and from their shoes.

In view of the mismatch between nurses' and patients' perceptions, the authors emphasised the need to elicit patients' perspectives on care. However, the two groups were in agreement that patients did not get as much sleep as they needed. It was recommended that nurses, managers and others should take action to ensure that patients' sleep should be disrupted as little as possible. Nurses need to be aware when patients are awake, and take steps to ease pain, discomfort and worries. It is also important to minimise the wide range of possible disturbances during the night.

Southwell M T, Wistow G 1995 Sleep in hospitals at night: are patients' needs being met? Journal of Advanced Nursing 21(6): 1101–1109

Box 25.2

What patients say about postoperative sleep and pain

Effects of tiredness on postoperative pain

- 'The pain is more nagging and it's harder to put up with if you're tired.'
- 'If you're tired, the pain's more draining, more severe, a down-puller. It can actually make you feel depressed.'
- 'If you're tired and in pain, you want to give up quicker. You could have shot me yesterday for all I cared.'

Effects of sleep on pain intensity

- 'If you've slept well, the pain isn't as bad a blow when you waken. If you don't sleep, you wonder when it'll ever end. It's a vicious circle.'
- 'If you're tired you're narky, if you're narky it hurts worse.'
- 'Sleep makes you relax and takes away some of the pain.'

Effects of sleep on coping with pain

- 'It's essential — you can't cope with anything unless you've slept, especially pain.'
- You're not so well able to cope if you're tired, you have a good attitude if you're rested.'
- 'It's impossible to cope properly if you haven't slept well.'

Effects of sleep on recovery

- 'Sleep is the best healer in the world. You know it's going to take longer to get better if you can't get your sleep.'
- 'You've got to get a good sleep before you get anything else. You feel fresh and don't get crabby, you can deal with the pain and everything else and it speeds up your recovery.'
- 'Sleep is a great healer — that's why I don't understand why they wake you up early in the morning. I think, why, what is it for? Certainly not for the patient. It makes you agitated. It's all done to their rules.'

From Closs (1991).

Diet

There has been a long history of research into the effects of diet on sleep. Brezinova and Oswald (1972) investigated the reasons why Horlicks malted beverage seems to enhance sleep. A link was noted between habitual bedtime practices and sleep rather than the content of the Horlicks: those who normally ate little or nothing before bedtime had no improvement in sleep after having Horlicks, while those who usually did have a bedtime drink slept better after Horlicks. Hot milky drinks are provided in some hospitals in the late evening, but these may not suit everyone.

It should be remembered that many people prefer to take an alcoholic 'nightcap' at home, and if they are normally heavy drinkers they will suffer from withdrawal symptoms in hospital if they are not permitted to drink alcohol. Withdrawal from alcohol will result in disturbed sleep, as will withdrawal of hypnotic medication. It should be noted that alcohol is not a good hypnotic, since, although it accelerates sleep onset, it disturbs sleep patterns later on in the night (Williams et al 1983) and can cause early waking due to a full bladder. Drinks such as tea, coffee and coca cola contain caffeine and therefore act as stimulants, disturbing normal sleep patterns. As early as 1976, Karacan et al showed that coffee disturbed sleep, even in those who felt unaffected by it.

Whilst the biochemical effects of diet on sleep are unclear, avoiding stimulants and adhering to dietary routines appear to enhance sleep. Although research in this area has so far been inconclusive, community nurses might be able to help poor sleepers simply by giving them dietary advice, while hospital nurses should allow patients to eat or drink as they would at home prior to bedtime, as far as that is feasible.

25.5 A middle-aged woman complains to a community nurse that she is having great difficulty in getting to sleep at night. She is extremely anxious about her health and says that this is preventing her from sleeping. She has started taking naps during the day. In addition, she has found no help from taking drinking chocolate or a small drink of alcohol immediately before going to bed. What advice could the nurse give?

Medications

There are many medications that affect sleep, hypnotics being perhaps the best known (see p. 893). In addition, there are many others that have side-effects on sleep, including antidepressants, antihistamines and anticonvulsants. L-dopa and beta-blockers may produce vivid dreams and nightmares, whilst diuretics increase urine production, leading to bladder distension and nocturia. Other medications, e.g. amfetamines, stimulate the CNS, delaying sleep onset and reducing total sleep time.

Sleep position and snoring

Sleep positions have been associated with objective and subjective sleep quality. Poor sleepers appear to spend a greater proportion of their time on their backs with their heads straight and to change position more frequently than better sleepers (Koninck et al 1983). Snoring has been associated with subjects who sleep flat on their backs. Since these symptoms are undesirable for the sleeper, and snoring may disturb others sleeping within earshot, nurses could perhaps encourage and assist poor sleepers to adopt alternative positions for sleeping. Many snorers may have problems such as sleep apnoea (see p. 891) which are amenable to some types of treatment.

Breathing

Hypoventilation and breathing irregularities are common during normal sleep but may sometimes be clinically important. Normal changes include hypoxaemia and hypercapnia due to the slight reduction in metabolic rate that occurs during NREM sleep; in REM sleep irregular breathing is the norm.

Patients at home who have respiratory difficulties might benefit from advice regarding sleep position and the use of pillows to prop themselves up in order to maximise lung expansion and their carers should be advised of this. In hospital, nurses should ensure that anyone with respiratory difficulties, such as postoperative patients or those with chronic obstructive pulmonary disease (COPD) or respiratory tract infections, receives adequate support and assistance, particularly regarding oxygen administration, posture, deep breathing and coughing.

For further information, see Carlsson & Mascarella (2003) and Gay (2004).

Temperature

Sleep patterns are affected by changes in temperature, either in ambient (room) temperature or in body temperature. Kendel and Schmidt-Kessen (1973) pointed out that unclothed and uncovered subjects awoke from cold at an ambient temperature of 26°C and below. Total sleep deprivation has also been shown to alter body temperature, resulting in a decrease in mean daily body temperature and an increase in subjective feelings of cold (Horne 1985).

Fever is associated with a greater number of awakenings, increased total waking time and reduced amounts of SWS and REM sleep. Elevated ambient temperature produces similar results. The duration of the REM phase is shortened in artificially induced fever as well as at high ambient temperature. Zulley (1980) found that the higher the body temperature at sleep onset, the longer the duration of sleep, while REM sleep was negatively correlated with body temperature. These findings suggest that active management of pyrexial patients, perhaps by giving antipyretic medication, such as paracetamol for children, might improve their sleep.

Room temperature should be carefully monitored on general wards so that it may be maintained at a comfortable level, and patients should be encouraged to request more or fewer bedclothes as required. Older people are particularly vulnerable to fluctuations in room temperature, especially at home, since their ability to perceive temperature changes may be diminished. Community nurses are well placed to identify at least some of those individuals susceptible to hypothermia, and have a useful role in advising them about adequate clothing, bedding and heating in the home (see Ch. 22).

Noise

Noise can disturb sleep under all sorts of circumstances. In the home, mothers may wake at the slightest noise from their children, whilst in other circumstances they may sleep deeply through traffic or aeroplane noise. Conversely, those who live near a busy main road may have great difficulty sleeping in a quiet environment. Similarly, town dwellers might have problems sleeping for the first few nights of a quiet country holiday, or a patient who has had a long stay in a noisy hospital ward might have some difficulty readjusting to the quietness of their home environment. Individuals become habituated to the normal circumstances surrounding their sleep.

Zepelin et al (1984) studied subjects aged 18–71 years and found a correlation between a decline in the intensity of noise required to arouse individuals from sleep and increasing age. This reduction was present in all sleep stages but was greatest in stage 4. Ersser et al (1999) also found that noise was one of the most frequently given reasons for older people to have disturbed sleep in hospitals and nursing homes.

In hospital, noise poses a considerable problem, particularly in acute areas (Soutar & Wilson 1986, Aaron et al 1996). Patients' sleep may be disturbed by a wide variety of sounds, including noise made by other patients, nurses talking, footsteps, telephones, traffic, equipment alarms, squeaky doors, trolleys, rattling windows and many others (Closs 1988a, Southwell & Wistow 1995, Simpson et al 1996). While some noise is unavoidable at night, careful maintenance of equipment and precautions such as wearing soft-soled shoes can considerably improve the night-time hospital environment (see Research Abstract 25.2). Where possible, nurses should acquaint the more long-term patients with the unfamiliar sounds on the ward, so that they become accustomed to these noises and develop the ability to sleep through them.

Having observed the detrimental effects of sleep deprivation in their patients, and become more aware of the amount of noise generated by ward activities at night, nurses in a surgical thoracic unit decided to set up a sleep promotion team within their unit, in order to investigate these two related issues (Cmiel et al 2004). The team initiated a quality improvement project, the aims of which were, firstly, to make an objective pre-intervention measurement of noise levels on the ward, using a noise dosimeter. This instrument gave continuous recordings of decibel levels between

RESEARCH ABSTRACT 25.2

Nursing care at night

There is very little research about nursing at night and the impact that good care during this part of the 24 h can have on people. This Swedish study, designed to evaluate nursing care provided at night in one hospital, focused on the perspectives of both patients (n = 356) and nurses (n = 178).

The study used a newly developed questionnaire known as the Night Nursing Care Instrument to gain the views of staff and patients, in order to make comparison between the nurses' assessments and the patients' perceptions of the nursing care provided at night. The researchers found that there were no significant differences between the two groups for areas of medical intervention and evaluation, but the two did differ around areas linked to nursing intervention, including the assessment of the patients' needs for nursing care at night.

The authors concluded by suggesting that night nurses need to improve their ability to assess patients' needs for nursing care at night, particularly in relation to their knowledge of which nursing actions promote patients' rest at night.

Oleni, M, Johansson P, Fridlund B 2004 Nursing care at night: an evaluation using the Night Nursing Care Instrument. Journal of Advanced Nursing 47(2): 25–32

10 p.m. and 7 a.m. Secondly, subjective assessments of noise levels were obtained. In an innovative approach, two registered nurses each spent one night in an acute hospital setting, their bed areas containing the standard equipment and monitoring devices, to which they were connected, in a simulation of a normal patient's situation. Their report contained graphic descriptions of the noise levels and interruptions which disrupted their sleep. Patients were also surveyed about their sleep while in hospital. The sleep promotion team then carefully analysed the data obtained, following which various changes were implemented to improve the night-time environment for patients.

For further information on this quality improvement project, see Cmiel et al (2004).

COMMON SLEEP DISORDERS

Although the existence of sleep disorders has long been recognised, it is only in the past few decades that the seriousness of these has been acknowledged and a greater understanding developed. Epidemiological studies in Europe and the USA have indicated that up to about 40% of these populations reported difficulties in sleeping (Liljenberg et al 1989), with about 17% considering the problem to be serious. Insomnia is the most common complaint and has been defined by the US National Institutes of Health (2004) as 'experience of poor quality sleep, with difficulty in initiating or maintaining sleep, waking too early in the morning, or failing to feel refreshed'. Chronic insomnia is defined as insomnia occurring for at least three nights a week for 1 month or more. General practitioners have reported that around one-third of the subjective complaints made by their patients are of difficulties in sleeping.

Researchers have investigated sleep difficulties for patients at home and in hospital. A large multinational study of approximately 8000 patients in the community who had attended sleep clinics showed that 25% suffered from various types of insomnia, while 39% suffered from excessive daytime sleepiness (Coleman 1983). Smirne et al (1983) investigated sleep disorders of patients in general hospital wards, asking them about their sleep prior to admission. Of 2518 people, 25% reported some kind of sleep disturbance. These figures indicate that sleep presents difficulties for about a quarter of the population, posing a challenge for nurses in all fields of care.

For further information and detail on the grouping of sleep disorders, see The International Classification of Sleep Disorders, Revised: Diagnostic and Coding Manual (2001).

Sleep apnoea syndrome

This problem was first recognised over 25 years ago. The literal meaning of sleep apnoea is cessation of breathing during sleep. Often these episodes are repetitive and each may last up to a minute or even longer. Such apnoeas frequently cause the sleeper to wake, in some cases many times during the night. The main symptom resulting from this disorder is usually daytime sleepiness, although some sufferers complain of insomnia.

There are two main types of sleep apnoea: central sleep apnoea is caused by impaired neurological control of breathing, so that the intercostal muscles fail to contract; obstructive apnoea is the result of an obstruction of the airway, e.g. by large tonsils, a large or oedematous soft palate, fat deposits around the airway, retrognathia (backward displacement of the lower jaw) or micrognathia (a small lower jaw). The cause may be treated if the problem becomes severe. Obesity is common among these patients, in which case weight loss is usually the first approach to relieving the problem. For the more severe cases, continuous positive airway pressure (CPAP; see Ch. 29) during the night may help, while corrective surgery may be required for others.

For further information, see Barthlen (2002) and Centre for Reviews and Dissemination (2005b).

Sleep-induced nocturnal myoclonus

This condition is characterised by repetitive twitching of the legs occurring at regular intervals of 20–60 s. These episodes may last from a few minutes to several hours, and one or both legs may twitch (Barthlen 2002). This does not always disturb the individual, unless they are a light sleeper or the twitching is severe enough to arouse them from 'deep' sleep. Associated with this condition is restless legs syndrome, where an unpleasant, crawling sensation is experienced in the calves or thighs. Nocturnal myoclonus has been associated with the use of tricyclic antidepressant medication and chronic uraemia. Several remedies have been recommended, ranging from reduced caffeine, vitamin E supplementation to medication with ropinirole (Allen et al 2003).

Narcolepsy

This disorder occurs in approximately 4 in 10 000 people and can be described as an imbalance between wakefulness, REM sleep and NREM sleep. Sleep frequently intrudes into wakefulness and this change in conscious state is often triggered by strong emotions such as anger or laughter. It is REM sleep that intrudes, either partially or totally, producing the possibility of four different symptoms, as follows:

- excessive daytime sleepiness
- cataplexy, when only the muscular paralysis of REM occurs: the sufferer may be awake but is paralysed
- sleep paralysis, a type of cataplexy which occurs at sleep onset; paralysis which occurs on waking from REM is benign
- REM dreaming during wakefulness: hypnagogic hallucinations.

Parasomnias/partial arousals

Sleepwalking

This behaviour, when it occurs, commences during SWS, although the sleepwalker appears to be in a part-sleeping, part-waking state. Sleepwalking can be very dangerous: sufferers have been known to walk out of windows and to attack family members. During an episode of sleepwalking, the individual is usually uncommunicative and returns to bed spontaneously, rarely remembering the event the next morning. Sleepwalking is difficult to treat, so it is advisable, if a person does sleepwalk, to take precautions such as locking windows at night.

Night terrors and nightmares

Night terrors also arise during SWS and occur mostly in children. The sufferer often screams and shows signs of panic, such as a dramatic rise in heart rate, respiratory distress and sweating. They may be very difficult to arouse, but usually calm down within a few minutes, usually without waking up. Most people remember nothing about the incident. Nightmares occur during REM sleep and are often remembered very vividly on waking.

THE EFFECTS OF SLEEP DEPRIVATION

Total sleep deprivation, for as little as 48 h, has been shown to result in changes in central nervous system function, such as behavioural irritability, suspiciousness, speech slurring and minor visual misperceptions. Increased suggestibility and/or a reduction in motivation and willingness to perform tasks may also accompany these. In hospital, this could impede a patient's willingness to be up and about and undertake aspects of self-care as well as to communicate. Detrimental psychological effects of sleep deprivation sometimes observed in hospital patients include lethargy, irritability, confusion and, in more extreme cases, delusions and paranoia. Sleep deprivation for individuals in the community could reduce efficiency at work and affect social and family relationships.

A meta-analysis of 19 research studies that addressed the effects of sleep loss (Pilcher & Huffcutt 1996) suggested that the effects of such deprivation might well be underestimated. From a total sample of 1932 people, it was concluded that mood is more affected by sleep deprivation than either cognitive or motor functioning. It was also found that partial or intermittent sleep deprivation produced a greater impairment of cognitive and motor functioning than either short- or long-term sleep deprivation. Both acute and prolonged sleep disturbances, including delirium, have been observed in acute care settings (Cronin-Stubbs 1996). As long ago as 1973, Hartmann assessed sleep requirements by interview and questionnaire and found that stress and illness were virtually always accompanied by an increased subjective sleep need. Taken together, these observations support the hypothesis that sleep aids healing, suggesting that conditions favourable to the promotion of sleep should be created in all areas where patients are suffering from infection or trauma or are recovering following surgery.

METHODS OF ASSESSING SLEEP

Although many researchers have attempted to assess sleep in clinical settings, the methods used have not always been suitable for routine use by nurses (Closs 1988b, Maher 2004). In general, these methods of assessing sleep can be classified into two groups: those which rely on patients' subjective reports of their sleep and those which obtain objective measurements of either physiological events which coincide with sleep or psychological attributes reflecting the effects of sleep. Many of the objective methods of sleep assessment involve the use of expensive and sometimes unwieldy equipment. In most cases, nurses would neither have access to such equipment nor the expertise to use it. In addition, although these methods may be suitable for relatively healthy, stress-free individuals, most hospital patients would probably find such monitoring to be anxiety provoking, restrictive or uncomfortable, which may impact on their ability to sleep. One method which may be used by nurses for assessing sleep is actigraphy. The actigraph, a wristwatch-sized electronic device, is usually worn on the non-dominant wrist and measures sleep through arm movements, as arm movements are known to be linked to wakefulness and not to sleep (Benson et al 2003, Landis et al 2003).

Nursing assessment of sleep

The assessment of sleep is an important and integral part of the general nursing assessment of each patient and is, on an ongoing basis, particularly important to high quality care during the night (see Research Abstract 25.2). While it is appropriate for researchers and clinicians in other disciplines to use sophisticated monitoring equipment, coupled with detailed observations, nurses rely mainly on a combination of their observations of sleep and their communication skills, both questioning patients carefully and listening to what they tell them, in order to make their assessments. Assessment should take into account the patient's age, gender, diet, medical diagnosis and medical/surgical treatments, as well as paying specific attention to issues related to sleep (Fordham 1996) (see also Box 25.3).

Finding out about sleep

Although people are unable to give accurate reports of the actual time it takes for them to fall asleep, or how long they

Box 25.3

Possible questions in the nursing assessment of sleep

- How long have you had a sleep problem?
- What is your usual going to bed and waking routine?
- What treatments, if any, have you used for your insomnia? How successful or otherwise did you find these?
- Do you take a little alcohol to help you sleep, and if so, how helpful or otherwise do you think this is?
- What things do you do to help you get to sleep?
- Do you have difficulty falling asleep and/or do you keep waking in the night? If you keep waking, what do you do to help you get back to sleep?
- What regular exercise do you manage to get?
- How much caffeine do you drink, and at what times during each 24 hours?

Adapted from Maher (2004).

lie awake during the night, they can give reliable accounts of changes in their sleep patterns. Information can be gained from direct questioning, from non-verbal clues, the descriptions provided by relatives and carers, and from the nursing and/or medical records. Where patients are unable to answer direct questions due to age or incapacity, it may be possible to use a relatively new technique which employs a pictorial sleepiness scale on cartoon faces (Maldonado et al 2003).

Encouraging patients, where possible, to talk about themselves, their feelings and their needs is vital to the assessment of sleep. The use of open-ended questions and prompts can facilitate disclosure (Ersser et al 1999, Maher 2001, 2004) (see Box 25.3). Nurses should ask both general questions about sleep, as well as more specific questions that could include details about time of settling down to sleep, time of morning waking, duration of sleep, night-time routines, diet, medication, pain and anxieties. The patient's disclosures should be recorded in the notes so that each nurse participating in their care is aware of their needs.

25.6 On your clinical placement, observe how and by whom the quality of patients' sleep is assessed.

Body language is also important: patients are less likely to be forthcoming if the nurse speaks from an uncomfortable distance, looking as if they are about to leave for some more important task. Planned nurse–patient interactions can provide ample opportunities for discussion and nursing assessment.

HELPING PATIENTS TO SLEEP

Once an assessment of the patient's sleep has been made, nursing care relevant to these sleeping habits/patterns can be planned. Fordham (1996) highlights several nursing interventions for sleep problems, including:

- *psychological causes* — teaching, counselling and relaxation techniques (see p. 895)
- *physical causes* — control or elimination of symptoms, e.g. nocturia, breathlessness or pain
- *medication-related causes* — assessment of the medication effects and of review with doctors or other prescribers
- *environmental causes* — controlling noise, temperature or light; maintaining dietary rituals as far as possible, e.g. where the person normally eats or what they do during meals, such as watch TV; considering exercise, activity or regularity in terms of sleep/waking patterns
- *scheduling difficulties* — postponement of sleep and discussion of regularity of sleep/wake patterns.

Nurses can also help by providing general information about sleep that enables patients and their carers/partners to have realistic expectations. The importance of including partners in the assessment and planning of care related to sleep disorders cannot be overemphasised since, as Strawbridge et al (2003) point out, a patient's sleep disturbances may impact on their partner's health and well-being.

Cultivating healthy sleep patterns

In addition, nurses can give advice for improving sleep through attention to behaviours and attitudes conducive to healthy sleep patterns. These might include:

- attitudes towards sleep
- the sleep environment
- attention to diet
- sleep scheduling
- pre-sleep activities and routines
- daytime sleep behaviours, e.g. napping.

More specifically, the points given in Box 25.4 should be borne in mind by nurses, on an everyday basis, as they assist patients to cultivate healthy sleep patterns.

Some people will have such serious sleep problems that they will require specialist treatments. If this is the case, the nurse should alert the appropriate professionals. In the community, this may be the GP or clinical psychologist; in hospital, specialist support may be available.

PHARMACOLOGICAL TREATMENTS FOR INSOMNIA

The major treatments available for insomnia are pharmacological, although alternative approaches, e.g. developing good sleep habits, sometimes referred to as 'sleep hygiene', alternative therapies and cognitive–behavioural therapies may be the preferred first line of treatment for many people.

Hypnotic medications

Most hypnotics which are currently prescribed belong to the benzodiazepine group, and include nitrazepam, temazepam and diazepam. Their use is dependent on the type of insomnia and associated symptoms, e.g. anxiety. These hypnotics provide temporary symptomatic relief but are not a cure. The sleep produced by these medicines does not resemble natural sleep: the duration of stage 2 sleep is increased at the expense of REM sleep and SWS. However, even though these medicines change the structure of sleep, most physiological processes associated with SWS

Box 25.4

Information and advice to assist patients to cultivate healthy sleep patterns

- Patients' expectations of sleep should be realistic. Many people think that there is something wrong with their sleep if they do not sleep for 8 h every night. Such incorrect assumptions may in themselves cause anxiety and sleep disturbance. The individual differences in sleep requirements and the normal effects of ageing should be explained clearly in order to encourage realistic attitudes towards sleep.
- Most people experience short episodes of poor sleep for which no particular treatment is needed. There is no evidence that transient insomnia has a detrimental effect on health. Chronic insomnia, i.e. lasting for at least 3 weeks, may require detailed assessment and treatment. If it is clear that the insomnia is transient, nurses may be able to reassure their patients on this point and, in so doing, help them to overcome it by reducing their anxiety about sleep loss.
- People suffering from insomnia tend to stay in bed even when they are unable to sleep. This interferes with their sleep by reducing the psychological association between bed and sleep. They should, if possible, avoid going to bed until they are sleepy, and if they cannot sleep, they should then get up and do something else. For example, they might read, watch television or engage in any other activity that they enjoy, preferably something relaxing.
- Establishing a regular time of waking up in the morning is helpful, even if the previous night's sleep was unsatisfactory. This strengthens the circadian rhythm and should be adhered to at weekends as well as weekdays. A reliable alarm clock or perhaps the assistance of a relative or friend can help to ensure a regular waking time.
- Patients who have difficulty sleeping at night may reduce their night-time sleep drive if they take day-time naps. Avoiding day-time naps also helps to reinforce circadian rhythmicity. Naps may be avoided by planning activities that can coincide with the times that naps are desired, so that there is always an alternative to napping available. If a post-lunch nap is to be missed, for example, the individual could plan to walk the dog or fetch a newspaper at that particular time.
- Poor sleepers should try to reserve the evening hours for relaxation and leisure activities. They should avoid strenuous mental or physical exertion immediately preceding bedtime, with the exception of sexual activity, which may increase relaxation and encourage sleep. The development of calming pre-sleep rituals such as reading can help patients drift off to sleep.
- Hunger and thirst can disturb sleep. If this is a problem, a light snack should be taken at bedtime. This may be anything, provided that it does not contain stimulants. A milky drink and a biscuit or a piece of fruit may be appropriate. There is no evidence to suggest that eating cheese before going to sleep has any adverse effects. Some may wish to keep a drink beside the bed in case they wake up during the night feeling thirsty.
- Many poor sleepers are sensitive to the stimulants found in some foods. It takes at least 8 h to metabolise caffeine, so caffeine-containing beverages and foods should be omitted from the diet after midday. This includes tea, coffee, coca cola and chocolate.
- Sleep is disturbed by the use of nicotine as well as by withdrawal from nicotine. Thus the prevention of disturbed sleep is yet another good reason for not smoking. The role of the nurse as health educator is important here since many people are unaware of any connection between smoking and poor sleep.
- Although small amounts of alcohol hasten sleep onset, larger amounts disturb sleep later on in the night. The detrimental effects of alcohol on sleep can outweigh any benefits. Again, the nurse may have an opportunity to provide health education in this regard, as it is a common misconception that alcohol enhances sleep.
- The sleep-disturbing side-effects of medications such as antihypertensives and anti-asthmatics should be understood. It might be that the patient has not linked their sleep difficulty with their medication. An explanation of such a connection could provide valuable reassurance. If disturbed sleep is accounted for in a rational manner in this way, the patient may perceive it as less of a problem.
- Sudden noises are more disturbing than constant ones. If occasional loud noise is inevitable, using earplugs or masking the disturbing noise with a monotonous background sound such as that made by an electric fan can help.
- Nurses should endeavour to create conditions favourable for sleep. Most people sleep best in a quiet, darkened room on a firm mattress, which is large enough to allow movement and stretching. Individual preferences, however, should be respected as far as is feasible.
- Being too hot or too cold can disturb sleep. Ambient temperature should be comfortable, and the amount and type of bedding adjusted to suit the individual.

continue as usual. It is difficult, therefore, to comment on the difference between the overall quality of sleep induced by hypnotics and that of normal sleep.

The effects of benzodiazepines vary, particularly with regard to their duration of action:

- Nitrazepam has quite long-lasting effects and is used less commonly than other forms, particularly for older people, in whom the medication's 'hangover effect' may cause loss of balance and result in falls.
- Temazepam acts for a shorter duration and has little or no 'hangover' effect.
- Diazepam is used for insomnia which is linked to daytime anxiety and is a long-acting drug which, in a single dose, may treat both insomnia and anxiety.

For further information, see Centre for Reviews and Dissemination (2005c)

Other non-benzodiazepine hypnotics, such as zaleplon, zolpidem and zopiclone, act in a similar fashion to the benzodiazepines. Zaleplon is very short acting, with zolpidem and zopiclone having a longer duration of action. These three medications should not be used for long-term treatment

since dependence has been reported in a small number of patients (see *British National Formulary*, www.bnf.org).

Generally, short-acting hypnotics are favoured, since they are less likely to produce hangover effects during the day. While hypnotics are initially effective in inducing sleep, their regular use produces some degree of 'tolerance'. As time goes on, the body requires increasing doses of the medication to achieve the same effect. The effectiveness of most hypnotics is diminished after 3–14 days of use.

Although hypnotics can provide short-term improvement in sleep, long-term use can result in more problems with sleep. After an initial improvement, hypnotics may actually cause tiredness because of the reduction in SWS and REM sleep. When hypnotics are withdrawn, the patient may suffer from rebound insomnia. This involves extreme feelings of edginess, greater difficulty in falling asleep and more intense dreams and nightmares. These symptoms gradually diminish over time. In spite of these drawbacks, the short-term use of hypnotics can be highly beneficial. For example, an anxious patient due to have surgery may benefit greatly from the limited use of hypnotics over, perhaps, 3 or 4 perioperative nights.

For further information and detailed descriptions of medication actions and side-effects, see the latest edition of the *British National Formulary* (www.bnf.org).

Herbal remedies

Although several herbs are claimed to have sleep-inducing properties, either when used as aromatherapy or dropped in bath water, e.g. lavender, geranium or rose oils, or taken as infusions or oral preparations, e.g. chamomile tea or St John's wort, valerian is the only one which has been scientifically evaluated (Centre for Reviews and Dissemination 2005d). Valerian taken orally has been shown to reduce significantly the time taken to fall asleep (Lindahl & Lindwall 1989), to prolong sleep time, increase deep sleep stages and reduce night-time awakening. It is believed that small doses of valerian act in several ways to affect sleep positively through reducing anxiety, exerting a calming influence, relieving stress and relaxing muscles. One of the stated benefits of using valerian is the lack of morning hangover that is commonly associated with other pharmacological preparations. However, noted side-effects include stomach upsets with small doses, and headaches and nausea with larger doses.

For further information on valerian use, see Taibi et al (2004).

Despite the emphasis in the literature on valerian, other unproven herbal remedies may also be effective, not least by virtue of a placebo effect.

PSYCHOLOGICAL AND BEHAVIOURAL TREATMENTS FOR INSOMNIA

While pharmacological treatments of insomnia are palliative, psychological treatments aim to deal with the cause of the sleeplessness. In some cases, insomnia may be attributed to physiological or psychological overactivity. Stress is a common cause of sleep disturbance and can be dealt with by a variety of techniques (see Ch. 17). However, some individuals who suffer from insomnia are constitutionally poor sleepers who are unlikely to respond to any treatment. These people usually have difficulties sleeping throughout their lives, and the process of ageing is likely to reduce further the quality of their sleep. For those whose sleeplessness is associated with physiological or psychological hyperactivity, many non-pharmacological methods of treating insomnia have been attempted, with varying degrees of success. Four of the most widely known — relaxation therapy, paradoxical intention, associative learning technique and cognitive therapy — are discussed below. These therapies are mainly provided by clinical psychologists, whose choice of strategy depends on the cause of the sleeplessness, and on the individual's temperament and personal preference.

For meta-analyses on non-pharmacological interventions for insomnia in older adults, and the identification of effective psychological treatments for insomnia, see Centre for Reviews and Dissemination (2005e and 2005g, respectively).

Relaxation therapy

Emotional problems such as anxiety can be modified using various types of relaxation therapy, which aim to reduce physical and mental tension. Autogenic training (Centre for Reviews and Dissemination 2005f) teaches people to concentrate on sensations of warmth and heaviness in their limbs by repeated suggestion. Progressive muscular relaxation achieves a similar effect by the alternate tensing and relaxing of a series of muscles. These methods have been successful in helping people to fall asleep and in increasing their satisfaction with sleep (Lacks 1987, Richards 1998, Richards et al 2003).

Alternative forms of relaxation

A variety of alternative forms of relaxation have been studied, for example the use of music. In a study of the use of music to promote onset of sleep and sleep maintenance in 52 women over age 70, Johnson (2003) found that its use decreased the time to sleep onset and also the number of night awakenings, thus increasing the women's satisfaction with the quality of their sleep. Lai and Good (2005), in a study of Taiwanese older people who listened to their choice of music prior to going to sleep, found very similar positive results.

Paradoxical intention

Paradoxical intention has been used with success in the treatment of patients who are particularly anxious about their difficulty in falling asleep. This anxiety produces the opposite of the desired effect, making patients too tense to fall asleep. When such individuals are instructed to stay awake all night, their anxiety about falling asleep is reduced, paradoxically allowing them to relax and fall asleep (Ascher 1980).

Associative learning technique

This is a useful technique where the bed and the bedroom have become associated in the patient's mind with

sleeplessness. For such people, going to bed is an aversive stimulus that produces an aroused state. Bootzin (1972) devised a method of avoiding all behaviours in the bedroom not associated with sleep, such as reading, eating, watching television or just lying awake. Individuals are instructed to go to bed only when they are sleepy and to get up if they lie awake for more than 10 min. Eventually this re-establishes the psychological association between bed and sleep.

Cognitive therapy

An individual who is plagued by intrusive and repetitive thoughts that keep them awake can be taught to use cognitive refocusing. Usually these are problems and worries which the individual can learn to control, first by recognising that they cannot solve their problems by turning them over and over in their mind at night, and second, by learning to suppress the troubling thoughts, often by concentrating on alternative, benign thoughts. Other techniques employed by cognitive therapists include meditation and guided imagery.

For further information, see Jacobs et al (2004) and Morin (2004).

Increasingly, nurses are learning to provide some of the above therapies, for example relaxation therapy, thus enhancing their already significant contribution to helping patients to sleep. Health visitors are already becoming involved in successful schemes designed to help adults with insomnia (Eaton 1996) and others may also develop such skills. Since sleep is such a fundamental activity of life and is essential to good health, this extension of the nurse's role would seem perfectly legitimate.

CONCLUSION

Despite sleep being a complex and universal behaviour that is prone to disruption by many internal and external influences, it remains an important individual experience. Since everyone needs sleep, every nurse needs to know how patients may be helped routinely to achieve the best sleep possible and how, in specific circumstances, to deal with individual sleep-related problems. Nurses have an important role to play in regulating individual and communal environments, in the hospital, nursing home or the patient's own home, so that they are as conducive as possible to the promotion of good sleep (Fordham 1996). The assessment of individual sleeping needs and of the environment within which patients are nursed should be a routine component of skilled nursing practice. Many difficulties can be overcome by simple changes in lifestyle and by adjustments to the individual's expectations of sleep. Where more serious problems occur, help from other health care professionals should be sought.

INTRODUCTION

This chapter aims to give an overview of the nursing care required by patients facing surgery. Discussion will include not only those interventions relevant to the period of hospitalisation, but also the support needed by patients during the diagnostic process and during their eventual rehabilitation at home. Patients undergo many types of surgery for a wide range of reasons, but the principles of care can, to a large degree, be generalised with reference to particular types of procedure. It should be stressed, however, that individuals often react quite differently to a given disease or treatment. What one person may regard as a 'minor' procedure may cause extreme anxiety in another. Nursing staff must be sensitive to each patient's individuality and try to appreciate the significance of the experience of surgery from the patient's own perspective.

26.1 Think of an intervention or form of treatment you have experienced, such as removal of wisdom teeth, a cervical smear or suturing of a cut. What sort of fears did you have, however irrational they might seem now?

Changing patterns of surgical care

Advances in surgical technology and anaesthesiology have had a dramatic effect in more recent years on the experience of patients undergoing surgery. Previously lengthy operations can be completed more quickly and recovery times are shorter. The recently developed anaesthetic agent, remifentanil, is short acting and can be used in day surgery because it reduces the time from extubation to full recovery (Mason 2002). Many standard invasive surgical procedures are being replaced by laparoscopy, angiographic catheterisation, endoscopy and laser techniques. Minimally invasive surgical interventions include laser treatment to shatter (ablate) renal stones (lithotripsy), arthroscopy is now the method of choice in managing tears of the menisci in the knee and many gynaecological procedures can be carried out laparoscopically, e.g. excision of ovarian cysts and tubal ligation.

Even recovery from major surgical procedures has been accelerated. In the last few years orthopaedic surgeons have developed a 'keyhole' approach to total hip replacement operations (Lucas 2004). The introduction of laparoscopically assisted colonic surgery has reduced most patients' hospital stay from 6–12 days (Retchen et al 1997, Chen et al 1998) to approximately 4–6 days (Lewis et al 2001). There are ongoing trials which aim to revolutionise further the recovery from colonic surgery by revising perioperative care programmes, improving optimal analgesia, introducing early mobilisation and early enteral nutrition (Kehlett & Morgensen 1999, Lewis et al 2001). Results suggest that the postoperative hospital stay may be reduced to 2–3 days. Such advances in perioperative practice and the introduction of minimally invasive surgical approaches have enabled sicker patients to be eligible for surgery.

Day surgery has become possible for many general surgical patients. Since 1986, the amount of day surgery being undertaken has risen by 30% (Mitchell 1997) and UK government targets propose that 75% of all elective surgery

should be undertaken as day cases (DH 2000a, Audit Commission 2001). A brief hospital stay increases patient turnover but in turn increases the responsibilities of informal carers and community nurses (Mitchell 2003).

There are increasing numbers of older people in our society and it is estimated that before the end of the current decade over 20% of the population will be aged 65 years or older (Sear 2003). This change in demographics results in greater numbers of older people presenting for surgery (Leung & Dzankic 2001, Sear 2003). Ageing affects all of the body systems. Most affected are the cardiovascular, renal and respiratory systems. Increasing age is mostly associated with a higher risk of developing postoperative complications (Vemuri et al 2004), particularly if the patient has coexisting disease. For example, patients with cardiovascular disease are more at risk of developing myocardial infarction (MI) or arrhythmias following surgery (Sear 2003). Leung and Dzankic (2001) found that approximately 21% of patients over the age of 65 develop one or more in-hospital postoperative complications involving the cardiovascular, neurological or respiratory system.

Nursing staff will also observe a pattern of certain problems requiring surgical intervention in this older population. For example, the severity of appendicitis is increased in the older patient and presentation is often atypical, leading to delayed diagnosis (Pissara 2001). Likewise, the development of diverticular abscesses, associated with a diet high in refined foods and low in fibre, is the leading cause of bowel perforation in older people. Perioperative care of older surgical patients is thus becoming an increasingly important part of nursing practice.

Public expectations of health care have also changed in recent years. Patients increasingly wish to be involved in their own care and to be able to exercise choice in care decisions. The patient facing surgery should be seen as a partner in the care process (DH 2000a, Edwards 2002, Scottish Executive 2003a).

The nature of surgical services is changing rapidly to keep pace with technology and with advances in knowledge and skills. Within surgical wards and departments, nurses are faced with the challenge of providing continuous, individualised care within a more restricted time frame. This is facilitated by the named nurse concept, implemented in its various forms: primary nursing, team nursing or patient allocation (Dooley 1999, Steven 1999). Structured care approaches such as protocols, clinical pathways and algorithms are being used increasingly to organise clinical knowledge and to guide patient care (O'Neill & Dluhy 2000). Mathieson (2000) highlights that nurses in surgical units are constantly facing new techniques and practices which require them to be up to date and receptive to change. Developments in nurse-led initiatives such as orthopaedic assessment units (Sutcliffe & Potter 2002) and nurses carrying out endoscopy (Smith & Watson 2005) will further expand the role of nurses in perioperative care.

PRE-SURGICAL CARE

Classification of surgery

Some patients experience long periods of ill-health or disability before undergoing an operation; others experience sudden illness or injury that necessitates immediate surgery. The degree of urgency of a surgical intervention is a useful criterion for its classification and prioritisation. An older patient with osteoarthritis of the hip who requires a total hip replacement operation would normally not be classified as 'urgent', but would be put on a waiting list and admitted 'electively'. However, if the same patient had fallen and fractured the neck of the femur, repair or, more commonly, total replacement of the hip to prevent further deterioration and ensure a speedy recovery would be regarded as 'essential'.

A given operation may be performed for different classifications of surgery. Surgery for a strangulated hernia will be handled as an emergency, whereas surgery for an irreducible hernia will be considered as essential, and for a reducible one as elective. Patients requiring essential surgery will be admitted to hospital within a week or two of presentation at their outpatient appointment, but elective patients may have to wait for some considerable time. In December 2000 approximately 2% of the UK population were waiting for an operation, some 1 197 000 individuals (DH 2001a).

There has been debate on the usefulness of this focus on waiting times. To say that all patients receive surgery within a given period may meet a standard, but for an individual who requires surgery within several weeks, the standard cannot apply. For those who have to wait longer, the effects can be painful, stressful and expensive (DH 2001a). For those waiting for a hip replacement, a year's wait may be intolerable.

Presenting for surgery

26.2 Ask a patient who has recently experienced surgery what signs and symptoms first brought the illness to their attention. What was it that made them seek out treatment? How do they define ill-health?

Personal definitions of health and ill-health and the decision to seek treatment are influenced by factors such as previous experience, social context, perceived severity of illness and judgements as to whether treatment would be beneficial. In Case History 26.1(A), Mr W was reluctant to take time off work to seek treatment but came to a point where pain and discomfort made it impossible for him to carry on. In Case History 26.2(A) Mrs B was reluctant to seek help, partly due to her fear of having cancer and partly due to what she felt was an embarrassing symptom. She had also convinced herself that she merely had haemorrhoids and could treat the condition herself.

In Case History 26.3, Mr A had made a voluntary decision to seek treatment based on information obtained through the internet, and from talking with his partner. The accessibility of the internet has meant that more and more of the public use it as a source of information. Patients may present with an increasingly sophisticated level of knowledge about procedures. However, there are no standards guaranteeing the quality of information from the internet. Some of the information Mr A found may not be from a medical source or be research based.

Pathways and progress

Patients may be referred for surgery by different paths. Figure 26.1 represents the progress of Mr W and Mr A

CASE HISTORY 26.1(A)

Mr W

Mr W works for a large construction company. He is married and has three young children. They enjoy a comfortable lifestyle and had bought their own home that year. Mr W has been able to get some overtime work and this helps considerably with the mortgage repayments.

Mr W had been having some pain and swelling in his groin for some time, but it usually resolved on its own over time. However, over the past few weeks the swelling had got worse and was limiting the range of work he could do. He made an appointment with his GP who quickly assessed the extent of his inguinal hernia and made a referral to the local hospital for a surgical opinion. Before leaving the GP's surgery, the practice nurse fitted him with a scrotal support and gave him some simple analgesics.

Three weeks before the scheduled date for surgery, Mr W was invited to the hospital pre-admission clinic where he was seen by a nurse and a doctor. The doctor asked him about his current state of health and examined him, listening to his chest and recording the findings in the medical admission form. The nurse recorded his blood pressure, pulse, took some blood to test for electrolyte abnormalities, levels of urea and full blood count, and asked for a sample of urine to test. The nurse advised Mr W that all of his up-to-date results would be available on the day of surgery, explaining what would happen on that day, and asked him if he had any questions about his proposed operation.

Mr W told the nurse that he was worried about taking time off work and being able to carry on with his job. The nurse reassured him that he would eventually be able to return to a full range of duties once he had completely recovered. The nurse also suggested that if he were able to give up smoking he would have less of the cough that was partly exacerbating his hernia, and that he would have a better chance of a quick recovery after the anaesthetic. Mr W had always found he put on weight when he stopped smoking and was already moderately overweight. They discussed a plan of how he might give up smoking, including the use of nicotine replacement chewing gum and patches. Mr W knew his wife would be very supportive but was less sure of his mates, whom he met in the pub on Friday nights. The nurse gave him a booklet on healthy eating to take home and look at with his wife. He quickly identified that his fried breakfasts and love of chips and beer were major sources of imbalance in his diet. They also talked about how long he should expect to stay in hospital and what sort of work he would be able to do after the operation.

Mr W mentioned his concerns about the effect of the operation on his ability to have sex and whether it would make him sterile. The nurse reassured him on these points and explained that the operation would tighten a track through to his scrotum and would not affect his genitals, although he might be a little tender in the groin for the first week.

CASE HISTORY 26.2(A)

Mrs B

Mrs B is a 78-year-old woman who lost her husband several years ago. Her eldest daughter lives nearby and is very supportive. Mrs B now lives in sheltered housing, which was a relief to her daughter, as she had previously lived in an isolated country cottage. Her sight has been gradually deteriorating in recent years and the arthritis in her fingers and knees limits what she can do. At the time Mrs B became ill, she was pleased that she still had her own home, and enjoyed going to the local day centre twice a week.

One of the care assistants at the day centre was a little concerned that Mrs B did not seem to be enjoying the singing quite so much as before and spent much of the afternoon dozing. Mrs B, being an independent and spirited lady, thanked the young girl for her concern and joked that she wasn't getting any younger and that there was no need to worry about her.

Mrs B thought long and hard that evening. She had been constipated for some time but had put it down to old age. Now she was also passing blood, and although she was frightened that it might be 'something nasty', she had decided that it must be piles. She had bought some ointment and laxatives from the chemist, but was reluctant to go to her GP, who had visited her when she just moved into the area. He was a nice young man, but she did not want him to examine her.

Several weeks later, the driver of the day centre minibus got no reply at Mrs B's door when he called to collect her. Worried that she might have fallen, he called the warden, who had a key to the flat. Mrs B was found still in her bed, in obvious pain and sweating profusely. The warden called an ambulance immediately and then phoned Mrs B's daughter. Mrs B was then taken to the Emergency Department of the local hospital.

through the health care system, and Figure 26.2 that of Mrs B. Patients might enter these pathways at various points; Mrs B, for example, was taken straight to the Emergency Department (ED) by ambulance without seeing her GP. Patients may also be transferred from other wards. For example, a patient on a medical ward may undergo investigations which lead to a diagnosis necessitating surgical treatment and therefore transfer to a surgical ward. A few patients admitted as emergencies may go straight to theatre from the ED and from there to the surgical ward following the operation. Some patients may need to go back to theatre or the intensive therapy unit (ITU) if their condition deteriorates or requires further intervention. Some hospitals have specialist surgical high dependency unit (HDU) facilities where patients can be closely monitored for the first 24–48 h following their operation. These units usually have a higher ratio of nurses to patients than general ward areas. HDUs are thus often used for patients following major surgery or where pre-existing medical conditions predispose them to complications (DH 2000b, Sheppard & Wright 2000). Occasionally, convalescence or rehabilitation may be required in another ward or hospital, e.g. following amputation or neurosurgery. However, increasingly these services can be provided by community health care teams.

Patients such as M (see Case History 26.4(A)), whose illness is of a chronic nature, may be readmitted to the surgical ward on one or more occasions. Patients with Crohn's disease can present at an early age and may require repeated interventions and admissions to hospital throughout their lives (Pullen 1998). In a busy surgical ward these patients require a sensitive approach. One must not assume that because a patient has been through a procedure before, they will need less support or information than they did the first time. The vast majority of patients are admitted to hospital from home and return to their own homes. Traditionally, the GP has been seen as the gatekeeper to services: the one who will refer the patient for further care from the hospital consultant unless the illness is a sudden emergency or an accident. In Case History 26.2(A) Mrs B was reluctant to visit her GP due to the embarrassment of a possible rectal examination. She could have received advice and support

CASE HISTORY 26.3

Mr A

Mr A is a 41-year-old teacher who lives with his partner and four children. The youngest child is 18 months old. Mr A and his partner did not plan to have any more children. The last pregnancy had been a rather unplanned but welcome event! Mr A looked up some information on sterilisation on the internet on his home computer and was surprised at the amount of information that was available about vasectomy. He had not realised that it could be done as a short outpatient procedure and that it did not necessarily require a general anaesthetic. He discussed it with his partner and they decided that this was the most appropriate course of action.

His GP told them that, in their area, vasectomy could be undertaken at the local Family Planning Clinic and that there was an opportunity to discuss the procedure and decision making in an appointment beforehand. Within a few weeks of the GP's referral to the clinic, a pack of information was sent out to Mr A's home along with a date for a vasectomy counselling appointment. At the clinic he and his partner met a family planning nurse who talked through the details of the procedure with them, including possible complications such as bleeding, infection and recannulation of the vas deferens, the tube connecting the sperm-producing epididymis to the urethra. The nurse ensured that he had no problems with blood clotting and that he was not allergic to lidocaine, a local anaesthetic agent used by the surgeon. Mr A did not know if he had ever been administered lidocaine before, but when the nurse told him that it was often used by dentists to numb the mouth before treatment, he was able to confirm that he had had no problems in the past. The nurse also explained to Mr A about the importance of continuing to use contraception after the procedure until two consecutive samples of ejaculate were found not to contain any sperm cells. It would take approximately 20 ejaculations to clear the sperm duct of stored sperm.

The nurse highlighted that vasectomy was essentially a permanent decision because although reversal operations were possible, the sperm produced following vasectomy were only viable in a small percentage of cases. The nurse therefore asked them to consider their decision in light of possible unforeseen circumstances such as the death of a child or break up of their relationship. They acknowledged that these issues could affect reproductive decision making but that neither of them wanted further children.

The nurse explained that the clinic could carry out vasectomy operations, in patients who were fit and well, and who had not previously had any surgery to the scrotum or surrounding area. Mr A said that he had only had an appendicectomy when he was 16. She reassured him that this would not affect the surgeon's ability to operate in the scrotal area. Based on this consultation, the family planning nurse was able to recommend Mr A for the procedure and gave him an appointment for vasectomy in 11 weeks' time.

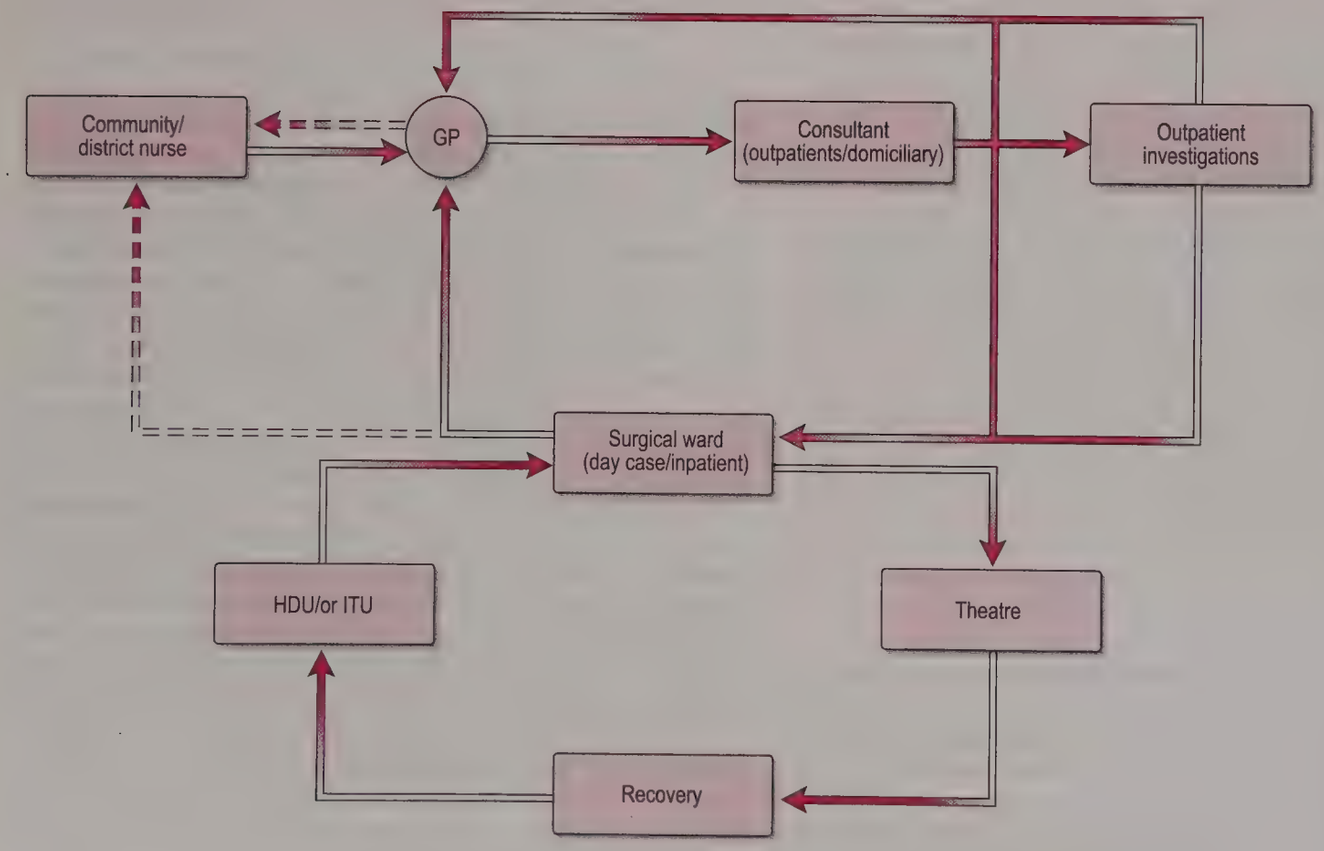

Fig. 26.1 Pathways to essential and elective surgery.

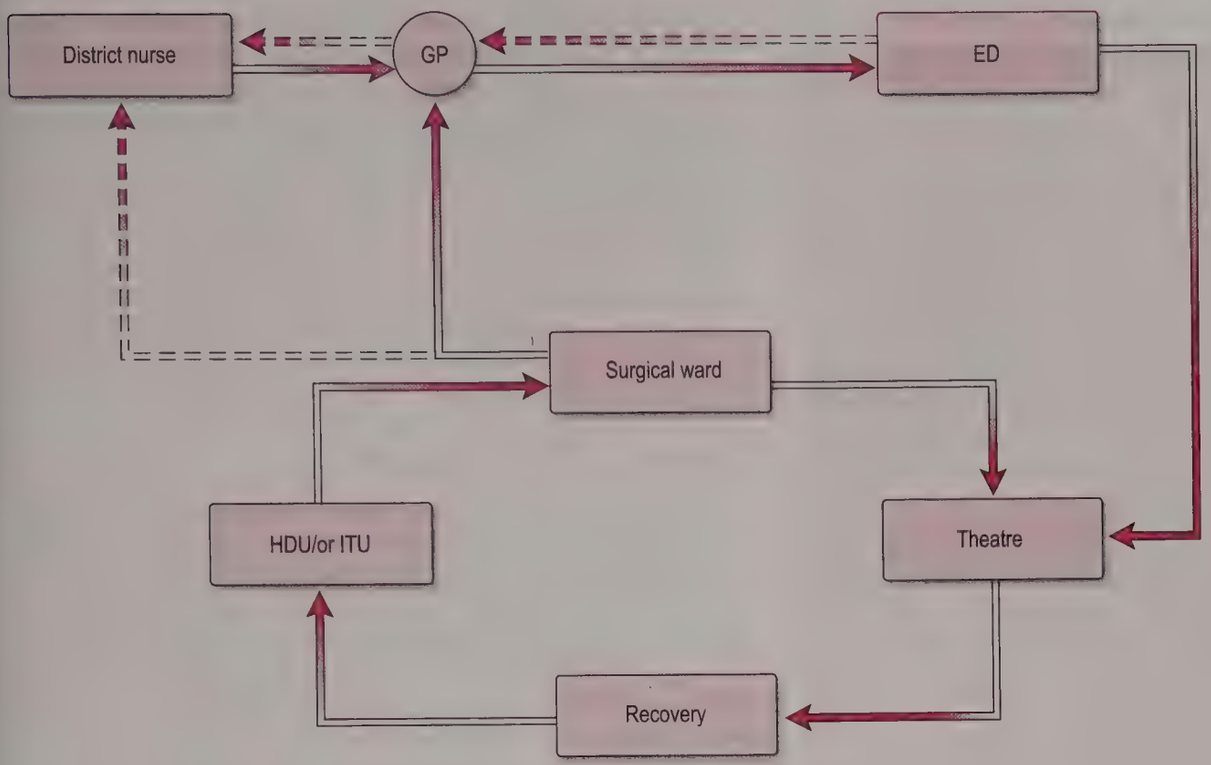

Fig. 26.2 Pathways to emergency surgery.

from the telephone helplines NHS Direct (England and Wales) and NHS 24 (Scotland) (see 'Useful websites', p. 943). These offer 24-h assistance and callers have reportedly found the advice helpful and reassuring (O'Cathain et al 2004).

A substantial morbidity exists among patients on waiting lists for surgery. Mordue (1994) found that around 38% of patients awaiting a cataract operation will experience further deterioration in vision before admission. Patients with gallstone disease requiring elective laparoscopic cholecystectomy make up a significant percentage of those awaiting surgery in the UK (Somasekar et al 2002). Whilst on the waiting list, some patients may suffer recurrent bouts of severe abdominal pain and require emergency hospitalisation (Somasekar et al 2002, Lawrentschuk et al 2003). Waiting for treatment not only causes patients pain, distress and anxiety but can also have expensive consequences, e.g. absence from work and emergency hospital admissions (DH 2001a). Mr W is fortunately supported by his practice nurse, who institutes measures to reduce discomfort and prevent further injury while he waits for treatment.

26.3 What actions might a community nurse take to improve the health of patients awaiting surgery?

INFORMED DECISION MAKING

The aim of this section is to introduce the issue of informed consent for surgery by discussing nursing responsibilities and highlighting areas for ethical debate.

For a wider discussion on the ethical aspects of consent, see Booth (2002).

The decision to operate

Once the outcome of investigations is known and these have been considered in the light of the patient's presenting signs and symptoms, the surgeon can make a definite or provisional diagnosis and recommend a course of action. This may involve diagnostic, curative or palliative surgery, a combination of these, or no surgical intervention at all. If the patient can be treated as successfully without surgical intervention, then the relevant alternatives will be pursued. Consider the following examples:

- A middle-aged woman is found to have Stage IIA cervical cancer (see Ch. 31) with infiltrating lymph nodes when she undergoes examination under anaesthesia (EUA). It is decided that surgery is not appropriate. She is referred to an oncologist, who prescribes a course of radical radiotherapy.
- Another patient has been referred to hospital for an oesophagoscopy and gastroscopy after complaining of heartburn. He is found to have a hiatus hernia and is prescribed an antacid and gelling agent (Gaviscon). The nurse in the outpatient department gives him advice on sleeping propped up at night, avoiding certain foods, weight reduction and how to take the prescribed medication.
- M (see Case History 26.4(A)) has been making frequent visits over the last few months to see her medical consultant about her vaginal fistula. Despite enteral diets, anti-inflammatory agents and antibiotics, the fistula does not resolve. She is referred to the surgeon and subsequently admitted to the surgical ward.

It may appear from these brief descriptions that it is the medical staff who take the decision on the course of

CASE HISTORY 26.4(A)

M

M is a 23-year-old hotel receptionist who had suffered from Crohn's disease for as long as she could remember. She had been in and out of hospital because of her condition on many occasions. This time she was sent straight up to the ward after her appointment in the outpatient department. The staff nurse who had looked after her on two earlier occasions felt a real friendship with her. When the nurse greeted her on the ward, M burst into tears, explaining how she had developed a horrible faecal discharge from her vagina and that she had been admitted for more investigations. She was pyrexial, looked pale and, with her small frame, appeared extremely fragile. The staff nurse offered her a single room as she was obviously distressed by her uncontrolled diarrhoea.

Once M had telephoned her boyfriend, with whom she had been living for the past year, and had taken time to collect her thoughts, she was visited by the consultant who suggested that a fistula was the cause of the current problem and that the best plan of action would be to close it surgically. M was informed that there was a chance that she would need a defunctioning stoma and spent some time talking to the staff nurse and the night staff about it.

The next day M started her bowel preparation. This consisted of 4 L of Klean-Prep to be taken over the next 24 h. She was not allowed to eat that day but could take extra drinks of clear fluids if she wished. She discussed with her named nurse the use of large pads to absorb leakage from her vagina. She was also given some soft wipes and a tube of barrier cream to avoid excoriation of the perianal area by the diarrhoea.

treatment to be given. However, whereas the doctor decides what treatment appears to be the most appropriate, it is the informed patient who must make the final decision as to what treatment is accepted (Nursing and Midwifery Council 2004). Thus the woman with cervical cancer is offered either radiotherapy or surgery, but is advised by her doctor that radiotherapy would be more suitable in her particular case. The doctor explains that the extent of surgery that would be necessary and the risks and morbidity associated with surgery outweigh the benefits. After being informed of and discussing the survival rates and adverse effects of both forms of treatment, the patient opts for radiotherapy.

Informed consent

'Consent is a patient's agreement for a health professional to provide care' (DH 2001b). When patients undergo any intervention or procedure, they must give consent. Touching someone without their consent and without lawful justification could be construed as trespass, civil assault or battery (Bradshaw 2001, Baxter et al 2002). In practice, it is preferable to obtain verbal rather than written consent from the patient for low-risk procedures, such as a chest X-ray or being given suppositories. However, when a patient is to undergo surgery or any invasive procedure, and when a general or local anaesthetic is required, it is advisable and standard practice to obtain written consent. As the medical team are in charge of these procedures, they are ultimately responsible for obtaining the written consent from the patient. Consent forms are traditionally used within hospitals and clinics to document that the patient and the medical staff have discussed and agreed the proposed treatment (Elliot Penels 1998). However, a signed consent form does not give any indication of what the patient was told, what was consented to or whether there was a meaningful understanding as to what they were agreeing to (DH 2001b). The doctor signing the consent form with the patient has therefore to ensure that:

- the patient understands the information, and not just that it has been given and received
- the extent of the information is sufficient for that patient to make the decision.

The role of the nurse

The nurse has an important role to play in obtaining consent prior to surgery. For a patient to give valid consent, they must comprehend fully what they are consenting to: i.e. their consent must be informed. The nurse can provide the team with knowledge of the individual's need for information and comprehension of the information given (Alderson 1995). The nurse will also provide the patient with information about the procedure and the recovery period, and may be able to clarify points previously discussed between patient and doctor. A strong case is made that doctors, rather than nursing staff, obtain consent for surgery, as nurses will not undertake the actual procedure (Elliot Penels 1998). Where nurses do take consent, they have to meet a medical standard of care and should receive thorough training (DH 2001b). In Mr A's case, specialist family planning nurses provided preoperative information and obtained his consent for his vasectomy. There may also be occasions when the nurse is in charge of a particular procedure and must therefore obtain written consent from the patient. In this instance, providing the information for consent is the nurse's responsibility.

The need for informed consent raises legal and ethical issues for both nurses and patients. The current social climate emphasises consumerism and patients' rights. Patients have an increased desire to be 'partners in care', i.e. to be well informed and to take responsibility for their own health (Coulter at al 1999, Scottish Executive 2003a). Patients have the right to be given an adequate explanation of proposed treatment, including any risks and alternative treatments. Nurses have a vital role to play in ensuring a patient's need for information is met and that full discussion takes place (Anderson & Helms 1995).

However, there may be occasions when the patient is less than fully informed. The depth and complexity of information held by medical staff may be overwhelming for a lay person to absorb and understand. This consideration must be balanced against individual needs and consumer demands. There is now heightened awareness of the need to explain the potential effects of treatments — adverse as well as beneficial (McIlwain 1999). The risks of some procedures are now clearly stated on the consent form itself. Both the chance of occurrence and the severity of potential adverse effects of the procedure must be addressed in considering whether to inform the patient of them. For example, a myelogram carries only a small risk of seizures and loss of power in the limbs, but as the effects would be severe, it is important to inform patients of these risks.

For further information on patients' perceptions of the consent process, see Kay & Siriwardena (2001).

There may be occasions when medical staff deliberately withhold certain information, believing that it would be detrimental to the patient to have this information. This is legal if the doctor is deemed to be acting in the patient's best interests. Our moral principles tell us that one should always tell the truth. However, if knowledge of the truth would have a negative effect upon the patient, then a difficult decision has to be made. If the patient has expressed a desire for full information about the diagnosis, the decision becomes clearer. It would not be legal or ethical to withhold information on the grounds that the patient might refuse treatment if given the full facts.

26.4 A young woman is told she has ovarian 'cysts' and, although distressed at requiring an oophorectomy and possibly a hysterectomy and so losing the ability to have children, she consents to the operation. Her husband and the surgeon have agreed that she would not cope well with knowing her true diagnosis of ovarian cancer at this time, and so withhold this information from her. She then questions the ward nurses, at first indirectly and then directly with questions such as 'It's cancer, isn't it?' and 'This is going to be the end of me, isn't it?'.

What might you do or say if faced with such a situation in the ward? How might the patient react if you told her you were not able to answer her questions? Discuss the example with your nursing and medical colleagues.

A nurse could face disciplinary action, or even dismissal, for going against the surgeon's expressed wish to withhold information, but this would be unlikely if the nurse was clearly acting in the patient's best interests. Nurses who think that patients are insufficiently informed should discuss their concerns with the surgeon, but not in the presence of the patient (Alderson 1995). Booth (2002) suggests that nurses are in a good position to mediate between doctors and patients, to facilitate two-way communication, and to prevent patients becoming 'passive recipients of [the doctor's] expertise'. However, it is more usual for nursing and medical staff to be sensitive to the individual needs of the patient and to work collaboratively with the patient and family to resolve such moral dilemmas.

In some cases, the patient may be too ill to comprehend what is proposed and thus to give informed consent. Also, within society there are groups of individuals who are 'unable to make decisions for themselves or who cannot communicate these decisions' (Lord Chancellor's Department 1997). This inability is known as 'mental incapacity' (Lord Chancellor's Department 1997). In Scotland, any issue relating to the welfare of an 'incapable adult' is governed by The Adult with Incapacity Act (Scotland) 2000 (Baxter et al 2002). Similar legislation has been introduced recently in England and Wales in the form of the Mental Capacity Bill (O'Dowd 2004). When an adult patient is unconscious or mentally incapacitated, it is necessary to find out whether a family member or friend has been given Power of Attorney, i.e. allowed to make decisions on the patient's behalf, or if the patient has previously indicated their wishes in an advance statement. An 'advance statement' is an expression of the patient's preference for treatment or care, given when they are legally competent. This may include the refusal of certain treatments such as surgical intervention or cardiopulmonary resuscitation (Brooks 1997). Any refusal of treatment must be respected, provided the decision is appropriate in the circumstances. The patient's relatives have no legal right to give or, more importantly, to refuse consent. Lifesaving procedures can be performed without consent using the doctor's clinical privilege (Lord Chancellor's Department 1997). A doctor has the power to take such action as is necessary, but only the minimal amount of treatment should be undertaken to alleviate the particular emergency, and should follow established practice (Elliot Pennels 1998). Good practice would suggest that the relatives are consulted and a decision is made in the patient's best interests (Lord Chancellor's Department 1997).

26.5 How can nursing staff clarify where decision-making responsibility lies in the following cases?

- A 25-year-old man with Down's syndrome is admitted to the ENT ward for elective tonsillectomy.
- An 81-year-old woman is admitted from a nursing home to the vascular ward with an ischaemic left foot. She has a 5-year history of dementia and is very confused. An embolectomy under local anaesthetic and sedation is proposed.
- A young motorcyclist is admitted to the Emergency Department following a motorcycle accident. He is unconscious and the CT scan reveals a subdural haematoma which requires emergency surgical evacuation.

Similarly, relatives have no legal rights in determining whether information should be given to or withheld from the patient. In fact, the doctor or nurse would be in breach of confidentiality if they were to tell the relatives first, or to tell them at all, without the patient's expressed consent. Where information is withheld from the patient, the patient cannot consent to its being divulged (Nursing and Midwifery Council 2004). There is an NHS code of practice on protecting patient confidentiality (Scottish Executive 2003b).

Resolving dilemmas

When a patient is too ill to be told, or cannot give informed consent, medical and nursing staff must carry out their professional duty to act in the patient's best interests, whilst considering the wishes of the relatives. The *Code of Professional Conduct* (Nursing and Midwifery Council 2004) provides guidelines on professional practice. Nurses are required to follow the Code in terms of acting to safeguard the patient's interests and to work in a collaborative and cooperative manner with other health care professionals.

It is essential that nurses are familiar with the Code and apply it in practice. Guidelines on informed consent have also been produced for doctors and nurses (DH 2001b, General Medical Council 2001).

PREOPERATIVE PREPARATION

Preoperative preparation might begin some time before the patient is admitted to a hospital ward or clinic. Mr W's practice nurse and Mr A's family planning nurse were

both involved in preparing their patients for surgery. As this aspect of care has already been considered, this section refers to the immediate preoperative period following admission to hospital.

Patients arrive for admission having experienced very different types of preparation. Mrs B had no preparation at all, being taken to the ED as an emergency. Mr A had already attended the family planning clinic where the vasectomy would be carried out and had discussed the procedure and after-care at length with one of the nurses. Mr W's local hospital has a pre-admission clinic where his admission details were obtained and a full assessment carried out a week before surgery. He was also given the opportunity to ask questions about his proposed operation. He arrived on the ward on the morning of admission having had nothing to eat since going to bed the night before, and only a cup of tea since 6 a.m. The named nurse showed him to a chair where he could wait for a bed to become available. All patients — whether emergency, essential or elective admissions — require appropriate preoperative assessment, information about their care, and safe preparation for anaesthetic and surgery.

Assessment

Assessment of the patient is required to identify any special needs, to highlight potential problems and to provide a baseline against which to measure postoperative progress.

Ideally, the named nurse would admit the patient in order to establish a relationship and to enable direct observation and questioning of the patient. The nurse may also use other sources of information, such as medical or nursing records, the patient's relatives and other health care professionals, to form a complete picture. The way a nurse assesses a patient will vary according to the model used. This might be one developed by the ward nurses or an established nursing model such as Roper et al's (2000) activities of daily living model. But while each nurse's approach to, and description of, the delivery of care may be different, the needs of the patient remain essentially the same. Care pathways have been developed to outline these needs for some types of surgery. They detail the care that a particular group of patients will receive at what point in their stay. Deviations from this pathway are recorded for quality assurance purposes and to enable individual variation in care. This approach to care has led to a reduction in length of hospital stay for some patients and has facilitated a continuance of care in the community for others (Calligaro et al 1996, Schaldach 1997).

Examples of surgical care pathways can be found in Johnson (1997) for patients facing transurethral resection of the prostate gland (TURP), and in Rogers et al (2000) for patients undergoing maxillofacial surgery.

Giving information

Reducing preoperative anxiety and stress is not only desirable on humanitarian grounds, but also promotes recovery. Giving the patient information and emotional support preoperatively is known to reduce pre- and postoperative anxiety substantially (Gammon & Mulholland 1996, Martin 1996). It also has a direct effect on reducing postoperative complications, partly by increasing collaboration between patient and staff. Patients who have received structured preoperative information or teaching have been found to mobilise earlier postoperatively, to have a shorter postoperative hospital stay (Gammon & Mulholland 1996) and to have a reduced need for analgesics postoperatively (Hayward 1975, Shade 1992, Teasdale 1993, Martin 1996) as compared with patients who receive standard ward or unstructured preparation. However, some studies indicate that patients want more information than is given to them (Coulter at al 1999, Thompson et al 2003).

Lack of information has also been found to be a major source of dissatisfaction among day-case patients. Costa (2001) investigated the lived experience of ambulatory surgery patients and suggested that many did not have a clear picture about what to expect preoperatively, postoperatively and throughout their convalescence at home. A small audit of 136 minor day surgery patients by Chowdhury et al (2000) found that 32% of patients did not know their diagnosis, including some receiving surgery for basal cell carcinoma. Nurses and researchers now need to devise approaches to delivering effective preoperative teaching in a reduced time frame and to provide the kind of information most useful to those patients and family members responsible for postoperative care activities at home (Bernier et al 2003). It is important that patients receive information at an appropriate level and on matters that concern them — not simply on what the nurse assumes they will be anxious about.

Cooper (1999) describes the problem of providing adequate preoperative teaching for ophthalmic day surgery patients in a short period of time. She suggests that nurses involve the patient in planning the programme because many adults wish to participate actively in learning, and learn more effectively as a result. This approach may be especially appropriate in the day surgery setting where patients are generally healthy participants who are able to process information and make informed decisions (Lisko 1995). For less able patients, a carer or family member can be involved. However, this approach may not be appropriate in other circumstances, such as emergency surgery, or when anxiety and pain interfere with the patient's ability to participate.

Mitchell (1997) argues that giving patients volumes of information will not lead to a reduction in anxiety for all. Information given should be dependent on the individual patient's preference and need, and be of high quality. Watts and Brooks (1997) studied patients admitted to an intensive care unit following surgery. They found that information about the management of pain, nausea and mouth care was important. This information was thought to reassure patients that they would be closely monitored by a nurse postoperatively and also in terms of bodily comfort. Potential anxiety about using a bedpan or a urine bottle could also be reduced by giving information about the use of urinary catheters.

26.6 How will this knowledge change the way you would approach giving information to your preoperative patient?

Skilled, systematic and sensitive assessment is essential in determining what is important for the individual.

Sensitive, open questioning can determine what the patient already understands and what they would like to know more about. Simply giving a factual account of what will occur is insufficient. Patients want to know what to expect and how it will feel. They also need the opportunity to discuss their fears and worries. Factual and sensory information, coping strategies and counselling are the essential components of preoperative education. During the admission procedure Mr W told his named nurse that he was afraid of feeling pain during the operation, as he knew he could be awake throughout the procedure. The nurse then described to him what kind of sensations he might expect:

> *Once all the checks and preparations have been completed in the ward, you will be given a tablet that will make you feel a little drowsy and more relaxed. The checks will take place again when you get to theatre and a nurse will stay with you at all times. When you go into theatre, the doctors will put up a screen using green cloth so you won't have to watch what is happening. They will also give you an injection around the top of your leg to begin to numb the area. It feels like a scratch under the skin as they make sure the skin is numb before giving you a deeper dose of anaesthetic. You will probably feel quite sleepy during the procedure, but you may feel the doctor pressing around the area, although there should be no pain or discomfort. You will never lose consciousness and would always be able to tell the doctor if you felt anything. If you would like to listen to some music on the headphones when you are in theatre, let me know before you go up and I can show you what tapes we have. Many people find it takes their mind off things and helps them relax. Remember there is always a nurse with you who you can talk to or ask about things whilst you are in theatre. How do you feel about things now?*

26.7 Can you identify the information given here in terms of knowledge, sensory information and coping strategies?

When and how information is given will influence its effectiveness. Many patients have difficulty in remembering verbal information. While a personal, verbal explanation is invaluable in that it allows for feedback from the patient, it is difficult to recall over time. Moran and Kent (1995) found that short-stay patients were most often dissatisfied with the extent of information given after the outpatient appointment prior to surgery. They advocate the wider use of pre-admission clinics where nurses can address this problem, and the development of information leaflets and patient-held shared care records to enable full information exchange between hospital, community staff and the patient. Sutcliffe and Potter (2002) highlight preoperative information giving as an important function of the pre-admission clinic because it gives patients time to assimilate information before their surgery. However, Mitchell (1997) argues that because of time limitations the emphasis of these clinics will be on physical assessment and little may be done to reduce the patient's anxiety.

Nelson (1996) found that patients preferred information to be given in a pre-admission programme prior to cardiac surgery. Pre-admission information allows for emotional adjustment over a longer period and enables patients to share information with, and seek support from, their families. Recall of information is also improved when information is given in a more relaxed setting. Beddows (1997) found that patients who were given information in their own homes prior to admission and again on admission were less anxious than those given information on admission only.

Pre-admission booklets for surgical patients can be beneficial in reducing patient anxiety and improving outcomes. Law (1997) found that preoperative information needed to be written as a back-up to verbal advice. Information can also be presented using other media such as video. However, there may always be patients that do not wish to watch information videos about their proposed procedure immediately prior to surgery (Hyde et al 1998). Information leaflets or videos are not, therefore, a substitute for personalised explanation but do provide a constant reference source and can prepare patients to use their contact time with nurses more effectively. This allows the nurse to focus on areas of concern and to devote more time to counselling than to information giving, as in reality it is often difficult to complete both tasks well in the busy preoperative period. Thus, in the example given above (Mr W), the named nurse was able to spend time providing more detailed information and suggesting coping strategies as Mr W had already read about his operation, discussed it at the pre-admission clinic and visited the ward to familiarise himself with the environment.

Preoperative information booklets should be easy to read without being patronising. Print size, reading ease and vocabulary should all be considered and the use of jargon avoided. Markham and Smith (2003) draw attention to the importance of tone in such booklets. A booklet must be comprehensive, as this improves recall and compliance with instructions (Bradshaw et al 1975). Many departments produce their own booklets giving general information about wards and surgery. Some also have leaflets about specific operations which can be given to the patient prior to admission. Preoperative education aims to produce a well-informed consumer, to promote healthy choices and to reduce anxiety. The informed patient is better equipped to make good decisions about their care and to discuss treatment fully and openly with staff. Information also serves to produce a more autonomous patient. One must then respect the view that the well-informed patient has the right to reject advice or treatment against professional judgement for personal reasons (Baxter et al 2002). What the professional advocates may conflict with what the patient wants. Simply informing someone of an objective fact that appears rational (e.g. smoking causes lung cancer) will be insufficient in some cases to promote healthy behaviour or coping mechanisms (Donovan & Ward 2001). It is also important to address the information needs of family members because they may have a role in providing support and care at home (Paavilainen et al 2001).

For additional information on the effects of giving patients preoperative information, see Hughes (2002).

Safe preparation for anaesthesia and surgery

In the admission assessment, the patient's specific needs and potential problems may be identified. The general risks associated with anaesthesia and surgical intervention will also be taken into account in any related medical or nursing procedure. Patients undergoing surgery require medical

assessment, the nature of which will depend on the extent of surgery, the age of the patient and on any pre-existing medical conditions. In some centres, an initial assessment is carried out by nursing staff so that patients most in need of anaesthetic review, such as those with poor exercise tolerance, asthma or previous problems during anaesthesia, are seen promptly (Hilditch et al 2003). Mr W was given a chest X-ray to screen for abnormalities of the lungs, a blood test for urea and electrolytes and a full blood count. An ECG was performed to rule out cardiac dysfunction, as it is important to ensure that a patient has no gross abnormalities of the cardiovascular and respiratory systems prior to the administration of an anaesthetic. The anaesthetist noted that Mr W had managed to stop smoking, and that he no longer had a productive cough. Smoking considerably increases the risk of chest infection and atelectasis postoperatively.

Risk of chest infection

All patients receiving a general anaesthetic are at risk of developing a chest infection (Richards & Edwards 2003). Drugs and gases used in anaesthesia dry the respiratory tract and inhibit the action of the cilia. Secretions of mucus become thick and tenacious, causing partial obstruction of the lower airways. Cigarette smoking also damages and paralyses the cilia and leads to excess mucus production. The secretions eventually pool in the base of the lungs and plug the bronchioles. The retained secretions obstruct the lower airways, inhibiting gaseous exchange and providing a source of bacterial infection.

Anaesthesia depresses respiration and, in the deep stage, breathing will actually cease. Artificial ventilation during the operation is at tidal volume and does not fully inflate the lungs (see Ch. 3). Normally, a person will sigh intermittently or increase demands for oxygen by activity, fully inflating the lungs and preventing stagnation and atelectasis. Changes of position, movement and coughing all serve to dislodge excess mucus or fluid, which is then expelled from the lungs as sputum. When under a general anaesthetic the patient will be lying still and unable to cough or sigh throughout the operation. There will also be a period of inactivity postoperatively and perhaps a reluctance to breathe deeply or cough if there is abdominal or thoracic pain. Opiates given for pain relief can also depress respiration (Sheppard & Wright 2000).

Patients should be advised to stop smoking, at least for 2 weeks prior to surgery, if not for good. Haddock and Burrows (1997) found that nurses could have a significant impact on helping smokers to quit before surgery by giving constructive advice and information in the pre-admission stage. All patients, regardless of whether they are smokers or not, must be taught deep breathing exercises and coughing. It can be difficult to teach a patient to contract the diaphragm in order to breathe deeply preoperatively, let alone postoperatively. The tendency is to use intercostal and accessory muscles to lift the rib cage and draw the abdomen in. Although instruction may be the responsibility of the physiotherapist in some wards, it will still require reinforcement from the nursing staff. In this context, the need for early mobilisation can be described to the patient.

For a detailed coughing and deep breathing regimen, see Sheppard & Wright (2000).

Patients should also be informed that they may have oxygen therapy via a mask or nasal cannula postoperatively to help maintain the level of oxygen in their bloodstream while recovering from the anaesthetic (Walker 2003). Oxygen therapy may have a drying effect on the mouth and the mucous membranes of the nose. Patients can be assured that ice chips or a mouthwash will be available to help relieve this.

26.8 Try some deep breathing exercises yourself. Did you draw in your abdomen and lift the rib cage? Try to breathe using the diaphragm. Place one hand on your abdomen. Breathe in through your nose while you try to feel your abdomen pushing your hand out (as the diaphragm moves downwards and displaces the stomach).

Risk of deep vein thrombosis (DVT) and pulmonary embolism (PE)

An intravascular clot or thrombus is most likely to occur when the following conditions, known as Virchow's triad, exist:

- trauma — damaged endothelium
- stasis — slow blood flow
- hypercoagulable blood.

Thrombus formation is initiated by the activation of factor XII in reaction to exposure to collagen filaments in the damaged endothelium. This results in platelet aggregation, formation of thrombin from circulating prothrombin, and stimulation of the production of insoluble fibrin from fibrinogen (see Ch. 11, p. 482). It has been found that, during surgery, the veins of the lower leg distend by up to 48% (Coleridge Smith et al 1991). This distension leads to subluminal endothelial damage, which can provide a site for clot formation. In the soleal and gastrocnemius veins, the blood flow is highly dependent on exercise, and so these are often the sites of initial thrombus formation following prolonged periods of inactivity and lack of calf muscle pressure to assist venous return. The general adaptation reaction to the stress of surgery (see Ch. 17, p. 695) results in reduced levels of the coagulation inhibitors protein C, protein S and antithrombin III. Fibrin clots may be broken down gradually by the enzyme plasmin in a process called fibrinolysis. However, the thrombus may persist, causing some degree of venous obstruction.

In a small proportion of cases, a fragment of the clot breaks away, forming an embolus. The embolus may travel through the venous system, through the right side of the heart and into the pulmonary arteries. Here it becomes lodged at a point where the arteries become too small to allow the embolus to pass through. The extent of the resultant pulmonary infarct depends on the size of the vessel occluded. Some patients may have no signs or symptoms of either DVT or PE if thrombi are small and infrequent (Dawes 1997) (see Ch. 2). A large PE is a very serious complication. Without treatment there is mortality of approximately 11% of such patients within 1 h of the embolic event and of 30% in those who survive longer than 1 h (Moccia 2000). Early detection and treatment significantly reduce this rate (Campling et al 1995, Gilles et al 1996, British Thoracic Society 1997, Moccia 2000).

After gynaecological surgery, up to 20% of perioperative deaths are attributable to PE (Nicklin & Franzcog 2002). All surgical patients are exposed to a number of risk factors for DVT. Without prophylaxis the overall risk of developing a DVT for surgical patients may be as high as 25–30% and up to 70% for orthopaedic surgery (Dawes 1997, Agu et al 1999). The incidence of DVT in patients undergoing various types of vascular surgery was found to be between 9 and 14% despite standard prophylaxis with anticoagulants (Fletcher & Batiste 1997). In abdominal surgery and neurosurgery the risk has been reported at approximately 5%, again with anticoagulant prophylaxis (Flinn et al 1996, Kakkar et al 1997). During the preoperative assessment, the nurse should assess the patient for the presence of known risk factors (see Box 26.1).

In the UK, the reports of the Thromboembolic Risk Factors Consensus Group (THRIFT 1992) and the Scottish Intercollegiate Guidelines Network Group (2002) make recommendations on the regimens to be used, based on the relative risk of DVT and potential bleeding complications in individual patients. It is now generally accepted that all patients should use graduated elastic compression stockings (GECS) (Jeffery & Nicolaides 1990, Amaragiri & Lees 2001). Although it is not fully understood how GECS work (Arnold 2002, Parnaby 2004), these stockings create a decreasing pressure gradient in the leg from approximately 18 mmHg at the ankle to 8 mmHg at the thigh (full length) or to 14 mmHg at the calf (below-knee length). The gradient increases blood flow in the femoral vein, inhibits stasis of the venous circulation, stops build-up of any nidus of thrombosis formation and prevents the venous distension that causes endothelial damage (Thomas 1999, Parnaby 2004). GECS are inexpensive and reduce the incidence of postoperative DVT by approximately 60% (THRIFT 1992, Williams et al 1996).

The nurse should ensure that a well-designed and well-fitting stocking is applied. Patients can be taught the correct fitting technique and nurses should ensure that patients understand the reason why and the importance of wearing GECS (Parnaby 2004). Stockings are fitted according to calf size and leg length and are available in a wide variety of sizes. If stockings roll down, a constricting band is created which may cause higher pressures, leading to an inverse gradient and delayed venous emptying. Thigh length stockings are suggested to be more effective (Byrne 2001, Scottish Intercollegiate Guidelines Network 2002). However, below-knee stockings have been found to be more comfortable and more accurately applied for patients with few risk factors and who are ambulant (Hui et al 1996, Williams et al 1996). They are also less costly than full-length stockings (Ingram 2003). Small studies comparing below-knee and full-length stockings have suggested that above knee and below knee are equally effective in prophylaxis against DVT (Porteus et al 1989, Hui et al 1996, Williams et al 1996, Parnaby 2004) but Ingram (2003) suggests that the use of below-knee GECS is variable. Every hospital should have DVT prophylaxis guidelines based on best available evidence (THRIFT II 1998) and larger studies are required to clarify this point (Ingram 2003).

Approximately 15–20% of patients are unable to wear GECS because of limb characteristics (Greerts et al 2001), marked leg oedema, severe peripheral arterial disease, dermatitis, severe peripheral neuropathy or other major leg deformity (Scottish Intercollegiate Guidelines Network 2002). The use of GECS is also contraindicated in patients with severe peripheral vascular disease or profound limb ulceration (Parnaby 2004). Patients should wear the stockings prior to surgery and up until discharge (Nicklin & Franzcog 2002).

Other measures that should be encouraged where possible are early activity and hourly leg exercises. The patient should be taught to dorsiflex the foot preoperatively. This will assist venous return by the action of the calf muscle compressing blood in the deep veins. Deep breathing exercises will also aid the respiratory pump, as deep inspiration reduces intrathoracic pressure and hence increases venous return. In addition, ensuring adequate hydration will reduce hypercoagulability.

Intermittent pneumatic compression stockings (IPCS) are mechanical devices that fill with air, periodically compressing the calf and/or thigh muscles of the leg and stimulating fibrinolysis. For patients at high risk of developing DVT, such as those undergoing orthopaedic and cardiac surgery, intermittent pneumatic compression of the legs has been shown to be particularly effective (Capper 1999, Scottish Intercollegiate Guidelines Network 2002), although Arnold (2002) suggests that patients are often reluctant to participate in this treatment. Patients may remove stocking sleeves or disconnect the pump because they find the stockings hot or uncomfortable (Murakami et al 2003). The pumps require connection to an external power source and are frequently disconnected when patients are out of bed or during transfer (Murakami et al 2003). A study by Cornwell et al (2002), investigating the compliance rate with IPCS prophylaxis, found that, out of a total of 1343 observations carried out in patients who were at risk of DVT following trauma, fewer than 20% of patients had their compression devices on, and functioning correctly, during six observations in a 24-h period. It is important that nursing staff exercise vigilance towards any patient receiving IPCS prophylaxis and ensure that the system is fully operational in order to optimise therapeutic effect.

Teaching leg exercises and applying GECS and/or IPCS devices prevent DVT by their action on two aspects of

Box 26.1

Risk factors for deep vein thrombosis (DVT)

- Age: increased risk in older patients
- Obesity
- Presence of varicose veins
- Previous DVT
- Clotting disorders
- Oral contraceptive pill/hormone therapy
- Immobility
- Pregnancy
- Spinal or epidural anaesthesia
- Surgery, especially major abdominal or orthopaedic surgery

Based on data from Scottish Intercollegiate Guidelines Network (2002) and Parnaby (2004).

Virchow's triad, namely stasis and endothelial damage. Hypercoagulability can be avoided to some extent by adequate hydration but will be stimulated by the general adaptation to stress response and by the effects of surgery initiating clotting mechanisms. Medical staff will seek to minimise hypercoagulability with the administration of anticoagulants in the form of prophylactic low dose unfractionated heparin (Breen 2000, Nicklin & Franzcog 2002). Usually 5000 IU are administered subcutaneously every 8 or 12 h and, to be effective, it should be commenced 30 min to 2 h preoperatively (Nicklin & Franzcog 2002). Low dose heparin does not cause full anticoagulation so the risk of bleeding complications is minimal, unless the patient has a clotting disorder. In such a case, administration of anticoagulants must be monitored closely and their value judged carefully against the risk of DVT. A combination of mechanical methods, such as GECS, and pharmacological agents, such as low dose heparin, can reduce the risk of DVT by more than 80% in general surgical patients and by 65% in orthopaedic patients (Parnaby 2004). Small wound haematomas may be more likely to occur in the patient receiving low dose heparin but, when cared for correctly, do not usually pose a threat.

Preoperative fasting

Patients who are to receive a general anaesthetic, heavy sedation or a local anaesthetic with the possibility of proceeding to a general anaesthetic, are all at risk of aspiration pneumonia. When a patient is anaesthetised or unconscious, the swallowing reflex is absent. From the point of induction of the anaesthetic, there is a risk that stomach contents may reflux and be inhaled through the open larynx into the lungs. This inevitably causes respiratory embarrassment and leads to the development of pneumonitis or a diffuse chest infection. In young and healthy individuals pulmonary aspiration is a rare complication of modern anaesthesia (Warner et al 1993, Crenshaw & Winslow 2002). However, because the ability of the respiratory system to protect against aspiration diminishes with age, older patients are more vulnerable to this complication (Cook & Rooke 2003, Rosenthal & Kavic 2004). Risks can be minimised, partly through the administration of certain drugs, but also by fasting the patient of both diet and fluids.

Different foodstuffs pass through the stomach at different rates. Clear liquids are eliminated immediately from the stomach, whereas solids must be broken down (Crenshaw & Winslow 2002). Patients who receive opioids and those with diabetes may also have reduced gastric motility. Gastric emptying is usually complete for most meals in 4–5 h but even fasting patients may have up to 200 mL in the stomach (Dougherty & Lister 2004). Taking this into account, the recommended minimum preoperative fasting period is between 2 and 4 h for fluids, 6 h for a light meal, e.g. tea and toast, and 8 h for a heavier meal. However, a study by Phillips et al (1993) found there was little difference in residual volume when patients were allowed to drink clear fluids up until the time of the premedication (approximately 2 h preoperatively). The patients had no problems with aspiration or regurgitation and they were less thirsty and more comfortable. Murphy et al (2000) found no difference in the rates of aspiration between patients given traditional nil by mouth (NBM) from midnight orders and those who had unlimited clear fluids before surgery. Those fasted for longer had, in fact, clearer gastric contents in the posterior pharynx. A group of Swedish surgeons (Ljungqvist et al 2000) administered a specially developed carbohydrate drink to cholecystectomy and hip replacement patients 2–3 h before surgery. This was thought to result in a less stressful physiological response to the surgical trauma. No adverse effects were reported and patients receiving the supplement had a reduced stay in hospital following surgery.

A classic study by Hamilton Smith (1972) found that patients were often fasted preoperatively for much longer than necessary. Chapman (1996) found that patients continue to be fasted for prolonged periods, with those on a morning list fasted for an average of 12 h and those on the afternoon list for 8 h. This continues to be the case (Jester & Williams 1999, Crenshaw & Winslow 2002). Prolonged fasting is associated with adverse effects (Crenshaw & Winslow 2002). The undesirable results of prolonged fasting are mainly dehydration and electrolyte imbalance. The liver's glycogen stores are sufficient to maintain blood sugar levels for approximately 18 h but even a fast of 6–8 h can reduce the body's ability to cope with stressors such as blood loss or infection (Dean & Fawcett 2002). Patients can experience both physiological and psychological effects including dehydration, headaches, hypoglycaemia, electrolyte imbalance, nausea and vomiting, confusion, irritability and social isolation when missing mealtimes (Jester & Williams 1999). Older patients are particularly vulnerable to fasting. Depending on their pre-existing health status, older people are at risk of dehydration and confusion, potentially rendering them unfit for anaesthesia and surgery (Jester & Williams 1999).

All patients, to some extent, suffer from the effects of fasting, e.g. hunger and a dry mouth. Some might not understand the reasons for fasting and eat or drink against advice, or think that fasting simply means 'no meals' and have snacks instead. Patients must be given adequate information in order to understand why and what they cannot eat or drink, for how long, and be offered choices on how to care for a dry mouth in the meantime, e.g. tooth brushing, chewing gum, sucking ice chips or boiled sweets (Crenshaw & Winslow 2002, Markham & Smith 2003). Markham and Smith (2003) examined written information given to patients preoperatively. They found that much of the information was out of date and did not sufficiently explain why fasting was necessary.

Research is widely available on the appropriate length of preoperative fasting times but normally, in practice, a wide margin of safety is set and patients are fasted for at least 6 h. Apart from that of the first person on the operating list, theatre times are always approximate, as one cannot be entirely sure how long each operation will take. Surgeons may alter the order of patients on the list, but this should not form part of everyday practice. Nurses work to the earliest likely time for theatre, but actual times often prove to be much later. A lack of individualised care leads to the imposition of one fasting time for all patients on the theatre list. A patient on the morning list may be fasted from midnight, but, if last on the list, may not go to theatre until 1400 h. Thus they may have fasted for at least 14 h. Individual fasting times and close liaison with the anaesthetist

can resolve such problems. Nursing staff must also feel confident to implement comfort measures in units where NBM has traditionally meant that nothing passes the patient's lips until theatre. If the patient has oral medication prescribed during the fasting time, it should not be routinely withheld; rather, medical staff should be consulted as to whether the drug should be given or not. Tablets can be taken with 30–60 mL of water. Crenshaw and Winslow (2002) highlighted that many patients did not know what arrangements had been made for administration of their medications.

To return to the case histories, Mrs B was to go to theatre as an emergency, so it was not possible to ensure she had fasted for at least 4 h. In this case, her stomach was emptied by aspirating the contents through a nasogastric tube. Mr W came into hospital on the morning of theatre but had received instructions about fasting in his booklet from the pre-admission clinic the week before. He was not sure whether he could have an early morning cup of tea and had asked his named nurse about this during his visit. As theatre would not start until 0930 h he was advised that he might have a drink at 0600 h but nothing after that. In fact, Mr W was third on the list and did not go up to theatre until 1130 h.

26.9 Observe how long patients are fasted preoperatively in your ward experience. How would you explain to a patient the necessity for fasting prior to theatre?

Skin preparation

The most significant cause of postoperative wound infection is the exposure to nosocomial pathogens (see Ch. 23, p. 840). The risk can be reduced by shortening the length of preoperative stay and the judicious use of standard infection control precautions by the nursing and medical team. The seminal work of Boore (1978) highlighted that by reducing preoperative anxiety, psychological and physiological stress can be reduced and the incidence of postoperative infection lowered.

Hair removal Shaving the skin before theatre has been thought for many years to be an integral part of preoperative preparation. However, shaving leaves small cuts and abrasions that can give rise to infection and delay discharge (Editorial 1983). It is no longer considered to be an appropriate routine preoperative procedure. Hair removal may be justified on humanitarian grounds where sticking plaster is to be used, if the hair occludes the surgeon seeing the anatomy of the operation site, or if adhesive leads, requiring a good skin contact, are to be applied.

If hair removal is necessary, then hair clippers or depilatory cream have been associated with fewer breaches of the skin than shaving (McIntyre & McCloy 1994, Small 1996). Clippers should be sterilised (Small 1996), and a patch test for sensitivity to creams must be carried out before use. Application of depilatories must also be avoided around sensitive mucous membranes in the genital area. When the above procedures cannot be applied, a well-lubricated shave with a sharp razor may be carried out immediately prior to theatre, since there is a link between timing of the shave and subsequent infection. In a classic study, involving analysis of 406 cases, Seropian and Reynolds (1971) found the wound infection rate to be 3.1% when the shave was done just prior to surgery, 7.1% when the shave was done during the 24 h before surgery, and 20% when the shave was done more than 24 h before surgery.

Where hair removal is considered essential, the nurse should ensure that the patient is not especially vulnerable to postoperative surgical infection because of other factors such as a pre-existing skin condition, or an immunocompromised status (Mangram et al 1999). If it is considered appropriate for patients to carry out their own skin preparation, the nurse is responsible for ensuring that they can do this safely and effectively (Small 1996).

Showering In the past, patients have been advised to shower prior to theatre using a skin antiseptic in an attempt to reduce the bacterial count on the skin (Brandberg & Anderson 1980). Although a single preoperative shower is unlikely to reduce the risk of infection, repeated washing with a chlorhexidine-based detergent does reduce the level of resident skin flora (Ayliffe et al 2000). This may benefit patients undergoing cardiovascular or prosthetic surgery (Ayliffe et al 2000). Unfortunately, some patients may have allergies or severe skin reactions to antiseptic solutions and so a patch test before use is essential. Bathing should be avoided where possible, as bacteria may multiply in the warm water and there is a risk of cross-infection from organisms already present in hospital baths. The patient should shower and/or shampoo before transfer to the operating theatre. If the patient is unable to do so, the nurse can wash the surgical site before the patient goes to theatre, or theatre staff can wash the surgical site immediately before application of the antimicrobial skin preparation solution. Removal of superficial soil, debris and transient microbes in this way reduces the risk of wound contamination by decreasing the organic debris from the skin (Anon 1996). It is unnecessary to change bed linen that is clean.

Specific measures

Premedication — 'premed' — is the term used for drugs given to the patient before leaving the ward for theatre. These drugs constitute part of the anaesthetic and are used to prepare the patient to receive a general or local anaesthetic (see Table 26.1). They are often also used to relax the patient and relieve anxiety. However, research by Hyde et al (1998) found that, although patients were often anxious about their surgery, many did not wish to be sedated in the immediate preoperative period. Instead they would rather listen to music, read and be able to move about freely. The premed is prescribed by the anaesthetist after assessing the patient for the administration of the anaesthetic. The prescription may be made for a set time or 'on call', i.e. the anaesthetist will telephone the ward to ask the nurse to administer the prescribed drug once it is clear how long it will take for the patient to be called to theatre. The nurse must ensure that the consent form has been signed, the patient has emptied their bladder and that all other preoperative checks are complete before giving the premed. The patient should then be advised to rest and asked not to get out of bed unsupervised if the premed contains a strong sedative or opioid agent.

Table 26.1 Common premedications

Drug	Usual adult dose	Route	Effects
Diazepam (Valium)	2–10 mg	Oral	Sedative: reduces tension and anxiety. Decreases muscle tone and potentiates non-depolarising muscle relaxants. Induces mental detachment and amnesia
Temazepam	10–20 mg	Oral	Sedative: reduces tension and anxiety. Induces drowsiness
Morphine sulphate	5–15 mg	i.m./s.c.	Opioid analgesic: induces drowsiness, reduces anxiety, induces mental detachment, respiratory depression*, nausea*

*Unwanted/undesirable effect.

Bowel preparation Some patients will require very specific types of preoperative preparation as ordered by medical staff. That most commonly seen is bowel preparation prior to surgery on the gastrointestinal tract or pelvic organs. If a paralytic ileus is anticipated, or the bowel is to be opened (resulting in a risk of infection), then oral laxatives and purgatives, or suppositories and enemas may be used to clear the bowel.

Music Again returning to the case histories, Mr W's anaesthetist prescribed a benzodiazepine sedative (diazepam 5 mg) as a premedication, being aware that Mr W was particularly anxious. Mr W had also borrowed one of the personal stereos from the ward and was enjoying listening to music. While research into the effects of music on anxiety and postoperative pain remain inconclusive, predominantly due to a lack of studies in the area, many patients do find listening to music a helpful distraction at this stage (Good 1996).

Theatre safety

The nurse must carry out preoperative checks before the administration of the premed, as the results of the checks may necessitate a delay in going to theatre. Moreover, the patient should not have received sedative or opioid agents before signing the consent form. Many hospitals have created their own checklists. Examples of criteria for checklists are given in Table 26.2.

Table 26.2 Preoperative checks

Criteria	Action	Rationale
Identification	Prepare two name bands with patient's full name, hospital unit number, date of birth, home address (as a minimum), plus ward and consultant	Correct identification of patient
	Clearly note allergies on the anaesthetic sheet and on wrist bands as well as the drug Kardex	Avoidance of all allergens
	Ensure site is correctly marked with indelible ink	Correct identification of site
Documentation	Ensure that medical notes, nursing notes, signed consent form, X-rays and anaesthetic sheet accompany patient to theatre	Ready availability of all necessary information
Fasting	Check when patient last had anything to eat or drink	Prevention of aspiration pneumonia
Empty bladder	Ask patient to pass urine prior to administering premedication	To prevent damage to full bladder during surgery To enable complete bed rest after premed To prevent postoperative discomfort due to a full bladder
Risk of diathermy burns	Ask patient to remove all jewellery, hair pins and other items containing metal (wedding rings may be covered with tape)	To remove all metal that may concentrate the diathermy current
Prostheses	Ask patient to remove all prostheses, e.g. dentures, hearing aids, contact lenses, false eyes, glasses, etc.	To prevent harm caused by prostheses To prevent loss
Care of valuables	Offer to receive valuables into safekeeping for the patient	Patient will be away from the ward and unfit to be responsible for these valuables
Circulatory assessment	Ask patient to remove all makeup, lipstick and nail varnish	To facilitate observation of colour of skin, lips and nail beds

In order for patients to understand and cooperate with preoperative procedures, adequate explanation and reassurance must be given. However, the nurse should also be aware that some information might cause unnecessary distress. For example, Mrs B did not want to remove her wedding ring. The nurse offered to tape this for her, but Mrs B said that she had never taken it off and that it would be secure. The nurse explained that it was to protect her from the use of electric current to seal blood vessels during the operation.

There are some patients who rely on their hearing aids and/or glasses. In such cases, these can be labelled with adhesive tape and worn by the patient until anaesthetised. Equally they may wish to retain their false teeth until anaesthetised. A note should be made to this effect on the checklist or anaesthetic form.

During the immediate preoperative period, the patient may feel extremely vulnerable and anxious (Costa 2001) — they will be wearing only a flimsy gown; their dentures may have been removed; they may be unable to see well without glasses, and they will feel drowsy from the premed. Anxiety about the impending operation can be high, especially among patients placed in the later part of the operating list (Panda et al 1996). Reassurance by the nurse at this time and, for some patients, distraction can be helpful. Suggestions for managing this period are made by Mitchell (1997) and Hyde et al (1998) and include having a family member stay with the patient. The patient should be encouraged to rest.

Nursing Care Plan 26.1 summarises the preoperative care given to Mr W.

PERIOPERATIVE SAFETY

Caring for the patient in theatre

The patient arrives in the operating theatre accompanied by a nurse from the ward and a porter or operating department assistant (ODA). Patients may be brought to the theatre on a trolley or on their bed from the ward. Once the patient transfers to the theatre table, the bed is taken to a holding area. The patient is then transferred straight back onto the bed at the end of the operation. This reduces the discomfort of transferring from trolley to bed in the ward, and reduces the amount of patient lifting by nurses, porters and ODAs.

The anaesthetic or theatre nurse receiving the patient goes through the preoperative check again (as in Table 26.2). The ward nurse will then usually return to the ward. If the patient is especially nervous or confused, it can be comforting if a nurse who knows them well can stay until the induction of anaesthesia. All patients must be supervised by a nurse in this pre-induction time, as the patient may have received premedication and is in an extremely stressful and unfamiliar environment. It is now common practice for theatre nurses to visit their patients preoperatively to carry out a nursing assessment, to introduce themselves and to give any information required about patient care in theatre (Crawford 1999, Scott et al 1999).

In emergency cases, the theatre nurse may continue the preoperative preparation. For example, Mrs B's daughter arrived at the hospital as these preparations were being carried out. She was escorted to theatre by the ED nurse and saw her mother for a few minutes in the anaesthetic room before she was anaesthetised. The theatre nurse briefly explained what was happening, and once Mrs B was asleep, made a cup of tea for her daughter and let her make a telephone call from the Charge Nurse's office. The theatre nurse then telephoned the named nurse, who sent a clinical support worker to take Mrs B's daughter to the ward.

For further reading on family involvement in perioperative nursing of patients undergoing emergency surgery, see Paavilainen et al (2001).

The roles of theatre staff are summarised in Box 26.2. The anaesthetist will visit the patient preoperatively in the

Box 26.2

The roles of the theatre staff

The anaesthetic nurse
- Receives the patient in the reception area of the anaesthetic room
- Checks patient in, deals with any irregularities
- Helps to relieve patient anxiety
- Assists in the induction (and maintenance) of anaesthesia
- Performs emergency preparation of patients for theatre
- Uses and checks anaesthetic equipment
- Maintains patient safety and comfort

The anaesthetist
- Visits the patient preoperatively:
  - — to assess fitness for anaesthesia
  - — to provide information and reassurance
  - — to prescribe a premedication
- Induces and maintains anaesthesia
- Monitors patient's condition during surgery
- Provides supportive treatment, e.g. fluid replacement, PO_2 level maintenance, correction of arrhythmias
- Initiates postoperative analgesia

The circulating nurse
- Assists with the provision of equipment
- Maintains nursing records
- Positions the patient
- Ensures safety with regard to instruments and swabs
- Cleans and sterilises equipment
- Observes, measures and records vital signs

The scrub nurse
- Positions the patient
- Provides appropriate sterile equipment
- Assists the surgeon
- Protects the patient's dignity
- Prevents diathermy and pressure injuries
- Ensures safety with regard to instruments and swabs
- Manages the high-risk patient

The recovery room nurse
- Maintains patency of the airway
- Observes patient for level of consciousness and safety
- Observes vital signs: colour, respiration, temperature (core and peripheral), pulse, blood pressure, fluid intake and output, wounds and drainage, specific checks as required
- Assesses pain and nausea and administers analgesics and antiemetics
- Reassures the patient and provides a quiet environment
- Provides total patient care
- Provides documentation and facilitates communication

Nursing Care Plan 26.1 Preoperative care for Mr W (see Case Histories 26.1(A) and 26.1(B))

Nursing considerations	Action	Rationale	Evaluation
Anxiety due to: • **hospital environment** • **diagnosis/prognosis** • **anaesthesia and surgery**	• Ensure Mr W is informed of and understands diagnosis, procedure, likely postoperative progress	To reduce anxiety and promote recovery	Anxiety is reduced to an acceptable level
	• Provide opportunity to discuss fears and anxieties		
	• Enhance or supplement coping mechanisms (e.g. use of personal stereo)		
Haemorrhage and shock*	• Record vital signs as baseline	To make data available for postoperative comparison	Staff are prepared to deal with bleeding and shock is prevented
	• Encourage intake of fluids until 4 h before theatre	To maintain good fluid balance	
	• Ensure blood tests and blood grouping completed	To ensure availability of blood products in case transfusion is necessary To ensure good haemoglobin status	
Wound infection*	• Have Mr W shower preoperatively • Provide clean theatre gown	To reduce superficial soiling, skin debris and transient microbes	No infection occurs
Chest infection*	• Teach deep breathing and coughing exercises	To inflate lungs fully and clear stagnating secretions	No infection occurs
	• Continue to support Mr W in not smoking	Patient is under stress and may return to inappropriate coping mechanisms	
Deep vein thrombosis*; pulmonary embolism*	• Teach leg exercises and stress importance of early mobilisation • Fit and apply graduated compression stockings • Teach deep breathing exercises (see above)	Contraction of calf muscle and graduated external compression; increase blood flow in the femoral vein and promote venous return	Thrombosis and embolism are prevented
Aspiration pneumonia*	• Have Mr W fast 4 h (fluids) and 6 (food) preoperatively from 06.00 h	Stomach must be empty prior to anaesthesia; Mr W may need general anaesthetic	Vomiting is prevented
Theatre safety	• Complete checklist prior to administration of premedication (see Table 26.2)	See Table 26.2	Patient is safely prepared for anaesthetic and surgery

*Potential problem.

ward to assess the patient's ability to tolerate the anaesthetic and give information and reassurance. A premedication will be prescribed if required.

If the patient is to have minimally invasive surgery or investigations, e.g. colonoscopy, endoscopic retrograde cholangiopancreatography (ERCP) or cardiac catheterisation, a general anaesthetic may not be used. Instead, the patient may be sedated by medication such as diazepam or midazolam which have amnesic properties, helping the patient to be less aware of what is happening and to remember very little about the procedure. In this situation, an anaesthetist may not necessarily be present but would be available should the need arise to proceed to a general anaesthetic or should other supportive treatment be required. The nurse may act as the surgeon's assistant and take part of the responsibility for monitoring the patient's condition. Some specialist nurses may conduct endoscopies independently. In main theatres, at least two nurses as well as the anaesthetist and surgeon will be present. One nurse acts as the circulating nurse, the other as the scrub nurse. The scrub nurse wears sterile gloves and will provide instruments for the surgeons, assist where necessary and ensure safety with equipment during the operation (see Box 26.2).

The emphasis of the nursing role in theatre is on patient safety and teamwork. Each professional has an important part to play in the patient's passage through theatre. As the team members develop trust and understanding amongst themselves, it may be difficult initially for the student to appreciate the communication links in place, especially when staff have half their faces covered with a mask.

Environmental safety

The environment in the operating theatre is designed to minimise the risk of exogenous infection to the patient. Some of the measures used to ensure safety are as follows:

- Clean filtered air is pumped into clean areas. Air pressure is higher inside the theatre than outside, in order to maintain an air flow from the theatre to the outside. This prevents potentially contaminated air from the rest of the hospital moving into the theatres.
- Humidity is controlled through the ventilation system to prevent static electricity build-up and the risk of sparks, as flammable gases may be in use. Staff are required to wear antistatic shoes (usually clogs or boots). All equipment must have antistatic rubber wheels or covers.
- Clean and dirty areas are delineated by doors or a line on the floor. All personnel moving into clean areas must be clean and appropriately dressed (see below). All items brought into clean areas must be clean. All dirty items leaving theatre should do so via dirty areas. It is essential that staff are aware which are the dirty and the clean areas and corridors. The use of sticky mats at the main entrance to theatre was thought to reduce contamination from the feet of staff entering. This has now been shown to be ineffective and the practice has been discontinued. Similarly, no evidence exists that overshoes reduce bacterial counts on the theatre floor. However, shoe covers may protect members of the surgical team from exposure to blood and body fluids (Mangram et al 1999).
- The numbers and movements of staff inside theatres are kept to an absolute minimum to reduce the number of skin scales shed and mixing of air (Mangram et al 1999).
- All staff entering clean areas are appropriately dressed. Clean theatre dresses or trouser suits are worn. Hair is completely covered by a bonnet-style cap and all jewellery, especially on the hands, is removed. Masks are worn inside the theatre to reduce airborne organisms. Masks, once applied, should be handled only by the tapes as the main fabric of the mask becomes contaminated with moisture and microorganisms which can then be transmitted to and by the hands.
- Practice varies as to whether staff leave the theatre area wearing theatre clothing. Some hospitals restrict staff to the theatre area when dressed in theatre clothing, while others allow for the wearing of gowns over scrub suits when personnel leave the theatre suite (Mangram et al 1999, Editorial 2003, Kaplan et al 2003).
- A sterile field is created around the patient. The patient and trolleys in this area are all covered with sterile drapes. The surgeon and scrub nurse wear sterile gloves and gowns to work within the sterile field.

Safety of the patient

The patient's safety in theatre is further ensured by the following precautions:

- Transfer to operating table and positioning are carried out with extreme care. The preoperative visit by the theatre nurse enables the assessment of any potential problems, especially in relation to joint mobility and the risk of developing pressure ulcers. Surgical patients are particularly at risk of developing pressure ulcers during the perioperative phases of their care because of the combination of immobility while surgery is carried out and circulatory and metabolic changes resulting from anaesthesia and surgical trauma (Scott et al 1999). Patients who have epidural anaesthesia may have reduced sensation in the lower extremities and impaired leg movement because of the effects of the anaesthetic mixture on the motor nerve pathways in the spinal cord. These patients are especially at risk of heel pressure ulcers because they may fail to change the position of their legs in bed, or feel the sensation of discomfort. Special types of pressure-relieving mattresses and overlays are used with high-risk patients. An overlay is placed directly on the mattress. Air, foam, gel or water are commonly used in overlays (Armstrong & Bortz 2001). Once patients are anaesthetised, they may lose muscle tone. Care should be taken with all limbs; for example, if the arm is left to hang over the edge of the table, irreparable damage to the brachial plexus may result. The nurse must also be aware when positioning patients on the operating table of limitations in movement that may result from previous joint replacement surgery; for example, hip flexion may be restricted in patients with a total hip replacement prosthesis (McEwen 1996).
- The diathermy pad is carefully positioned. A self-adhesive pad may be used and the pad is usually placed under the buttocks or strapped to the thigh to ensure good contact over the entire surface. A poor contact by

only part of the surface may concentrate the current, causing it to leave a burn.
- Swabs, needles and instruments used during theatre are counted and checked throughout and at the end of the operation by the scrub and circulating nurses. This ensures that all items used are accounted for and none left inside the patient.
- Allergies to drugs, skin antiseptics and dressings are assessed preoperatively by the theatre nurse and anaesthetist, so the use of any allergens can be avoided. For example, although not fully understood, allergy to latex is present in increasing numbers of patients (Yuill et al 2003).
- The patient's skin is cleaned at the start of the procedure. Alcoholic solutions containing chlorhexidine, povidone–iodine or triclosan are quick acting and produce a rapid reduction in skin flora and the risk of endogenous infection (Ayliffe et al 2000). Once applied, alcoholic solutions must be allowed to dry completely lest they ignite on contact with diathermy. Some surgeons also use a sterile plastic adhesive drape over the skin (Incisa-drape) through which to make the incision. This prevents the surgeons' and nurses' sterile gloves being contaminated with the patient's skin flora.
- Prophylactic antibiotics may be given (usually intravenously) during the operation, or the site of the surgery may be irrigated with an antibiotic solution. These measures are usually taken only if there is a specific risk of contamination, or if contamination from an abscess or the gastrointestinal tract is already present.
- During surgery the patient is at risk of primary haemorrhage. When an incision is made, the patient will bleed until a clot is formed or until the pressures within the vessel and the cavity into which it is bleeding have equalised. Bleeding during surgery is minimised by the use of clamps and ligatures, local pressure or diathermy to seal small vessels. Topical haemostatic agents such as cellulose and collagen may also be used. To facilitate the surgeon's vision, the site of operation is kept free of blood by swabbing or suctioning. The circulating nurse may weigh the swabs or note the volume of blood in the suction bottle to estimate 'total blood loss'.
- Special procedures must be followed for the care of patients identified as carriers of certain infectious diseases — commonly blood-borne diseases with a high morbidity and mortality (see Ch. 11). To prevent cross-infection and to reduce risks involved with cleaning and spillages, disposable equipment may be used where possible (see Ch. 16). In many hospitals, such procedures are now followed for all patients as it is often not known whether a patient is a carrier of an infectious disease. The surgeon and scrub nurse may wear two pairs of gloves, and the patient may not be taken into the recovery room after the operation, in case of further blood loss, but recovered in theatre instead. The patient should be at the end of a theatre list to enable recovery in theatre and to allow thorough cleaning and disinfection of the theatre before it is used again.

In summary, the safety of the patient in theatre is the prime responsibility of all members of the theatre team.

For further information on patient safety in theatre, see the National Association of Theatre Nurses' 1998 publication, *Principles of Safe Practice in the Perioperative Environment.*

Anaesthesia

An anaesthetic is used to block any sensations of pain during surgery. It may be applied locally or regionally to the area of surgery or generally throughout the body. A brief introduction to the use of anaesthetics is given here.

For further information on medications used in anaesthesia, see Waller et al (2001) and Chapters 17–20 and 27.

Local anaesthesia

Local anaesthesia blocks transmission of pain from the region operated upon. In some cases, only the sensory receptors may be blocked; this is more correctly termed local analgesia. A local anaesthetic, e.g. lidocaine, is often combined with adrenaline to constrict blood vessels and delay absorption of the anaesthetic into the bloodstream. This reduces the amount of local anaesthetic required and prolongs its action. Types and common uses of local anaesthetics are summarised in Table 26.3. Epidural or spinal anaesthetics may be used when a general anaesthetic could be harmful or is undesirable, e.g. in older patients with arteriosclerosis or diabetes, in patients with respiratory disorders and in patients with hypertension. An infusion of epidural anaesthetic agents can also be continued after surgery to provide effective postoperative analgesia (see p. 929). The procedure causes hypotension and so should be avoided in patients with this condition.

Care must be taken to prepare the patient psychologically in order to reduce anxiety and ensure cooperation. Psychological support should continue throughout the operation and the nurse should ensure that the patient's vision of the procedure is adequately screened.

Both Mr W and Mr A were conscious during their operations as they were carried out under local anaesthetic. Mr W's anaesthetist had prescribed a sedative for him which was administered an hour before going to theatre. Both patients were reassured and informed of progress throughout the operation by the surgeon and the nurse.

General anaesthesia

General anaesthesia is characterised by loss of consciousness, analgesia and muscle relaxation. These effects occur according to the stage of anaesthesia, as follows:

Stage 1 The pain is reduced or relieved, but the patient is still conscious. Heavy sedation can produce 'dissociative anaesthesia' and some muscle relaxation, while local analgesics supplement pain control as necessary. The patient may remain drowsy but conscious throughout the procedure.

Entonox (50% oxygen with 50% nitrous oxide) can be self-administered during childbirth or painful procedures to achieve stage 1 anaesthesia for pain control. This application is discussed with other methods of pain relief in Chapter 19.

Stage 2 Consciousness is lost, but the patient may exhibit wild movements and irrational behaviour. With i.v.

Table 26.3 Local anaesthetics

Method of administration	Effect	Example of drugs and their uses
Topical: solution or cream applied to skin or mucous membranes	Blocks local sensory nerve receptors	Lidocaine, benzocaine Minor ENT procedures Insertion of cannulae
Infiltration: injection into surgical site	Blocks local sensory nerve receptors	Lidocaine, procaine Removal of skin moles Insertion of Hickman line Drainage of abscess
Nerve block: injection close to relevant nerve trunk	Blocks conduction of sensory impulses to central nervous system	Lidocaine with adrenaline Brachial plexus procedures on the arm (Bier's block) Intercostal blocks for pain relief
Epidural: injection into space outside the dura	Blocks nerves as they enter the spinal cord	Lidocaine, bupivacaine Rectal or pelvic surgery Caesarean section
Spinal: injection into the subarachnoid space below the second lumbar vertebra	Blocks preganglionic fibres (motor and sensory) Position of patient determines distribution of drug and spinal nerves affected	Lidocaine, bupivacaine Amputation Abdominal surgery

induction of anaesthesia, this stage is passed through very quickly and may be more in evidence when the patient is recovering from anaesthesia.

Stage 3 Breathing becomes regular and there is relaxation of the muscles along with loss of reflexes. This is the level of surgical anaesthesia. The degree of muscle relaxation required to facilitate surgery can be achieved by deepening this stage but this has undesirable side-effects such as fall in cardiac output, respiratory depression and liver damage. To overcome this problem, muscle relaxants can be administered to enable a relatively light anaesthetic to be used and so reduce the risks of anaesthesia in older people and those with cardiovascular and respiratory complications. This has also aided the development of day-case surgery.

Premedication can be used to relieve anxiety, induce a state of analgesia, reduce bronchial and salivary secretions, prevent vasovagal stimulation (mainly bradycardia) and make the patient less aware and somewhat drowsy. Usually, a sedative or anxiolytic is given orally (see Table 26.1).

The induction of anaesthesia is usually achieved with a short-acting i.v. agent administered with a short-acting muscle relaxant (see Tables 26.4 and 26.5). This rapidly produces surgical anaesthesia, in which the patient is unable to maintain their own airway (due to lack of reflexes) and the muscles of breathing are paralysed. An endotracheal tube is passed through the relaxed larynx and artificial ventilation is maintained throughout the operation. For emergency patients who have not fasted, the anaesthetist may decide to use rapid sequence induction with cricoid pressure (Hurford 2000). Pressure is applied to the cricoid cartilage in the throat as the patient becomes unconscious (Frakes 2003). Pressure on the cricoid cartilage will mechanically occlude the oesophagus and reduce the likelihood of aspiration of any regurgitated gastric contents.

For further information on rapid sequence intubation, see Stewart (1999).

Anaesthesia can be maintained during surgery, usually by means of inhaled anaesthetics and a longer-acting muscle relaxant. At the end of the operation, the anaesthetic gas is discontinued and the effects of the muscle relaxant are reversed with the appropriate drug. The patient gradually regains consciousness, passing through stages 2 and 1 of anaesthesia and regaining muscle tone, which enables

Table 26.4 General anaesthetics

Method of administration	Effect	Example of drugs and their uses
Intravenous: for induction	Sedation, surgical anaesthesia Respiratory depression Some cause hypotension	Thiopental, etomidate, ketamine, propofol, remifentanil Induction of anaesthesia Short surgical procedures, EUA, dental extraction
Inhalation: for maintenance of anaesthesia	Surgical anaesthesia Some cause hypotension, nausea and vomiting	Halothane, nitrous oxide, isoflurane Maintenance of anaesthesia Wide range of surgical procedures

Table 26.5 Muscle relaxants

Name of drug	Effect	Use
Suxamethonium (depolarising): binds and blocks acetylcholine receptors	Skeletal flaccid paralysis Increased K^+ release Rarely: prolonged apnoea and malignant hyperpyrexia	Short acting (15 min) Induction, manipulations, ECT No drug available to reverse effects
Atracurium, pancuronium and rocuronium (non-depolarising) Prevents acetylcholine gaining access to receptor site	Skeletal flaccid paralysis Can cause hypotension	Longer acting (30–45 min) Maintenance of relaxation during anaesthesia or controlled ventilation Reversed by neostigmine (anticholinesterase — raises levels of acetylcholine)

independent breathing. During this time, the patient is transferred to the recovery room.

Recovery from anaesthesia

Once surgery is completed, the patient will normally be kept in the recovery room until the immediate effects of the anaesthetic have worn off. The patient should be able to maintain their own airway and be considered stable before transfer back to the ward. In some cases the patient will be transferred directly to the intensive therapy unit (ITU) while continuing to be intubated and their respiration is maintained by artificial ventilation. Alternatively, the patient may be ventilated in the recovery room overnight, hereby avoiding unnecessary admission to ITU.

Whilst the patient is still unconscious, the nurse must ensure that the airway is kept open. This can be achieved by placing the patient in a lateral or semi-prone position, tilting the head backwards and pulling the mandible forwards, or inserting a Guedel airway. If a Guedel airway is used, it can be left in position until, as reflexes return, the patient expels it spontaneously. There is a risk of aspiration pneumonia should the patient vomit while regaining consciousness; therefore, suction equipment must be available. Anaesthetics, muscle relaxants, narcotics and severe pain itself can cause nausea and vomiting. Pain must be adequately controlled and antiemetics may be required.

The nurse should observe the patient's level of consciousness and be aware that a stage of excitement (stage 2) may occur. Close observation and the use of side rails may be required. Many patients will be prescribed oxygen until fully awake, in order to maintain PO_2 while there is still some respiratory depression due to anaesthesia. The patient should be encouraged to commence deep breathing and leg exercises as soon as consciousness is regained.

As the patient regains consciousness, the nurse should bear in mind that hearing is usually one of the first senses to return. Verbal reassurance that the operation is over should be given. It may be appropriate to return hearing aids and spectacles at this point. The patient should be allowed to rest as quietly as possible during this period and will usually fall asleep after regaining consciousness. Close and frequent observation of vital signs is required for the early detection of changes in the patient's condition. During the recovery period patients are especially at risk of reactionary haemorrhage as their blood pressure rises. Hypotension is often induced during surgery due to anaesthetic agents. A ligature or clot may become dislodged, leading to signs of haemorrhage and hypovolaemic shock (see p. 718). Observation of wound dressings and wound drainage will also aid assessment of the patient in the recovery period.

In surgery, the patient may have had a large surface area exposed, leading to loss of body heat. A high risk of hypothermia, a core temperature of less than 36°C, exists in older patients, in surgery where the peritoneal cavity is opened or when large amounts of unwarmed irrigation fluids are used (Scott et al 1999). Shivering will have been suppressed, due to the use of skeletal muscle relaxants. The environmental temperature in theatres is therefore kept fairly high, but patients may still have a low body temperature. As well as feeling uncomfortable, the patient may also suffer adverse effects on postoperative recovery. A drop of 2°C during colorectal surgery has been shown to triple wound infection rates and to lead to an increased length of stay (Kurz et al 1996). Shivering in the recovery period increases oxygen demand and is distressing and painful for the patient (Scott et al 1999). Extra blankets, forced air system (e.g. Bare Hugger) and warming of i.v. fluids can be used, but the nurse must be wary of warming the patient too quickly, as this can lead to peripheral vasodilatation and a consequent fall in blood pressure.

Pain control begins before, or as, the patient regains consciousness. A patient such as Mr W may have the operation site infiltrated with more local anaesthetic at the end of surgery. Adrenaline may also be given to cause vasoconstriction and so localise the effects. This type of analgesic for herniorrhaphy has been found to provide good pain control and reduce recovery time to around 3 h for day-case surgery patients (Morris 1995). The anaesthetist may also prescribe some opioid analgesics and a simple oral analgesic for the patient's return to the ward.

Mrs B was commenced on an i.v. infusion of morphine which she was able to administer herself using a patient-controlled analgesia system (PCA, see p. 930). Many patients will receive their first dose of analgesic in the recovery room via the rectal, i.m., s.c. or i.v. route. The patient's pain should be controlled before leaving the recovery room. In a partially conscious patient, a sudden rise in blood pressure and restlessness may indicate the presence of pain. The nurse must also be aware that opioid analgesics may cause a fall in blood pressure and respiratory depression,

and that severe pain in itself can lead to shock and shallow breathing.

The patient may spend several hours in the recovery room and will, in many respects, require the same care as an unconscious patient (see Ch. 28). Most patients will require attention at least to the mouth, as mucous membranes will be dry due to oxygen therapy, fasting and perhaps dehydration, as well as to pressure areas. The recovery room nurse will document the care given and provide a summary to the ward nurse who collects the patient. In this way, continuity of care can be achieved. The role of the recovery room nurse is summarised in Box 26.2.

For further reading on patient assessment in recovery, see Starritt (1999).

POSTOPERATIVE CARE

All patients require close observation during the immediate postoperative period in order to detect any complications. This close observation may be continued for hours or days for the patient requiring intensive nursing care, or perhaps for an hour or two if a local infiltration of anaesthetic or a very light general anaesthetic has been used. The next stage of postoperative care focuses on recovery and repair and on the active prevention of complications. Rehabilitation will be achieved at a different pace and to differing levels by each patient. The patient with a hip replacement may find that their joint pain is almost immediately reduced postoperatively and that their functional ability is far better than before the operation. Some patients may not be able to achieve the desired level of recovery and others may be seeking palliation rather than cure.

For purposes of clarity, this section will focus on the postoperative recovery, repair and rehabilitation most commonly experienced during the hospital stay, while the section on 'Rehabilitation' focuses on continued care after discharge from hospital. It is recognised, however, that many patients will still be recovering from the effects of the anaesthetic after discharge following day surgery. This can take up to 24 h to be eliminated from the body. Examples of postoperative care are given in Nursing Care Plans 26.2 and 26.3.

Shock and haemostasis

Shock is discussed here with specific application to the care of surgical patients. For a wider discussion of the types and mechanisms of shock and their signs and symptoms, see Chapter 18.

When the patient returns from theatre to the ward, they require frequent observations for signs of impending shock or haemorrhage. As blood pressure continues to rise, there is a continued risk of reactionary haemorrhage for the first 24 h. Hypovolaemic shock may also occur due to a slow, continuous loss of fluid; this might be a slowly bleeding vessel or the pooling of fluid in the gastrointestinal tract during the paralytic ileus that occurs as a consequence of surgery. The loss of fluid may be detected as soakage on the dressing or blood in the wound drains, but if the patient is bleeding into a body cavity or losing fluid into the gut it may be less obvious. Distinction should also be made between hypovolaemic and other forms of shock, i.e. cardiogenic, septic, anaphylactic and neurogenic.

- Cardiogenic shock is caused by failure of the heart to pump and maintain adequate cardiac output. Possible causes following surgery may be pulmonary embolus, causing massive resistance to the output from the right side of the heart, fluid overload and concomitant heart failure, anaesthetic depression of cardiac output or myocardial infarction. Patient signs and symptoms and measurement of central venous or pulmonary wedge pressures along with other vital signs can help the nurse to distinguish between hypovolaemic and cardiogenic shock.
- Secondary haemorrhage can occur 1–7 days postoperatively due to vessel erosion by infection or from a long, slow bleed. The patient may collapse suddenly and will usually need to return to theatre. Fortunately, this is not a common problem.
- The patient may also be at risk of:
  — neurogenic shock, usually due to severe pain
  — anaphylactic shock, usually due to drug reactions
  — septic shock, from infections following surgery.

The aim of nursing observations in the first 24 h following surgery is to detect changes that might indicate the initial stages of compensation to hypovolaemic shock. As the circulating volume falls, the nurse may see increased loss of blood on dressings or in wound drainage bags or bottles. There will be a slight rise in heart rate to maintain cardiac output but systolic blood pressure may remain unchanged, or even rise slightly. Peripheral vasoconstriction to conserve blood supply to vital organs, i.e. brain, heart and lungs, and the eccrine response may lead to a pale, clammy appearance. The vasoconstriction of the veins maintains diastolic (end) volume and therefore increases stroke volume. This, along with increased cardiac contractility, maintains blood pressure to at least pre-shock levels. As the brain is extremely sensitive to hypoxia, the respiratory rate may be increased and the patient may also appear restless.

If the blood or fluid loss continues, then these mechanisms may eventually fail to compensate effectively, leading to further vasoconstriction of the arterioles to increase peripheral resistance. There is also reduced parasympathetic activity to increase heart rate and stroke volume, resulting in increased cardiac output. At this point the heart rate increases further and blood pressure begins to fall. Urine output decreases rapidly, due to decreased renal perfusion over and above the effects of increased antidiuretic hormone (ADH) and aldosterone (see p. 359), as blood flow is conserved to maintain the brain, heart and lungs as a priority.

The patient appears breathless, centrally cyanosed and may be quite confused due to hypoxia. The signs and symptoms of the initial compensation and failing compensation are summarised in Box 26.3.

Shock must be detected at the first level of compensation and not when the classic picture of falling blood pressure and rising pulse occurs and a crisis ensues. If a patient is allowed to continue at the first level of compensation, all but the vital organs will be deprived of oxygen and newly anastomosed tissue will have an increased tendency to breakdown and infection due to prolonged vasoconstriction and hypoxia.

Nursing Care Plan 26.2 Care for Mrs B on her third postoperative day (see Case History 26.2(A) and 26.2(B))

Nursing considerations	Action	Rationale	Evaluation
Abdominal pain	• Discontinue i.v. opioid PCA • Undertake hourly pain assessment • Administer regular oral analgesics as prescribed • Offer s.c. opioid analgesic, up to 1-hourly as prescribed for 'breakthrough' pain and 10–20 min prior to activity • Reassess pain after 20 min to ascertain effect of analgesic • Involve Acute Pain Specialist Nurse if pain is unrelieved by prescribed analgesics • Record respiratory rate hourly • Ensure that Mrs B is positioned comfortably • Encourage her to support wound on moving • Apply heat pad for 'wind pains'	To prevent pain and foster recovery by enabling Mrs B to cough, exercise, rest and sleep comfortably	Mrs B is sufficiently pain free to cooperate with therapy
Fluid and electrolyte imbalance	• Encourage intake of oral fluids and supplemented drinks • Monitor oral intake, supplement with i.v. infusion if intake below 1000 mL/24 h • Observe pulse and BP 6-hourly • Observe for dyspnoea • Record all fluid intake and output • Observe for nausea, vomiting and diarrhoea	To detect any sign of dehydration and electrolyte imbalance early	Fluid and electrolytes maintained at satisfactory levels
Postoperative ileus	• Observe for passage of flatus/faeces in stoma bag	To detect return of normal peristalsis	Mrs B is comfortable until normal peristalsis returns
	• Administer antiemetics as prescribed	To prevent nausea and dehydration	
	• Give oral fluids and supplemented drinks as tolerated	To facilitate recommencement of oral nutrition at early opportunity	
	• Observe for abdominal distension, nausea and vomiting	To observe for signs of unresolved ileus	
Retention of urine	• Record urine volumes on fluid balance chart 6-hourly	To ensure adequate urinary output	Diuresis is adequate
	• Report volumes of <180 mL in 6 h		
	• Observe urine for signs of infection, i.e. cloudy appearance, malodour	To detect early catheter-related urinary tract infection	

Continued ▶

Nursing Care Plan 26.2 Care for Mrs B on her third postoperative day (see Case History 26.2(A) and 26.2(B)) *(Continued)*

Nursing considerations	Action	Rationale	Evaluation
Wound infection	• Check wound daily for colour, exudate and surrounding inflammation (redness) • Record axillary temperature 6-hourly • Observe exudate from wound drain. Remove drain according to medical staff's instructions • Recommence oral nutrition at early opportunity, e.g. supplemented milky drinks	To detect early signs of infection and promote healing	Wound is kept free of infection
Pressure ulcers*	• Use a pressure-relieving mattress overlay • Assist Mrs B to change position in bed 2-hourly, do not have her lie on left shoulder • When Mrs B is sitting up, have er stand hourly to relieve pressure • Consider parenteral nutrition if unable to recommence oral intake (see Ch. 21)	To prevent loss of skin integrity	Mrs B does not develop pressure ulcers
Chest infection*	• Keep Mrs B as upright as possible in bed • Encourage her to sit out of bed and help her to mobilise for short distances • Humidify oxygen therapy • Assist her hourly with deep breathing exercises, with spirometer • Assist with chest physiotherapy twice daily • Encourage coughing and expectoration • Observe any expectorate produced for signs of infection (greenish/yellow sputum) and send sample for culture and sensitivity • Observe temperature and respiration	To prevent build-up of secretions To detect early any chest infection and treat appropriately	No shortness of breath Sputum is clear
Deep vein thrombosis and pulmonary embolism*	• Assess daily for calf tenderness and inflammation • Use graduated elastic compression stockings (GECS), full length • Encourage hourly leg exercises while in bed or sitting in chair • Encourage early activity, e.g. walking in ward twice daily with nurse • Encourage Mrs B to sit out of bed for 1–2 h periods as able • Encourage a good fluid intake	To detect early signs of thrombus and encourage good circulation	No detection of DVT

Continued ▶

Nursing Care Plan 26.2 Care for Mrs B on her third postoperative day (see Case History 26.2(A) and 26.2(B)) *(Continued)*

Nursing considerations	Action	Rationale	Evaluation
Pain in knees and left shoulder	• Ensure Mrs B's position is comfortable • Administer analgesics as prescribed • Apply heat pad • Assist with passive exercise and gentle massage	To alleviate pain and prevent stiffness	Mrs B's comfort is maintained at acceptable level
Inability to maintain own hygiene	• Encourage Mrs B in self-care tasks • Assist with washing only for areas she cannot reach, i.e. back and lower half • Assist with oral hygiene • Change and wash GECS daily • Give psychological support when Mrs B changes nightclothes in view of stoma's effect on body image (see Nursing Care Plan 26.3)	To promote return to independence To help Mrs B maintain dignity	Mrs B is able to resume self-care and cope with changed body image

Nursing Care Plan 26.3 Stoma care plan for Mrs B (see Case History 26.2(A) and 26.2(B))

Nursing considerations	Action	Rationale	Evaluation
Patient's lack of knowledge about her colostomy	• Explain the reasons for the colostomy, liaising with medical staff • Assess Mrs B's level of understanding and her wish for knowledge • Include Mrs B's daughter in teaching • Provide a colostomy booklet for Mrs B to read and to use as a guide for teaching • Give basic information about appliances • Discuss the effects of colostomy on lifestyle • Check Mrs B's retention of information from previous sessions	To provide a sound basis for good stoma care	Mrs B acquires an understanding of the rationale of stoma care
Anxiety about stoma formation and change in body image	• Encourage Mrs B to voice fears; provide reassurance in the form of accurate information • Support Mrs B in her grief, provide privacy, passive listening, counselling, touch • Provide support for daughter	To provide an outlet for anxiety	Mrs B is better able to adjust to her new situation

Continued ▶

Nursing Care Plan 26.3 Stoma care plan for Mrs B (see Case History 26.2(A) and 26.2(B)) *(Continued)*

Nursing considerations	Action	Rationale	Evaluation
Lack of skill and confidence to care for the colostomy	• Implement the following stages: – encourage Mrs B to look at stoma; give reassurance – show her how to check and clean stoma, then supervise as she does this – discuss the range of appliances available, and guide her in making a suitable choice – show Mrs B how to fit appliance and teach skin care – encourage her to fit appliance under supervision and to check and clean stoma independently – encourage her to care for stoma independently	To build confidence by helping Mrs B to succeed at each stage	Mrs B achieves independence in colostomy care
Inability to cope with the stoma at home*	• Liaise with community stoma nurses about support at home prior to discharge • Give advice and information on the following as appropriate: diet; fluid and electrolyte balance; alcohol consumption; clothing; prescriptions; flatus control; disposal of appliances; travel; pursuing hobbies and interests; intimate relationships; local colostomy association; attitudes of loved ones • Provide on discharge: supply of equipment; prescription care; prescription exemption form	To prepare Mrs B for her discharge home	The transition from hospital to home care is smooth; Mrs B feels that she is able to cope

* Potential problem.

The nurse should report any significant changes to the nurse in charge of the patient's care, who may then decide to call in the medical staff. Actions to correct shock must be taken swiftly and must be appropriate to the cause and presentation. For example, raising the foot of the bed to aid venous return could have disastrous effects in patients undergoing gastrointestinal surgery. If there is bleeding or large volumes of fluid due to paralytic ileus or obstruction in the abdomen, these contents would fall against the diaphragm, impeding respiratory and cardiac function. Equally, aggressive fluid replacement in older patients can lead to heart failure, arrhythmias and cardiogenic shock.

Once assessed, oxygen therapy will be started or increased to reduce hypoxia. In hypovolaemic shock the lost fluid must be replaced or returned to the circulation. Some patients may have large amounts of fluid available in the body, as in paralytic ileus or peripheral oedema, but in the wrong body compartment. This fluid can be drawn back into the circulation by treating the cause and by raising the osmotic pressure of the circulation.

Crystalline fluids can be given intravenously but are soon lost from the circulation. Colloids such as plasma protein substitutes (PPS) or Gelofusine are given as plasma expanders. These raise the osmotic pressure and draw extracellular fluid into the circulation (Kavanagh et al 1995). Interstitial fluid also moves into the capillaries as hydrostatic pressure falls in response to lowered blood pressure and arteriolar constriction. In haemodynamic shock, rapid transfusion of blood may be required and should be given through a blood warmer (see p. 726). Central venous pressure measurements are of great value in assessing the volume of blood returning to the heart and the heart's

Box 26.3

Signs and symptoms of shock, by stages

Initial compensation

- Appears clammy, pale
- Peripheral cyanosis
- Appears restless; may complain of feeling generally unwell
- Falling urine output but may remain above 30 mL/h
- Increase in pulse rate
- Slight rise in systolic blood pressure
- Increased soakage of blood on wound dressings and in wound drains

Failing compensation

- Appears cold, clammy
- Central cyanosis
- Appears confused, often agitated, and then increasingly drowsy
- Urine output falls below 30 mL/h
- Tachycardia
- Fall in blood pressure
- Large volumes of blood may be lost

ability to pump (see Ch. 18). A central venous catheter may be inserted as an emergency in a patient whose shock proves difficult to manage. Nursing Care Plan 26.4 illustrates the type of nursing care required to detect the early signs of shock.

Fluid and electrolyte balance

Most patients experience some loss of fluid during surgery which may be compounded by electrolyte disturbances resulting from the illness itself or trauma during surgery. Preoperative dehydration due to excessive fasting should be avoided (see p. 912). Patients having a general anaesthetic will be fasted postoperatively until they are fully conscious and cough and swallowing reflexes have returned. Some may be required to fast for longer than this if there is a paralytic ileus or after facial or laryngeal surgery. These patients require fluid and electrolyte replacement via the i.v. route to meet normal demands and some require over and above this volume to replace fluid lost at theatre.

Fluid and electrolyte balance can be significantly affected by the physiological response of the body to the stress of surgery. Glucocorticoid secretion increases reabsorption of sodium and water in the renal nephrons with a reciprocal loss of potassium and hydrogen ions. Elevated levels of ADH also increase water reabsorption and high aldosterone levels increase sodium reabsorption further. The net effect is to increase the extracellular fluid volume and reduce urine output. Consequently, it would not be unusual for a well-hydrated patient to retain fluid and have a high positive fluid balance for the immediate postoperative period (Bove 1994).

As a result of trauma to the tissues during surgery, the intracellular electrolyte potassium is released. This is excreted in part-exchange for retained sodium. Potassium levels will be closely monitored by medical staff in patients who have undergone major surgery and appropriate replacement with i.v. fluids given.

Many surgical patients complain of thirst and a dry mouth postoperatively. This is due partly to dehydration, to the drying effects of oxygen therapy and to the anticholinergic effects of drugs given during anaesthesia. As a result, thirst is an unreliable measure of hydration.

Metabolic and stress responses

Surgery and general anaesthesia are major stressors which result in the 'general adaptation syndrome' (Selye 1976). The psychological effects of stress are often seen as anxiety and withdrawal in surgical patients and are addressed in detail in Chapter 17. The importance of adequate preoperative education and counselling in minimising stress is discussed on page 908.

The physiological effects of stress can be reduced by minimising anxiety both pre- and postoperatively. In the immediate postoperative period, and up to 4 days after a major operation, the patient utilises protein (normally spared) as a source of energy along with fats and carbohydrates. The amino acids act as a source of glucose for the brain. Blood glucose levels can be elevated, resulting in glycosuria. This will be a cause for concern and careful monitoring is required in diabetic patients and in those receiving parenteral nutrition. It is important that patients are in a nutritional state sufficient to withstand this period of catabolism and negative nitrogen balance. If the patient has a poor nutritional status, and/or is undergoing major surgery with or without prolonged fasting, parenteral nutrition is generally indicated.

Well-nourished patients can tolerate catabolism and some starvation for approximately 7–10 days after major surgery (Everitt & McMahon 1994). Many become anabolic after 24–48 h and begin to rebuild proteins, while hormones released in stress decrease. A large diuresis and negative fluid balance may be seen at this point. Chapter 21 describes nursing interventions to improve the nutritional status of the patient and provides a complete discussion of parenteral nutrition.

Surgical trauma to the gastrointestinal tract causes temporary paralysis of the smooth muscle known as postoperative or temporary paralytic ileus (Field 2002, Holte & Kehlet 2002). This is manifest by the absence of bowel sounds and cessation of peristalsis. Bowel sounds are high-pitched gurgling noises caused by liquid and air moving through the gastrointestinal tract (Field 2002). Traditionally a period of fasting was commonplace following gastrointestinal surgery involving an intestinal anastomosis (Holte & Kehlet 2002). Oral intake was restricted during this time to reduce the demands on the anastomosis, allowing it to heal, and to prevent postoperative nausea and vomiting (Lewis et al 2001). Neither eating nor drinking was allowed until bowel sounds had returned or other signs of gastric motility were apparent, such as passing of flatus or stool. In fact, conclusions in *Consensus in Clinical Nutrition* (Everitt & McMahon 1994) suggested that, following major surgery, nutritional support would not be considered in well-nourished patients unless it was expected that it would be more than 7–10 days before they could eat (Beier-Holgersen & Boesby 1996).

Nursing Care Plan 26.4 Immediate postoperative care plan for M (see Case History 26.4(A) and 26.4(B))

Nursing considerations	Action	Rationale	Expected outcome
Shock due to haemorrhage and pain*	• Observe TPR and BP ½-hourly • Observe for pallor, sweating and confusion • Record urine output hourly • Give O_2 therapy at 4 L/min as prescribed • Implement pain control (see below) • Check wound and drains ½-hourly • Maintain circulatory volume as prescribed	To ensure pulse is maintained at 65–90, BP at 100/65 to 140/95, urine output at ≥ 30 mL/h	Shock does not develop
Abdominal pain	• Provide patient-controlled analgesia as prescribed • Record respiratory rate hourly • Assess effectiveness of analgesia using appropriate assessment tool • Ensure comfortable positioning • Encourage M to support wound while moving	To control pain and enable deep breathing exercises to be performed	Pain is kept at an acceptable level
Fluid and electrolyte imbalance*	• Provide i.v. infusion as per chart; change giving set after 24 h • Observe for dyspnoea, irregularities in CVS • Record all fluid intake and output • Observe for nausea, vomiting and diarrhoea	To maintain circulatory volume	Fluid and electrolytes maintained at satisfactory levels
Nausea and vomiting	• Allow only sips of water or ice chips for first 4 h postoperatively • Regular assessment of nausea • Administer antiemetics promptly and regularly as prescribed	To detect and treat any nausea or vomiting in the postoperative period	Any nausea experienced in postoperative period is recognised and treated effectively
Loss of bladder tone	• Observe and record urine output; urinary catheter with 10 mL balloon inserted in theatre • Perform catheter care morning and evening • Maintain asepsis of closed drainage system	To prevent urinary retention and infection	Diuresis satisfactory Infection of urinary tract does not develop
Wound infection*	• Check wound and drains ½-hourly • Do not disturb dressing until 48 h postoperatively • Observe vaginal loss twice daily	To promote healing and prevent infection	Wound begins to heal normally

Continued ▶

Nursing Care Plan 26.4 Immediate postoperative care plan for M (see Case History 26.4(A) and 26.4(B)) *(Continued)*

Nursing considerations	Action	Rationale	Expected outcome
Pressure ulcers*	• Carry out assessment of M's skin for risk of pressure ulcers • Change M's position according to comfort needs and prior to hyperaemia of skin • Observe for reddening of pressure areas • Ensure skin is clean and dry • Use pressure-relieving mattress	To safeguard skin integrity	M does not develop pressure ulcers
Deep vein thrombosis and pulmonary embolism*	• Administer subcutaneous heparin as prescribed • Use TED stockings below knee • Assist with leg exercises hourly • Have patient sit out of bed on first postoperative day	To encourage good circulation, especially venous return	No thrombosis or embolism
Chest infection*	• Nurse M as upright as possible • Assist with deep breathing exercises hourly • Encourage coughing and expectoration • Assist with chest physiotherapy	To prevent build-up of secretions and resulting infection	Chest remains clear
Inability to maintain personal hygiene	• Assist M to wash and change into own nightclothes when appropriate • Provide bed bath with complete assistance on first postoperative day • Provide oral hygiene as required • Change and wash TED stockings daily	To assist M in maintaining dignity and regaining independence	M's comfort and hygiene maintained
Anxiety about outcome of surgery	• Reassure M about the outcome of the operation • Repeat information as required if she is drowsy post anaesthetic	To reduce anxiety	M is encouraged about prospects for the future

* Potential problem.

There is growing evidence of the importance of early nutrition after surgery (Lewis et al 2001). Research suggests that early enteral feeding can improve the quality of healing at the anastomosis site and reduce septic complications while being tolerated well (Lewis et al 2001). Moreover, some studies suggest that early oral feeding can reduce the duration of temporary ileus to 1–2 days (Holte & Kehlet 2002, Di Fronzo et al 2003).

Most patients who have abdominal surgery may commence oral fluids on the first postoperative day (Field 2002, Feo et al 2004) and progress to normal diet over the first 2–3 days. Field (2002) recommends a proactive approach, starting by giving patients milky drinks rather than water, which has no nutritional value. Nurses should be vigilant for any symptoms which suggest that the postoperative ileus has not resolved, such as abdominal distension, nausea and vomiting. Such patients may need a nasogastric tube to be inserted in order to decompress the stomach contents and decrease tension on the anastomosis. Further oral intake should be withheld and referral to the nutrition team may be indicated if it becomes apparent that feeding will be delayed for more than 7 days (Field 2002).

Pain

Postoperative pain deserves close attention in nursing practice, research and education. Issues relating to pain specifically in the postoperative period are discussed here. The reader is also referred to Chapter 19, where broader but equally pertinent issues are addressed. Being in pain has been and remains the major preoperative concern of many patients (Biley 1989, Macintyre & Ready 2001). While thoracic and abdominal operations tend to cause most pain, Mitchell (2003) suggests that pain management is a considerable issue for day surgery patients in the first 24 h postoperatively.

Despite advances in pain management, recent studies suggest that between 75 and 80% of patients still report moderate to severe pain postoperatively (Macintyre & Ready 2001, Manias 2003). The Royal College of Surgeons and College of Anaesthetists Working Party in 1990, and the Audit Commission in 1997 reported that health professionals working in acute care environments are not effectively managing and relieving pain. More alarmingly, they also suggested that nurses lacked the knowledge and commitment to achieve satisfying postoperative pain control (Sheppard & Wright 2000).

Pain control after surgery is a prime concern on humanitarian grounds alone. Sherwood et al (2003) highlight that patients often expect to experience pain, and may express satisfaction with pain management even if they are in pain, postoperatively. However, pain is not a 'natural, inevitable, acceptable or harmless consequence of surgery' (Macintyre & Ready 2001). It has significant effects on other aspects of the patient's recovery. Good pain control allows for early activity, so minimising problems of immobility such as chest infection, urinary tract infection, deep vein thrombosis, pressure ulcers and muscle wasting. Pain after surgery has been cited as one of the main reasons for poor sleep (Closs 1992, Dawson et al 1999). Older patients are at an increased risk of the postoperative complications described above, and their subsequent recovery will be influenced by pain management.

Ineffective pain relief in the postoperative period can have serious psychological consequences for patients facing subsequent surgery and is also associated with the development of chronic pain (Perkins & Kehlet 2000, Macintyre & Ready 2001). Macrae (2001) suggests that the development of chronic postsurgical pain is common, resulting in distress and disability for many patients. A variety of surgical procedures are associated with the development of chronic pain including thoracic, breast and gall bladder surgery and amputations (Perkins & Kehlet 2000). Chronic pain is reported in 5–13% of patients undergoing dental surgery and in 5–33% of men following vasectomy (Macrae 2001). The causes of chronic postsurgical pain are not clear. Some pain specialists believe that patients who suffer from certain conditions such as irritable bowel syndrome, Raynaud's disease and migraine headaches are more at risk of chronic pain after surgery. These conditions may be related to changes in the nervous system, and such changes may result in amplification of painful sensations (Macrae 2001). Nurses should be aware that uncontrolled postoperative pain can develop into a chronic condition and must ensure that pain is managed optimally.

According to Lovett et al (1994), nurses have two specific roles in the management of postoperative pain: pain assessment and provision of the means to alleviate the pain. Assessment is the cornerstone of care and accurate and systematic assessment of pain is essential. Sjostrom et al (2000) found that nurses consistently underrated patients' postoperative pain and made little use of pain assessment tools. Visual analogue scales, verbal numerical rating scales and other assessment techniques are valuable (Macintyre & Ready 2001) but have limitations (see Ch. 19, p. 747). Findings by Manias (2003) suggest that linear scales can be problematic where patients' first language is not English.

Postoperative pain can vary according to the site of the incision, being greater with midline, subcostal and intercostal incisions (see Fig. 26.3). The small incisions required for laparoscopic technique usually cause the least discomfort. However, patients can suffer extreme 'wind pain' following laparoscopic surgery which is disproportionate to the size of the incision, and 35–63% of patients complain of shoulder tip pain (Hong & Lee 2003). Pain following laparoscopic surgery occurs as a result of stretching of the peritoneum and irritation of the diaphragm by the CO_2 used to establish inflation of the abdomen to allow visualisation of the internal organs (Wills & Hunt 2000). This pneumoperitoneum can persist for a number of days postoperatively and patients undergoing laparoscopy will require information and advice on how to control any pain following discharge.

Thoracic and abdominal drain sites can also cause pain, at both change of dressing and during removal of the drains (Critical Care Extra: Critical Questions 1999) and may require short-term pain relief (Sheppard & Wright 2000). Inhalation of Entonox works rapidly and allows patients to have a degree of control over their pain relief during short procedures (Sheppard & Wright 2000). One source of

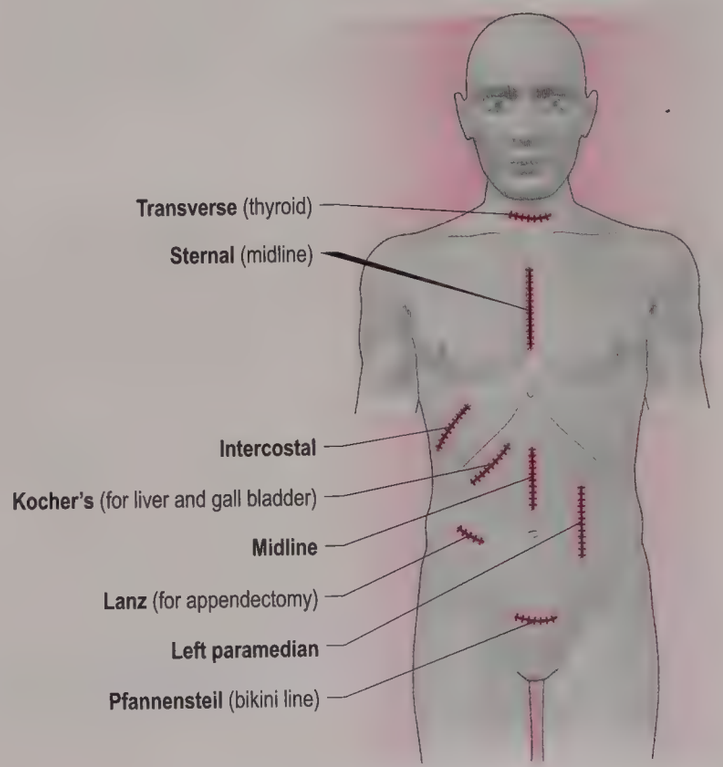

Fig. 26.3 Some incision lines used in surgery.

controversy in pain management concerns the assessment of pain as part of the diagnostic process. The location and nature of the pain, especially abdominal pain, is an important diagnostic aid, which can result in medical staff withholding analgesics until a full assessment has been carried out and a provisional diagnosis has been made. Town (1997) asserts that early pain management will not obscure diagnosis of patients who have acute abdominal pain. Instead, it is likely to decrease diffuse pain and splinting, the muscle contraction and rigidity to avoid pain, and will help the surgeon to localise the pain during the physical examination, facilitating diagnosis.

Controlling pain in the immediate postoperative period is the responsibility of the anaesthetist and, increasingly, of the acute pain team.

For a review of the role of the acute pain team, see McDonnell (2003).

The anaesthetist visits the patient preoperatively to discuss the prevention and relief of pain and to make a full assessment of the individual's needs.

Opioid analgesics are the mainstay of postoperative pain control. Some commonly used analgesics are given in Table 26.6. Traditionally, i.m. injection has been the most commonly used method of administration, but is not always the most effective (Macintyre & Ready 2001). In addition, patients may fear the discomfort of the injection itself. Injection of the analgesic via a small cannula or 'butterfly' via the s.c. route avoids the need for repeated skin punctures and the rate of absorption of morphine into the circulation is similar to that following an i.m. injection (Macintyre & Ready 2001). Recent 'Best Practice Guidelines' recommend that this method of administration replace i.m. injection (NHS Quality Improvement Scotland 2004a). Subcutaneous morphine can be administered hourly if required. The nurse should explain to the patient that the opioid is not absorbed to therapeutic levels immediately, so they should ask for an analgesic at the first indication of discomfort; the patient should be advised not to wait until the pain is unbearable (suffering the ill-effects of this pain) as they may continue to suffer for a further 15–20 min until the injection takes effect.

Other methods of pain control aim to prevent large fluctuations in plasma levels. Continuous infusions of opioid analgesics can be given through the i.v., s.c. or epidural route. Intravenous infusion can be advantageous as it enables the rate of infusion to be altered immediately, according to the patient's respiratory rate, as opioid drugs may depress respirations if too large a dose is given.

Patient-controlled analgesia (PCA)

PCA allows the patient to control the administration of small boluses of i.v. analgesic (see Ch. 19). A special infusion pump is set to give a specific volume of solution (and therefore a set dosage according to the dilution of the drug) when the patient presses a hand-held button. The machine is programmed to provide a bolus only after a certain length of time has elapsed (lockout) and a maximum total number of boluses over a specified time period.

PCA can be very effective. Mackintosh and Bowles (1997) found that patients using PCA postoperatively gained significantly greater relief of pain than those receiving i.m. injections. However, patients given a PCA without sufficient explanation beforehand, or inadequately educated staff to support them while using the device, still may not achieve optimal pain relief (Macintyre & Ready 2001). Some patients are unable to understand the function of the system and press the button inappropriately. Therapeutic levels of opioid can fall while the patient is sleeping, leading to awakening in pain. Some patients develop association nausea when they press the button and antiemetic medication should be prescribed and administered appropriately (Dawson et al 1999).

Intravenous opioids should be given carefully to older patients. It should not be assumed that they have higher pain thresholds, but they may receive slightly lower doses of analgesics as their clearance and metabolism of analgesics are slower (Gagliese et al 1999). Intravenous doses of analgesic medications should also be given more slowly as peak blood concentrations after a single i.v. medication will be

Table 26.6 Analgesics commonly used in postoperative pain control*

Method of administration	Example of dug used	Example of types of surgery
Epidural infusion	Bupivacaine and lidocaine, fentanyl and bupivacaine mixture, diamorphine	Major pelvic or lower abdominal, e.g. colectomy
Intravenous or subcutaneous infusion	Diamorphine, morphine sulphate, fentanyl	Major pelvic or abdominal, e.g. gastrectomy
Intramuscular injection	Morphine sulphate, tramadol, codeine	Many types, e.g. total hip replacement Specifically used in neurosurgery
Nerve blocks and local anaesthetic	Lidocaine with adrenaline	Thoracic surgery, wound areas can be infiltrated after surgery
Sublingual	Buprenorphine	Many types of major and minor surgery
Oral	Diclofenac sodium (Voltarol), tramadol, co-codamol, paracetamol	Many products are available Used in continued recovery and rehabilitation or alone after minor surgery

*For further reading, see Macintyre & Ready (2001).

higher due to reduction in cardiac output in the older patient.

Epidural analgesia (EA)

EA is becoming increasingly common following major surgery, e.g. following radical prostatectomy or colonic surgery (Kehlett & Morgensen 1999). Major surgery places patients at significant risk of postoperative complications because of the effects on the lungs of prolonged anaesthesia and the creation of large incision sites. Patients may be unable to cough or deep breathe postoperatively because of severe wound pain. EA is an effective form of postoperative pain relief for this group of patients because a solution of local anaesthetic and/or opiate is infused into the epidural space in the spine. This blocks the dermatomal nerves supplying the area of the wound (Greenland 1995). Such patients may have little or no sensation of pain at all in the immediate postoperative period (Richardson 2001) and are able to carry out breathing exercises and get out of bed shortly after surgery, thus minimising the risk of complications. EA is also associated with decreased levels of postoperative anxiety (Caumo et al 2001). There are, however, a number of complications associated with EA and for this reason patients should be cared for in areas where staff have special skills and knowledge in this form of pain relief, such as a high dependency unit.

For further reading on the use of epidural analgesics, see Greenland (1995) and Cox (2002).

All opioid agents have similar side-effects, e.g. central nervous system and cardiovascular depression, and the risk of addiction and the possibility of nausea and vomiting.

Fear of respiratory depression can lead to doctors underprescribing and nurses underadministering (Hunt 1995). Opioid agents (except buprenorphine) can be reversed with naloxone should respiratory depression occur. It should also be remembered that respiration will, in fact, be hindered by inadequate pain control (see p. 929). The fear of addiction from the administration of opioids is largely unfounded. When opioids are administered only in the postoperative period less than 1% of patients will develop problems of addiction (Sheppard & Wright 2000).

The amount of opioid a patient requires can be reduced by the use of other medications and local anaesthetic agents. This is known as the multimodal approach. The use of non-steroidal anti-inflammatory drugs (NSAIDs) such as diclofenac sodium and ibuprofen, used in conjunction with opioids in the perioperative stage, can result in a 20% reduction in opioid analgesic requirements (Sheppard & Wright 2000), but are associated with undesirable side-effects including bleeding, renal failure and gastric ulceration. The role of one of the most common analgesics, paracetamol, should not be overlooked. Paracetamol can be used alone to treat mild pain, or in combination with opioids, because of its morphine-sparing properties. It can be given orally or via the rectal route and an i.v. preparation has recently become available (Hahn et al 2003). Medications used in association with an opiate are most effective if given regularly, rather than 'as required' or 'PRN' doses (Sheppard & Wright, 2000). Other drugs may also be utilised; for example, hyoscine butylbromide (Buscopan), which has an anticholinergic effect causing smooth muscle relaxation, can be useful in the treatment of intestinal colic (Sheppard & Wright 2000). In day surgery, where side-effects such as respiratory depression, sedation and nausea can delay discharge, opioid-sparing strategies are particularly important (Rawal 1998).

The variety of causes of postoperative pain and discomfort and the wide range of nursing interventions available clearly demonstrate that the nurse has a key role to play in alleviating postoperative pain (see Table 26.7 and Case Histories 26.1(B), 26.2(B) and 26.4(B)). A sensitive individualised approach to patient care will also improve the management of postoperative pain, as one experienced nurse can get to know the patient well. Detailed knowledge of the patient and their reaction to pain assists in planning and evaluating care, while the close relationship between nurse and patient instils trust and confidence. This not only reassures the patient, but also has a placebo effect that supplements the analgesic administered. The therapeutic contribution of the nurse in relation to pain control is addressed in detail in Chapter 19. The nurse's knowledge of pain assessment, measurement and relief, and knowledge of the psychological impact of surgery and pain, together with assertiveness and communication skills, are all vital

CASE HISTORY 26.1(B)

Mr W *(cont'd from Case History 26.1(A), p. 903)*

Mr W had had his incision site for inguinal hernia repair infiltrated with lidocaine at the end of the operation. He did not experience any pain on return to the ward and was up and about that evening. He had some difficulty with lower back stiffness and pain, but found some relief from a gentle back massage by one staff nurse who had taken a course in this technique. The staff nurse also used some aromatherapy oils to help him relax and get to sleep that evening. Mr W did not require any analgesics until the following morning, when he took some co-codamol before getting up. After being seen by medical staff he got ready to go home. He had already bought some paracetamol to take at home as instructed in his pre-admission booklet.

CASE HISTORY 26.2(B)

Mrs B *(cont'd from Case History 26.2(A), p. 903)*

Mrs B was surprised to be given a handset with a button to control her pain (patient-controlled analgesia, PCA). She found this difficult to press because of the stiffness in her hands. The Acute Pain Nurse Specialist exchanged the handset for one she was able to squeeze which made things easier. Mrs B had not been told much about this kind of pain relief preoperatively because she had gone to theatre overnight as an emergency, but her named nurse explained that she could give herself pain-relieving medication every time she wanted, and before she planned to move or cough. Mrs B was a bit nervous that she could accidentally give herself too much of morphine, but the nurse reassured her that this was unlikely to happen because of the lock-out facility on the pump. At first Mrs B pointed the handset towards her abdomen every time she used it, but her named nurse explained that the handset was connected to a pump which delivered the medication directly into her vein.

Table 26.7 Some specific causes of postoperative pain and discomfort

Cause	Suggested nursing action
Joint, neck and back pain and stiffness	Prevent overextension of the neck at intubation point. Exert care in assessment and positioning of patients with rheumatoid arthritis and osteoarthritis. Assist with frequent change of position and passive exercises. Administer analgesics (NSAIDs can be given as suppositories as well as orally). Provide massage, heat pads.
Anastomotic leak (in GI surgery)	Identify patients at risk preoperatively, i.e. immunocompromised (e.g. steroid use), malnourished and those with low cardiac output, and observe such patients closely. Observe for signs and symptoms of peritonitis, gradual or sudden onset of abdominal pain and shock, pyrexia, shallow breathing, abdominal distension, obvious change in drain output. Alert nurse in charge of the patient and/or medical staff immediately. Anastomotic leak typically presents 5–7 days after initial surgery.
Nasogastric (NG) tube	Keep nasal passages clean, lubricate with petroleum jelly. Ensure tape is secure, clean and does not obscure view. Support the weight of the tube and/or bag by taping or pinning it to nightclothes (this also helps to prevent the tube being pulled out by sudden movement). Pass NG tubes while the patient is under anaesthetic where possible.
Wound drains	Wound drains with softer tubes cause less pain. Sudden or severe pain at a drain site should be reported. (In cases of anastomotic leak or haemorrhage, relieve weight of drainage bags by regular emptying, if appropriate.) Secure drains well with tape to prevent pulling on the securing suture. Label tubes if there is more than one. (The exit may become obscured from view by securing tape.) Provide analgesic cover prior to drain removal. Encourage patient to use relaxation techniques to reduce muscle tension.
Sutures, clips, staples	Sutures should not normally be a cause of pain. Deep tension sutures, wounds under tension (e.g. perianal) or clips catching on nightclothes can cause discomfort. Check wounds daily for signs of infection. Teach patient to support wound when coughing and moving. Cover clips with a light dressing to prevent catching. Provide reassurance and encourage use of relaxation techniques on suture removal.
Dressing changes	These should not be painful for the vast majority of patients, provided good practice is followed. Irrigate wounds with warm saline to clean and use non-adherent wound care products. Wounds tend to become painful when granulating, as nerve endings are exposed. Any adherent dressings should be soaked to aid removal. Excess hair around site may be removed in theatre to prevent adherence (see p. 913). Analgesics ranging from paracetamol to a general anaesthetic may be required for some dressings. Entonox can be extremely useful in providing short-acting pain relief during dressing changes.
Urinary retention	Observe urine output in uncatheterised patients having pelvic or abdominal surgery, or reduced mobility postoperatively. (Urinary catheters should be inserted in theatre if their need can be predicted.) Observe for a palpable bladder and rising blood pressure. (These signs may also be present in a catheterised patient if the catheter blocks up; measurement of specific gravity of the urine indicates if urine output is truly falling as urine becomes more concentrated.) Ensure privacy and comfortable positioning of patient when bedpans or bottles are being used. Discuss continued retention with medical staff and perform residual catheterisation if necessary, leaving the catheter in situ. Blocked catheters should be irrigated or changed. (See Ch. 24 for care of patients with urinary catheters.)
Colic and wind	When the patient's paralytic ileus is resolving, strong pains and spasmodic muscle contractions may be experienced. Pockets of gas may also have collected in the GI tract and may cause distension. Early and frequent activity can reduce these pains. With approval of medical staff, peppermint water can be given, or, if appropriate, peppermint oil can be used in aromatherapy. Drinks of warm water may also give some comfort. Antispasmodic drugs such as hyoscine butylbromide (Buscopan) can be prescribed, but can cause a return of the ileus and constipation and precipitate tachycardia. Heat pads and gentle massage (by experienced hands) can be helpful.

elements of the ability to provide effective postoperative pain control.

Nausea and vomiting

In the past, the use of ether as an anaesthetic agent led to a 75% incidence of postoperative nausea and vomiting (PONV) (Thompson 1999). Modern-day anaesthetics have fewer side-effects yet PONV continues to be a common postoperative complication experienced by 20–30% of patients (Jolley 2001). Some studies report PONV as the most unpleasant symptoms for patients, even more so than pain (Chimbria & Sweeney 2000). The causes of PONV are multifactorial and complex, but include patient-related factors (Janknegt et al 1999), the nature of surgery undergone (Jolley 2000) and the anaesthetic agent used (Jolley 2001) (see Box 26.4).

CASE HISTORY 26.4(B)

M (cont'd from Case History 26.4(A), p. 906)

M had undergone two operations over the last few years for her Crohn's disease. She did not like having injections to control the pain and had become more frightened and anxious about pain with each operation. The anaesthetist decided she would be a good candidate for patient-controlled analgesia (PCA) and spent some time teaching her about this preoperatively. M kept her infusion until she was able to manage her pain control with a simple compound analgesic. She made a quick postoperative recovery and said she had experienced far less pain than with her previous operations. She had also felt reassured that pain relief would be there as soon as she needed it.

Box 26.4

Risk factors for postoperative nausea and vomiting (PONV)

- Obesity
- Age: older age is associated with a decreased risk of PONV
- Female gender
- Prior history of travel sickness
- High preoperative anxiety
- Type of surgery
- Anaesthetic agent used

Based on data from Jolley (2001).

Women are three times more likely to experience PONV than men (Jolley 2001). Gynaecological and abdominal procedures have an increased risk because of mechanical disturbance to the gut during surgery (Jolley 2000). In orthopaedic surgery, the use of opioids in extradural infusions has been linked to the high incidence of PONV (Alexander & Fennelly 1997). Patients undergoing gynaecological and orthopaedic procedures have an incidence of above 40% (Jolley 2000). Patients receiving thiopental as an induction agent are more likely to experience PONV than those who receive propofol (Jolley 2001) and spinal and regional blocks are less likely to cause PONV than general anaesthetics. There is some evidence to suggest that smokers are at less risk of PONV (Chimbria & Sweeney 2000).

PONV is exacerbated when patients have pain and inadequate pain relief (Thompson 1999). Quinlan (2002) reports that relief of postoperative pain is usually associated with relief of nausea. Unfortunately, PONV is also a common side-effect of opioid analgesics.

A period of prolonged starvation can cause PONV but so also can inadequate preoperative fasting and the collection of secretions in the stomach. Paralytic ileus can lead to the accumulation of a large quantity of gastrointestinal secretions. Following some surgery, e.g. partial gastrectomy, patients may have some bleeding into the stomach postoperatively which can induce nausea.

Postoperative hypotension is another common cause of PONV which can be avoided by helping patients to move in bed or sit up slowly. Jolley (2000) advocates the use of a risk assessment tool by nurses and anaesthetists. Thomas et al (2002) compared two PONV risk assessment tools and found nurses greatly underestimated the actual incidence of PONV.

Although it remains unclear which risk factors, in combination or alone, are most likely to lead to PONV (Thompson 1999), the effect of unresolved PONV is not insignificant. Patients are at risk of complications such as aspiration, dehydration, electrolyte imbalance and pain. Patients may also suffer psychological effects such as distress, shame and embarrassment (Jolley 2001). This has been shown to heighten anxiety prior to subsequent surgery. Assessment and management should be performed using a tool or treatment algorithm. The cause of PONV should be identified and an appropriate antiemetic used prophylactically and regularly. Studies show that of 75% patients prescribed antiemetics, only 56% were administered any medication (Ernst 1994). Caution must be taken with the administration of metoclopramide as this promotes gut motility and should be avoided in a patient who has obstructed. Ming et al (2002) found that PONV can be reduced by the use of acupressure bands on the wrist. Small studies have evaluated the use of complementary therapies such as inhalations (Tate 1997, Merritt et al 2002) and ginger root preparations (Visalyaputra et al 1998) but so far have been inconclusive. It is important, however, that patients be made aware preoperatively that PONV is not an inevitable outcome of anaesthesia, and that medication can and will be provided.

Sleep

Closs (1992) argued that surgical patients have very disrupted sleep patterns. In addition to factors affecting the sleep of all hospital patients, surgical patients are exposed to pain, general discomfort and restricted positioning. Postoperative patients may experience hypoxia and hypercapnia due to anaesthetic sedation or shock, severely compromising CNS control of sleep patterns (see Ch. 25). Opioids can alter normal sleep patterns (Dawson et al 1999). Typically, patients report dropping off to sleep and feeling they have slept for hours, only to find that just a few minutes have passed. Some patients will be distressed by this and nursing staff can support and reassure them, explaining that this is a common but temporary side-effect of the analgesic. It is important to ascertain whether the patient has stopped using their PCA or asking for analgesics in an effort to relieve this symptom, because this will cause an exacerbation of pain. For many patients, the presence of a nurse during this wakeful period may be all that is required. In the postoperative period, frequent observations and recordings are necessary, often into the first postoperative night. These disturbances, along with the general noise generated by procedures, new admissions and emergency action that may occur, all add to the disruption of patients' sleep.

Sleep is especially important for the postoperative patient as the all-important protein synthesis for optimal recovery takes place predominantly during sleep and rest. Growth hormone is secreted during periods of rapid eye movement (REM) sleep. Sleep and rest are therefore essential, not

only for a feeling of well-being, but also for anabolism and tissue repair. Older patients are especially vulnerable as they have fewer physiological reserves and may have concurrent and chronic illness. Equilibrium is disturbed by lack of sleep and this may be related to development of delirium in some postoperative older patients (Bowman 1997).

Pain control and general comfort measures are paramount in promoting a good night's sleep. Bowman (1997) noted the impact made when nurses modified the environment to promote sleep, and suggests that warmth and effective pain control facilitate natural sleep in older patients.

The measurement of O_2 saturation via pulse oximetry can be useful to indicate night hypoxia in vulnerable patients, e.g. those who have had thoracic or abdominal surgery; however, oximeters require careful use to prevent undue disturbance. Nursing observations should be minimised to safe levels and noise reduced where possible.

Elimination

Postoperative constipation is a common problem which arises as a consequence of immobility, the use of opioid analgesics and dehydration. Conversely, diarrhoea can occur as postoperative temporary ileus resolves, but normal bowel function should resume spontaneously in a few days. Patients may experience colicky pain due to flatus and muscle spasm; this can be reduced by increasing mobility and offering peppermint water (see Table 26.7). Ensuring adequate hydration and early activity help prevent constipation before it becomes necessary to resort to oral laxatives.

Urinary retention may occur due to immobility, the relaxation of bladder muscle tone caused by anaesthesia, or as the result of temporary ileus following abdominal or pelvic surgery. When urinary retention is anticipated, the patient should be catheterised in theatre to minimise discomfort. Otherwise, patients should be given the opportunity for privacy and assistance to assume a normal position to pass urine where possible. If retention leads to distension of the bladder and discomfort, or is a cause for concern, urinary catheterisation may be carried out.

Once the temporary ileus resolves, as detected by return of bowel sounds or passage of flatus or faeces, the urinary catheter is usually removed. If the catheter is used for monitoring in haemodynamic shock, or in retention due to immobility, it can be removed when monitoring is no longer required or the patient is sufficiently active to pass urine successfully.

Use of urinary catheters should be avoided where possible due to the associated risk of infection (Winn 1996, NHS Quality Improvement Scotland 2004b). The postoperative patient may also be at risk of urinary infection without catheterisation, as a result of immobility when a small volume of concentrated urine may remain in the bladder for prolonged periods, providing a medium for the growth of bacteria.

Following some surgical procedures on the bladder, for example transurethral resection of the prostate (TURP), continued blood loss and clot formation may obstruct the urethra. To prevent this, patients are catheterised with a three-way/triple lumen catheter and continuous bladder irrigation given to wash out potentially obstructing clots or debris (see Ch. 8).

Wound care

Wound care is given with the aim of promoting healing and minimising the risk of infection (see Nursing Care Plan 26.4). Buggy (2000) argues that 9–27% of patients undergoing colorectal surgery acquire a wound infection. Methods of promoting healing depend on the individual patient's circumstances. Factors that should be considered, especially with the surgical patient, are prolonged hypoxia due to shock, dehydration or local pressure, protein calorie malnutrition, and the local wound dressing. Factors to be considered in all patients with regard to wound healing are discussed in Chapter 23.

Prevention of infection begins in the preoperative period with reduction of anxiety, and skin and, if necessary, bowel preparation (see p. 914). Asepsis in theatre reduces the threat of exogenous infection (see p. 915). Tissue perfusion of the incision site during surgery is thought to be an important factor in influencing wound healing (Buggy 2000). Good tissue perfusion ensures that oxygen, neutrophils, nutrients for cellular regrowth and systemically administered antibiotics are carried to the incision site. However, tissue perfusion during surgery may be diminished because blood loss and manipulation of body structures aggravate the stress response, causing vasoconstriction of the skin, gut and renal vessels. The anaesthetist aims to reduce the impact of the stress response by maintaining the patient's tissue perfusion during the operation. This is done by increasing oxygen delivery during and after surgery, administering optimal fluid replacement therapy and avoiding hypothermia (Buggy 2000).

The use of wound drains and aseptic technique, along with precautions against haematoma formation, will help to reduce wound infections postoperatively. However, some patients will be more at risk of infection than others, depending on the type of surgery and on exposure to endogenous bacteria (see Table 26.8). In the immediate postoperative period, the wound and any drains in the operation site must be checked frequently for signs of bleeding. To assess the degree of soakage on a wound dressing, a ballpoint or felt-tipped pen can be used to mark the margin of the soakage. Any advancing margin can then be easily detected. Volume markings on drainage bottles and bags give a clear indication of the amount of blood or fluid lost. Large volumes of bloodstained fluid may be due to the fluid used to wash out a cavity but this should still be reported. Wound dressings should not be changed if they become soaked with blood; instead, fresh pads should be added on top to promote clot formation beneath both dressings. To disturb dressings on the first or second postoperative day also increases the risk of infection. The patient's nutritional status and wound healing are necessarily closely linked. Patients who are malnourished preoperatively are at risk of delayed healing and have increased susceptibility to wound or systemic infection. Early postoperative nutritional support clearly improves healing (Collins 1996) (see p. 928).

Wound drains

The aim of wound drains is to drain blood and inflammatory exudate, to prevent haematoma formation and infection, and to give an indication of blood loss. Some drains may have suction applied to collapse the space left in the

Table 26.8 Risk of infection in different types of surgery*

Type of surgery	Percentage of patients with infected wounds (% risk)	Example of types of operation
Clean: hollow organs not opened, no preoperative inflammation or infection	2–5	Inguinal hernia repair, mastectomy, total hip replacement
Clean contaminated: hollow organs (not bacteriologically clean, e.g. respiratory and urinary tract) opened	5–10	Transurethral resection of prostate, pneumonectomy, elective cholecystectomy
Contaminated: in areas known to be heavily contaminated, e.g. lower GI tract or in the presence of infection	10–50	Large bowel surgery, traumatic wounds, abscesses

*For further reading, see Mangram et al (1999) and Ayliffe et al (2000).

tissues after an operation. Drains can also indicate when an anastomosis has broken down by discharging blood, digestive or faeculent fluid and, when an abscess has resolved, the cessation of discharge of pus. Some examples of the more common types of wound drain are given in Figure 26.4.

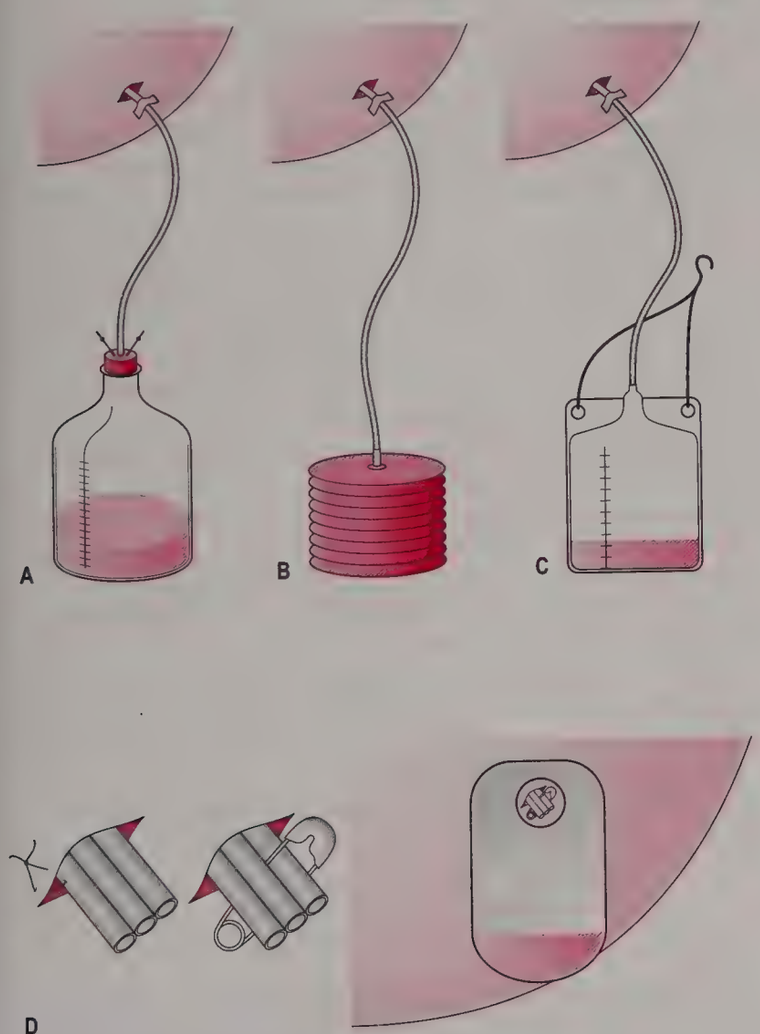

Fig. 26.4 Some types of wound drain A: Redivac drain (prongs come together as vacuum is lost). B: Concertina-type drain. C: Simple tube/Penrose drain. D: Corrugated drain: secured by a suture and then a safety pin as the drain is shortened to prevent it from falling back into the patient. Fluid drains down the channels and into a bag.

To prevent infection, the entry site should be dressed aseptically and a closed drainage system maintained. If bags or bottles need to be changed, e.g. when the vacuum is lost or the receptacle is full or heavy, then asepsis must be maintained and sterile equipment used.

The decision to remove the drain is made by the doctor when there is minimal or no further drainage. Non-vacuum drains may be shortened before removal to encourage the space left behind to collapse and granulate, otherwise a cavity might be left that could fill with fluid and give rise to an abscess. Before a drain is removed, the procedure should be explained to the patient and careful assessment performed as analgesics may be required (Critical Care Extra: Critical Questions 1999). Relaxation exercises can help to reduce the patient's anxiety and muscle tension. Vacuum drains should have their suction released and the securing sutures removed. Shortened drains should be secured to prevent them slipping below the skin surface; alternatively, a large, sterile safety pin can be passed through the tube to prevent this from occurring. Drains that do not move smoothly may be eased by rotating the tube slightly. Traction should not be applied to drains if they are fixed or tethered. Such cases must be referred to the medical staff.

After the first 24 h, the wound and drains should be checked to ensure optimal healing is occurring. As stated previously, wound dressings should not be disturbed for the first 48 h to reduce the risk of infection. However, most infections typically do not appear until at least 3 days postoperatively. Regular temperature monitoring may also detect signs of infection. Patients discharged within the first 2 days after an operation should be taught how to recognise a wound infection and know how to report it. Mr A was advised to inspect his scrotal suture area for redness, oozing or swelling postoperatively. He was advised to inform his GP if symptoms occurred. Community and practice nurses may continue checks on patients with wounds who have been discharged home early.

After 48 h, wounds healing by 'primary intention' have laid down a layer of epithelium across the wound. The wound is effectively sealed from exogenous infection and may be left exposed, which allows for easy observation. Dressings are not necessary unless the wound has been closed with clips or staples that may catch on clothing or there is continued discharge from the wound. Some wounds may be left to heal by 'secondary intention' due to lack of

Box 26.5

Examples of factors that may predispose patients to delayed wound healing

Mrs B (see Case History 26.2)
- High risk of wound infection due to:
  - — perforated bowel
  - — unprepared bowel
- Anaemia (preoperative)
- Malnutrition and dehydration (preoperative) and fasting (postoperative)
- Prolonged shock (postoperative)
- Immunosuppression (due to cancer and prolonged stress)
- Age

M (see Case History 26.4(A) and 26.4(B))
- Steroid therapy (pre- and postoperative)
- Contamination of wound (bowel opened and infection present)
- Low body fat/protein reserves
- Pre-existing inflammatory condition

tissue to close the wound or to the presence of infection in the tissues, where closure may well lead to abscess formation. Care of such of wounds is discussed in Chapter 23.

Wounds heal at different rates according to growth rate and blood supply of the local tissues and the patient's general physical condition (see Box 26.5). Clips would be removed from a thyroidectomy incision line at 2–3 days postoperatively, whereas Mrs B's abdominal sutures were not removed until 10 days postoperatively. There is an increasing trend towards the use of absorbable continuous sutures where good healing is expected. This is especially useful when the patient is to be discharged home in the first few days. Most patients are also relieved to hear that their sutures do not have to be removed. Patients discharged home with non-absorbable sutures in situ may be referred to the community or practice nurse for their removal and some cosmetic procedures or facial wounds may be closed using adhesive preparations (Davies 1994).

For a description of some common types of suture and their removal, see Jamieson et al (2003).

Potential complications

Virtually all surgical patients will be at some risk of developing deep vein thrombosis (DVT), pulmonary embolism (PE), chest infection and atelectasis. Prevention is the mainstay of care and is described on pages 910–912. Preventive measures such as leg and breathing exercises, thromboembolic deterrent (TED) stockings and s.c. heparin are all continued throughout the postoperative recovery. Early mobilisation contributes significantly to the prevention of these complications. Mrs B's care exemplifies the type of proactive preventive measures required (see Nursing Care Plan 26.3). As with pain, pressure ulcers may deter patients from optimal return to normal activity.

Obese, immunocompromised and older patients are at risk of wound dehiscence, the separation and opening of the wound. Nursing management for a patient whose abdominal wound dehisces is to apply sterile pads which have been saturated with normal saline to prevent the abdominal organs from drying and becoming damaged. Assistance from the surgical team is required rapidly. Reassurance and support of the patient is vital as this can be both distressing and frightening and further surgical intervention is likely. Lewis et al (2001) and Candido (2002) suggest that surgical dehiscence is a major complication of abdominal surgery, carrying with it considerable mortality and morbidity.

For case studies explaining the management of wound dehiscence, see Candido (2002).

Communication

When a patient recovers from a general anaesthetic, the first sense to return is that of hearing. Care of the patient in the recovery room can be enhanced by having aids to communication, such as their hearing aid and glasses, available. A number of patients, especially older people or the very ill, may become and remain confused postoperatively (Bowman 1997). This may be due to the effects of the anaesthetic or to systemic illness. Efforts must be made to detect and treat the cause, and nursing measures to reorientate and minimise confusion should be taken. The use of anticholinergic drugs that cross the blood–brain barrier, such as atropine and hyoscine, should be avoided in older patients as they may cause confusion. Opioid analgesics are undoubtedly the cause of delirium in some patients and non-opioid analgesics, such as diclofenac sodium, might be employed.

Patients with provisional diagnoses are often anxious to speak to the doctor about findings in theatre and their prognosis. When information is not immediately given, a moral dilemma may exist for nursing staff (see p. 907). Patients are often reluctant to raise all their concerns with the consultant or registrar, possibly surrounded by an entourage of junior doctors and medical students on ward rounds. The nurse has an important role to play in clarifying the patient's understanding and answering questions where possible or referring the patient's queries to others. The nurse will require to support both patient and family at this anxious time, particularly if samples have been sent to pathology for diagnosis.

Good communication among professionals in the postoperative period is essential. Medical and nursing staff must rely on one another for information and advice in order to provide a coordinated plan of care. Other health professionals, such as physiotherapists and dietitians, also have an important role to play in a patient's postoperative recovery.

Body image

Body image is the mental picture we hold of our body and its functions. This is influenced not only by physical appearance but also by our attitude towards ourselves (Bredin 1999). Gibson (2001) suggests that body image consists of three essential components:

- body reality — an individual's actual physical appearance

- body ideal — how an individual wishes their body to be
- body presentation — an individual's efforts to find a compromise between body reality and ideal.

Body image forms part of our total self-concept and, as such, can have enormous impact on psychological, socio-cultural and physical concepts of self. Body image can be altered by a change in physical appearance, such as when a patient undergoes amputation of a limb (Gibson 2001), or when something causes an individual to change their attitude towards their body, for example following a diagnosis of cancer (Bredin 1999), or a combination of both these factors. If this alteration leads to a negative self-concept, educational and psychological support will be necessary to help the patient regain a positive self-concept. Mr W's body image became very positive after his operation as his appearance was restored in line with cultural values such as youth, health, beauty, intactness and vigour. His ability to provide for his family was restored and he felt he would be seen by his workmates as able to cope with all aspects of his job again. Fortunately, the practice nurse had already provided education to correct his misconception about the operation's effect on his sex life and fertility.

M needed much psychological support from her named nurse. She understood how a vaginal fistula had formed and how it could be treated, but felt that her sexual relationships and ability to have children might be affected. She could not come to terms with the continuous loss of fluid through her vagina and having to wear large incontinence pads. She associated wearing the pads with babies and the debilitated older patients she had seen in the wards previously. She felt everyone could see the pads and could detect an unpleasant odour. The named nurse provided a 'listening ear' for M so that she could talk about her fears and her relationship with her new boyfriend. The nurse also comforted and reassured her.

Mrs B recovered from the anaesthetic to find herself attached to lines and tubes, loosely draped in a hospital gown and, worst of all, wearing a colostomy bag. As Mrs B went to theatre as an emergency, there was no time to prepare her for this. At first, she was acutely distressed by the stoma and refused to look at it. She was only able to begin to accept it and learn about it once she learned that, in her particular case, it could be reversed in several months' time. Her attitude towards her body was also influenced by knowing that she had had cancer. Mrs B saw cancer as stigmatising and she felt that everyone would know she had a bag and why. Her self-esteem was severely threatened. Mrs B's stoma care plan (see Nursing Care Plan 26.3, p. 924) outlines the care planned by the named nurse to help her cope with this threat.

For information on the physical and psychological management of patients undergoing stoma surgery, see Black (1997) and Borwell (1997).

Mrs B had a considerable need for education but required support, often given non-verbally through touch or simply by having someone with her before she was able to assimilate the information. The stoma nurse visited Mrs B in hospital to offer expert advice, to begin to establish a relationship and to plan her home care following discharge. The therapeutic role of the nurse in offering psychological support should not be underestimated (Jenkinson 1996).

It is not only patients with obvious outward structural changes in appearance who experience a change in body image. Perceived or actual alterations in function can change individuals' body image and self-concept, such as patients who experience changes in libido and sexual functioning following hysterectomy (Walsgrove 2001).

DISCHARGE PLANNING

Discharge plans aim to provide a smooth transition from hospital to home for continued patient care, often called seamless care, and should be considered from the time of admission. However, decreasing lengths of hospital stay have reduced the time available for nurses to meet patients' post-discharge needs. Inadequate discharge planning can lead to patients being readmitted because they are unprepared for self-care (Maramba et al 2004). Communication is fundamental to the process of collaborative discharge planning. However, Anderson and Helms (1995) found that information passed to the community carers on discharge was of poor quality and often late. Maramba et al (2004) suggest that a designated discharge coordinator who implements a discharge protocol can facilitate this process by providing consistent advice and initiating referrals.

In a busy surgical ward there is often an urgent need for beds, which can lead to hasty and poorly planned discharge. All patients are referred to their GP on discharge from hospital by the surgeon (see Figs 26.1 and 26.2). The nurse will decide whether the patient also needs to be referred to the community nurse. Referrals can be made for nursing interventions ranging from wound care to providing psychological support for the patient and family where there is a poor prognosis. If patients are able to attend the health centre or clinic for wound dressing procedures, then arrangements for an appointment can be made before discharge. It should be remembered, when starting a patient on a course of treatment, that not all wound dressing materials are available in the community.

However, as indicated, information for community nurses is not merely procedural or task centred; the patient's emotional state, mobility, social circumstances and informational needs are also included. Raiwet et al (1997) argue that care maps covering the whole patient care episode, including community care, can facilitate continuity of care. A personal telephone call, a copy of the care plan on discharge, or a visit by the community nurse to the ward can all be useful. Mrs B's stoma nurse had visited her in hospital on several occasions prior to discharge and had liaised closely with her named nurse to ensure she was well prepared to go home.

Forward planning and continuous responsibility as an element of primary nursing may help nurses to achieve the goal of effective discharge preparation. This has been given greater significance by the growth of day surgery where the necessity for discharge planning is heightened, and responsibilities are often taken by lay carers (Mitchell 2003).

Discharge education

Patient teaching for discharge begins on or before the day of admission to hospital. Mr W had received a booklet at his

preoperative visit which helped him plan for convalescence at home. He also had learned, from his practice nurse, about healthy diet, interventions to help him stop smoking and about expected function and return to work.

For further reading on patient education, see Naidoo & Wills (2000) or Ewles & Simnett (2003).

Patients require specific information to continue their recovery from surgery, but the opportunity for more general health education should also be taken. The opportunity to teach patients about their care on discharge may be limited, as with day-case patients, or more prolonged, as during an inpatient stay after major surgery. Information may also be given to relatives, with consent from the patient, to enable them to continue support at home (Mitchell 2003). Heseltine and Edlington (1998) implemented a telephone follow-up service which allowed nurses to respond to patients' questions about pain relief and to clarify any points in their postoperative recovery. This also allowed an audit of patient satisfaction with the care they received, and of the follow-up service. Mr A received only a local anaesthetic to his groin area. He was advised to use cold packs for 5–10 min on the local area for the first 1–2 days postoperatively. He was advised that some local swelling and bruising was common but that any sign of bleeding or extensive swelling should be referred to his GP. The family planning nurse suggested that if he required to contact his GP he should highlight that he had undergone vasectomy surgery that day.

Some patients may be quite unsure, or have misconceptions, about how they should progress during their recovery at home. In day case surgery it is essential that patients understand that the anaesthetic may take a full 24 h to be eliminated from the body. Therefore they must not drive home from hospital, should be accompanied for the first 24 h after surgery and should not drive to work the following morning. Some individuals expect to feel fully fit and to be able to care for themselves immediately on discharge. According to Correa at al (2001), following day surgery, patients may be 'home ready' but not 'street ready'. Advice may be given such as:

- Do not drink alcohol.
- Do not drive a motor vehicle.
- Have a responsible adult stay overnight with you.
- Do not make important decisions for 24 h following a general anaesthetic, regional anaesthetic and/or i.v. sedation.

Nurses should be aware that there is a high rate of failure to follow such recommendations, but cooperation is always enhanced if patients can understand the importance of this advice. Many will feel a little insecure without the presence of the nurse and feel anxious about their health (Mitchell 2002). Cooper (1999) suggests that taking home tape recordings made of their consultation for ready reference may be helpful for some.

Mrs B was to return home for several months before the surgeon would consider reversing her colostomy. She had to be independent in caring for her stoma and so required staged teaching and much support (see Nursing Care Plan 26.3). She had a booklet to reinforce the teaching given by the nurses, which also acted as a focus for discussions of the stoma with her daughter. The stoma nurse had given Mrs B a telephone number and promised to visit her in her own home in the next week.

All patients should be clear about seeking advice or treatment from the most appropriate source on discharge. Referral to community nurses and GPs, when possible, establishes continued support and may be preferable to telling patients just to ring the ward.

REHABILITATION

Rehabilitation of the patient does not take place exclusively in either hospital or home, but is nonetheless an increasing focus of care in the community setting. The needs of patients in terms of recovery from surgery do not differ dramatically from the time they leave hospital to their arrival at home. Discharge from hospital is therefore a stage in patient care, involving transfer of care from one setting to another. The plan of care for the discharged patient may thus address similar factors to that of the patient who continues recovery in hospital. Many interventions described in the sections on postoperative care will be equally relevant to the patient in hospital or at home.

Rehabilitation can be a lengthy process, requiring continued support by community nurses, or a short event with minimal professional intervention. There are increasingly sophisticated services such as community high dependency nursing teams who can provide care for ventilated patients in the long term. Mrs B was visited by the health visitor to assess whether she needed any additional support at home. She was also visited regularly by the stoma care nurse whom she had first met in hospital. Mr A recovered well at home and was able to undertake all of his normal daily activities. As his surgery was on Friday, he 'took it easy' over the weekend, avoiding any lifting or exertion such as carrying shopping bags, or golf clubs, and vacuum cleaning. His incision site and surrounding area were tender but this responded well to paracetamol 1 g, taken every 6 h. He avoided aspirin or ibuprofen in case of bleeding problems. His stitches were absorbable, eliminating the need to attend his GP surgery, and he sent semen samples to the hospital at 11 and 15 weeks as arranged. After the second sample Mr A was informed by the laboratory that his results were 'all clear' and that he could discontinue contraception. At work Mr W talked to an occupational health nurse about resuming a full range of duties.

The demands made by postoperative patients upon the community nursing services have increased greatly in recent years. This is partly due to an ageing population making greater demands on the service. Older people are known to be vulnerable on discharge and are more likely to have contact with community nurses (Dash et al 1996). The trend towards day case surgery and early discharge (see p. 901) places more responsibility for postoperative care in the hands of community health care workers. A phenomenological study by Edwards (2002) provides an insightful glimpse into the difficulties experienced by a group of older patients following elective orthopaedic surgery. One patient felt the nurses had 'washed their hands' of after-care. Edwards (2002) advocates flexible support such as telephone helplines run by specialist nurses and 'drop in' clinics, e.g. NHS Direct or NHS 24 (see 'Useful websites', p. 943).

Jester and Turner (1998) describe a 'hospital at home' scheme which facilitated early discharge into the care of a multiprofessional care team.

Trends towards increased day surgery have been driven partly by public demand. In 1991, the Audit Commission reported that 80% of day case patients preferred this option. A number of studies (Otte 1996, Heseltine & Edlington 1998, Hunt et al 1999) support this. An increasing number of patients are therefore recovering from surgery at home.

Patients undergoing surgery require a range of care from nurses in both the hospital and community settings, in both the pre- and postoperative periods. Whilst care can often appear to be focused on performing tasks in a standardised manner, it has been proposed in this chapter that patients enter the surgical experience for a wide variety of reasons with differing health care needs. The nurse is ideally placed not only to coordinate and humanise the surgical experience, but also to facilitate a safe and speedy recovery in an individualised manner.

INTRODUCTION

Every year, 15 million patients attend Emergency Departments (ED) in England and Wales (Audit Commission 2001). They present with a wide variety of injuries or conditions, some that may be considered as life threatening and others that are relatively minor. This means that nurses working within an ED environment are required to have a broad knowledge base and a wide range of skills to enable them to meet the needs of all patients. This chapter considers this diverse nature of emergency nursing. As many of the medical and surgical conditions have been discussed in other chapters of this book, this chapter will focus on the concept of trauma. It will outline the process of triage, which includes the concept of 'see and treat'. This concept is based around the principle that the first clinician is able to treat and discharge the patient (Heyworth & Holt 2002).

Two case studies will be used to highlight the principles of emergency nursing care and will examine what is meant by trauma, by exploring the range of injuries that may be encountered by an ED nurse, whilst highlighting key principles of care. The case studies will focus on:

- the care of a patient who has multiple injuries and who therefore requires immediate resuscitation
- the care of a patient who attends with a minor injury and who is assessed, diagnosed, treated and discharged independently by a nurse.

Whilst trauma accounts for a large proportion of ED work, it is important to consider other distinct areas of practice that require specific skills to enable the nurse to meet both the patient's and the family's physical and psychosocial needs. Bereavement is an extremely sensitive and emotional area of emergency nursing, as relatives and friends have had no opportunity to anticipate or prepare themselves for their sudden loss. Principles of caring for families during their crises will be explored with specific reference to the loss of a baby as a result of sudden infant death syndrome (SIDS). It is also important to acknowledge the ED staff's personal needs during these difficult periods, and the concept of critical incident stress debriefing (CISD) will be outlined.

The Emergency Department provides an interface between the community and the hospital setting. Operating an 'open door' philosophy confronts the ED nurse with many practical and ethical challenges, which are often linked to wider sociological and political issues. Strategies that may be adopted to prevent incidents of violence and aggression will be discussed and the Emergency nurse's responsibility to the law highlighted. The dynamic nature of the ED environment means that the workload is often unpredictable and Emergency nurses have to be prepared for the unexpected. For this reason, a section of this chapter is devoted to the key aspects of an Emergency Department's response to disasters, which involve large numbers of

casualties. Also considered is the subsequent psychological impact this may have on the survivors, their families, the witnesses and the rescuers and health care workers involved, both at the scene of the disaster and within the hospital environment. Throughout the chapter, the importance of patient and family involvement in the planning and delivery of nursing care will be emphasised.

Trauma

Trauma may be defined as any physical wound or injury. It can be caused by a variety of accidents, but may also be self-inflicted or result from acts of violence. The impact of traumatic events on victims, witnesses and staff may also cause psychological problems long past the event itself (Van Der Kolk 1998) (see 'Post-traumatic stress disorder', p. 962).

The severity of the wound or injury may be as minor as a simple graze, which can be self-treated within the home environment, or one which requires more specialised treatment in a hospital Emergency Department. Conversely, the trauma victim may present with life-threatening multiple injuries, such that they are vulnerable to imminent death within the initial hours following the traumatic event. In England alone, 873 000 people are admitted to hospital each year via Emergency units, following an injury (Department of Health 2003a). Trauma is the main cause of death in young people. Annually in the UK, 14 500–18 000 deaths occur as a result of trauma, with 60 000 patients being admitted to hospital each year as a result of a road traffic collision (RTC) (Bonnett et al 2003). Whilst there has been legislation to reduce the number of accidents, e.g. the wearing of seat belts for car users, helmets for motorcyclists, drink driving laws (Hill 1990) and the Health and Safety at Work Act (Health and Safety Commission 1974, still extant), society can still view risk-taking behaviour as a positive characteristic so that these measures are not always adhered to (Brannon & Feist 2004). Despite this, statistically there has been a reduction in the incidence of trauma, but still the cost to the health and social services of caring for injured people is £1.2 billion/year (Department of Health 2002a). It is for this reason that Emergency nurses must be able to meet the immediate needs of patients who attend with both life-threatening and less serious conditions.

Reception in the Emergency Department

The ED is designed to accommodate patients who arrive by a variety of means and who present with a diversity of problems. Within the NHS it is generally accepted that the general practitioner (GP) is the primary source of medical care through which patients are referred to hospital facilities and specialist practitioners. Those who require acute specialist care will more often than not be admitted through the ED and will be seen and assessed by the relevant medical or surgical team. However, patients present to the ED via other channels. With the knowledge that they can gain immediate access to hospital facilities without GP referral, many individuals self-present to the ED. Other patients are referred via occupational health services and schools. Generally, more seriously ill or injured patients will arrive via the local ambulance service by road transport; however, there is an increase in the use of helicopters within the United Kingdom to transfer seriously injured or ill people to hospital (Black et al 2004). Usually these patients arrive singly, but on occasion, as in the case of RTCs that involve several vehicles, there will be many patients arriving at one time, often with injuries of differing severity.

For this reason the ED environment must be flexible. The physical division of any department facilitates this. There are usually two points of access to the ED, one for ambulance patients, which provides direct access into the clinical area, and one for other patients which leads into a reception and waiting area. In most units there are separate areas allocated to treat patients with minor injuries and areas that contain individual examination cubicles for those who require a more thorough examination. All departments have a designated resuscitation area for those patients who present with life-threatening conditions. Larger departments may have separate plaster areas, theatres for minor operations and specially equipped cubicles for eye and dental problems. In departments where children are seen, it is recommended that there are separate waiting areas and cubicles which are suitably decorated and equipped to meet the needs of children (Royal College of Nursing 2003).

Although the concept of triage, which involves the nursing assessment of the patient's illness or injury to determine a priority of care, is still utilised in some emergency departments, the process of 'see and treat' is now being used more widely throughout the country (Cooke et al 2002). The key principles of 'see and treat' are that upon arrival in the Emergency Department patients are seen, treated and referred or discharged by one clinician. This clinician may be a member of the nursing team. Therefore, the nurse must be able to make autonomous clinical decisions about treatment, investigations and discharge. More seriously ill patients, or those who require more in-depth assessment or treatment, should be taken to, and treated in, a separate area (Department of Health 2002b).

In order for members of the nursing team to be able to practise 'see and treat' competently, they need to have excellent interpersonal as well as clinical and diagnostic skills, thus allowing the pertinent information to be collated. For medicolegal reasons this information needs to be documented in a clear and logical manner (Nursing and Midwifery Council 2004). One way to organise this information is by using a model, which means that all nurses working within its framework use the same guidelines (Sbaih 1992). One framework that can be used is based upon the medical model (Talley & O'Connor 2000) (see Box 27.1).

In order to make a correct diagnosis, the most important skill that a nurse needs to develop is one of obtaining a clear and concise history from the patient. The nurse initially must establish why the person has attended the Emergency Department. This will establish the presenting complaint (PC). It is then important to determine the history of the presenting complaint (HPC), i.e. how the injury occurred, known as the mechanism of injury. The mechanism of injury will assist the nurse in making a provisional diagnosis and enable a decision to be made on which investigations are required, e.g. X-rays and the administration of analgesics. Working within protocols allows nurses, on reaching the limit of their expertise, to refer on to another clinician, either an Emergency Nurse Practitioner (ENP) or doctor.

Box 27.1

Medical model used in assessing minor trauma

PC — presenting complaint
HPC — history of presenting complaint
PMH — past medical history
DH — drug history including allergies
SH — social history, including living arrangements and activities of daily living
O/E — on examination — includes all the major systems
CVS — cardiovascular system
CNS — central nervous system
RS — respiratory system
MS — musculoskeletal system
GIT — gastrointestinal tract
GUS — genitourinary system
IMP — impression of information gained
DD — differential diagnosis based upon the information gained
Plan — what investigations, e.g. X-rays etc., are needed to confirm or refute the differential diagnosis. Also includes the treatment that is needed

Adapted from Talley & O'Connor (2000).

Box 27.2

Trimodal distribution of death following trauma

First peak
Mortality during this peak occurs very shortly after the time of injury and usually at the scene of the incident. The person's injuries are so grave that no resuscitative intervention would be successful. The primary way of avoiding such deaths is through accident prevention programmes such as drink driving campaigns and seat belt legislation.

Second peak
Mortality occurs hours after the incidence of trauma and patients may die from airway, breathing and circulatory problems. Many of these deaths are preventable during this period, which is commonly known as the 'golden hour' — the period during which the patient is in the resuscitation room of an Emergency Department.

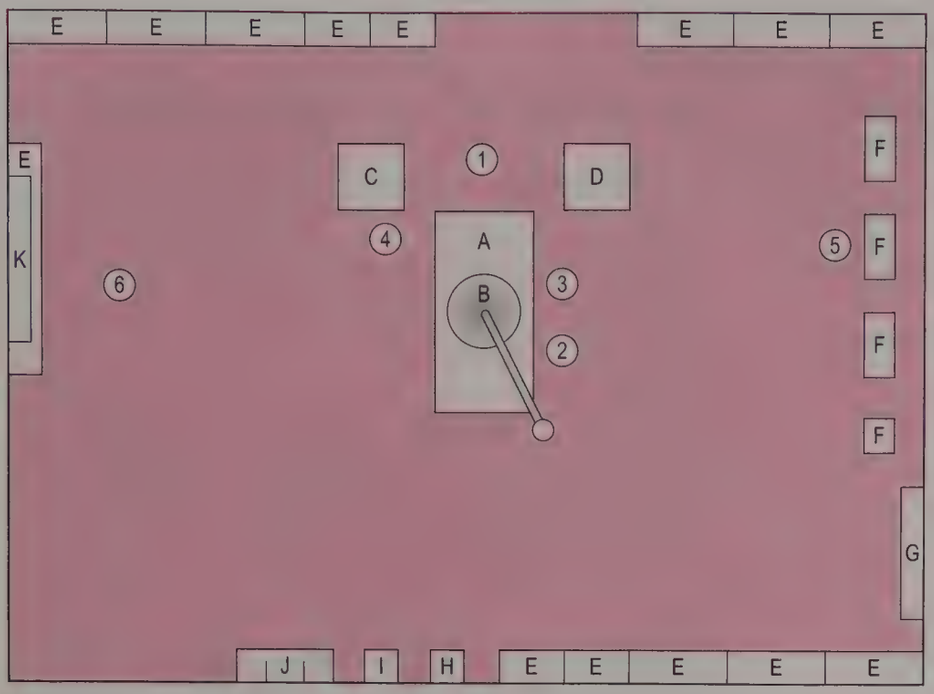
Third peak
Mortality occurs days or weeks following the initial incident and patients may die from multi-organ failure, acute respiratory distress syndrome (ARDS) or sepsis.

Adapted from Bonnett et al (2003).

Many benefits of the 'see and treat' process have been identified:

- There is a significant reduction in the time that each patient has to wait (Cooke et al 2002). This therefore improves the patient's experience within the ED, by improving the flow through the department and reducing the number of steps that the patient goes through.
- There is also an indication that this has improved job satisfaction for nursing staff (Department of Health 2002b). However, in order for the 'see and treat' process to be in place, considerable educational resources must be available to enable the nursing staff to learn about the process of assessment, the requesting of X-rays and the administration of analgesics. Specific protocols must also be written, to allow the 'see and treat' nurse to have clear parameters within which to work.
- The process of 'see and treat' can be used in conjunction with a simplified triage system. For example, if there is an influx of patients, they will go through the 'see and treat' process, following which a priority allocation can be given to each patient to be seen by either the ENP or a doctor. The Manchester Triage (Manchester Triage Group 1997) is seen nationally as an effective system of prioritisation.

IMMEDIATE TREATMENT OF EMERGENCIES



In 1988, The Royal College of Surgeons of England identified that approximately one-third of emergency-related deaths were preventable and were often due to hypoxia, continuing haemorrhage and missed diagnosis. Bonnett et al (2003) describe a 'trimodal distribution' of death which identifies three peaks following trauma when casualties die as a result either of their injuries or of subsequent events (see Box 27.2). For these reasons it is important that any ED is fully prepared to receive any patient, no matter how severely injured, at any time of the day or night.

It is also vital that there is a predetermined system, such as the advanced trauma life support (ATLS) protocols (American College of Surgeons 2004), to guide personnel through the initial assessment of the patient, enabling them to identify any life-threatening conditions quickly and to treat them appropriately. Patients admitted with such life-threatening injuries will be cared for in a resuscitation area which is designed to have the necessary equipment readily available and the space to enable a trauma team, consisting of nurses, doctors and a radiographer, to care for the patient efficiently and effectively (see Fig. 27.1).

The trauma team

Effective staffing is as important as the organisation of equipment. Having too many people in the resuscitation room may be as problematic as having too few, as overcrowding can lead to confusion and delays. A trauma team consists of an integrated group of nurses and doctors who are needed to ensure that there is an efficient and organised resuscitation approach. There should be a system of identifying, from the total nursing staff in the department, a group of at least three nurses who will contribute to the team in the resuscitation room. Both a nurse and a doctor lead the team.

The aim of resuscitation is to stabilise the patient, identify injuries and initiate a definitive management plan. It has been shown that the most efficient resuscitation will occur if a 'horizontal organisation' approach is adopted (Bonnett et al 2003). This is when each member of the team carries out individual tasks simultaneously rather than sequentially. This reduces the time taken to resuscitate a patient and

initiate life-saving procedures, which will improve the patient's chances of survival. For this to be successful, each member of the team must be aware of his or her precise role, which will have been designated by the team leaders. The size of the team will depend on the size of the individual department. As well as the designated nurses, there will be either an ED consultant or a senior doctor from the ED and an anaesthetist and surgeon on call. An example of the responsibilities of each nursing team member can be seen in Box 27.3.

On the patient's arrival at the ED, an initial history will have been received from the ambulance crew, but further information may become available with the arrival of relatives or friends. Collecting this information should, where possible, be the responsibility of a fourth nurse who can act as liaison between the trauma team and the patient's family or friends. The paramedics routinely leave a copy of their clinical documentation for the patient with the ED.

The advanced trauma life support (ATLS) system

To care effectively for seriously injured patients, they must be rapidly assessed, their injuries identified and any life-threatening conditions immediately treated. Within the ED environment, this includes completing a primary and, where possible, a secondary survey to ensure a full assessment is made. Within the primary survey, an ABCDE process is followed to ensure that logical and sequential treatment priorities are identified:

A — Airway maintenance, with protection of the cervical spine
B — Breathing and ventilation
C — Circulation, with haemorrhage control
D — Disability, which involves a neurological assessment

Box 27.3

Responsibilities of nursing members of a trauma team

Nurse One
This nurse will coordinate the team, as well as assisting the other nurses by preparing appropriate equipment as necessary for procedures, and recording any clinical observations and laboratory findings.

Nurse Two
This nurse is often referred to as the airway nurse and has two key responsibilities: first, to assist the anaesthetist in securing and maintaining the patient's airway, whilst protecting the patient's cervical spine; second, to establish a rapport with the patient, giving psychological support whilst in the resuscitation room. Ideally, all information to the patient should be relayed through this nurse.

Nurse Three
This nurse may be referred to as the circulating nurse. Her responsibilities include removing the patient's clothes, attaching the patient to monitors and measuring the patient's clinical vital signs. Subsequently, this nurse will ensure that i.v. access has been established and will be responsible for the patient's fluid requirements. This nurse will also assist with any procedures, e.g. catheterisation, insertion of a chest drain.

E — Exposure of the patient, ensuring that the environment is optimal to prevent further hypothermia.

If any life-threatening condition is identified during the process, it is treated before moving on to the next stage, e.g. if the patient is found to have a compromised airway, this is stabilised before the patient's breathing and ventilation are assessed.

The secondary survey is only started when the primary survey is complete and the patient's condition is stabilised. If the patient is critically injured, this secondary survey may not take place in the ED, as the patient is likely to require surgical intervention to stabilise their condition. However, if the patient's condition does permit, then the secondary survey involves a full head-to-toe examination and gives the nurse the opportunity to complete a thorough set of clinical observations, including neurological observations.

The resuscitation room

It is important that the resuscitation area is designed to complement both the assessment principles (e.g. the ATLS protocols) which are to be applied when examining the patient and the team who have to work within its environment. Usually staff are given some warning via their local ambulance service that a patient with severe or life-threatening injuries will be admitted shortly. This may mean that there is little time for preparation before the patient is rushed into the department. It is vital that the resuscitation area is always prepared for such emergencies and it is the nurses' responsibility at all times to ensure that all areas are fully stocked and, at the beginning of each shift, that the equipment is in working order. It is also vital that health and safety issues are considered to prevent any further harm occurring to the patient and to prevent staff becoming inadvertently injured during the haste of a resuscitation. This includes the availability of plastic aprons, disposable gloves and protective goggles for all staff.

Most resuscitation rooms have spacious trolley areas for the team to work in. A policy of keeping 'a place for everything and everything in its place' should be followed, so that staff can learn the location of every item and find anything that is needed immediately. Certain items may be prepared in advance. For example, the cardiac monitor may have its chest electrodes attached, and receivers with the most commonly used blood sample bottles, corresponding forms and large syringes may be kept ready. Clipboards with the usual documentation may also be prepared in advance. As well as the technical life-saving equipment, it is important to ensure that sharps boxes and clinical waste bins are strategically placed so that nurses or doctors do not have to walk far to dispose of their needles and clinical waste. Furthermore, patients vary in size and weight. It is therefore necessary to have a range of appropriate sizes of all equipment stored within the resuscitation area. The arrangement of the resuscitation room and its cupboards should not be changed unless all staff are informed.

Staff must continually update their knowledge of the procedures that may be performed. It is easy to forget skills that are used infrequently, but patients' lives may depend on the rapidity with which certain measures are undertaken. When equipping the resuscitation area it is useful to consider the above-mentioned ABCDE assessment process.

Airway maintenance with protection of cervical spine

Equipment that will help to clear and maintain a patient's airway should be readily available at the head end of the patient trolley. On arrival, the patient's airway should be examined for any type of obstruction and appropriate steps taken to clear it if necessary. Piped suction with a rigid catheter attached will facilitate this process. If the patient is unable to fully maintain their airway, the airway nurse can try several manoeuvres. Manual procedures such as a jaw thrust or chin lift can be done in the immediate instance, but doing this will mean that the nurse is unable to assist the rest of the team. Using adjuncts such as oropharyngeal or nasopharyngeal airways will free the nurse and may be all that is required in the patient who has an altered level of consciousness. The best place to store this equipment is attached to the wall at the head of the patient.

For patients who have more serious injuries, it may be necessary to protect their airway definitively. This is done by an anaesthetist who will intubate the patient using a laryngoscope and endotracheal (ET) tube. Again, if this has to be done as a life-saving measure, the equipment must be to hand. Occasionally it will be necessary to sedate and paralyse the patient to facilitate this process. The anaesthetist will require a range of drugs and the airway nurse should be familiar with the current drugs used and have them ready for immediate use. Once the ET tube is in place, a mechanism for ventilation will be required which must be attached to a high percentage of oxygen via a piped oxygen supply. Ideally, all this equipment should be pre-prepared for rapid use. In patients who have sustained massive facial injuries, a surgical airway may be the only way to oxygenate them adequately. This requires specialist equipment, which, again, should be pre-prepared and ready for immediate use.

Patients who present with multiple injuries have often been involved in high-velocity accidents, e.g. RTCs or falls from a height. It is vital that the patient's cervical spine is protected in in-line immobilisation until the trauma team is sure that the neck is uninjured. This requires the nurse either to support the patient's neck manually or to place a semi-rigid collar around it. Further support is then achieved by placing a sandbag at each side of the patient's face and applying tape across the forehead to the sides of the trolley. The airway nurse must be vigilant in observing the patient for any signs of nausea or vomiting. With the spine immobilised, the patient is unable to move. If vomiting is likely, the team would have to log roll the patient (see p. 951) to protect the spine and assist the patient with suction apparatus.

Breathing and ventilation

The patient's respiration rate must be measured and recorded; this should include the rate, depth and use of any ancillary muscles. However, it is also important to note how effectively the patient is ventilating, i.e. that there is effective gas exchange taking place at the alveolar capillary membrane. All patients who have sustained significant injuries should receive a high flow of oxygen. This can be delivered via a mask with a reservoir bag (non-rebreather oxygen mask) with a flow rate of 12–15 L/min (American College of Surgeons 2004). By the addition of a reservoir bag the patient will receive up to 90% oxygen concentration compared to only 50% oxygen concentration with an ordinary oxygen mask (Resuscitation Council (UK) 2000). Using pulse oximetry enables the nurse to monitor continually the patient's oxygenation saturation of arterial

blood so a pulse oximeter should be situated by the trolley side. Usually this is part of an extensive system that monitors the patient's heart rate, blood pressure, respiration rate and oxygen saturation continuously and simultaneously.

There are six immediately life-threatening chest conditions: airway obstruction, cardiac tamponade, tension pneumothorax, massive haemothorax, open chest wound and flail chest (Bonnett et al 2003). If a patient has sustained any of these injuries, immediate treatment will be required and the necessary equipment for chest drain insertion (see Ch. 3, p. 98) or pericardiocentesis (aspiration of fluid from the pericardial sac) must be easily accessible. This type of equipment is usually pre-packed in sterile trays ready for use at a moment's notice. It is the nurse's responsibility to become familiar with the contents of these trays in order to assist the medical staff with any necessary procedures.

Box 27.4

Differing types of intravenous access

Access via peripheral veins
- Veins in the forearm
- External jugular vein
- Femoral vein

Access via the central veins
- Internal jugular vein
- Subclavian vein

Other types of access
- Intraosseous access via proximal tibia
- Cutdown using long saphenous vein of the leg

Adapted from Resuscitation Council (UK) (2000).

Circulation, with haemorrhage control

In severely traumatised patients, the most common circulatory problem is hypovolaemia (see Ch. 18). Any overt bleeding should be controlled by direct pressure using absorbent dressings and bandages. Emergency treatment consists of restoring the circulatory volume as rapidly as possible by the administration of i.v. fluids. One method of estimating the amount of fluid a patient has lost, or is continuing to lose, is to monitor clinical vital signs. This includes regular measurement and recording of the patient's heart rate, blood pressure and respiration rate, which can be done using the technical equipment described above.

Simply observing the patient's skin colour can provide some indication of the degree of shock present, whilst talking to the patient will indicate their current mental status. The greater the blood loss, the paler the patient will look, and as oxygen availability decreases in the blood supply, the patient will become increasingly confused and perhaps agitated (Bonnett et al 2003). Once 50% of total blood volume is lost, the patient will become unconscious. A further guide is the patient's urine output. A catheterisation tray should be readily available and, if the patient has been catheterised, the urine output should be measured at regular intervals using a urometer. The normal urine output for an adult is 30–50 mL/h.

To prevent any deterioration as a result of hypovolaemia, the circulating nurse should ensure that two wide-bore peripheral cannulae are inserted simultaneously into large veins such as the antecubital fossa found at the elbow joint. In some EDs, it is the nurse who has developed the clinical skills to carry out this procedure, ensuring that enough blood is withdrawn for the necessary laboratory investigations to assess the patient's condition. To facilitate this process, sample bottles, forms and large syringes should be prepared and a policy should be in place for the quick transport of samples to the laboratory. Once the peripheral lines have been established, replacement fluids, either crystalloids or colloids, warmed via a warming cabinet to approximately 39°C (American College of Surgeons 2004), must be administered. If the patient appears severely compromised, it may be necessary to use a mechanical pump, e.g. the Level One Blood Warmer, to infuse the fluid more quickly. However, by the time the patient reaches hospital, their peripheral circulation may be 'shut down' (see Ch. 18). This occurs in hypovolaemia as a result of the body's attempt to preserve the vital organs by constricting the peripheral blood vessels and redirecting the available blood to the major organs. Therefore it may be impossible to insert an i.v. cannula in a surface vessel and it may be necessary to perform an i.v. cutdown procedure. This involves making an incision in the skin and subcutaneous tissues and locating a deeper vein in which to insert a cannula. Again, the necessary equipment should be ready (see Box 27.4 for differing types of intravenous access).

In order to monitor the patient's progress, it is important that all findings are recorded at regular intervals. In the initial stages of the resuscitation this may be as frequently as every 5 min. The appropriate charts should be available for the recording of vital signs and fluid balance.

Disability: neurological assessment

It is important that a rapid assessment is made of the patient's neurological status using the AVPU scale. On arrival, it is easy for the airway nurse to determine if the patient is **Alert**, i.e. eyes open and responding, or if they respond only to **Voice**. If the patient does neither of these, then the nurse needs to assess if the patient responds to **Painful** stimuli. If not, the patient is considered to be **Unresponsive**. Concurrently, the nurse should use a torch to assess the patient's pupils to see if they are equal in size and react to light. Again this should be documented as a baseline for future comparison. For a more in-depth neurological assessment, the nurse should proceed to use the Glasgow Coma Scale (see Ch. 28).

Exposure, ensuring environmental control

Whilst the patient's dignity should be preserved as much as is possible, it is essential that all clothing is removed so that the entire body can be examined from head to toe, front and back, to ensure that no injuries are missed. It is important to remember that exposure can cause rapid body heat loss, so it is vital that the resuscitation room temperature is warm enough to preserve the patient's body temperature. The use of warmed blankets, which must be

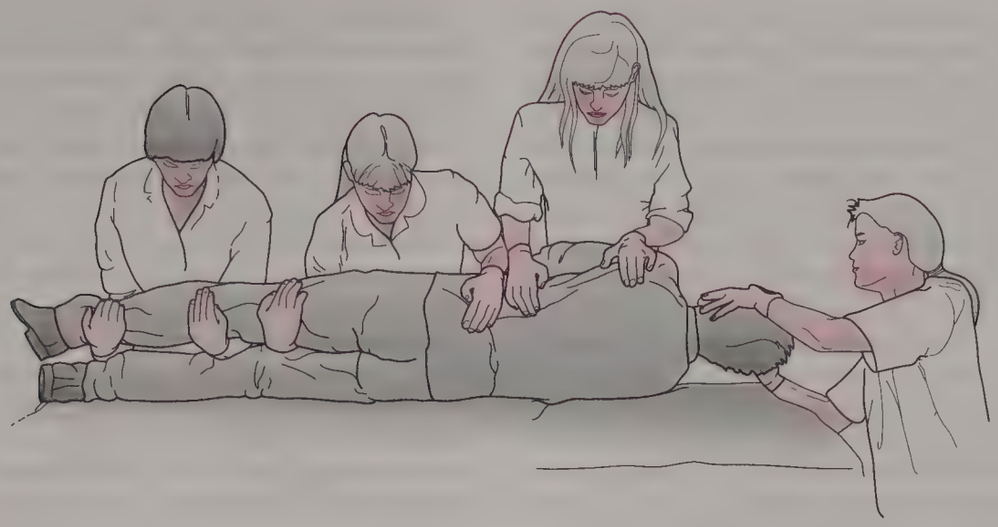

Fig. 27.2 The log roll technique. (Reproduced with kind permission from Lisa Hadfield-Law, Oxfordshire.)

replaced between any procedure or examination, will also prevent further temperature drop. The log roll technique (see Fig. 27.2) should be used to enable full examination of the patient's spine. To ensure total spinal immobilisation, a coordinated approach, using a team of at least four people, is required. The leader of the team will manually immobilise the patient's cervical spine, whilst the three assistants will control the patient's thorax, pelvis and legs.

27.1 Find out from your mentor or lecturer how to carry out a log roll safely and effectively. Practise this with your fellow students in your clinical laboratory.

A PATIENT WITH MULTIPLE TRAUMA

Assessment and immediate treatment

In Case History 27.1, the ambulance team have informed the Emergency Department by radio patch of J's condition and given an estimated time of arrival of 10 min. The trauma team and radiographer have been summoned and the resuscitation room prepared. Due to the nature of the accident, the paramedics, having safely removed his helmet, immobilised J on a spinal board with full cervical spine immobilisation.

On arrival, J is transferred onto a trolley, which allows X-rays to be taken without moving him. At the same time the paramedics provide an immediate verbal handover outlining the nature of the accident, i.e. speed, involvement of any other vehicles or any other injured patients, and an overview of J's clinical condition during his transportation to hospital. The paramedics later provide a written handover of the incident.

Once transferred, the airway nurse assesses J's airway. She notes that J is now more alert and trying to remove the oropharyngeal airway that is causing him to gag. His airway is clear and there is no overt evidence of facial injuries. J is responding to her voice. Whilst reassuring him, she applies an oxygen mask with reservoir bag attached to 15 L/min of oxygen. She continues to explain to J what is happening to him. Meanwhile the circulating nurse removes J's clothes by carefully cutting them. This allows her to attach the monitor, which will record J's pulse, blood pressure and oxygen saturation, whilst one of the doctors looks, listens to and feels J's chest. The nurse counts J's respiration rate, noting the depth of each breath. All clinical observations are passed to the team leader who records them on a trauma chart. J's breathing appears rapid (24 breaths/min) and laboured and, on inspection, it is found that the left side of his chest is not inflating. His oxygen saturation is 91% despite the high-flow oxygen administration. Palpation of the chest wall reveals swelling and crepitus on the left side, indicating possible fractured ribs and a possible pneumo/haemothorax. To ensure adequate gaseous exchange and tissue perfusion, a chest drain must be inserted (see Ch. 3). This will also prevent mediastinal shift. Whilst the equipment is being prepared by the team leader and the radiographer is taking chest X-rays, the circulating nurse (see Box 27.3) ensures that two wide-bore cannulae are inserted in J's arms and 2 L of Hartmann's solution, warmed to 39°C, are administered rapidly. The blood taken from one of these lines is sent directly to the laboratories for a full blood count, urea and electrolytes, and group and cross-match for at least 6 units of blood. The equipment is prepared and the chest X-ray confirms a haemothorax and three fractures of the lower ribs on the left side. The chest drain is inserted using local anaesthetic and strict asepsis. Its placement is confirmed by X-ray and by visible oscillations in the drainage tube. The amount of blood drained from the chest is carefully measured and recorded. Continued observation of respiratory rate,

CASE HISTORY 27.1

J

J is an 18-year-old man who has been knocked off his motorcycle while travelling at high speed. He was wearing a crash helmet but is unconscious when brought into the department by ambulance. He has an oropharyngeal airway in situ and has been given oxygen by the paramedics. His left leg is splinted from the groin to the toes and a closed fracture of the femur is suspected. The police who were called to the scene of the accident have succeeded in finding identification and are now trying to contact J's family.

rhythm and depth reveals that J's respiration rate has improved (18 breaths/min), with fairly good expansion on both sides. His oxygen saturation is increasing (now measuring 95%). His colour is pale but not cyanosed.

(Note — motorcyclists often wear expensive leather protective clothing. Conscious patients will frequently forbid this clothing to be cut, preferring to suffer pain rather than have their leathers damaged. In a situation such as the one described here, the clothing must be cut to prevent further injury. Care should be taken, however, to cut clothing along the seams if at all possible, so that it can be repaired later. However, the patient's condition will dictate the urgency with which clothing should be removed.)

As J's breathing has stabilised, the circulating nurse is able to palpate J's radial pulse. She notes its rate, which is rapid (120 beats/min); rhythm, which is regular; and strength, which is thready. At the same time she notes that J's skin is cool, clammy and pale. The monitor displays that J is also hypotensive, with a blood pressure of 70/30 mmHg. These recordings show evidence of hypovolaemia (see Ch. 18). There is no overt sign of haemorrhage, although there appears to be an obvious closed fracture to J's left femur and right wrist. J's clinical findings indicate that he may be bleeding internally. Simultaneously, the radiographer has completed pelvic X-rays, and these show no fracture. However, there is bruising over the left upper quadrant of J's abdomen and he is tender on palpation. A ruptured spleen is suspected, as this is often associated with left lower rib fractures. As the spleen is a highly vascular organ, the likelihood is that J has lost a considerable amount of blood into the abdominal cavity. A nurse contacts the general surgeon on call. Further assessment is carried out while the team waits for the surgeon.

Whilst the circulating nurse has been attending to J's circulatory status, the airway nurse has determined that J continues to respond to her voice. He knows who he is, where he is and what month it is. He is complaining of severe pain in his left leg and right wrist. His pupils are checked and found to be equal, within normal limits (2–5 mm) and both react to light. The nurse informs the medical team leader of J's distress, who then decides to apply a Thomas splint to J's left leg and administer an i.v. opioid, e.g. morphine, to relieve J's pain, plus an antiemetic to prevent any nausea or vomiting. The splint will provide some pain relief as it realigns the fractured bone. Pre- and post-application of the splint, J's dorsalis pedis pulse is checked and is easily palpable.

Using members of the medical and nursing team, J is now 'log rolled' so that his back and spinal column can be examined (see Fig. 27.2). Since his known major injuries are on the left side, he is rolled to the right. Spinal injury has not yet been ruled out, so great care is taken to keep his spine in anatomical alignment. The spinal column is palpated for loss of normal continuity and abnormal curves or 'dips'. J is asked to indicate any areas of pain. No abnormality is detected and J reports no back pain. After preparing J, and prior to passing a urethral catheter (American College of Surgeons 2004), a rectal examination is performed to check for a high riding or absent prostate gland, which may indicate urethral damage. Other signs of urethral damage include blood around the external urinary meatus and scrotal haematoma in the male patient.

The cross-matched blood has now arrived and the rapid transfusion of two units of whole blood is commenced. The appropriate care and observations for a patient having a blood transfusion are maintained (see Ch. 11). The urinary catheterisation set is ready, and after explaining why it is important to monitor J's urine output, the catheter is inserted and a urometer attached. A plaster of Paris (POP) backslab is applied to support J's wrist. The surgeon arrives and agrees that J needs immediate transfer to theatre for a laparotomy. Once this has been done and J's condition has further stabilised, the orthopaedic surgeon will reduce and immobilise the fractures more definitively while J is still anaesthetised. The operating staff are informed and a theatre will be prepared. A ward is identified for J's subsequent transfer, but in the meantime J's clinical condition continues to be monitored at 15-min intervals.

Care of relatives

J's mother, Mrs S, has now arrived in the department. She has been met by the senior nurse of the ED and brought to the relatives' room. Ideally, each department should have a quiet room where the family and friends of seriously ill or injured patients may wait. This room should have comfortable chairs as waiting may often be long, facilities for making tea or coffee, and a telephone, so that other family members or friends can be contacted (British Association for Accident and Emergency Medicine and Royal College of Nursing 1995). A nurse should, if at all possible, stay with the relatives. People who are in a strange and, in this case, threatening environment are often unsure of how to behave and what is expected of them. They may have questions to ask, such as where the toilets are located, but may be reluctant to leave the room they have been shown into in case they miss some vital information about their loved one. They may also feel that if they come out and ask questions they are depriving their relative of a key member of staff who is essential to the team. Clearly, much anxiety and distress can be avoided if a member of staff remains with the family. Where pressures of work or staff shortages make this impossible, the family should be reassured that their relative is being constantly monitored and is never left alone. They should also be introduced to a nurse, usually Nurse One of the trauma team, who will act as their contact. The family should also be told where this nurse can be found, and encouraged to voice any queries or problems. This nurse should be responsible for seeing the relatives every 15 min or so in order to bring them up to date with developments.

Mrs S has not had the opportunity to contact her husband, as she has come straight to the hospital with the police. She is offered the use of a telephone to get in touch with him but requests that a member of staff does this for her instead. She is given details about her son's condition. These details are truthful, conveying the seriousness of J's condition. It is neither helpful nor compassionate to reassure people falsely in such circumstances. They need time to adjust their feelings in order to cope with what may be very bad news. If relatives are falsely reassured that everything will be all right, they will understandably feel cheated, and trust will be lost, if the outcome is not a happy one. At the same time, all hope should not be destroyed. In

encounters such as this, it is essential that the nurse is an experienced communicator, since there is a fine line to be drawn between giving false hope and causing unnecessary anguish. Relatives also have needs at such a stressful time, which the nurse must assess before embarking on lengthy explanations. Mrs S, for example, may have preferred to wait until her husband arrived before being given any information. Breaking bad news thus requires distinct skills, which nurses must learn and practise.

The police have already told J's mother of the circumstances of the accident. Traffic police investigate all RTCs to determine if there are any legal implications of the accident. The police are frequently used as a liaison for the relatives and are a valuable resource for the ED staff. Mrs S wishes to 'know the worst' about J's condition and is now informed of his injuries and the treatment he has received so far. The fact that he has a chest drain and is receiving i.v. fluid is explained, so that she is not alarmed by the presence of this equipment. Mrs S is told that a surgeon has been called and that J is at present being prepared for theatre, but that she may see him if she wishes. The trauma team need not interrupt their treatment of J to allow his mother to see him. The team's first priority is, obviously, the patient's physical condition, and they may become so caught up in this that other considerations are forgotten. Often, all that is necessary to reassure relatives and patients is that they can see each other briefly. Family members may be more content if they can see that the patient is actually alive, and it can comfort the patient to know that the family is present. As Mrs S is keen to see her son, she is taken to the resuscitation room accompanied by the same nurse. She is encouraged to stand by the airway nurse and speak to her son. Everything that is happening is explained to both J and Mrs S. The surgeon has now arrived and J's mother returns to the relatives' room with the nurse to wait for her husband. She asks if J's brother, sister and girlfriend should be contacted, and is told that it may, in fact, do everyone good if they are all together at this time of family crisis.

J's vital signs continue to be recorded at regular intervals. It is found that his pulse and blood pressure have stabilised, remaining at 100 beats/min and 90/50 mmHg, respectively. The doctor now has time to spend with J's family, who have now arrived, and explain in more detail the implications of J's injuries. Meanwhile, in the resuscitation room, all documentation is assembled. J's clothing and valuables have already been placed in property bags and are now given to his mother. Departments differ as to policy for dealing with property; some record details in a property book, while others leave this task to the admitting ward.

In certain circumstances, notably in cases of violent assault such as shootings, stabbings or rape, the victim's clothes should be carefully bagged, recorded and given to the police for forensic examination. This may also apply in the case of hit-and-run accidents. It is preferred that items are bagged separately, so that one item does not contaminate another. If property is given to the police, it is important that a police officer signs the property book as receiver of the property and that the nurse who hands it over also signs so that future queries from any source can be readily answered.

J is now ready to be taken to theatre (see Ch. 26). His family and girlfriend are called to accompany him. They will be able to talk to him along the way and to say their goodbyes when he reaches theatre. The theatre staff are informed that J's family are going to wait, so that they can be kept informed of his progress and be notified when he is returned to the recovery ward. The family is taken to a relatives' room beside the wards, and theatre staff are told where they can be contacted.

It is likely that J will make a full recovery; however, what would have happened if he had died in the Emergency Department? The following section deals with the nurse's role in supporting relatives who are bereaved by the sudden death of a loved one.

DEATH IN THE EMERGENCY DEPARTMENT

A very difficult dilemma for the ED staff may arise when they begin to realise that resuscitative measures are not going to succeed. If staff know that the resuscitation attempts are likely to be futile and the family has arrived, it is important that the relatives are gently made aware of the situation by the nurse caring for them, who can outline the gravity of the situation. This provides the family with time, even just a few minutes, to internalise the seriousness of the situation. The decision to stop resuscitation efforts is a difficult one, and one that should be made after considering individual team members' views. If the relatives have arrived in the ED, it may be possible to offer them the option of seeing their loved one to say goodbye before the resuscitation efforts are stopped.

All bereavement is traumatic, but sudden death is recognised as one of the most traumatic of experiences (Wright 1996). The deceased was usually last seen alive and well and the fact that they are now dead is very difficult for loved ones to comprehend, as they have had no opportunity to prepare for grief. Feelings of guilt may also prevail if the bereaved person begins to reflect upon things not said or done when the loved one was still alive. Caring for distressed relatives in these circumstances is one of the most draining of nursing interactions (Cudmore 1998) and it is important that the nurse is prepared for a wide range of emotional reactions. It is also important that the nurse is aware of the individual's religious and cultural beliefs, particularly concerning the disposal of the body following a sudden death. Each Emergency Department should have direct access to religious ministers from different faiths who can either offer advice or, if the family members request it, be present to support them during this difficult period.

If relatives wish to see their loved one, nurses can do much to help. If possible, those parts of the body that are exposed should be washed. One or (if possible) both of the deceased's hands should be left outside the sheets. The head of the trolley should be slightly raised, otherwise the face may seem distorted when the family first sees the body. False teeth should be replaced for the same reason and the hair combed or smoothed. Where there are severe head injuries, bandages should be left in place and perhaps covered with a clean outer layer. A nurse should initially accompany the relatives, and, if they seem hesitant, can indicate that it is all right for them to touch the body, perhaps by doing so personally or by asking the family members if they wish to hold the loved one's hand. The nurse should then offer to withdraw. Not everyone will want to be left alone, but some may have private words of parting to

say and should be given the opportunity to do so. Where a whole family is present, this chance should be given to each person individually. One family member may not feel able to ask for this for themselves, but when it is suggested by the nurse, they may gratefully accept. Relatives should also feel free to hug or kiss the body; in the case of a dead child, the parents should be able to take the child in their arms. This seems to help people to cope with the denial stage of grieving, especially in cases of sudden death (Kubler-Ross 1984).

Following this period, some relatives may find it difficult to leave the department and may need some assistance. Part of the concluding process may be to give the relatives information relating to the immediate future. Relatives should be made aware that where death has occurred as the result of trauma, under legal requirements a postmortem is always required and there will probably be an inquest at a later date. Providing a card with the departmental telephone number allows the relatives to ask further questions. It is particularly helpful to provide the name of the liaison nurse who cared for them as this provides some continuity. At the same time, it is important to determine how the relatives are going to get home and arrange transport if necessary. On their departure it is wise to inform the family GP, who may offer assistance. Families may also be directed to a variety of support groups such as CRUSE or Compassionate Friends (see 'Useful websites and addresses', p. 964). Most groups have local branches and it is helpful if the department can supply their addresses and telephone numbers. Many organisations produce leaflets or other information that may be beneficial to the bereaved.

Organ donation

In situations where it has become clear that resuscitation will not be successful, it may be possible to approach the family regarding the question of organ donation. Organs and tissues which may be used for transplantation may come either from the 'beating heart' donor — when the patient will usually be admitted to an intensive care unit until brain stem death tests are completed (see Ch. 28) — or from patients who have died, i.e. when cessation of circulatory and respiratory function has occurred within the ED. In both instances, the subject may be broached in the ED, so that the family have time to consider their decision. However, it is important that nurses have a sound knowledge base about the different aspects of donation and transplantation, together with an awareness of their own fears surrounding death, to give them greater confidence in communicating with potential donors. This may seem a cruel intrusion at a time of great grief, but in the long term the donation of the organs of the deceased may help the family to come to terms with their tragedy. By helping someone else to live, their loved one's death may come to seem less futile (Dolan 2000).

Sudden infant death syndrome

The parents of babies who have died from sudden infant death syndrome (SIDS) are particularly vulnerable. This is when an apparently healthy baby has died unexpectedly for no apparent reason (Foundation for the Study of Infant Deaths 2004). The parents will be asked to identify their baby in the presence of a police officer, before the post-mortem examination. This may produce great anxiety and distress, as the parents may feel that they are being accused of causing their child's death. The police are very sensitive to this situation and extremely supportive of parents, but if staff forewarn the parents of this formality they can be saved much anguish. A further supportive measure that may be offered to these parents is to take a photograph of their baby and/or a lock of the baby's hair or a hand/footprint. Sometimes this is not wanted at the time, but the parents should be reassured that they can collect it at any time in the future. Most importantly, parents need to be given the opportunity to be with and hold their baby. They are going to need help and support at this difficult time and should be given information on how to contact the Foundation for the Study of Infant Deaths (see 'Useful websites and addresses', p. 964).

Staff grief

It is very difficult for staff to have worked hard to save a life but without success. Feelings of inadequacy and failure may arise, especially when the patient is young or when the circumstances of the accident seem senseless. Repeatedly caring for patients and relatives in these circumstances may take its toll, both emotionally and physically, which means that the caregivers themselves may become casualties. It is important, therefore, to consider the grief that will be felt by staff who have been involved with the patient and/or the relatives. There should be a forum for expressing feelings and anxieties within the department. One method is a 'defusing' session which can be described as a short type of crisis intervention for staff involved in such an incident (Wright 1996). It allows staff to talk with one another about the experience in a relaxed atmosphere and provides an opportunity to give all staff the key information relating to the whole episode of the incident. This ventilation of feelings and re-run of events can be of benefit in two ways: it can allow staff to express their emotions, and it can highlight defects in the system or ways of improving practice in the future.

For particularly distressing incidents, a more formal type of debriefing may be required. Critical incident stress debriefing (CISD) (Cudmore 1998) is a session which may be facilitated by someone who has knowledge of counselling skills. It usually takes place 24–48 h after the event and follows a structured format that focuses on the emotional consequences for staff involved in these types of resuscitation. Most importantly, staff should be prepared to help them cope with these types of stresses. Knowledge about stress and coping mechanisms will help staff to recognise their own limitations and to know when they themselves need help.

A PATIENT WITH MINOR TRAUMA

Development of the emergency nurse practitioner role

Emergency Departments and minor injury units (MIUs) have seen the development of an enhanced nursing role.

Within the emergency environment these nurses are often referred to as emergency nurse practitioners (ENPs). To date, over 60% of EDs offer a service which includes the role of an ENP (Marr et al 2003). One of the fundamental rationales for these rapid developments is the need to reduce waiting times for patients who have suffered minor trauma (Sakr et al 1999). Nurses who practise in this role will have received formal post-basic education in:

- holistic assessment
- physical diagnosis
- prescription of treatment
- promotion of health.

They will also be working within pre-arranged guidelines as recommended by the Royal College of Nursing (2002). A generally accepted definition of a nurse working within this role describes the practitioner who is able, without reference to a doctor, to see a patient and elicit data which enable the nurse to reach a diagnostic conclusion and make decisions about the patient's treatment (Hunt & Wainwright 1994, Cable 1995). Despite this definition, there are no nationally accepted boundaries of practice for ENPs to work within. The *Code of Professional Conduct* (Nursing and Midwifery Council 2004), which provides guidelines for any nursing role expansion, requires that the nurse accept full responsibility and accountability for any nursing actions. It further requires that any developments within nursing practice must maintain the continuity of patient care whilst meeting the needs and serving the interests of the patient. These guidelines are broad and unspecific, but have enabled Emergency Departments and MIUs to develop the ENP role to meet the needs of patients presenting with minor injuries. Generally, ENPs are able to see, assess, diagnose and treat or refer patients who present with injuries that are considered to fall under the umbrella title of minor trauma. This ensures that the ENP is working within the *Code of Professional Conduct* by using expanded skills to ensure the continuity of care and, in many cases, to treat the patient's entire injury episode (Nursing and Midwifery Council 2004). Examples of some common areas of practice can be seen in Box 27.5.

Box 27.5

Common areas of practice within the emergency nurse practitioner role

- Assessment, examination and treatment of uncomplicated
  - — lacerations and wounds
  - — hand/wrist/arm/shoulder injuries
  - — lower limb injuries
  - — minor scalds and burns
  - — specified dental, ophthalmic and ENT problems
- Assessment, examination and referral of the above, when there is evidence of any neurovascular or tendon injury or other complications that require specialist intervention
- The requesting of X-rays
- The removal of foreign bodies
- The issue of specified drugs, e.g. tetanus toxoid, antibiotics, analgesics, within identified protocols

Adapted from Royal College of Nursing (2002).

Assessment and treatment

In Case History 27.2, Mrs N is seen by the 'see and treat' nurse who assesses her injury using the medical model shown in Box 27.1. Mrs N is able to provide the history of the presenting complaint and describes how her finger was cut whilst she was washing up some dishes. The water was fairly clean, as she had just put some glasses in to soak. She felt the wound had bled a fair amount since the accident happened approximately 30 min ago and became concerned because the wound looked deep and began to bleed again every time she bent her finger.

CASE HISTORY 27.2

Mrs N

Mrs N is a 44-year-old mother of four. She lives with her family and her husband has brought her to the Emergency Department. Whilst washing up, she 'cut' her left ring finger on a broken glass. This has produced a wound that is still bleeding.

On examining the wound, the 'see and treat' nurse obtains objective information, i.e. there appears to be no evidence of neurovascular compromise as Mrs N's finger is pink and warm to touch and she can feel light touch at the end of her finger. The bleeding can now be described as a controllable minor haemorrhage. The 'see and treat' nurse then obtains further drug and past medical history. Mrs N states that she is usually fit and well and has no other illness or conditions that may complicate this injury. Using this information, the 'see and treat' nurse considers the severity of her condition and decides that, within her limit of expertise and training, she can initiate the request of an X-ray to determine if there is any glass in the wound and administer an analgesic such as paracetamol for pain, if needed. The 'see and treat' nurse documents her assessment on the medical notes (see Fig. 27.3) and, using the Manchester Triage system, allocates a prioritisation category to Mrs N.

In the interim period it is important that the 'see and treat' nurse ensures that no further harm is caused, and because of the possibility of swelling and the potential of impairing the circulation to Mrs N's finger, the nurse removes Mrs N's wedding ring into safe keeping. A pressure dressing is applied to the finger and Mrs N's arm is held elevated by the patient or may be placed in a high arm sling to stop the bleeding and prevent any further swelling. Mrs N is then sent to the X-ray department for an X-ray of her finger. Her husband returns home to care for the children.

Once Mrs N has had her X-ray she is called through to the treatment area by the ENP, who continues to gather a thorough history and complete a more extensive assessment of the injury, an outline of which can be seen in Box 27.6. Using a more in-depth examination technique, the ENP confirms that there is no neurovascular damage and that the finger can be moved within its full range of movement, which indicates that there is no injury to the underlying tendons.

Key factors to consider in the assessment of wounds: history, examination, investigations

History
- How did the injury occur?
- When did the injury occur?
- In what environment did it occur?

Examination
- What size is the wound?
- What type of wound is it?
- How deep is the wound?
- What is the associated neurovascular status?

Investigations
- X-ray for any foreign bodies
- Consider the possibility of infection — bacteriology

If there were evidence of damage to the vessels, nerves or tendons, the ENP would refer Mrs N to the relevant medical specialist team, e.g. the plastic surgery team or orthopaedic team who specialise in hand injuries. The ENP reviews the X-ray requested by the 'see and treat' nurse and determines that there is no glass visible. Despite this, it is still important that the wound is explored thoroughly under local anaesthetic. Mrs N is transferred to the minor theatre where she is asked to lie on a trolley. The wound that she has sustained can be described as a laceration. The edges are jagged and the wound crosses over a joint, so it gapes open every time Mrs N bends her finger. Because of this Mrs N requires some form of primary wound closure, the purpose of which is to approximate the wound edges accurately, thus creating the right conditions to enable an epithelial covering to form over the defect and result in a thinner scar line (Wardrope et al 1999). The most common methods of wound closure used within EDs are plastic adhesive strips (Steri-Strips), staples, tissue glue and sutures. Whilst the first three of these methods are less invasive for Mrs N, they are normally used for wounds where the edges come together easily and preferably not over a joint. In Mrs N's case the wound edges are jagged and do not oppose easily, and therefore the most appropriate method to ensure adequate wound closure is to insert sutures which will keep the edges firmly opposed during the healing process.

The ENP first infiltrates the wound with 2.5 mL 1% lidocaine using a needle and syringe; this is the most common local anaesthetic used in the ED (Wardrope et al 1999). Adrenaline can be added to the local anaesthetic. However, as adrenaline has a vasoconstrictive action and is useful on wounds which are bleeding, e.g. scalp lacerations, it should never be used on digits, or on the nose or penis, because of the risk that it could cause ischaemia and necrosis. It is important that approximately 5 min is allowed to ensure that the full effect of the local anaesthetic is achieved, so the ENP prepares the equipment that is needed to insert the sutures into the wound. Having checked local anaesthesia has been achieved, and following aseptic procedures throughout, the wound is cleaned using a warmed sodium chloride solution and the ENP explores the wound carefully. Not only is it necessary to explore the wound for any contamination or foreign bodies, but it is also important to examine the underlying structures to ensure that they are fully intact. There is no evidence of any foreign bodies and the wound is not contaminated. The ENP then inserts four interrupted sutures, using an aseptic technique, while explaining all these actions to Mrs N. Once this is completed and the ENP is sure that there is no further bleeding, a dry, non-adhesive dressing is applied to ensure that the wound is kept clean and dry. Again, Mrs N is asked to keep her arm elevated or it may be placed in a high arm sling for 24 h to minimise any swelling and prevent any further bleeding. The ENP explains the need to remove the sling after 24 h in order to prevent stiffness of the shoulder. The ENP has ascertained that Mrs N has recently had a tetanus vaccination and so does not require this cover. Since 2003, the tetanus vaccination has also contained a low dose of diphtheria vaccine (Td). This is based upon WHO recommendations (Department of Health 2003b) because there is evidence of an increase in the occurrence of diphtheria internationally, particularly in the older population.

Due to the implementation of the 'see and treat' system, Mrs N has received a rapid and seamless assessment of her wound, the required investigations have been rapidly initiated and treatment carried out. This has enabled Mrs N to be seen in a more timely fashion, enabling her to return home quickly.

Health education and discharge advice

For ED staff, the main involvement in health education activity is in primary health education, concerning accident prevention, and secondary health education, involving first aid and discharge advice (McConnell 1997). The aim of health education in the ED is to empower patients to take responsibility for their recovery and future health status. Patients require practical, achievable solutions to help them cope with their injury. Discharge advice can, if understood and followed, hasten the patient's recovery and prevent complications, but may require the patient to change some aspects of their usual daily activities.

As well as completing a full physical assessment, it is important that the ENP complete a psychosocial assessment. In the case of Mrs N, she has good family support and her children are old enough to contribute to the running of the family home. It is important that Mrs N keeps this finger clean and dry for at least 48 h after primary suture to allow epithelial cover over the wound (Wardrope et al 1999). She will need to keep the sling on for approximately 24 h. This may have been difficult if she had young children to care for, and no one to help her with, for example, the cooking and washing up. Mrs N should also be warned against driving until her injured finger is completely healed. Were she to do so, she might not have complete control of the steering wheel. In addition, if she were to be involved in an accident even through no fault of her own, normal car insurance would be unlikely to provide cover for her if it became known that she had an injured finger. It is important that she can get transport home. If necessary, she should be given the opportunity to telephone her husband to ask him to collect her. Mrs N should be told that if, during the healing period, the wound becomes increasingly painful

or swollen, she should contact her GP or practice nurse for a review of her wound, as she may be developing an infection. In most parts of the UK information leaflets have been superseded by the use of computerised discharge plans for ED patients; these are not only quick and easy to use but also allow patients to be given printed, individualised instructions (McKenna 1994). Mrs N is given instructions that remind her to have the sutures removed in 10 days' time (Wardrope et al 1999) and the signs and symptoms of potential infection are reiterated. The sutures are left in for 10 days as the wound is over a joint. This allows extra healing time and reduces the risk of the wound opening again once the sutures are removed. Mrs N is advised to have the sutures removed by the practice nurse at her GP's surgery and either to visit the surgery or return to the Emergency Department if she has any problems. The ENP completes the relevant documentation (see Fig. 27.3) which includes a discharge letter to Mrs N's GP so that there is a complete record of Mrs N's medical history.

RESEARCH ABSTRACT 27.1

A study of violence at work

Violence in the workplace is a growing concern for both employers and employees. A study which considered two service sector groups, including hospital staff, investigated the incidence of violence, observed the nature of violent incidents and observed the antecedents of any reported violent incidents, the actual behaviour and how the incident ended. Key findings identified that 24% of hospital staff had experienced aggressive physical contact and 69.8% had experienced verbal abuse in the preceding 12 months. Antecedents included patients' questioning medical/nursing procedures, and individuals thought to be under the influence of alcohol. The most common methods of bringing an incident to a close included reassurance, discussion and walking away, although in 18% of cases hospital security was called and in 3% the police were called to intervene. The report concluded that training can help to equip an employee to be more competent in a range of situations.

Harkness L 1997 Part of the job? A study of violence at work. Occupational Health Review 65: 25–27

AGGRESSION AND VIOLENCE IN THE EMERGENCY DEPARTMENT

Our changing society

Emergency nursing is a challenging and rewarding area in which to work. The dynamic nature of the job means that one never knows what will happen next. One minute the nurse may be required to comfort an elderly gentleman who has unexpectedly lost his partner of 50 years, and the next to support a mother who has unexpectedly gone into labour and is about to deliver her baby. Likewise, caring for patients with minor injuries ranges from caring for a child who has sustained a fall, to irrigating a patient's eyes as a result of a chemical splash incident whilst at work. As a result, nurses are able to practise a wider range of skills than is perhaps used in other clinical settings.

However, there are drawbacks to operating an 'open door' policy. It means that nurses will be required to care for patients with a range of conditions and problems. The nature of these events may put the individual concerned into a sudden state of crisis that may produce various types of stress reaction. These include intense emotions, e.g. fear, anxiety, confusion and loss of control, all experienced as a result of the uncertainty of the situation. On occasion, this may display itself in the form of aggression and, in extreme cases, physical violence. The Zero Tolerance Zone campaign (Department of Health 1999) defines violence as 'any incident where staff are abused, threatened or assaulted in circumstances related to their work, involving an explicit or implicit challenge to their safety, well-being or health'. In 2000/01 there were over 84 000 reported incidents of violence or abusive behaviour to staff within the NHS (Department of Health 2002c).

Harkness (1997) (see Research Abstract 27.1) identified two frequently influential factors with regard to the occurrence of violence: the presence of alcohol or other drugs, and levels of perceived frustration of the aggressor. Within the ED environment, patients are often treated for injuries that are alcohol related or that have been self-inflicted, e.g. drug overdoses. Added to this is the frustration experienced by many patients over long waiting times. As a result of government initiatives such as *The Patient's Charter* (Department of Health 1991), patients are more aware of their rights, and sometimes their expectations to be seen and treated quickly exceed what the ED can provide. However, the zero tolerance policy within the NHS has highlighted the rights of staff to work in a safe environment. The NHS now takes a more proactive stance in preventing violence and aggression within the workplace and will actively seek prosecution, with the assistance of the police, of patients who attack staff. Therefore, it is important that nurses working in this environment are able to anticipate possible situations and prevent them from escalating to a point where potential harm may be caused.

Defusing a potentially aggressive situation

Nurses should remember that aggression is seldom directed towards them personally. It is important that they are able to recognise the factors that influence aggression in the ED situation. These include a lack of information either about the condition of a relative or about the excessive waiting times. Waiting rooms that have poor facilities can contribute to an individual's level of frustration, e.g. a telephone box that does not work, uncomfortable seating and an unwelcoming decor. The attitude of staff to patients, particularly if it appears judgemental and unsympathetic, may contribute to the development of a confrontation between patient or relative and nurse.

However, it must be acknowledged that not all aspects of aggression are avoidable within the ED environment. Sometimes the aggression is a result of metabolic disorders which cause acute confusional states, e.g. hypoxia or diabetes mellitus, or a result of head injury. In these situations the patient has no control over their actions. However, there are usually warning signs, such as those given in

Box 27.7

Warning signs of aggression

Emotional
- Individual appears agitated and tense
- Individual's voice increases in volume and pitch, apparent in the abrupt response to questions
- Individual may use sarcasm and obscenities when talking to staff

Behavioural
- Body posture may reveal muscular tension in face and limbs
- Individual may be making fists with hands, banging fists or hitting out at objects

Physiological
- Pupils may be dilated, although this may be difficult to observe

Adapted from Morcombe (1999).

Box 27.7, and it is essential that nurses are able to recognise these if they are to prevent the situation escalating. Other strategies that help to defuse difficult situations include the use of good verbal and non-verbal communication and the adoption of a calm, non-threatening approach.

Adopting appropriate body posture

Trying to resolve situations within large groups often increases the aggression so it is preferable to invite the aggressive individual to a separate area. Ideally this should be in a private place, but this should not compromise the safety of the member of staff. Adopting an oblique posture is less confrontational and, if standing, the nurse should take a position with feet slightly apart and body weight on the slightly flexed back leg. The nurse should be aware of the individual's personal space and remain at least an arm's length away. These actions serve two purposes: they are less threatening and they allow a quick escape should the need arise (Morcombe 1999). The nurse must demonstrate genuine interest in what the individual has to say. Direct eye contact may be interpreted as being provocative, but completely avoiding eye contact may be perceived as dismissive and suggestive of disinterest, so it is better to focus away from the face, just below the larynx area.

Listening to aggressive patients

The nurse should listen carefully to the complaint and offer an explanation. It is difficult not to shout back when being shouted at, but it is more effective if the pitch, tone and volume of the nurse's voice remain within a normal conversational range (Morcombe 1999). The nurse should be sensitive to the individual's circumstances and a sympathetic approach may avoid the escalation of the aggressive confrontation. If the individual is confused for any reason, the nurse may have to repeat what is being said several times before being understood. If possible, a plan of action should be agreed with the individual to resolve the situation. It is unwise to give false information or agree on solutions that are unachievable, as this will result in trust being lost and may cause further aggression at a later stage.

Avoiding physical danger and attack

Unfortunately there are times when, despite all the strategies, violence does occur and it is vital that the nurse considers this possibility in all encounters with aggressive patients. For this reason, nurses should never place themselves in a situation where they are trapped in an enclosed area. If interviewing an aggressive individual alone in a private room, the nurse should ensure that the area is free of objects that may be used as weapons and that the door is not lockable. Potential weapons include equipment such as scissors and stethoscopes carried by the nurse which, if grabbed, could be used to threaten. The safety of the staff and the other patients is of paramount importance. If it appears that violence is going to erupt, the nurse should slowly back away from the situation and not attempt to restrain the individual. Help should be summoned using agreed departmental procedures. All EDs have panic buttons that, when activated, summon help either from other ED staff or security officers, or are connected directly to the local police station. Until help is available, the nurse should make every attempt to avoid physical contact. This may involve the use of hospital equipment to create space between the nurse and the aggressive individual. It is preferable that hospital equipment is damaged rather than people hurt.

It is important that, following any incident of aggression or violence, whether verbal or physical, an incident form is completed and that this is reviewed by the hospital's health and safety officer or risk management team. This monitors the escalating problem and may reveal patterns of aggression in the workplace, thereby allowing preventive strategies to be formulated. These may include extra education opportunities for the staff or an increase in staffing levels. If it is apparent that there is an increase in violent and aggressive situations, statistical evidence is useful when making a bid to management staff for more security staff or better protection.

27.2 Find out about the procedure to follow in your hospital/health centre should a member of staff be injured. What documentation is required? Who should complete it and where should any forms be sent?

Emergency nursing and the law

Due to the nature of ED work, nurses are, on occasion, required to work in close collaboration with the local police force. Victims of crime and those who have committed an offence may require hospital treatment and the medical findings are used as evidence in a court of law. If a death has occurred under suspicious circumstances, the police may require that forensic evidence be collected to assist them with their enquiries. This sometimes creates a conflict in the nurse's professional practice. All patients are entitled to confidentiality in respect of information pertaining to them and it is the nurse's responsibility to ensure that this right is respected (Nursing and Midwifery Council 2004). However, there are exceptions to this which particularly arise within the ED environment, e.g. if a person has been involved in a RTC then the law requires that any relevant information should be given to the police. Other examples are outlined in Box 27.8. As part of this process, the nurse may be required to make a statement which will form part

Box 27.8

Exceptions to the duty of confidentiality

- Consent of a patient
- Best interests of the patient
- Court orders
  - subpoena
  - The Civil Procedure (Modification of Supreme Court Act 1981) Order 2004
- Statutory duty to disclose
  - Misuse of Drugs Act (1971) (Modification) Order 2001
  - Prevention of Terrorism Act (2002)
  - Public Health Act (1984)
  - Road Traffic Act (1999)
- Public interest

of the police investigation, especially if witnessing an event such as a violent incident within the department. It should be noted, however, that it may be several years before a case, whether criminal or civil, comes before the courts and the nurse is asked to write the statement. For this reason it is important that careful attention is paid to accurate documentation within the patient's nursing and medical records.

MAJOR INCIDENTS

There is no one standard definition of a major incident. For the purpose of guidance, the National Health Services Executive (1998) states that:

> *A major incident can have a huge impact on one part of the health service, while leaving others relatively unaffected. In a similar way, an NHS major incident is not necessarily a major incident for other emergency services, such as police, or local authority services and vice versa.*

This definition is deliberately non-specific, because what constitutes a major incident for a small rural hospital may have minimal impact in a large inner city hospital. Similarly a large-scale disaster may affect only one hospital or may require the services of several hospitals within a region. The purpose of emergency planning for such situations within the NHS is to ensure that all the emergency services are able to work collaboratively and provide an effective response to any type of incident.

Major incident planning

In this era of global terrorism the approach to dealing with and preparing for major incidents has not only had to be re-thought (Hayward 2003) (see also www.ukresilience.info) but, with each new incident, e.g. the July 2005 London bombings, re-appraised. It is essential that every hospital has a major incident plan, including a chemical decontamination plan. The ED plays a major role in this, as it is required to provide the initial and rapid response. A National Audit Office survey (2002) found that while many hospitals were not prepared for 'mass casualties', they were better prepared for major incidents (Crouch 2003).

To enable the ED to manage effectively in such a situation, it is vital that the department has the support of all other services within the hospital. Extra equipment will be needed, patients will have to be moved quickly and it should be anticipated that more staff will be needed than usually work on a shift. For this reason it is important that all hospital departments, including portering, catering staff, cleaning staff, as well as other clinical support areas, are involved in the development of the major incident policy. The essence of any plan is that it is flexible enough to cater for any situation, which may include chemical contamination incidents or a large number of patients with multiple or thermal injuries.

In the event of an incident, the ED will be notified by the police or the local ambulance service, which will inform the ED of the type of incident that they are dealing with. The ED will have to prepare quickly to receive the predicted number of patients. This is achieved by clearing the department as quickly as possible and restocking principal areas with extra equipment, such as decontamination equipment if dealing with a chemical incident, whilst calling in extra staff. The ED may be asked to provide an on-site mobile medical team (MMT). The MMT is formed from ED personnel, supported by an anaesthetist, usually from intensive care. Each MMT is made up of four members: an experienced doctor to act as the team leader, an anaesthetist, a senior ED nurse and a second experienced nurse (Eaton 1999). It is vital that these staff are adequately equipped with correct personal protective equipment (PPE) (Hayward 2003) as they will be required to support the ambulance service in difficult and potentially dangerous environments (see Box 27.9). Casualties are predominantly brought into the department by ambulance, although the 'walking wounded' will often be brought in by local people not involved in the incident. However, if there is a chemical incident no casualties should leave the scene of the incident until they have been thoroughly decontaminated by the Fire Service. Inevitably, some casualties may 'slip through the net' and will require immediate decontamination on arrival in the department.

Due to the volume of patients, it is important that careful attention is paid to adequate identification of all individuals. The police documentation team, which is based in the hospital, will operate a 'casualty bureau', where all

Box 27.9

Personal protective equipment for a mobile medical team

- Good quality helmet, with chinstrap, light and Perspex visor; it should be green with 'nurse' in white
- Pair of fire-retardant overalls with kneepads
- High visibility tabard and jacket, marked front and back with wearer's designation, such as 'nurse' or 'doctor'; it must have reflective strips and be green in colour
- Leather boots with steel cap toes that are fire, oil and acid resistant
- Heavy duty and latex gloves

Adapted from Keane & King (2001).

information regarding the patients is collated. Members of the public can contact the bureau for further information regarding casualties. The ED staff will have to keep this unit updated with details of patients. Many relatives will arrive at the hospital seeking information and, as in all public interest events, the media will require regular press statements. It is important that this does not interrupt the staff's care of the patients. The hospital will need to ensure that adequate facilities and support staff are in place to care for friends and relatives waiting to see the injured, whilst establishing separate communication networks for the media. Once all the casualties have been cared for and transferred to other areas for their definitive care, the ED must resume its customary work as soon as possible.

Because of the relative infrequency of major incidents and the pattern of staff changes, it is recommended that hospitals carry out regular major incident exercises, together with the ambulance and other emergency services, so as to ensure a rapid and effective response (National Health Service Executive 1998).

27.3 Where is the major incident and chemical decontamination plan held in your hospital? Ask your mentor or lecturer if you may see it and have an opportunity to discuss its content, perhaps during a seminar.

Post-traumatic stress disorder

It has become apparent in recent years that the survivors of major incidents may suffer from a range of long-term psychological and physical symptoms, often unrelated to injuries sustained at the time. These may include feelings of desperation, helplessness, guilt at having survived where others have died and shame at the loss of control. The survivors may also experience anger, feelings of loss and profound sadness, and may be unable to put the incident out of their minds. Physical symptoms may include insomnia, nausea, diarrhoea, dizziness and palpitations, to name only a few (Sowney 1996; see also Ch. 17). It is important for survivors to realise that these manifestations are normal reactions to a terrible tragedy and that they are not 'losing their minds'. However, if these symptoms persist and start interfering with the individual's normal life then it may be that they are suffering from what has been described as 'post-traumatic stress disorder'. In these instances, some of the victims will require prolonged counselling in order to come to terms with their feelings and anxieties, and members of their families may also need to be included in counselling sessions.

Witnesses of disasters may also be deeply affected. Following the Lockerbie air disaster in 1988, when, as a result of a terrorist bomb, a Pan American aircraft disintegrated over this small town in Scotland, killing 259 passengers and 11 town residents, more than 100 residents were referred to community psychiatric nurses. O'Byrne (1989) reported: 'The brush with death had forced many of the town's inhabitants to re-evaluate what they were doing with their lives'. Close media coverage of such events may give those who were not involved, but who were bereaved as a result of the incident, the feeling that they were present when it happened. These people may also experience the feelings of guilt suffered by the actual survivors. This will naturally involve the families of the victims but may also include a much wider range of people. One example of this was when more than 200 people drowned in the Zeebrugge car ferry disaster in 1987 — 160 off-duty crew members of the *Herald of Free Enterprise*, some of whom had changed duties with their shipmates, were among the circle of people requiring counselling and support (Johnston 1989).

Rescue workers, ED staff and other personnel involved in the event are also vulnerable to serious emotional disturbances following such incidents (Collins 2001). Even with good deployment of staff, disasters provoke an 'all hands on deck' situation. Staff may need to be called in from off duty, and others will volunteer after hearing about the incident on the news. Staff will be required to work long hours under difficult conditions, especially if they are part of an on-site team. Some victims will not be saved and this may produce feelings of inadequacy or guilt. Because of the need for the department to return to normality as soon as possible so that it can deal with other patients, there may be insufficient time for staff to rest and recover before returning to more routine jobs. A rush of adrenaline will keep everyone going at the time, but afterwards they may display sheer exhaustion and emotions ranging from anger to guilt or deep sorrow.

It is apparent that following major incidents a range of facilities must be made available to staff (Robson et al 1995, Nutt et al 2000). The nature of these facilities may differ from place to place, but they should include educational programmes and a support network for all staff, and should ideally be in place before any such incidents occur. Where these networks are available and accepted, staff may be less inclined to feel stigmatised if they make use of them when the occasion arises. Now that it is recognised that staff of all disciplines who are involved in disaster situations may suffer from post-traumatic stress disorder, it is essential that provision should be made in disaster planning for the support of these carers following a traumatic event.

CONCLUSION

This chapter has explored the diverse nature of emergency nursing and various aspects of the experiences of patients who attend the ED with trauma. The concept of trauma covers a wide range of injuries, from patients who present as acute emergencies, suffering from life-threatening conditions and multiple trauma, incorporating multisystem injury, to others who present with relatively minor injuries. The roles of nurses working within the ED multidisciplinary team — whether as part of the department's trauma team, as the 'see and treat' nurse or as Emergency Nurse Practitioners — are also explored. The chapter highlights the areas of practice that require specific skills to enable the nurse to meet both the physical and psychosocial needs of individual patients and of their families.

INTRODUCTION

The unconscious patient presents a special challenge to the nurse. Medical management will vary according to the original cause of the patient's condition, but nursing care will be constant. The unconscious patient has no control over themselves or their environment and is therefore dependent upon the nurse to accept responsibility for the management of their activities of living and for monitoring their vital functions.

A high quality of nursing care is of crucial importance if the patient is to relearn to perceive self and others, to communicate, to control their body and their environment and to self-care. The responsibility placed on the nurse is considerable and can be a source of anxiety, even for experienced nurses. It is essential that the nurse has a firm understanding of the mechanisms causing altered states of consciousness, as well as a sound knowledge of the potential and actual physiological, psychological and social problems that these patients face. Skills training, exploring attitudes and using support systems can all help the nurse to overcome anxiety and take up the challenge.

To nurse an unconscious patient back to recovery must be one of the most rewarding aspects of nursing; however, even with all the medical advances made recently, not all patients can hope for complete recovery. Some may not survive and others may be left with a residual mental and/or physical handicap. These patients and their families will need considerable emotional support and reassurance. The nurse, who is with the patient more than any other member of the multidisciplinary team, is in the best position to give this support.

Defining consciousness

Normal conscious behaviour is dependent on intact brain function, specifically on intact cerebral hemispheres and an intact reticular activating system (see below). Impaired, reduced or absent consciousness implies the presence of brain dysfunction and demands urgent medical attention if potential recovery is to be expected. In order to appreciate the importance of altered states of consciousness, a basic understanding of the physiology of consciousness is required.

Hickey (2002) defines consciousness simply as 'a state of general awareness of oneself and the environment' and includes the ability to orientate toward new stimuli. The individual is wakeful, alert and aware of their personal identity and of the events occurring in their surroundings. Deep coma can be defined as the opposite — unrousable and unresponsive to external stimuli — and there may be varied states of altered consciousness in between the two extremes. The difference between sleep and coma is that, in sleep, the individual can be aroused by external stimuli, whereas in a coma this cannot be done. Consciousness therefore depends on whether the person can be aroused to wakefulness. Different stages of consciousness will be discussed later in this chapter.

ANATOMICAL AND PHYSIOLOGICAL BASIS FOR CONSCIOUSNESS

The reticular formation (RF) and the reticular activating system (RAS) are responsible for collating and transmitting motor and sensory activities and controlling sleep/waking cycles and consciousness (see Fig. 28.1 and Ch. 25).

The reticular formation (RF)

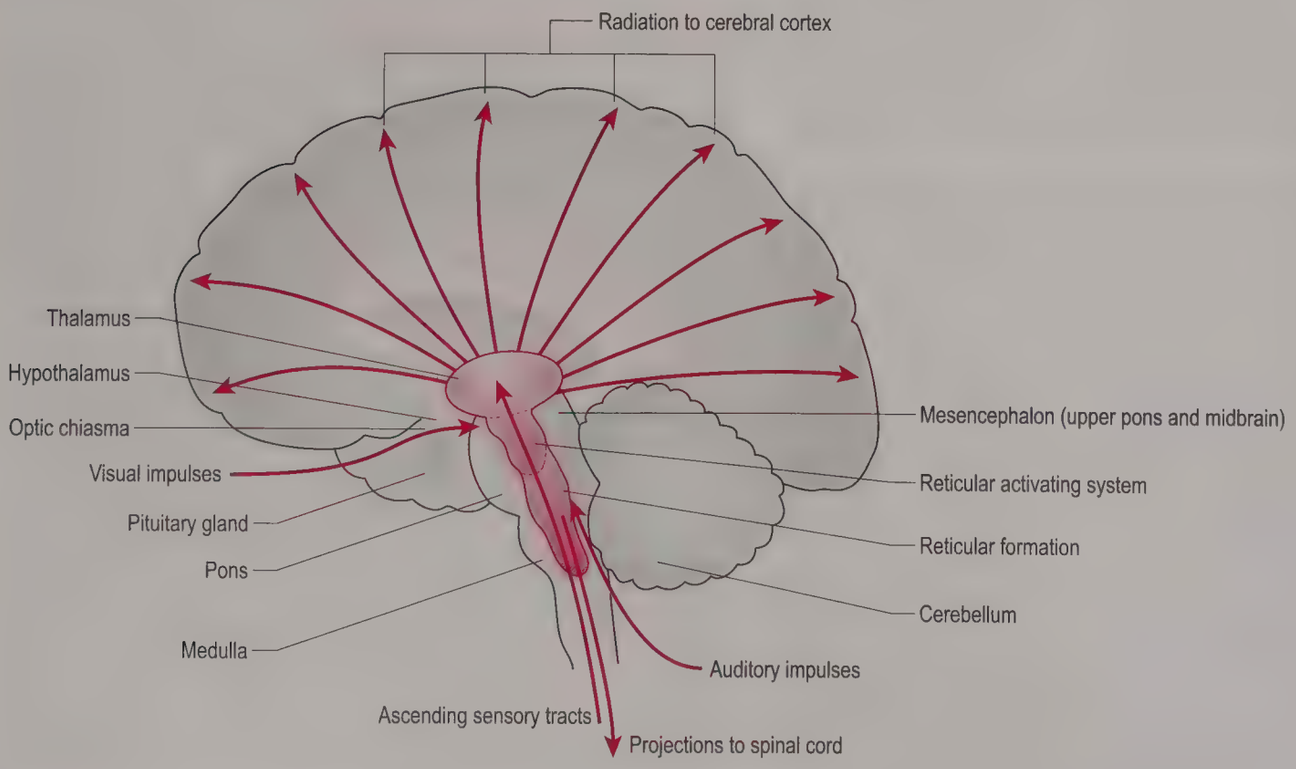
The RF is a network of neurones in the central core of the brain stem (Waugh & Grant 2001). These neurones connect with the spinal cord, cerebellum, thalamus and hypothalamus. The RF is involved in the coordination of skeletal muscle activity, including voluntary movement, posture and the maintenance of balance. It is also concerned with automatic and reflex activities and has links with the limbic system. All sensory pathways, including those of the special senses, link into the RF (Fitzgerald 1996). Neurones that produce aminergic neurotransmitters are embedded within the RF. Some of these have a stimulating effect and some an inhibitory effect on other neurones, although their exact functions are not yet fully understood.

The reticular activating system (RAS)

The RAS is a physiological component of the RF and the neurones which project (or radiate) to ocular motor nuclei and to the cerebral cortex via the thalamus and hypothalamus. It is concerned with the arousal of the brain in sleep and wakefulness (Marieb 2004).

Two main parts of the RAS have been identified (Guyton & Hall 2000):

- the mesencephalon
- the thalamus.



The mesencephalic area is composed of grey matter in the upper pons and midbrain of the brain stem. Stimulation of this area causes a diffuse flow of nerve impulses which pass upwards through the thalamus and hypothalamus. The impulses then radiate out to wide regions of the cerebral cortex (see Fig. 28.1). This causes a generalised increase in cerebral activity and general wakefulness.

Stimulation of the thalamus activates localised areas of the cerebral cortex. Signals from specific parts of the thalamus initiate activity in specific parts of the cortex, rather than activating the whole cortex. This selective stimulation prevents the cortex from receiving too much information at once and may play a part in directing one's attention to specific mental activities.

The reticular nucleus, which receives impulses from the RF, surrounds the front and sides of the thalamus. It is this nucleus that sends inhibiting messages back to thalamic nuclei via the neurotransmitter gamma-aminobutyric acid (GABA). In animal experiments, it has been demonstrated that thalamocortical neurones are inhibited by the reticular nucleus during sleep (Fitzgerald 1996).

In order to function, the RAS must be stimulated by input signals from a wide range of sources. These are transmitted via the spinal reticular tracts and various collateral tracts from all the modalities of sensation, e.g. the specialised auditory and visual tracts (see Ch. 9). The RAS is also affected by signals from the cerebral cortex, i.e. the RAS may first stimulate the cerebral cortex, and the cortical areas responding to reason and emotion may 'modify' the RAS, either positively or negatively, according to the 'decision' of the cerebral cortex. The RAS filters information to prevent sensory overload (Marieb 2004).

When an individual is in a deep sleep, the RAS is in a dormant state. However, almost any type of sensory signal can immediately activate the RAS and waken the individual,

966 Fig. 28.1 The mid-sagittal section of the brain, showing the reticular activating system and related structures.

e.g. pain stimulus or unaccustomed noise. This is called the 'arousal reaction' and is the mechanism by which sensory stimuli wake us from deep sleep (Guyton & Hall 2000) (see Ch. 25).

Sleep is induced by a hormone called melatonin. This is synthesised from serotonin in the pineal gland. The normal arousal from sleep occurs as it gets light. Daylight is detected by the retina of the eye, which sends impulses to the suprachiasmatic nucleus of the hypothalamus. This activates sympathetic nerve fibres that inhibit the secretion of melatonin in the pineal gland. There is also evidence from animal experiments that histamine, produced in the posterior hypothalamic area, activates the cerebral cortex. Lesions in this area can cause excessive sleepiness or even coma (Fitzgerald 1996).

There are numerous pathways to both mesencephalic and thalamic portions from the sensory and motor cortex and from cortical areas that deal with the emotions. Whenever any of these areas becomes excited, impulses are transmitted into the RAS, thus increasing the activity. This is termed a 'positive feedback response'.

The feedback theory

Guyton and Hall (2000) claim that the cerebrum regulates incoming information by a positive feedback mechanism (Fig. 28.2). A second feedback cycle that stimulates proprioceptors in skeletal muscles is also shown in Figure 28.2.

After a prolonged period of wakefulness, the synapses in the feedback loops become increasingly fatigued, reducing the level of stimulation and activity directed to the reticular activating system, thereby inducing a state of lethargy, drowsiness and eventually sleep (Guyton & Hall 2000).

Figure 28.2 illustrates a number of activating pathways passing from the mesencephalon upward. Conversely, if all pathways are activated simultaneously, a high level of consciousness ensues.

The return to consciousness demonstrates that the RAS is still functioning and capable of screening and discrimination.

The content of consciousness

The content of consciousness refers to the sum of cognitive and affective mental functions. It is dependent upon relatively intact functional areas within the cerebral hemispheres that interact with each other as well as with the RAS.

Injury to, or disease of, the cerebral hemispheres, resulting in diffuse damage, can inhibit or block the signals from the RAS and consciousness cannot be completely maintained. The damaged cortex is unable to interpret the incoming sensory impulses and therefore cannot transmit them to other areas for action.

Localised damage to the cerebral hemispheres can also diminish the content of consciousness to a lesser degree. For example, a patient who has suffered a stroke, causing aphasia, may appear awake and alert. Their inability to understand or to use language, however, decreases their full awareness of self and their environment. Such localised defects are not generally regarded as a true altered state of consciousness, but this example highlights the difficulties in defining true conscious behaviour.

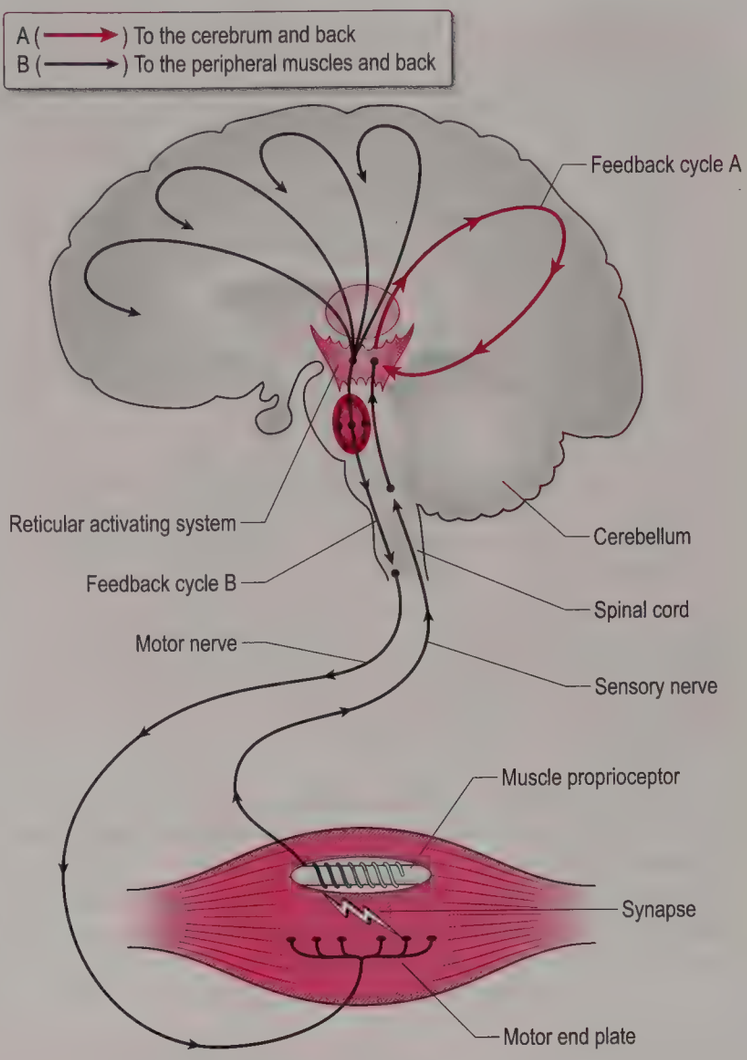


Fig. 28.2 The feedback mechanism, showing two feedback cycles passing through the RAS. In cycle A, the RAS excites the cerebral cortex and the cortex in turn re-excites the RAS. This initiates a cycle that causes continued intense excitation of both regions. In cycle B, impulses are sent down the spinal cord to activate skeletal muscles. Activation of the muscle stimulates proprioceptors to transmit sensory impulses upward to re-excite the RAS. Consciousness results when the RAS, in turn, stimulates the cerebral cortex.

STATES OF IMPAIRED CONSCIOUSNESS

There is no international definition of levels of consciousness but, for assessment purposes, differing states of consciousness can be considered on a continuum between full consciousness and deep coma (Hickey 2002) (see Box 28.1). Consciousness cannot be measured directly but can be estimated by observing behaviour in response to stimuli. The Glasgow Coma Scale (GCS) (Teasdale 1975) is widely used as an assessment tool and helps to reduce subjectivity during assessment. The GCS is explained on pages 970–974.

Signs of deterioration in a patient's level of consciousness are usually the first indications of further impending brain damage. The nurse must be able to assess and observe the patient accurately so that appropriate intervention can be instituted if the level of consciousness changes. Sleep is considered a normal phenomenon and is discussed in Chapter 25.

Box 28.1

Continuum of levels of consciousness

- *Full consciousness* — awake, alert, orientated, cognitive (mental) functioning intact
- *Confusion* — disorientated to time/place/person, short attention span, memory problems, may be agitated/restless/irritable
- *Lethargy* — orientated, slow speech, slow mental processes, slow motor activities
- *Obtundation* — rousable with stimulation, responds verbally with one or two words, follows simple commands, very drowsy
- *Stupor* — quiet, minimal movement, generally unresponsive except to vigorous stimuli, responds in normal way to painful stimuli
- *Coma* — unrousable, no verbal sounds, inappropriate or no response to stimuli

It is difficult to classify levels of consciousness exactly, but this is a useful guide to help to describe various levels.

Adapted from Hickey (2002).

Impaired states of consciousness can be categorised as acute or chronic. Acute states are potentially reversible, whereas chronic states tend to be irreversible as they are caused by destructive brain lesions. The following definitions of impaired states of consciousness can be used as broad guidelines to describe the patient's condition. Individual patients are unlikely to exhibit all the stages noted on the continuum (see Box 28.1), even if they pass from full consciousness to coma or vice versa. Deterioration or improvement will depend on a number of factors such as type, extent and site of injury, age, previous state of health, length of coma and whether or not the altered level of consciousness is a result of acute or chronic insult. Common causes of unconsciousness are illustrated in Figure 28.3.

Acute states of impaired consciousness

Intracranial diseases and metabolic disease, such as hypoglycaemic coma, renal and hepatic disorders or drug overdose, cause acute states of impaired consciousness, including:

- reduced awareness
- delirium
- illusions
- hallucinations
- delusions
- stupor
- coma.

Reduced awareness

Reduction in awareness reflects generalised brain dysfunction, as seen in systemic and metabolic disorders (see Fig. 28.3). These disorders interfere with the integrity of the RAS, thus affecting the arousal response.

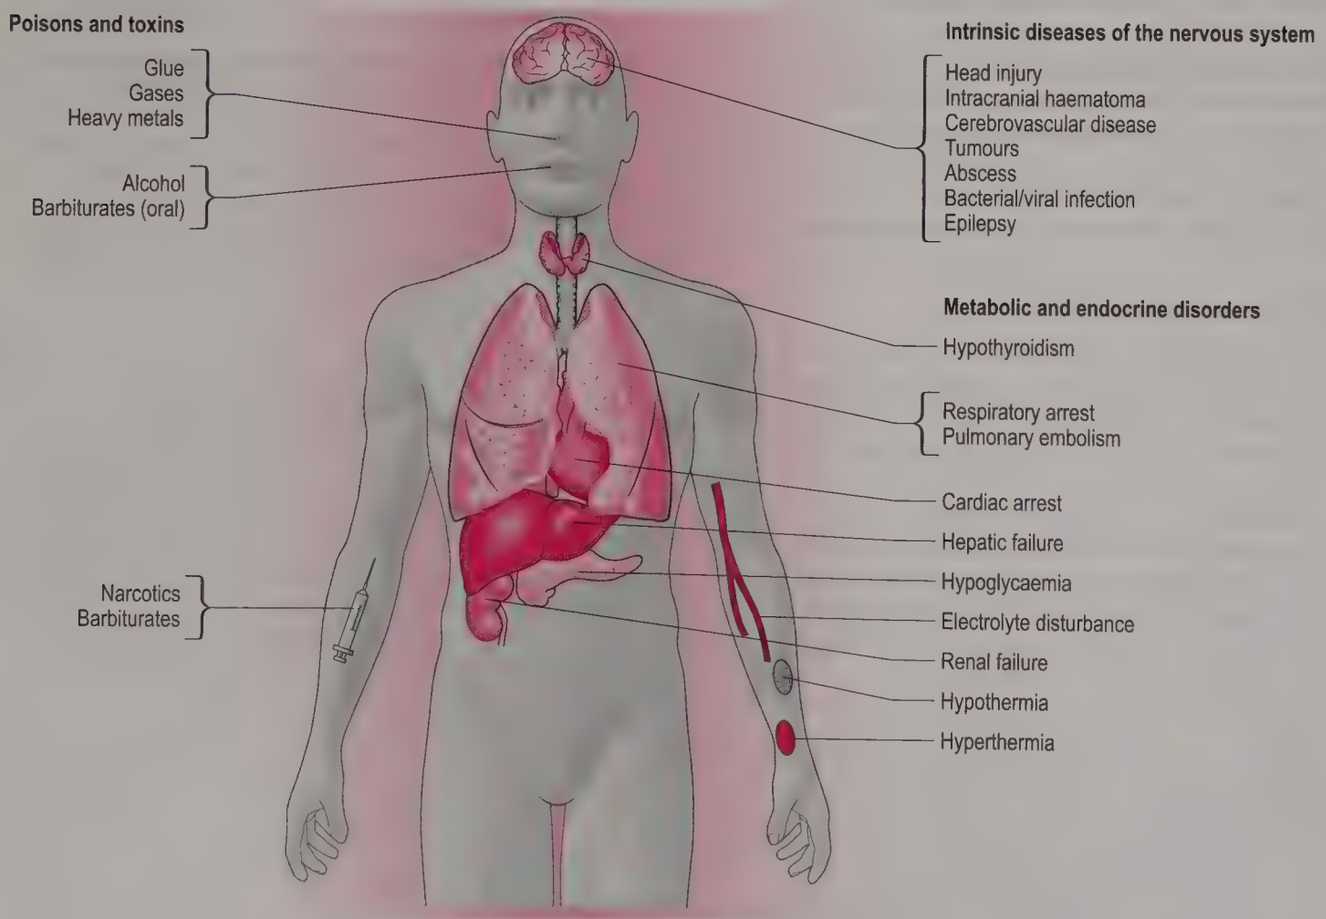

Fig. 28.3 Common causes of unconsciousness.

In the early stage, the patient may exhibit signs of hyperexcitability and irritability, alternating with drowsiness. This may progress to a confused state and increased levels of disorientation. The patient is bewildered and often has difficulty in following commands.

Initially, subtle changes may occur in the patient's behaviour. Minor disturbance of consciousness can easily go undetected if attention is not paid to what the patient says and does. If a normally placid and cooperative patient becomes irritable and aggressive, this denotes a behaviour change that requires further investigation. Similarly, comments from a relative such as 'she does not seem to recognise me today' should alert the nurse to the fact that something is not quite right with the patient. Martin (1994) suggests that nurses who are expert in the care of head-injured individuals can identify cues which indicate behavioural, cognitive, motor and sensory changes even in mild head injury.

Any change in the patient's behaviour must be reported to the appropriate nursing or medical staff, particularly if the patient has not previously exhibited any of these signs. The patient's nursing care plan will also need to be evaluated and new goals for care set.

Cognitive disabilities, e.g. poor concentration and memory changes, may only become apparent when a patient returns home. These can cause emotional distress for both the patient and family if they go unheeded and help is not provided. Hemingway and McAndrew (1998) suggest that the community mental health nurse could have a role in supporting people with acquired brain injury, and their families, in the early stages following injury and through to long-term community care.

Delirium

Delirium is a fluctuating mental state characterised by confusion, disorientation, fear and irritability. The patient is usually loud, talkative, offensive, suspicious and agitated. This behaviour reflects generalised brain dysfunction due to interference with the RAS, affecting arousal. The causes and manifestations of delirium are listed in Box 28.2.

Box 28.2

Causes and manifestations of delirium

- Toxic disorders of the nervous system, e.g. acute poisoning by:
  - — metals
  - — gases
  - — drugs
  - — alcohol
- Metabolic disorders, e.g.:
  - — renal failure
  - — hepatic failure
  - — encephalitis
- Severe head injury
- Psychological manifestations
  - — illusions
  - — hallucinations
  - — delusions

Illusions are defined as misinterpretations of sensory material in the patient's environment. A shadow on the wall is seen as an animal or a person, for example, or noises are misinterpreted as voices of strangers who have come to do harm.

Hallucinations are defined as seeing or hearing something in the absence of the relevant sensory stimuli; for example, the patient will hear voices when no-one is present or see objects that do not exist in their environment. Other senses, such as touch, taste or smell, can be affected; with acute disorders of the brain, however, hallucinations are usually visual.

Delusions are defined as persistent misperceptions that are firmly held by a person, even though they are illogical or contrary to reality.

Illusions and hallucinatory experiences are common in temporal lobe epilepsy (see Ch. 9). Perceptual disturbances and delusions can also occur in patients exposed to sensory deprivation or overload, e.g. in intensive care units or in sleep deprivation (Phipps et al 1999, Jones et al 2001, Hewitt 2002). Therefore, when undertaking an assessment, it is important to consider the environment as well as the patient's physiological state.

Stupor

The term stupor describes a state whereby the patient is quiet and tends not to move, except in response to vigorous and repeated noxious stimuli (Hickey 2002).

Coma

Coma is an impaired state where the patient is totally unaware of themselves and their environment. It may vary in degree and, in its deepest stages, no reaction of any kind is obtainable.

For further reading, see Hickey (2002), Chapter 8.

Chronic states of impaired consciousness

The chronic states of impaired consciousness are:

- dementia
- vegetative
- locked-in syndrome.

Dementia

This condition is caused by a generalised and progressive loss of cortical tissue from the brain. Mental functions decline progressively. There is global deterioration of memory, thinking, motor performance, emotional responsiveness and social behaviour; however, arousal remains intact.

As the condition develops, speech may become hesitant with eventual aphasia. Behaviour becomes increasingly unreasonable and often disruptive, until control of basic and vital processes is disorganised. There are numerous causes of progressive dementia. The most prevalent type is Alzheimer's disease.

Dementia is usually an irreversible condition. However, there are some occasions when the decline in cognitive functions can be halted and even partially reversed, e.g. in normal pressure hydrocephalus, which can be treated by

insertion of a ventricular shunt (Dalvi 2004, Wilson & Islam 2004; see also Life NPH in 'Useful websites', p. 988).

Vegetative

Vegetative state (VS) is a term used to describe a condition that can occur following brain injury, where there is severe damage to the cerebral cortex. In a vegetative state, the patient has sleep/waking cycles and will open their eyes when awake. The thinking, feeling part of the brain is destroyed, although many reflex responses may remain. Physiologically, the brain stem is functioning but the cerebral cortex is not. Patients can survive for many years in this condition and require full-time care. 'Continuing vegetative state' describes the patient's condition prior to confirmation of 'permanent vegetative state' (PVS). The British Medical Association recommended 'that the diagnosis of irreversible PVS should not be considered or confirmed (and therefore treatment not be withdrawn) until the patient has been insentient for 12 months' (British Medical Association 1996). The Royal College of Physicians (2003) issued new guidance on the diagnosis and management of patients in a vegetative state, as assessment, management and legal requirements had changed.

There is ongoing debate, both in the UK and abroad, about the moral, ethical and legal issues surrounding the care and treatment of these individuals (Multi-society Task Force Report on PVS 1994, Day et al 1995, British Medical Association 1996, Grubb et al 1996, Smith 1997, Royal College of Physicians 2003). Cases such as those of Bland in England (Airedale NHS Trust v. Bland E 1993), Cruzan in the USA (Cruzan 1990) and Johnstone in Scotland (Law Hospital NHS Trust v. The Lord Advocate and Others 1996) brought the dilemma of 'the right to die' and withdrawal of treatment to media, and thus public, attention. Research into the views of doctors and nurses in Europe on PVS was conducted by a project committee headed by Professor Andrew Grubb (Grubb et al 1996).

Locked-in syndrome

This condition results in paralysis of voluntary muscles without interfering with consciousness and cognitive functions. The patient is unable to speak and is sometimes unable to breathe spontaneously, the latter requiring artificial ventilation. The patient is, however, able to control vertical eye movements and blinking and may be able to use these movements to develop a simple communication system. It is important to remember that the patient is aware of their surroundings, even if appearing to be mentally and physically inert.

The pathological basis for this condition is damage to the pons in the brain stem, which may result from cerebral vascular disease or trauma.

For further information on PVS and locked-in syndrome, see Randall (1997), Smith (1997) and the Report of a working party of the Royal College of Physicians (2003). The ongoing and wider debate about an individual's 'right to die' can also be followed on various media and the internet — see also www.justice4diane.org.uk.

28.1 What implications may there be for the patient and family if PVS is misdiagnosed?

ASSESSMENT OF THE NERVOUS SYSTEM

Nurses must be competent to monitor the conscious level for signs of deterioration, improvement or stability and they must understand what the observations mean. The need to assess conscious level may arise at any time in any ward in any hospital. In seminal work, Teasdale (1975) noted that ambiguities and misunderstandings can result when passing on information about the patient's level of consciousness to other staff. There was clearly a need for a standardised system of assessing the conscious level, so that different nurses and doctors would make similar observations on the patient at any one time. In 1974, Teasdale and Jennett developed the Glasgow Coma Scale (GCS), a process used throughout the UK and worldwide as part of the neurological assessment and ongoing observation of the patient (see Fig. 28.4). Its use provides the detail from which to determine any change in the patient's level of consciousness, i.e. is it static, improving or deteriorating, so that appropriate action can be taken expeditiously (Waterhouse 2005). The National Centre for Clinical Excellence (NICE) (2003) has published guidelines for the management of patients with head injury, which stipulate the use of the GCS for all head-injured patients (see also Ch. 9).

The Neurological Observation Chart

The Glasgow Coma Scale

In monitoring the patient's conscious level, the functional state of the brain is assessed as a whole. The nurse observes and describes three aspects of the patient's behaviour:

- eye opening
- verbal response
- motor response.

Each of these is independently assessed and recorded on a chart (see Fig. 28.4). Each aspect shows a variety of possible responses. The patient's response is recorded by placing a dot in the appropriate square. The dots are joined to form a graph, making the chart easier to read. The decision about the time intervals between recording the assessments will be based on the patient's condition. The best response for each of the three aspects is recorded as a numerical score. In the case of eye opening, the best response would score a 4, the best verbal response would score a 5 and the best motor responses would score a 6. The lowest response for each of the three parameters is a score of 1.

The scores can be added together to give a total which could range from 3 to 15. The higher the score, the better the patient's condition; a score of 8 or less is generally considered to indicate that the patient is in a coma. However, it is important to consider each of the three aspects (eye opening, verbal response and motor response) separately as well as together. A patient may be blind, deaf, mute or have paralysis unrelated to their current condition and these other conditions would affect the scores. In some wards/hospitals, the numerical scores are not recorded. It is also worth noting that, although the GCS is widely used, there may be some slight variations in the layout of the assessment chart in different hospitals.

The Neuroscience Nurses' Benchmarking Group (NNBG) (see 'Note', p. 988) has set the standard for the assessment

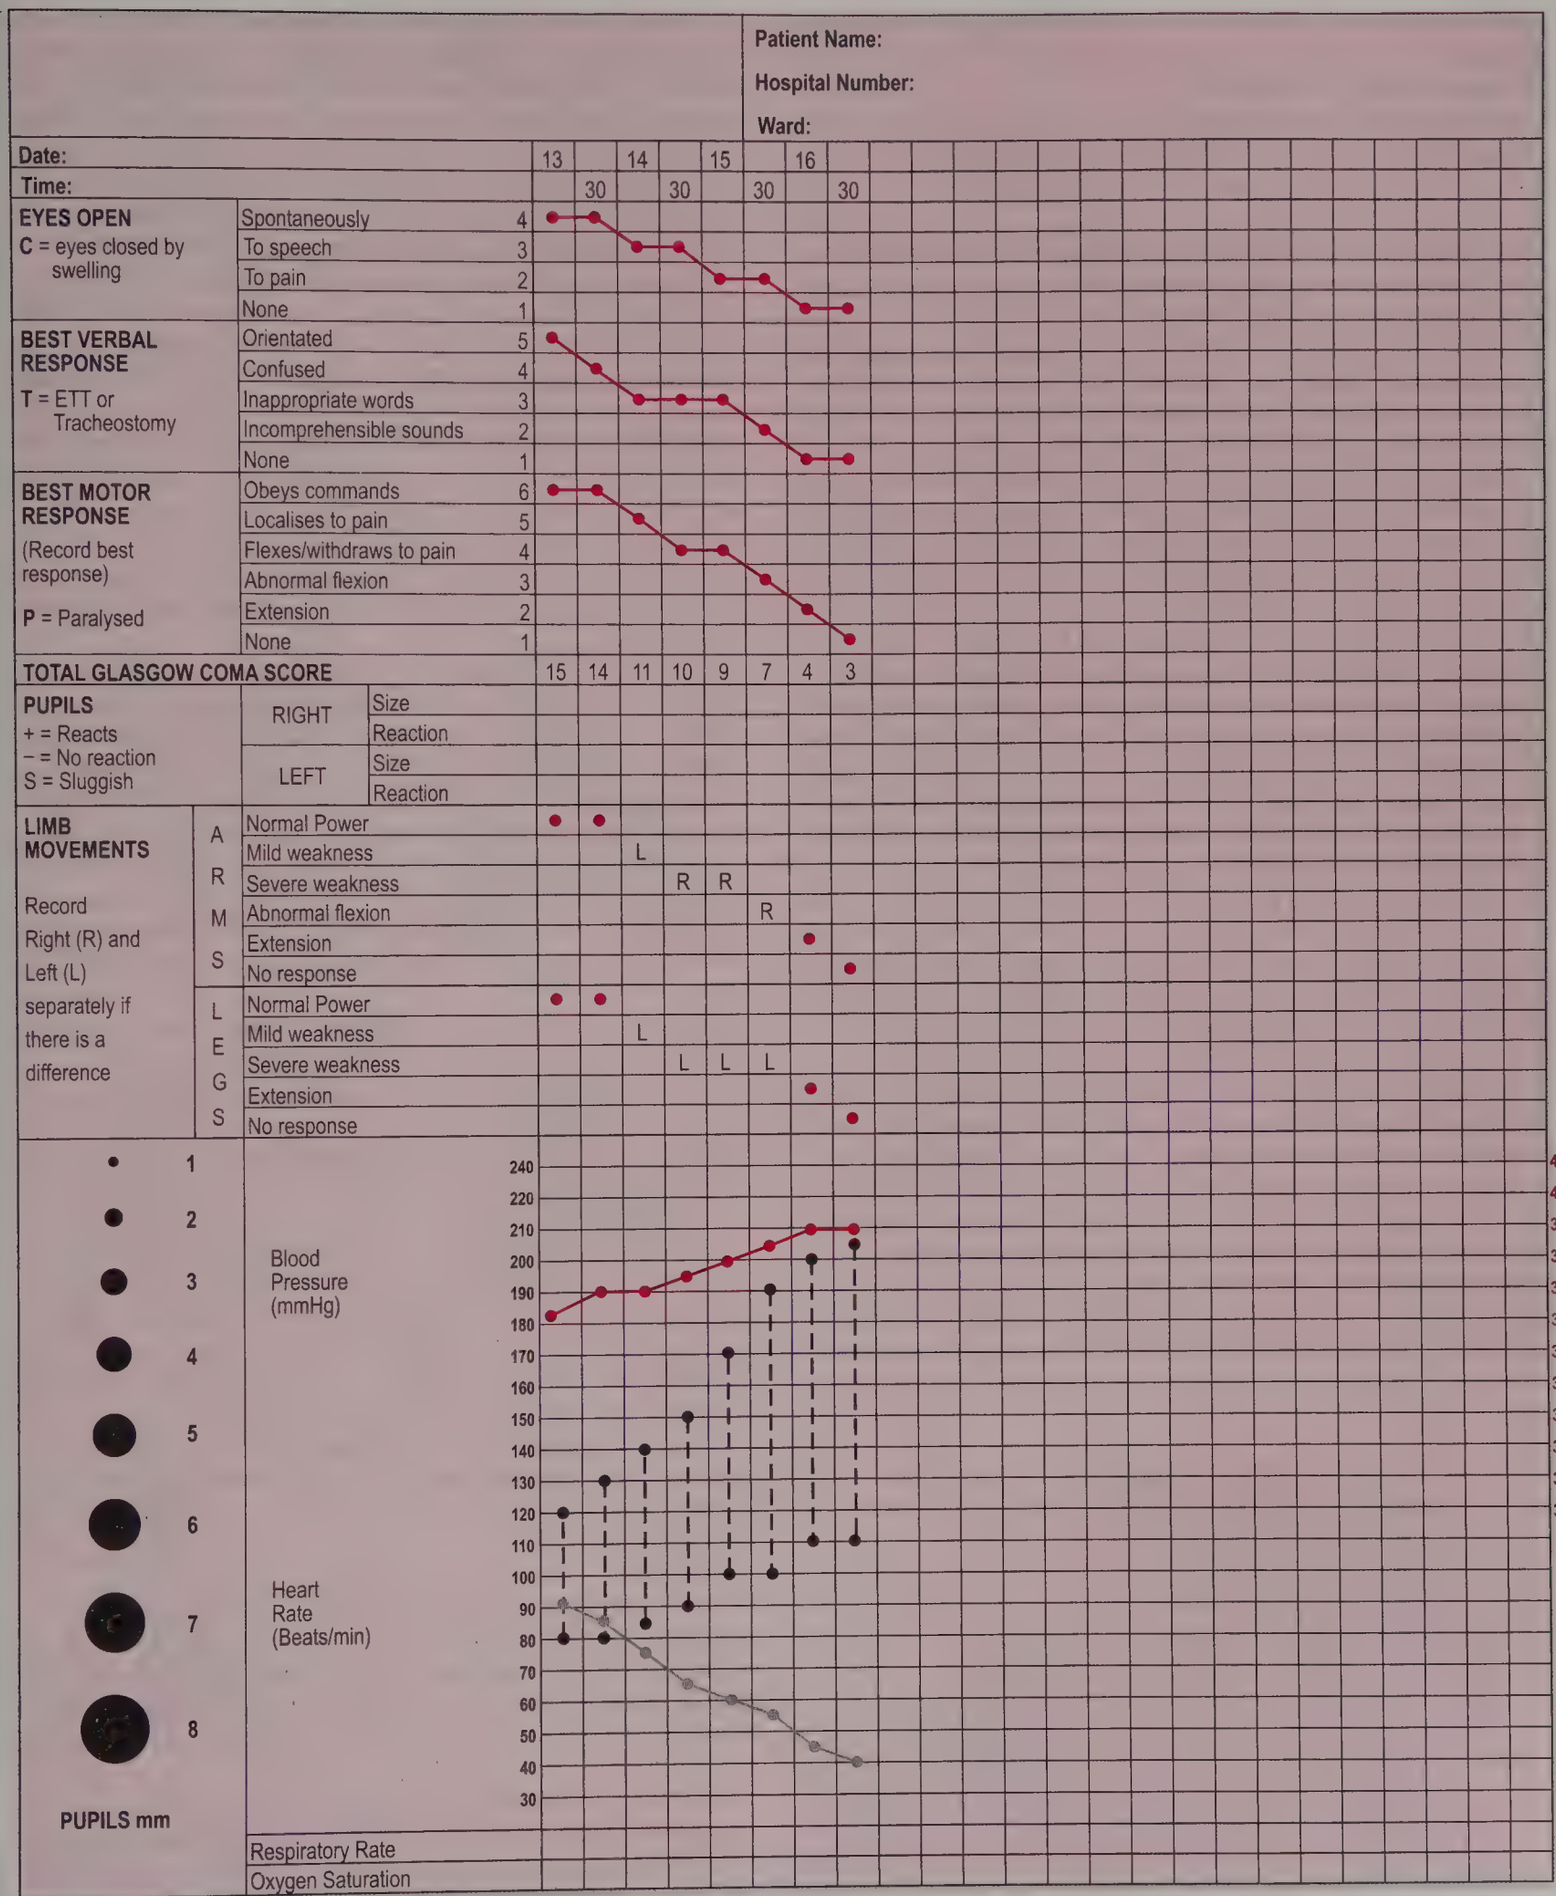

Fig. 28.4 The Neurological Observation Chart.

and recording of a patient's neurological status using the Glasgow Coma Scale (Fairley & Cosgrove 1999, Shah 1999, Mooney & Comerford 2003).

For further information on the use of the Neurological Observation Chart and GCS in practice, see Woodward (1997a–d), NICE (2003) and Waterhouse (2005).

Eye opening The degree of stimulation required to make the patient open their eyes is observed and recorded using the following categories.

Spontaneously The patient opens their eyes when first approached, which implies that the arousal response is active. This response is given a score of 4. Allowance must be made if the patient is in a natural sleep.

To speech The patient's eyes are not open when first approached. The nurse should speak to the patient by calling their name and then ask them to open their eyes. It may be necessary to increase the level of the verbal stimulation to gain a reaction. A successful response scores 3.

To pain Initially, a gentle shake of the patient's shoulder may be sufficient to elicit a response. If the patient still fails to open their eyes, a peripheral painful stimulus must be used. Pressure is applied to the lateral inner aspect of the second or third finger using a pen or pencil, held at a right angle against the finger, for a maximum of 30 s (Fig. 28.5). This response scores 2 on the coma scale. Care must be taken not to exert pressure on the patient's cuticle as this will damage the nail bed.

None If the painful stimulus does not cause the patient to open even one eye, then this is recorded as having no eye-opening response. This indicates a deep depression of the arousal system and is scored as 1 on the scale.

Possible assessment problems The patient who is in a deep coma with flaccid eye muscles will show no response to stimulation. If the eyelids are drawn back, however, the eyes may remain open. This is very different from spontaneous eye opening and should be recorded as 'none'.

The nurse needs to be aware if the patient has any hearing deficits as, if the eyes are closed, this could affect the initial response. Congenital deficits of the eye or previous removal of the eye should also be taken into account.

After trauma or surgery, eyelid swelling occasionally prevents eye opening, as does tarsorrhaphy where upper and lower eyelids are sutured together. A condition such as ptosis (palsy of cranial nerve III) will also have this effect, although this seldom results in complete closure of both eyes. Enforced closure of the eyelid(s) should be recorded as 'C' on the chart.

Opening of the eyes implies arousal, but it must be remembered that this does not necessarily mean that the patient is aware of their surroundings. This can be misleading and be a source of false optimism in relatives.

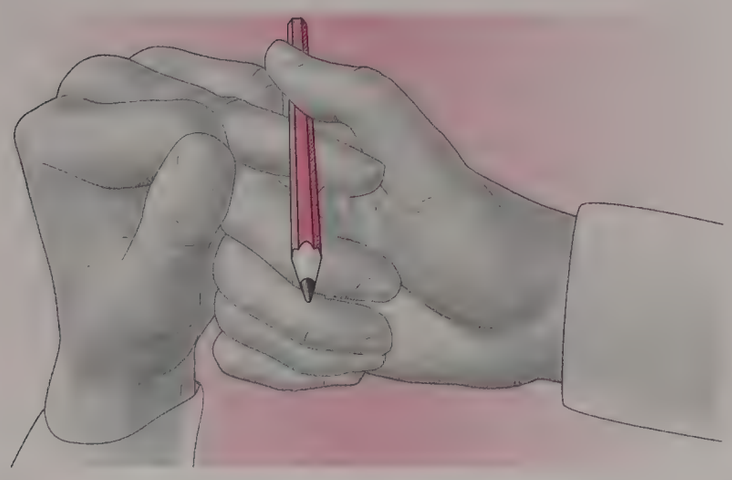

Fig. 28.5 Applying a peripheral painful stimulus: fingertip stimulation. (Adapted from Teasdale 1975.)

Verbal response The patient's best achievement in respect of verbal response is observed and recorded using the following categories.

Orientated The patient is orientated if they can state their name, where they are and what the year and month are. This is orientation in person, place and time, respectively, and is given a score of 5. Questions can be varied but they must be kept simple; for example, the date and even the day are not easily remembered, especially after a period in hospital.

Confused If the patient is capable of producing phrases or sentences but the conversation is rambling and inappropriate to the questions about orientation, it is a confused verbal response and scores 4.

Inappropriate words The patient will speak only one or two words, usually in response to physical stimulation. The words and phrases make little or no sense and may be obscenities. On occasion, the patient may shout out obscenities or call a person's name for no apparent reason. These all indicate a lower level of responsiveness and score 3.

Incomprehensible sounds The patient will moan or grunt in response to physical stimulation. The verbal response may contain indistinct mumbling but no intelligible words. This response scores 2.

None The patient will not produce any verbal response even when prolonged and repeated stimulation is given. This scores 1.

Possible assessment problems The patient may be unable to understand the nurse's questions or commands because they do not understand the language or have a hearing defect. The patient's verbal response may be impaired as a result of a speech defect such as dysphasia. If appropriate, written instructions and replies can be used to assess the patient's language ability. The verbal response may also be compromised by the presence of an endotracheal or tracheostomy tube. This is indicated on the patient's chart as 'T'.

Motor response The patient's best motor response is observed (see Fig. 28.6). Only upper limb responses are recorded, as leg responses to pain are less consistent and inappropriate spinal withdrawal reflexes occur more readily in many patients who would otherwise show a total absence of brain function.

Obeys commands The patient has the ability to appreciate instructions (see Fig. 28.6A). These are usually given by verbal commands such as: 'Put out your tongue, please' or 'Lift up your arms, please'. If the patient obeys these instructions, a score of 6 is given.

Localises to pain This is the response to a central painful stimulus. If the patient does not obey commands,

the NNBG guidelines advocate the application of pressure over the supraorbital ridge. The nurse's hand rests gently on the patient's forehead and the flat of the nurse's thumb is placed on the patient's supraorbital ridge under the eyebrow. Pressure is gradually increased for a maximum of 30 s. The response is recorded as 'localising to pain' if the patient moves their arm across the midline, to the level of the chin, in an attempt to locate the source of the pain (see Fig. 28.6B). In the presence of facial fractures or gross orbital oedema, the trapezium pinch is an effective alternative. The patient's shoulder is exposed and the trapezius muscle is squeezed between the nurse's fingers and thumb (Frawley 1990). Localisation to pain will score 5.

During the course of the day, the patient may display a localising response to other sources of irritation, e.g. attempts to remove their oxygen mask, nasogastric tube or urinary catheter.

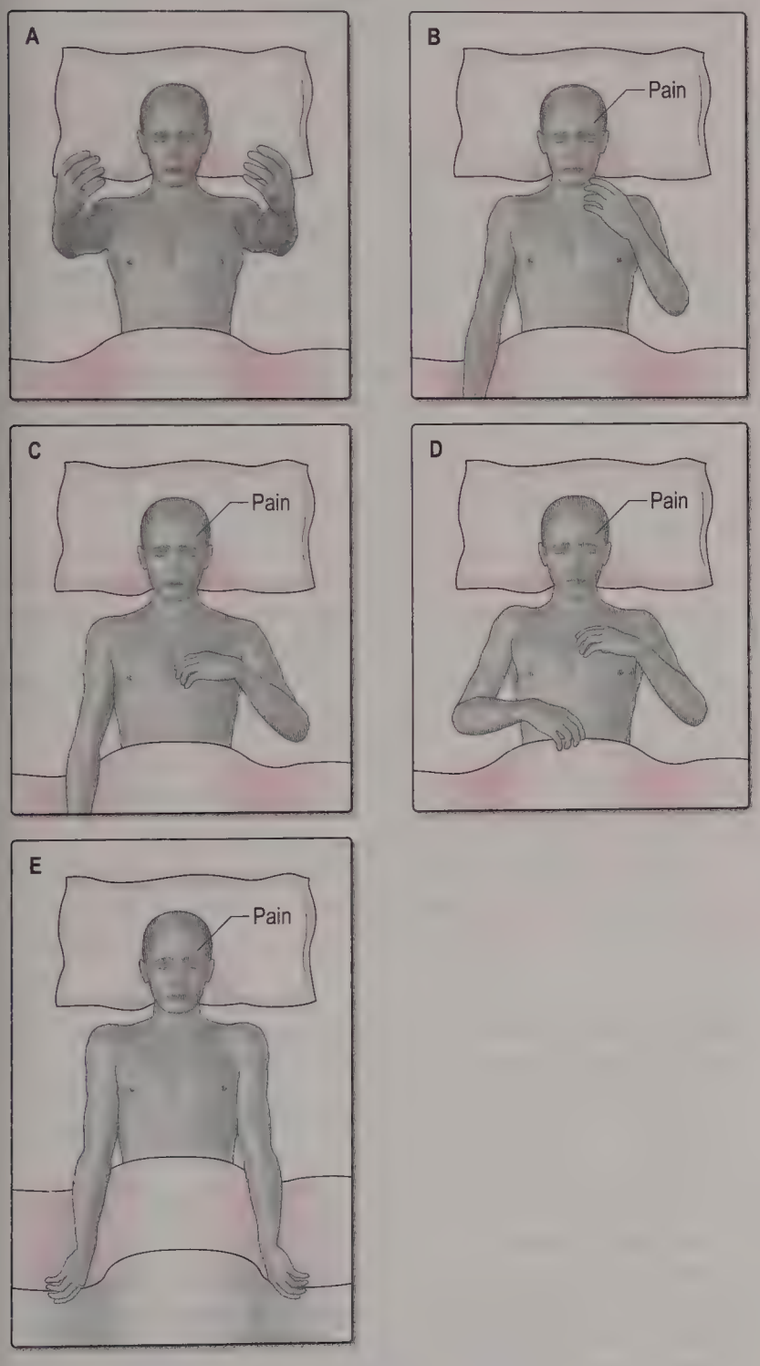

Fig. 28.6 Motor responses. A: Obeys commands ('lift up your arms'). B: Localising to pain. C: Flexing to pain. D: Abnormal flexion. E: Extending to pain.

Flexion to pain Following the application of a central painful stimulus, the patient responds by bending their elbow and withdrawing their hand, but no attempt to localise is made (see Fig. 28.6C). This is 'flexion to pain' and scores 4.

Abnormal flexion This involves the patient bending their elbow with adduction of the upper arms and spastic flexion of the wrist and fingers, otherwise known as decorticate posturing (see Fig. 28.6D). Abnormal flexion is scored as 3.

Extension to pain After painful stimulation, the patient responds by rigid extension, i.e. straightening the elbows and hyperpronation of the forearms, otherwise known as decerebrate posturing. The response usually includes spastic hand and wrist movements, with an inward rotation of the shoulders and forearms (see Fig. 28.6E). The legs are generally straight, with the feet pointing outwards. This response scores 2.

None This response is only recorded when sufficient painful stimulus has been applied to the patient to provoke a response and no detectable movement has been observed. This will score 1 on the scale.

Decortication and decerebration Painful stimuli can initiate abnormal postures if motor nerves are interrupted at specific cerebral levels. A patient with severe brain damage may exhibit one or a combination of these postures without any stimulation.

Possible assessment problems Variations in the motor response may occur during the assessment. Therefore, it is the best response that should be scored; for example, if the patient localises to pain on the left side but flexes to pain on the right, the localising response is recorded. Asymmetrical responses are significant, indicating that a focal neurological deficit is present, but overall brain function is more accurately reflected by the level of best response on the better side (see 'Limb movement' below).

When applying a painful stimulus, it is important to explain to the patient and relatives what you are about to do and why you are doing it, otherwise they may feel that unnecessary trauma is being inflicted.

Recording other measurements

The Neurological Observation Chart is used to record additional measurements (see Fig. 28.4) as follows:

- vital signs
  - — blood pressure
  - — heart rate (pulse)
  - — respirations
  - — temperature
- pupil size and reaction
- limb movements.

Vital signs

Blood pressure and pulse The famous Canadian neurosurgeon Harvey Williams Cushing (1869–1939) noted that a rise in intracranial pressure (ICP) led to a rise in blood pressure (elevated systolic pressure and widening pulse pressure) and a slowing pulse (see Ch. 9), termed 'Cushing's

response'. However, this is a very late sign of raised ICP, and the Glasgow Coma Scale will show evidence of deterioration much earlier.

Changes in the blood pressure and pulse can indicate injury or disease elsewhere in the body; for example, falling blood pressure and a rapid and weak pulse are indicative of haemorrhage and shock (see Ch. 18).

Respiration Conditions that impair consciousness may also cause respiratory changes. The pattern and rate of respiration may be directly affected by brain damage. The rate of respiration is recorded on the chart, but it is also important for the nurse to observe the depth, rhythm and characteristics of respiration. Deep lesions in the cerebrum tend to produce a periodic pattern such as Cheyne–Stokes respiration. Lesions affecting the pons and medulla cause more irregular patterns. If the patient is being ventilated, abnormal respiratory patterns will not be evident.

Temperature Impaired brain function seldom causes significant changes in body temperature, unless there has been direct damage to the temperature-regulating centre in the hypothalamus (see Ch. 22), when the temperature can rise rapidly. Each rise in degree of temperature increases the brain's metabolic rate, and must be treated urgently to prevent further neurological deterioration. A gradual elevation in temperature is likely to be an early sign of infection in the lungs or urinary tract, or in a wound.

Pupil size and reaction

The size of both pupils is measured by comparing them with a series of circular millimetre measures on the chart (see Fig. 28.4) or by descriptive terms (Hickey 2002). Reaction to light is recorded by a plus (+); no reaction is recorded by a minus (–). Pupil reactions should be assessed in dim surroundings, using a small bright flashlight. To elicit the direct-light reflex, the nurse holds both of the patient's eyelids open in turn, brings the light in from the outer side of the eye and shines it directly into the eye. This should cause a brisk constriction of the pupil, and withdrawal of the light should produce brisk dilatation of the pupil. The size and reaction are observed and recorded on the chart. The shape of the pupils should also be assessed.

Abnormal pupillary size and reaction can indicate brain dysfunction and/or raised ICP. It is important to note any changes, particularly if they occur in conjunction with other changes in the neurological observations.

For further information on the Glasgow Coma Scale and other neurological observations, see Hickey (2002), Chapter 8, NICE (2003), Department of Health (2005) and Waterhouse (2005).

Limb movement

Disturbances of limb movement indicate localised (focal) brain damage and vary according to the site and extent of the damage; for example, the right arm and leg will be affected by a lesion in the left cerebral hemisphere. Diffuse brain damage will result in a greater disturbance of movement.

When no localised brain damage is suspected, such as in metabolic or drug coma, the best motor response on the coma scale is usually sufficient for monitoring responses. When localised brain damage is suspected, an additional detailed assessment of each limb is necessary (see Fig. 28.4).

The nurse examines the arms and legs for movement and strength, and compares the right and left sides. When the two sides are the same, recordings are made in the standard manner (see p. 971). When differences exist, right and left are recorded independently, noting 'R' for right and 'L' for left. Responses can be elicited by verbal commands, such as asking the patient to grip the nurse's hand as tightly as possible, to lift up their arms or to bend their knees. To test strength, the nurse may need to provide some form of resistance, such as pressing down on the patient's knee when the patient is trying to bend it.

Painful stimuli may be applied to the appropriate limb if verbal comments fail to elicit a response.

CAUSES OF UNCONSCIOUSNESS

The major causes of unconsciousness are shown in Figure 28.3.

Unconsciousness occurs when the RAS is damaged or its function is depressed so that there is an interruption of the normal arousal mechanisms. This may be caused by a primary or secondary insult to the nervous system: primary insults are commonly caused by intrinsic diseases of the brain; secondary involvement is most often caused by metabolic, endocrine or toxic conditions, where the critical insult is manifested elsewhere in the body.

Information on some of the conditions that can result in loss of consciousness can be found in Chapters 5 and 9.

EMERGENCY CARE OF THE UNCONSCIOUS PATIENT

Whatever the cause of unconsciousness and wherever the event occurs, the patient's life depends on the knowledge and skills of those who find and care for them. The first aid and care that the patient receives until consciousness is regained, if this is achievable, will help to determine the outcome (see Box 28.3).

A hospital emergency

In hospital, an individual can be rendered unconscious by any of the causes shown in Figure 28.3. The person does not necessarily need to be a patient; visitors and members of staff are also at risk from events such as cardiac arrest, cerebrovascular accident or falls resulting in head injury. The measures a nurse should take on finding someone collapsed are as follows:

1. Shout for assistance and press the emergency call button.
2. Move the person into a wider space if this is possible.
3. Following the ABC principles (see p. 34), initiate cardiopulmonary resuscitation (CPR) if the individual is not breathing and the carotid pulse is absent. The cardiac arrest team should be called at this point.
4. If the person is breathing and a pulse is present, place them in a semi-prone (recovery) position. However, if spinal injury is suspected, do not move the person or place them in the semi-prone position without keeping

Box 28.3

First aid for someone who is unconscious

N.B. If alone, the first action normally is to seek help.

1. Check the victim's breathing and pulse. If they are not breathing and a pulse is not felt in the carotid artery, turn them onto their back and initiate cardiopulmonary resuscitation (see Ch. 2). If possible, get help to do this.
2. Clear the victim's airway if necessary. Remove dentures or dental plates, if possible, and keep them in a safe place.
3. Call for help. If outside the hospital setting, send someone to telephone for an ambulance. Make sure that the person knows the location and has some details of the victim. Ask the person to return to confirm that the telephone call has been made.
4. If the victim is breathing and has a pulse, loosen their clothing at the neck, chest and waist. Keep bystanders away from the victim. If necessary, and if possible, move them to a safer place.
5. Check for any other injuries or bruises and stem any bleeding.
6. Place the victim in the semi-prone or recovery position, as follows:
   (a) Kneel beside them and place their arms alongside their body.
   (b) Cross the victim's ankle furthest away from you over the one nearest to you.
   (c) Cushion their head with your hand.
   (d) Place your other hand on the victim's hip furthest from you and roll them gently towards you.
   (e) Maintain a clear airway by grasping under their jaw and moving their chin upwards and backwards. This extends the neck and prevents the victim's tongue from blocking their throat.
   (f) Pull up the arm nearest to you so that the point of the elbow is in line with the victim's shoulder.

   This position prevents the victim's tongue from falling into the back of their throat and blocking the airway. It also allows fluid, such as blood or vomit, to drain from their mouth.

   Note: The position is contraindicated in victims with suspected spinal injury, when movement risks further damage to the spinal cord (see Chs 10 and 27).
7. Stay with the victim until the ambulance arrives. Give a detailed account of events to the paramedics. This should include how the victim was found and what resuscitative measures were taken.

the head, neck and spine in alignment. In the hospital setting it may be possible to obtain a cervical collar or spinal board if necessary. Stay with the person until assistance arrives and they can be moved to an appropriate place for further treatment and investigation.

Planned admission

When an unconscious patient is to be admitted to hospital, the following measures must be taken:

- Remove the top bedclothes and the head of the bed to facilitate easy access to the patient.
- Check that the oxygen supply and suction apparatus are functioning and that there is an adequate supply of relevant equipment.
- The necessary equipment should be available for immediate use:
  (a) a resuscitation trolley containing the following:
  — Guedel airways (usually size 3 or 4 for an adult)
  — Ambu bag with universal catheter mount. If the patient is unable to breathe spontaneously, they must be ventilated manually via an endotracheal tube, using an Ambu bag, until they can be transferred to an intensive care unit
  — laryngoscope and selection of endotracheal tubes, sizes 6.5–10.00 mm
  — lubricating jelly; strapping or tape; 5 mL syringe to inflate the endotracheal tube cuff
  — emergency drug box or pack
  (b) an intravenous infusion stand
  (c) equipment for passing a nasogastric tube to aspirate the stomach contents
  (d) a neurological examination tray
  (e) the appropriate charts and admission forms.

Priorities of nursing management

The following checklist itemises the priorities of nursing management in an emergency situation, in order to sustain the patient's vital functions:

1. Maintenance of a clear airway
   (a) the patient's position
   (b) artificial airways
   (c) suction
   (d) oxygen
   (e) nasogastric tube.
2. Assessment of the central nervous system
   (a) Glasgow Coma Scale
   (b) vital signs
   (c) pupillary reactions
   (d) limb movements.
3. Maintenance of fluid balance
   (a) intravenous infusion
   (b) catheterisation of the urinary bladder, if necessary.

Care of relatives Measures to sustain the vital functions of the patient must take priority. Anyone accompanying the patient must also be considered, and a nurse who is not involved in the immediate care of the patient should be allocated to care for them. The nurse should provide them with written information regarding hospital procedures and explain the investigations related to the patient's condition. At the same time, the nurse may be able to gather the patient's biographical data and other information to help in planning the patient's care.

Medical management

An unconscious patient is a medical emergency, unless the unconscious state represents the terminal state of a progressive and not specifically treatable disease. Although life support measures have priority, the cause of the unconscious state must be determined before the appropriate

treatment can be given. These life support measures include establishment of an adequate airway, control of haemorrhage, and fluid or blood replacement. When the patient has ingested an overdose of drugs, gastric lavage may be indicated, but is only performed under advice from the National Poisons Information Service (see 'Useful websites').

The patient must be intubated before gastric lavage is carried out, to minimise the risk of aspiration of fluid into the lungs.

28.2 What are the guidelines and protocols in the Emergency Department of your hospital for management of unconscious patients suspected of ingesting drugs or toxic substances?

The medical history

The doctor or an experienced nurse will need to gain further information about the patient. If an appropriate person has accompanied the patient to hospital, it is important that this person does not leave until the doctor or nurse has had an opportunity to ask them about the patient's medical history and the circumstances preceding and surrounding the onset of the unconscious state.

The physical examination

The general physical examination of the unconscious patient will include special attention to the patient's:

- vital signs
- pattern of respiration
- signs of trauma
- skin colour and texture
- breath odour.

The signs and symptoms listed in Table 28.1 can provide clues to the cause of the unconscious state.

The neurological examination of the patient will include assessment of the cranial nerves, motor and sensory function, and the patient's reflexes. A nurse should be present at the initial neurological assessment so that any future changes in the patient's condition can be monitored in relation to their initial state.

Laboratory tests

Laboratory tests for unconscious patients usually include a complete blood count, blood glucose levels and blood urea, and electrolyte estimation. Blood gas analysis is obtained when the patient's respiratory and/or cardiovascular state are compromised. Screening tests of blood and urine are carried out if drug intoxication or ingestion of poison or alcohol is suspected. The patient's urine may be checked for glucose, acetone, blood and infection.

Radiological studies and imaging

Radiological investigations are carried out once the patient has been resuscitated and their condition stabilised. Skull and cervical spine X-rays are obtained when head trauma is obvious or is suggested from neurological signs; possible injury to the cervical spine should always be suspected in cases of head trauma.

If other injuries are apparent or suspected, X-rays will be taken as appropriate. Angiography, computed tomography (CT) or magnetic resonance imaging (MRI) scans may be undertaken if further investigation is considered to be necessary, and in some hospitals facilities to undertake positron emission tomography (PET scan) are available and may be used.

Table 28.1 Clues to the cause of unconsciousness on general physical examination

Sign or symptom	Possible cause
Elevated temperature	Infection Heat stroke
Subnormal temperature	Dehydration Excessive intake of alcohol Barbiturate intoxication Hypothyroidism Exposure to the cold
Bleeding from the mouth	Epileptic seizure Trauma
Pulse irregularities	Hypoxia from inadequate cardiac output
Slow, regular respirations	Hypothyroidism Morphine or barbiturate intoxication
Cheyne–Stokes respiration	Bilateral cerebral dysfunction Late stages of increased intracranial pressure Severe cardiopulmonary disease
Ataxic, irregular (cluster) respirations	Lesions of the brain stem — signifies impending apnoea
Breath odour	Excessive intake of alcohol Hepatic dysfunction Renal dysfunction Ingested poisons Diabetes mellitus
Skin	
Jaundice	Hepatic dysfunction
Cyanosis	Cardiopulmonary problems
Rash	Infection; reaction to medication
Needle puncture marks	Drug abuse
Hypertension	Raised intracranial pressure Intracranial haemorrhage
Hypotension	Blood loss Septicaemia Myocardial infarction Pulmonary embolism

Further investigations

Further investigations may be undertaken to aid diagnosis, e.g.:

- electroencephalogram (EEG)
- lumbar puncture (LP)
- electrocardiogram (ECG)
- Doppler (ultrasonic) studies.

NURSING MANAGEMENT OF THE UNCONSCIOUS PATIENT

The Roper et al activities of living model as applied by Holland et al (2003) is used to illustrate the nursing management of the unconscious patient (see also Ch. 9).

Breathing

Oxygen is essential for the survival of all body cells. Irreversible damage to the brain cells will occur if they are deprived of oxygen, even for a few minutes. Consequently, all activities of living and life itself are entirely dependent on breathing, and the establishment and maintenance of a patent airway are essential for the unconscious patient.

Any obvious potential obstructions to the airway, such as dentures or dental plates, should be removed. The nurse also needs to be aware of the presence of loose teeth, caps or crowns, as these could become detached and obstruct the airway. Bleeding into the oropharynx from head or facial injuries may also cause obstruction. Vomiting presents another hazard. The insertion of a nasogastric tube in the initial stages of coma will facilitate the emptying of the stomach, thus helping to avoid the potential aspiration of gastric contents into the respiratory tract.

Position of the patient

Unconscious patients, unless their condition contraindicates, should be nursed in a semi-prone or lateral recumbent position with the head of the bed tilted slightly upwards (10–30°). This prevents the tongue from obstructing the airway, encourages the drainage of respiratory secretions and saliva and therefore reduces the danger of aspiration into the lungs. Patients who have sustained a head injury will also benefit from head elevation to aid cerebral venous drainage and help to reduce intracranial pressure (Hickey 2002) (see Ch. 9). Pillows positioned at the patient's back and between the knees will help to maintain the position. If the patient has any spinal injuries, there may be some variation in positioning and extra care must be taken when carrying out any procedures (see Ch. 10).

Artificial airways

The unconscious patient's cough reflex is depressed or absent, so they are unable to cough and clear their own airway. The use of artificial airways and suctioning may be required.

Oropharyngeal airway The Guedel airway is the oropharyngeal airway most commonly used in UK hospitals. This has the advantage of relatively easy insertion and is available in varying sizes to facilitate the needs of individual patients. The airway is designed to lie over the tongue and permit the passage of air into the pharynx (see Fig. 28.7). It keeps the patient's tongue from obstructing the throat and it has a hollow centre that allows the patient to breathe through the device. It also allows easier access to facilitate suction of the oropharynx and trachea. An oropharyngeal airway can stimulate the gag and cough reflex, causing the patient to retch or cough, in which case a nasal pharyngeal airway may be tolerated better as this is passed through the nose and does not exert a stimulus on the rear part of the tongue.

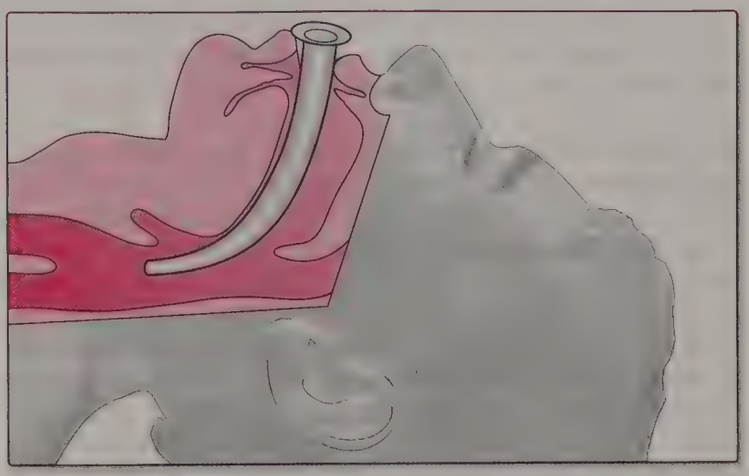

Fig. 28.7 A Guedel airway in situ.

Endotracheal tube An endotracheal tube is indicated if either the Guedel or nasal pharyngeal airway proves inadequate or when mechanical ventilation is required. The tube is made of plastic and has an inflatable cuff (see Fig. 28.8). The tube is normally inserted through the mouth by a doctor or a nurse who is competent to carry out the procedure. It is then passed into the trachea to the point just above the bifurcation of the bronchi. This permits deep suctioning. Breath sounds are determined immediately after insertion to make certain that the tube is properly positioned and is not obstructing one of the primary bronchi. The cuff of the tube is then inflated with air. The inflated cuff provides an airtight seal around the outside of the tube, particularly when mechanical ventilation is required. It also prevents the aspiration of material from the digestive tract. The tube is secured in position externally using hypoallergenic tape or tied with ribbon gauze. It is the nurse's responsibility to check the patency and position of the tube at regular intervals.

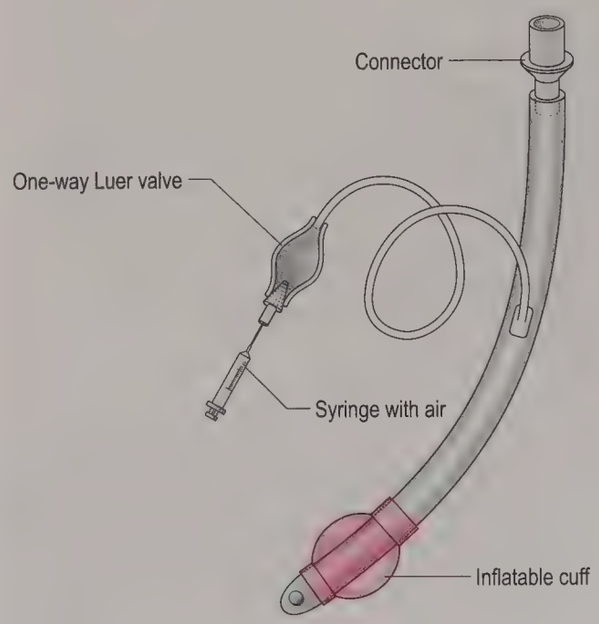

Fig. 28.8 Endotracheal tube.

An endotracheal tube is not usually left in place for more than 5–7 days because of the increased risk of erosion to the tracheal wall.

Tracheostomy tube A tracheostomy, a surgical opening in the anterior wall of the trachea, may be used to facilitate breathing and is usually indicated if intubation needs to be prolonged, or if there are difficulties in inserting an endotracheal tube. The tracheostomy tube bypasses the nose, pharynx and larynx, enabling air to flow directly into the lungs, thus reducing dead space and therefore the effort required by the patient to breathe, and facilitates suctioning of bronchial secretions (see Ch. 14).

A variety of different types and sizes of tracheostomy tube are available, made of silver, plastic or nylon, and the tubes may be cuffed or uncuffed. In the acute area, cuffed tubes are used more frequently because they are made with high volume, low pressure, soft cuffs to reduce the risk of pressure trauma to the trachea.

Most tubes consist of three parts: an obturator inside the tube to keep it rigid during insertion, an outer cannula and an inner cannula. The advantage of a tube with an inner cannula is that this can be removed every 2–4 h for cleaning, and then replaced. This prevents the potential danger of obstruction with secretions. The procedure can also be carried out without disturbing the outer tube. This reduces the frequency of outer tube changes, thus minimising the risk of trauma to the stoma and trachea.

Infection is a potential problem and the tracheal stoma should always be treated as an open wound (see Ch. 23). The incidence and severity of infection may be minimised by keeping the wound area free of secretions that collect around the tube. The stoma is cleansed using an aseptic technique, and a sterile absorbent, non-adherent dressing may be applied.

The NNBG (see 'Note', p. 988) recommends the following for best nursing practice:

- use proprietary stoma dressings which should be changed at least once a day
- change tracheostomy tubes in line with manufacturer's guidelines
- inflate the cuff slowly with air, in 0.2–0.5 mL increments, using a 10 mL syringe
- measure the amount of air in the cuff using a pressure gauge. Pressures should be maintained between 15 and 25 cm H_2O unless otherwise directed by medical staff (Dikeman & Kazandijan 1995)
- if a pressure manometer is unavailable, listen for air leaks with a stethoscope over the thyroid cartilage until no airflow is detected from around the cuff (Ganner 2001).

Suctioning

Suctioning is carried out to remove potentially dangerous secretions from the oropharynx, trachea and bronchi. The nurse's assessment of the patient's colour, respiratory rate and pattern will indicate how often this is required. Suction must be applied if one or more of the following occurs:

- signs of cyanosis
- increased and irregular respirations
- noisy, gurgling respirations.

The following equipment is required:

- a piped source of vacuum pressure, indicating calibrated pressures, or a portable suction device
- a collection jar and disposable connecting tubing
- disposable plastic sterile suction catheters of the correct size for the patient, usually 12–14 French gauge for an adult; the catheter should be no more than one-half the diameter of the tracheostomy/endotracheal tube
- non-sterile examination gloves
- sterile disposable plastic gloves
- sterile normal saline
- a sterile bowl
- masks.

The use of a closed suction catheter system and disposable suction equipment is recognised as good practice.

Procedure Each hospital will have its own policy regarding suctioning, but the procedure described below is based on good practice and provides a general example (Buglass 1999, Laws-Chapman et al 2000).

1. Explain the procedure to the patient.
2. Assemble the equipment needed — masks are advocated in some areas for the nurse's protection.
3. Turn on the suction device to 80–120 mmHg.
4. Wash hands and pour the sterile normal saline into a sterile bowl.
5. Patients who are dependent on oxygen should continue with their therapy until immediately prior to inserting the suction catheter.
6. Put on a pair of non-sterile examination gloves for your own protection.
7. Open the pack containing the sterile catheter and put a plastic sterile glove on the dominant hand.
8. Attach the catheter to the connecting tube, taking care not to contaminate the catheter.
9. Remove oxygen mask/nasal cannula from the patient.
10. Insert the catheter into the airway without applying suction.
11. Advance the catheter as far as it will easily pass, until resistance is met.
12. Withdraw the catheter 1 cm. Continuous suction is applied as the catheter is slowly withdrawn (Glass & Grap 1995, Laws-Chapman et al 2000).
13. Remove secretions within a time limit of 15 s.
14. Use the catheter once only and then wrap it around the gloved hand. Remove the glove with the catheter inside and discard both.
15. Rinse the suction tubing through with sterile water.
16. Give the patient at least 60 s to recover before suctioning again. Give oxygen again, if required.
17. If all the secretions have not been removed, repeat the procedure using a new sterile glove and sterile catheter.
18. Use a new catheter to suction the patient's mouth and nose at the end of the procedure if necessary. Nasal suction is contraindicated if the patient has sustained a frontal skull fracture or has nasal leakage of cerebrospinal fluid (CSF rhinorrhoea). The passage of a suction catheter through the nose could lead to damage to brain tissue and infection.

19. If a piped disposable system is not available, empty the collection jars and disinfect them at least once every 24 h during regular use; cleaning should be according to local policy.

Some policies advocate the instillation of 5–10 mL of sterile normal saline into the airway, immediately before suctioning, in order to loosen the secretions; however, the value of this technique is questioned (Raymond 1995, Ackerman 1996). Ackerman argues that this practice can irritate the mucosa and has little or no value in thinning, mobilising or removing dried secretions. The preferred option is the use of a saline nebuliser which will deliver tiny droplets of moisture to the alveoli to optimise humidification and mucociliary transport.

Humidification

Normally the air drawn into the lungs is warmed, moistened and filtered through the nose and upper respiratory tract. If the patient has an endotracheal or tracheostomy tube in situ, the air entering the lungs is dry and so a humidifier must be used, otherwise irritated mucous membranes and dried tenacious secretions will soon result.

Oxygen

The amount of oxygen prescribed depends on the respiratory status of the patient and the laboratory evaluation of their arterial blood gases. A specimen of arterial blood is taken to ascertain the pH and partial pressures of oxygen (P_aO_2) and carbon dioxide (P_aCO_2). Ideal values should be: pH, 7.36–7.44; P_aO_2, 11–15 kPa; P_aCO_2, 4.6–5.9 kPa. Deviations from normal may be corrected by an increase or decrease in the amount of oxygen delivered. Mechanical ventilation may be indicated to ensure adequate oxygenation. The ventilated patient is cared for in an intensive therapy unit or a high-dependency unit.

There are various methods of administering oxygen and the doctor's prescription will include instructions about the rate of flow, duration of therapy and type of equipment to be used. The nurse must monitor the administration of oxygen and observe the patient for complications. (Ch. 3 gives a more detailed account of the administration of oxygen and mechanical ventilation.)

Nursing and physiotherapy

The prevention of respiratory complications is a priority in the nursing management of the unconscious patient, but infection may occur despite every precaution being taken. Antibiotics can be effective against organisms but the patient could drown in their own purulent secretions unless these are removed. Effective respiratory management is dependent on the skill and cooperation of the nurse and physiotherapist.

Communicating

The patient

Research undertaken by Podurgiel (1990), albeit with small numbers, explored patients' experiences and recollections of impaired consciousness (see Research Abstract 28.1). There is much anecdotal evidence of patients recalling, with startling accuracy, conversations they have overheard whilst unconscious. It can be concluded therefore that conversations not intended for the patient should not be held in their presence, as unguarded or misinterpreted expressions can cause distress.

It is imperative that the nurse explains clearly and simply to the patient every aspect of their care, whether it is related to procedures being carried out, the associated equipment or to the patient's progress. The explanations and reassurances should be repeated whenever a procedure is carried out. With the advent of ICP monitoring, several studies were undertaken to determine the effects of verbal and physical interactions on ICP (Treloar et al 1991, Chudley 1994). Some interactions were shown to cause a rise in ICP, some a decrease and some no change. However, authors of such studies advocated a need for further research.

Once the patient has come through the acute phase of the illness, recovery may be helped through the use of sensory stimulation. For example, common smells, distinctive flavours, soft or harsh fabrics, visual stimuli and certain sounds, such as favourite music, may be used.

The family and others significant to the patient

Relatives and other visitors may be bewildered and frightened when they see the unconscious patient, together with the associated equipment, particularly for the first time. Time should be spent with them before they see the patient in order to explain what is happening and what the patient looks like. A brief explanation of the immediate environment and the function of any equipment should be provided. Relatives and others significant to the patient should be encouraged to speak to and touch the patient. The family should be given an opportunity to ask any questions and to speak with the doctor and nurse in charge about the patient's progress. Many misconceptions about coma

RESEARCH ABSTRACT 28.1

The unconscious experience

A small pilot study was carried out in the USA (Podurgiel 1990) involving patients who had been unconscious and returned to consciousness and nurses who had talked to such patients. The study describes how people consistently reported on four particular states:

- near-death — at peace, leaving the body, seeing a light, returning to life
- unconsciousness — no perception of external environment
- semi-consciousness — aware of external and own internal environment but unable to communicate
- dreams and nightmares.

There appeared to be movement back and forth between these states, rather than progressive stages, and patients were able to respond emotionally to what was happening to them. Warm, caring, personal contacts were noted as positive. Some procedures and negative statements the patients overheard had a more detrimental effect.

Podurgiel M 1990 The unconscious experience: a pilot study. Journal of Neuroscience Nursing 22(1): 52–53

have developed, particularly through the media. The nurse should therefore explore the relatives' or significant others' understanding of the patient's condition and try to correct any misconceptions.

28.3 Can you think of any of these misconceptions? How might you correct them?

For further information, see Johnson & Roberts (1996) and Hemingway & McAndrew (1998).

Rest and sleep

Providing adequate rest and sleep for a patient is one of the most difficult challenges confronting the nurse, and it is doubtful whether it is ever overcome, given the associated hospital background noise. (More information on sleep can be found in Ch. 25.)

It must be borne in mind that, in the unconscious patient, the RAS, the system that is normally responsible for the sleep/waking cycle, is impaired. Therefore it could be assumed that a normal sleep/waking pattern is not possible in the unconscious patient. However, patients whose level of consciousness fluctuates may experience periods of sleep and periods of wakefulness even though they may not be responsive to external stimuli. Podurgiel (1990) reported that some patients recalled dreams and nightmares (see Research Abstract 28.1). As noted earlier in this chapter, patients in vegetative states also exhibit sleep/waking cycles.

Treloar et al (1991), Chudley (1994) and Hickey (2002) mention the need to provide rest periods for patients between nursing and other activities. However, there does not appear to be any conclusive evidence in the literature about the need for sleep and rest in the patient with an altered level of consciousness. Nurses should consider this potential need when planning care. It could be detrimental to patients to be stimulated constantly by nurses undertaking frequent observations and procedures, along with other members of staff who are attending to the patient.

Eating and drinking

The unconscious patient will be unable to eat or drink in the normal way and will need to receive nourishment and fluids by an alternative method. An adequate fluid intake helps to prevent dehydration, which can cause drying and thickening of secretions, making suctioning difficult and creating a breeding ground for bacteria.

In any very stressful situation, whether physical or emotional, calorie intake may need to be increased to meet an increased metabolic rate. For example, a severely head-injured patient may require 30–35% additional calories/day in the acute stages (Segaran & Glynn 2002).

Fluids

The most common method of administering fluids to an unconscious patient is intravenously, either peripherally or via a central line. Intravenous (i.v.) fluids are also given to:

- administer medications, such as antibiotics
- administer additional electrolytes, such as potassium, to correct imbalances.

Intravenous fluids are normally prescribed by medical staff, following estimation of the patient's serum electrolyte levels, which are measured on a daily basis. Fluids are usually prescribed for the following 24 h; however, in seriously ill patients, prescriptions may be adjusted more frequently. It is essential that the correct fluids are administered at the prescribed rate to maintain fluid balance and metabolic needs. Fluids may be restricted if cerebral oedema is suspected (see Ch. 9).

The patient may also have an arterial line, which looks very similar to an i.v. cannula and could easily be mistaken for one. An arterial line must be clearly identified and multiple lines and ports can be labelled with different colours to distinguish them.

An infusion pump will be used to ensure accurate flow rates in the seriously ill patient (see Chs 20 and 21 for more information).

Nutrition

Provision of adequate nutrition is important in the unconscious patient. Malnourishment will result in weakening of the body's immune system and loss of muscle mass and energy, both of which are essential for recovery. The patient's nutritional status must be reappraised at regular intervals.

Daily nutritional requirements are usually calculated on the basis of body weight, gender, height and age. However, weight may need to be an estimation as it may not be possible to weigh the unconscious patient, unless a bed with an integral weighing scale is available.

Nasogastric feeding The easiest and most economical way to provide an alternative means of feeding is via a nasogastric tube. Nasogastric tube feeding is the most frequently used method of providing nutritional support in the unconscious patient, provided that the patient's alimentary tract is functional. With the help and advice of the dietitian, the patient's nutritional requirements should be assessed and the appropriate dietary solutions prescribed.

Occasionally, it may be necessary to use an orogastric instead of a nasogastric tube, e.g. if the patient has a nasal injury, CSF rhinorrhoea or blockage of the nose.

Care must be taken when inserting an intragastric tube via the nose or mouth of an unconscious patient as insertion is more difficult if the patient is unable to sit up or cooperate. There is also a higher risk of aspiration of stomach contents into the trachea and lungs if the patient is in the lateral recumbent position. The patient must be observed carefully for any sign of aspiration which will compromise respiration. Suction equipment must be at hand and ready for use at all times.

Parenteral nutrition

Parenteral feeding is delivered either through a central venous line or a peripherally inserted central line (PIC line) (see Ch. 21). Unconscious patients who may benefit from parenteral nutrition include:

- multiple trauma patients, particularly if there are gastrointestinal and/or facial injuries
- malnourished patients

- patients with sepsis or multisystem failure
- patients with inflammatory bowel disease which is extensive and life threatening
- patients in prolonged coma who are unable to tolerate intragastric feeding.

Percutaneous endoscopic gastrostomy feeding

Whenever possible, it is preferable to deliver food directly into the gut to prevent the risk of translocation of bacteria from the unused gut. Long-term feeding is better achieved by using a percutaneous endoscopic gastrostomy (PEG) tube. This is easier to manage than intragastric or parenteral feeding and relatives/carers can be taught how to administer feeds through the tube. PEG tubes are particularly useful if the patient is later cared for at home.

When the patient recovers consciousness, it is essential to ensure that gag, cough and swallowing reflexes are present before giving oral fluids or food. The speech and language therapist (SALT) may assess the patient for any swallowing difficulties. (For further information on enteral feeding and parenteral nutrition, see Ch. 21.)

Elimination

The normal means of elimination of urine and faeces are altered by confinement to bed, and the ability of the patient to control elimination is impaired due to their altered level of consciousness.

The unconscious patient will not be able to indicate when they need to pass urine or defaecate, although they may become restless. Despite the acknowledged dangers of urinary tract infection and urinary calculi, if the patient is unconscious, early catheterisation will be required. This helps to retain the patient's dignity, avoid the embarrassment of incontinence and prevent skin breakdown. Catheterisation will be undertaken on admission if an accurate measurement of urinary output is required (Cioffi 2000, McArthur-Rouse 2001). A closed urine collection system helps to reduce the risk of infection. Local protocols should be followed with regard to catheter care (see Ch. 8).

Once the initial acute period is over and the patient is stabilised, many male patients will be able to manage with external penile collection devices such as uri-sheaths. There is no ready solution for the management of defaecation. The patient's bowel movements should be monitored, particularly if being tube fed. Hospital protocols should be followed for the prevention and management of constipation and diarrhoea (DH 2001). If necessary, prophylactic stool softeners may be administered in order to produce a regular stool. It is important for the patient to avoid straining to defaecate as this will raise intracranial pressure.

Personal cleansing and dressing

The unconscious patient is dependent upon the nurse to attend to all aspects of personal cleansing and dressing, but still has the right to have these procedures performed in privacy. This is especially important when performing intimate procedures such as the provision of personal hygiene in the menstruating female or in giving urinary catheter care.

Bathing in bed is necessary for any totally dependent patient, but when turning the unconscious patient there is a danger that the airway may become compromised and the patient's chest movement may be impeded. To avoid this, turning should be planned and requires a minimum of two nurses to execute it safely. If a mechanical hoist is available, the patient can be bathed using this. Bathing, hair and nail care should all be performed as often as necessary. Hair washing may be difficult and, if the use of a wet shampoo is impossible, a dry shampoo may be used. Nails should be kept short and clean. Male patients may require a daily facial shave and an electric razor is recommended. If the patient has a moustache/beard, this should be trimmed as necessary.

As unconscious patients do not blink, the corneas become dry; in some unconscious patients, the eyelids may remain open. Eye care is therefore carried out on a regular basis to prevent damage to the cornea.

The eye and surrounding area are cleaned with sterile normal saline, followed by the instillation of artificial tear drops. If the patient's eyelids do not close naturally, tape may be applied. If tape is used, the delicate skin of the eyelid must be observed closely for excoriation. This can be minimised by using hypoallergenic tape and regularly altering the position of the tape. Alternatively, the eyes could be protected by gauze pads, eye shields or eye patches. If the area around the eyes is swollen or bruised, ice packs or compresses may be used. Local protocol should be followed.

Oral hygiene should be maintained following initial and ongoing assessment of the individual patient (Turner 1996, DH 2001) (see also Ch. 15). A number of authors note that mouth care tends to be based on traditional and ritualistic practices rather than being scientifically or research based (Moore 1995, Holmes 1996, Pearson 1996). These authors and others note that evidence suggests that a toothbrush is the most effective tool, whereas foam sticks tend to be popular amongst nurses for cleaning a patient's mouth (Buglass 1995).

The unconscious patient who has an artificial airway or endotracheal tube in place may present with particular problems such as a dry mouth and difficult access to the oral cavity.

When possible, the use of a small, soft toothbrush to clean the teeth, tongue and gums with a small amount of fluoride toothpaste and plain water will be of benefit. Many oral care products are available; for example, chlorhexidine gluconate 0.2% 5 mL in 100 mL has an antimicrobial effect and can help to remove debris, tenacious mucus and reduce plaque formation (Buglass 1995). Petroleum jelly may be used to prevent dry lips, although there appears to be no research evidence as to its effectiveness (Holmes 1996, Turner 1996). Dentures can be stored dry, after being cleaned, and should be cleaned again and rinsed in cold water before reinsertion. Some nurses may prefer to store a patient's dentures in water or a proprietary denture solution, particularly if relatives request this. Dentures should be stored in a covered container that is labelled with the patient's name and hospital number. Local protocols should be followed.

The *Essence of Care* initiatives (DH 2001), developed from the commitment made in the *Making a Difference* document

(DH 1999), highlighted the need for further research to improve standards and practice for a patient's personal and oral hygiene requirements. The guidance is to address this through local initiatives.

Maintaining a safe environment

The unconscious patient is physically vulnerable to many threats, such as pressure ulcers and infection, and nursing staff must always be alert to the need to maintain a safe environment.

Prevention of pressure ulcers

The prevention of pressure ulcers is important for the comfort of the patient and is good practice. Regular alteration of the patient's position and relief of pressure are paramount, particularly in the unconscious patient, who may be immobile (see Ch. 23).

28.4 Apart from direct pressure on the skin, what other factors can contribute to the development of pressure ulcers? Can you think of any additional hazards that may lead to tissue damage in the unconscious patient?

Infection

The unconscious patient is particularly at risk of infection occurring in the chest and bladder. Wounds and drains, e.g. external ventricular drains, are also potential sites for infection. Gram-negative bacillary pneumonia causes 40–60% of respiratory infections that are acquired in institutionalised settings (see www.mold-help.org/pulmonary infections). Most people are resistant to this organism, which is constantly present in the environment, but certain factors contribute to the breaking down of physiological and immunological defences. The unconscious patient is exposed to many of these, including endotracheal intubation and the presence of invasive lines such as i.v. cannulae and urinary catheters. Antibiotic-resistant infections have become a problem in many hospitals. For example, methicillin-resistant *Staphylococcus aureus* (MRSA) is a potentially life-threatening organism, particularly in vulnerable patients. In areas where patients are at high risk of acquiring MRSA, routine screening of staff will be determined by local policy (Mackenzie 1997, Royal College of Nursing 2004a) (see also Ch. 16, p. 663).

The mechanism of infection Infection will occur if a sufficient number of microbes reach the lower respiratory tract or urinary bladder. The likelihood of infection occurring depends on the virulence of the organism, the susceptibility of the patient, the cleanliness of the environment and the hygiene of other people in contact with the patient. Ironically, the original source of the Gram-negative bacilli is often the patient themselves. Infection can spread from the digestive tract, its usual and commensal location, into the lungs or bladder. Endotracheal or tracheostomy tubes, which bypass the normal protective mechanism of the nose, encourage the spread of infection, and a depressed cough reflex enables pooling of secretions within the lungs, resulting in stasis. Urinary catheterisation provides a ready entry route for bacteria to the bladder. Preventive measures, in which the nurse plays a major role, include:

- unit design, e.g. facilities for hand washing, facilities for cleaning and disposal of equipment, provision of single/isolation rooms
- a control-of-infection policy which is meticulously followed
- aseptic techniques.

The nurse needs to be aware of and conscientious about implementing standard infection control precautions and local policies with regard to prevention and treatment of infection (see Ch. 16). Hand washing is acknowledged to be the single most effective intervention to promote infection control in the clinical setting (Voss & Widmer 1997, Royal College of Nursing 2004b).

Medication

The hazards of administering medication to patients are well documented, but the risks are increased in the unconscious patient for two reasons:

- The routes that are used carry a greater risk for the patient. The simpler and safer oral route is contraindicated. Other methods of administration have to be utilised, including i.m. injections, i.v. infusions, via an intragastric tube and per rectum.
- The patient cannot confirm their identity, so the nurse must ensure that the correct medication is being given to the correct patient via the correct route and in the correct dose.

The types of medication most commonly used in the unconscious patient include analgesics, anticonvulsants, antibiotics and laxatives, depending upon their condition and individual requirements.

Motor and sensory loss or impairment

The motor and sensory loss experienced by unconscious patients may be drug induced or part of the underlying disease process. Whatever the cause, the nursing intervention remains the same.

Motor loss See 'Mobility' below.

Sensory loss The sensory system is part of the body's defence system and the unconscious patient is unable to process sensory information. It is imperative that the patient is not exposed to extremes of temperature, particularly in a localised area of the skin, e.g. if heating or cooling devices are used.

Care must be taken when moving and positioning the patient as they will not be aware of friction or pressure. The patient may have a reduced or absent sensation of pain or, if experiencing pain, may be unable to communicate that feeling.

Seizure

The main role of the nurse (or onlooker) when the unconscious patient, or indeed anyone, has a seizure is to ensure that the patient does not harm themselves. First aid, as recommended by Epilepsy Action (British Epilepsy

Box 28.4

First aid for seizures

What to do when someone has a seizure
With some seizure types very little first aid may be needed. For example, in a partial seizure, guiding someone away from danger may be all that is necessary.

DO ...
- Protect the person from injury — move any sharp or hard objects. Guide the person away from danger if they are having a partial seizure.
- Cushion the person's head if they fall down.
- When the convulsive part of the seizure is at an end, place the person in the recovery position. This will help their breathing.
- Be quietly reassuring.
- Stay with the person until they have regained full consciousness.
- Go over any missed events.

DO NOT ...
- Try to restrain the person having the seizure.
- Put anything into the person's mouth or force anything between the teeth.
- Try to move the person unless they are in danger.
- Give the person anything to drink until they have fully regained consciousness.

It is not usually necessary to call for an ambulance when someone has an epileptic seizure. However, it may be necessary in the following circumstances unless a doctor can attend straight away.

Call for an ambulance if ...
- It is the person's first seizure, the cause of which is uncertain and needs investigation.
- Injuries have occurred during the seizure, e.g. a cut that needs stitching.
- A generalised seizure shows no signs of stopping after 5 min or 2 min longer than is usual for that person.
- A second seizure occurs without the person regaining consciousness.

Status epilepticus
A prolonged seizure or series of seizures without regaining consciousness is called 'status epilepticus' and is a medical emergency.

Lack of normal respiratory movements combined with extreme muscular contractions during a seizure throws stress on the cardiovascular system. The continuing lack of oxygen may lead eventually to brain damage.

Status epilepticus is usually convulsive, but sometimes it can be non-convulsive, i.e. absence or complex partial status. This will need intervention, although the urgency is not as great. Status epilepticus is a rare occurrence, except in a very few patients with difficult to control epilepsy.

When status epilepticus occurs, a doctor will usually give an intravenous injection of diazepam at the scene of the seizure or in hospital. Other intravenous compounds may be used as an alternative.

Diazepam can now also be given in the form of a rectal application. It can be administered by a trained, competent and willing individual, who has received permission from the person or the parents of the person with epilepsy.
It is reassuring for some parents to feel they can use this treatment at home. Ultimately it is safer and quicker in an emergency situation and allows the person with epilepsy to lead a broader lifestyle and participate in a wider range of activities.

(The above is based on the availability and use of diazepam in the UK — practice in other countries may vary.)

Reproduced with kind permission from Epilepsy Action, from which further information on seizures can be obtained (see 'Useful websites').

Association) (see 'Useful websites'), for someone having a seizure is outlined in Box 28.4. Further information about epilepsy can be found in Chapter 9.

Mobility

The nursing management of mobility and activity remains the same, whatever the cause of the unconsciousness. Lack of attention to mobility could lead to the development of:

- contractures
- muscle atrophy
- pressure ulcers
- postural hypotension
- deep vein thrombosis
- hypostatic pneumonia.

Any one of these hazards will delay the patient's rehabilitation and result in additional pain and discomfort.

Whilst the patient remains dependent, the nurse is responsible, together with the physiotherapist, for ensuring that the patient maintains a full range of movement.

Correct positioning is important and the following should be considered:

- body alignment, especially if spinal injury is suspected
- use of aids such as pillows, foam pads or splints, if required, to help to support the patient
- avoidance of pressure, e.g. an arm trapped under the body, the pinna of the ear bent forward, bedclothes too tight
- avoidance of friction when moving the patient
- changing the patient's position; this should be done frequently — at least every 2 h is recommended
- careful handling of joints and paralysed or weak limbs
- safety — e.g. if the patient is restless, padded bed rails may be required.

Safety/restraint

Some patients experience confusion and can become aggressive as they recover consciousness and many patients in critical care environments may undergo changes to their normal behaviour. This may be due to their underlying

illness and pathology, medication, sensory deprivation or the unfamiliar environment. Health care teams face difficult decisions about identifying strategies to prevent the patient inadvertently dislodging tracheostomy tubes, invasive lines or dressings. Providing diversional therapy, involving the patient's family and friends or providing one-to-one nursing supervision may distract the patient. Balancing the best interests of the patient to ensure safety and promoting the patient's well-being may be difficult, but it is the responsibility of all nurses who must adhere to their *Code of Professional Conduct* (Nursing and Midwifery Council 2004). When all other alternative therapies have failed, and only as a last resort, short-term restraint may be necessary, following communication and discussion with the patient and their relatives (Department of Health and Welsh Office 1999, DH 2001, Royal College of Nursing 2004c). The Mental Health Act, article 5, relating to restraint, was amended in 2004.

Recovery from coma

A multidisciplinary approach is essential to facilitate early mobilisation of the patient. Patients who have been nursed in bed for just a few days often experience dizziness and light-headedness due to postural hypotension when they sit up for the first time.

28.5 What are the causes of postural (orthostatic) hypotension?

The patient recovering from coma may also have some motor weakness and sensory loss, which makes them feel insecure. Many units now have adjustable or electronically operated beds that will enable the patient to adopt a more natural sitting position in bed. This will help the patient to get used to the position and will give them a psychological boost.

On first raising the patient to a sitting position, the nurse should check the patient's vital signs and colour, and ask whether they are experiencing any untoward symptoms. If they are, the mobility programme should be implemented at a slower rate.

Initially, the patient may be unsure and apprehensive about the prospect of getting out of bed. Repeated explanations of what is expected of them will provide the necessary reassurance. The patient may need to practise sitting on the side of the bed whilst the nurse and physiotherapist assess balance and head and trunk control. If there are no ill-effects, the patient can progress to sitting out of bed for a short period. The nurse should continue to observe the patient's colour and vital signs. If the patient's status is not compromised, the length of time and frequency of sitting out of bed can be increased gradually. Highly dependent patients with motor loss or impairment may require a specialist chair that will provide additional support and security. The physiotherapist will normally carry out an assessment of the patient prior to provision of this equipment.

Once in the chair, anything which the patient is able to use, such as a call bell, drinks, radio or newspapers, should be readily available to them. The amount of time that the patient is up in the chair should be noted; it is more beneficial for the patient to sit up for several short intervals rather than for one long period (see Ch. 34).

An individualised mobility rehabilitation programme should be devised in conjunction with the physiotherapist.

Controlling body temperature

Body temperature must be maintained within a relatively constant range to sustain life, i.e. 36–37.5°C. It is controlled by the heat-regulating centre in the hypothalamus, which acts like a thermostat (see Ch. 22). Pyrexia, an abnormally high temperature, is more commonly seen in the unconscious patient than is hypothermia, an abnormally low temperature, although hypothermia may be the primary cause of unconsciousness (see Ch. 22).

Pyrexia may be due to damage to the heat-regulating centre in the hypothalamus or to an infective process or metabolic disorder. The danger is that, for each degree of temperature over the normal range, the cerebral metabolism significantly increases, adversely increasing the brain's oxygen demands, which may have serious implications for recovery.

The nursing interventions remain similar, irrespective of the cause of pyrexia. In the acute stages it is important to monitor the patient's temperature continually with an electronic probe, sited over the patient's skin, rectally or into the patient's bladder. The use of mercury-in-glass thermometers is now contraindicated for health and safety reasons.

Dying

Skilled care of the unconscious patient often saves life, but some patients will die despite all measures taken. Active treatment may have been continued right up until the last moment or it may have been decided that no further active intervention would benefit the patient. The emphasis would then move from curative to palliative care. If the patient is on a mechanical ventilator it may be that they fulfil the criteria required for assessing brain stem death.

Brain stem death

Some patients in apnoeic coma can suffer severe and irreversible brain damage but continue to have their blood pressure, heart beat and respirations artificially maintained for a period of time by ventilation, drug therapy and other life support interventions. Some, however, will never recover and the brain stem death criteria have been developed to identify such patients, in order that therapy can cease.

Brain stem death may be clinically diagnosed by following a set of guidelines issued by the Working Group of the Conference of Medical Royal Colleges and their Faculties (1976, with revisions in 1979) and according to the concept of death endorsed by the Working Group of the Royal College of Physicians in 1995. These guidelines consist of a number of tests that can be applied only after a series of preconditions have been fulfilled (see Fig. 28.9).

Preconditions include positively diagnosed structural brain damage that is irremediable and that the patient is unresponsive and on a ventilator. The examiners, both doctors, must satisfy themselves that any reversible causes of coma have been eliminated, including:

- drug intoxication, e.g. as the result of an overdose or the administration of a neuromuscular blocking agent to facilitate passage of an endotracheal tube
- primary hypothermia

Diagnosis to be made by two doctors, one a Consultant and the other a Consultant or Specialist Registrar.

Diagnosis should not be considered until at least 6 hours after the onset of Coma; 12-24 hours will be more usual.

NAME: ..... UNIT NO. .....

PRE-CONDITIONS

Time of event leading to coma

Nature of irremediable brain damage

Dr A ....

- metabolic or endocrine imbalances such as uncontrolled diabetes.

Testing brain stem function Once satisfied that the preconditions have been fulfilled, testing of brain stem function can be performed. Two doctors should carry out the tests. Usually one is the consultant responsible for the patient and the other is of at least senior registrar status. If organ donation from the patient is being considered, neither doctor must be a member of the transplant team. The doctors may carry out the tests separately or together. There are six parts to the test:

1. The pupillary response to light is tested, using a bright torch. Absence of response indicates loss of function, although the examiner should be satisfied that a non-responsive pupil is not due to the instillation of paralytic eye drops or damage to cranial nerve III.
2. The integrity of the corneal reflex is tested by drawing a wisp of cotton wool across the exposed cornea. Absence of a blink response indicates loss of function, although the examiner should be satisfied that the presence of corneal oedema is not preventing the normal blink response.
3. Cranial nerve motor responses are tested at several sites, including the head and face, in case the patient has a cervical cord injury. Again, no response indicates loss of function, although spinal reflexes can remain intact even in a brain-dead patient (Pallis & Harley 1996).

4. The cough and gag reflexes are tested by moving the endotracheal tube back and forth or by applying suction and observing the patient's throat muscles for movement. No response would indicate loss of the pharyngeal and laryngeal reflexes.
5. Absence of the oculovestibular reflex rules out the existence of normally functioning anatomical pathways within the brain stem and is a very sensitive test of brain stem function. It is tested by syringing 20 mL of ice-cold water into the patient's ears in turn and noting any eye movement in response. This is called 'cold caloric testing'. Before testing, the examiner should use an auriscope to look directly at the tympanic membrane to ensure that it is intact and that there is no obstruction preventing the water from making contact with the membrane.
6. The final test is that for apnoea. Arterial blood gases are checked and P_aCO_2 should be 5.33–6.00 kPa (40–45 mmHg). The patient is disconnected from the ventilator after providing a continuous flow of 100% intratracheal oxygen for 10 min. The patient's chest wall is observed closely for any respiratory movement and the P_aCO_2 is allowed to rise above threshold level to stimulate breathing, usually to at least 6.65 kPa (50 mmHg). The time taken to achieve this will vary, but is no more than 10 min for most patients.

The ventilator is then reconnected and the entire process is repeated after a minimum time lapse of 30 min (in practice, usually 24 h) before the patient is declared brain dead. Although the second set of tests is not required by law, for medicolegal purposes the completion of the second testing determines the time of death. After consultation with the relatives, the patient is normally disconnected from the ventilator by medical staff.

In some countries, further neurophysiological tests are recommended, such as electroencephalography, evoked cerebral potentials and cerebral perfusion, to confirm the clinical diagnosis (Haupt & Rudolf 1999).

Previously, it may have been indicated that the patient wished to donate organs and/or tissues for transplantation. If the next of kin is in agreement, following the usual preliminary procedures and consultation with the hospital administrator and local coroner, the patient would remain ventilated until the organs were removed (Great Britain Parliament 1961, amended 1989, United Kingdom Parliament 2004). The doctor or transplant coordinator must obtain permission from the patient's next of kin before taking organs and tissues. The transplant coordinator will offer counselling to the patient's relatives and/or those who have a significant relationship with the patient.

For further information on brain stem death, see Pallis & Harley (1996); on issues in organ donation and transplants, see www.uktransplant.org.uk; on organ shortage, see Meeting the Organ Shortage (1999); and on organ transplantation, see NHB Organ Transplantation (www.nap.edu).

28.6 Discuss with your lecturer and mentor the ethical and legal implications in procuring organs/tissues for transplant or medical research.

Physical and psychological care

The patient The principles of care for the dying unconscious patient are the same as those for all patients requiring palliative care (see Ch. 33). The unconscious patient must be treated with dignity and sensitivity even though they are unable to respond.

The family A sensitive and coherent strategy for caring for the relatives is needed. The nurse should know what information has been given to the relatives by other members of staff, including doctors. This will enable the nurse to reaffirm what has been said and avoid confusing the family members at a time when their ability to process information is drastically reduced. They need to see and feel that the patient, even if unconscious and unresponsive, is still being treated as a person, through the humane, caring attitude of the nurse (Sque et al 2003).

Some relatives may be helped by being encouraged to perform simple acts of care for the patient such as bathing them or, providing their head is not shaved or bandaged, combing their hair. This reduces their feelings of passivity and helplessness in the strange, alien world of the hospital and in a situation in which they are unlikely to be able to draw on previous experience.

Psychologically, this is a traumatic and emotionally distressing period for the patient's family, friends and/or those who have a significant relationship with the patient. They have perhaps spent the last few days (and in some cases, much longer than that) with the patient, in the unfamiliar technical surroundings. They may be relieved that an ending has been achieved or may find it difficult to accept the death, particularly if the patient has been artificially ventilated.

The support of a religious advisor may be appreciated. The nurse can contact the hospital chaplain/religious advisors if the relatives need assistance with this, or if the patient has previously spoken of it. Bereavement counselling and support should be offered as well as practical information (preferably written) about registering the death and other formalities.

CONCLUSION

Inevitably, this chapter has focused on the care of unconscious people in hospital because, at the present time, only a small minority is cared for at home. This may change in the future, at least to some extent, as new technology is developed. Where the outcome is death, some families may cope more easily with the stress and sadness in the familiar surroundings of the home. Wherever the location of care, it is important for nurses to be sensitive to the fundamental changes the unconscious patient has wrought in the lives of those who know them as a responsive human being. Not only is the patient totally reliant upon the nurse, but the family and/or carers also require a great deal of support.

As noted at the outset of this chapter, caring for the unconscious person is a major challenge for nurses. Whatever the outcome, be it death, permanent disability or complete recovery, meticulous attention to nursing observations and care is vital.

NOTE

The Neuroscience Nurses' Benchmarking Group (NNBG)
The NNBG was established in 1995. It consists of nurses from a number of neuroscience units in the UK and Eire, and membership is open to any neuroscience nurse who is interested. The group meets every few months to share ideas and information. A benchmarking system is used 'to identify and achieve continual improvement in best nursing practice'. Literature reviews, research and evidence-based practice are discussed to reach a consensus between the members on best practice relating to a specific aspect of nursing. The specific nursing activity is then 'tested' against the benchmark in the nurses' own areas of practice and comparisons made at the next meeting. The benchmarks are not static and are reviewed in the light of changing practice and updated as necessary. Further information about the NNBG and its benchmarks can be found on the British Association of Neuroscience Nurses website (see 'Useful websites', below).

INTRODUCTION

The term 'critically ill' is used to describe people who have acute, life-threatening conditions but who might recover if they are given prompt, appropriate, effective and often highly technical nursing and medical care. Critically ill patients, the conditions from which they suffer and the care and treatment they need are so varied that elements from every chapter in this book are relevant to their care.

Patients who present in a critically ill state can be considered in three main categories:

- those who have never before had a significant illness and who have suffered a sudden, acute life-threatening event, e.g. extensive trauma, severe burns, near drowning, major childbirth complications or deliberate self-harm
- those who suffer from chronic illness, perhaps involving frequent previous hospital admissions, e.g. chronic obstructive airways disease (COAD) or chronic pancreatitis, and who present as critically ill as a combination of their chronic illness with a life-threatening event
- those who have become critically ill as a result of surgery — in some cases, the life-threatening situation is not expected, while in others, postoperative intensive care is a recognised necessity.

Increasingly, the major health issues and inequalities in our society will be underlying factors, with varying degrees of significance in the presentation of the critically ill patient, e.g. drug, alcohol and other substance abuse or dependence, smoking, poor dietary habits, lack of exercise and mental health concerns. Because most of these patients will be nursed in specialised units, such as an intensive care unit (ICU), their treatment and nursing care will be viewed primarily within that context. Criteria for admission to an ICU vary from hospital to hospital, but in most general ICU settings the main admission criteria are the patient's respiratory status and its maintenance. Intensive care has been defined as 'a service for patients with potentially recoverable diseases who can benefit from more detailed observation and treatment than is generally available in the standard wards' (Spiby 1989). In some hospitals there now exist critical care outreach teams. This new and steadily

growing service can address the need for early intervention at ward level and may avert the need for admission to ICU, and can also follow up patients discharged from ICU (Odell et al 2002). However, where admission to ICU is necessary, duration of stay will vary greatly, from the overnight ventilatory support that may be required postoperatively, to months of intensive therapy vital to such as multiple trauma victims. In recent years there has been considerable progress in the management of many acute life-threatening conditions and consequently there has been a substantial growth in both the number and size of such units.

The nursing care of the critically ill patient is an extensive area of care and one that will not be covered fully in this chapter. It is therefore expected that those interested in this field will refer both to relevant chapters within this textbook and to more specialised texts and journals.

The Mead model for nursing

The primary responsibility of the nurse in the ICU setting is to provide care to patients with life-threatening illnesses who require continuous monitoring and life support, embracing a holistic approach. Any model used to guide intensive care nursing must therefore be flexible and allow for creativity. This chapter introduces the model for nursing developed by staff at St Thomas' Hospital, London (Mead ward), which was devised specifically to guide the nursing care of critically ill patients. Although developed two decades ago, the Mead model for nursing is still in use in a large number of ICUs. Adapted from Roper et al's (1996) activities of living (AL) model, the Mead model places the patient at the centre of all activities. Those factors which influence the ALs are given a higher profile and are used as a framework for care. Unlike Roper et al's model, the Mead model places explicit emphasis on the physical aspects of critical care nursing, such as the status of the respiratory, cardiovascular, neurological and other body systems. Generally, it is these physical needs that must take priority, often reflecting the patient's reason for admission. However, the Mead model also addresses the important contextual factors that can affect the patient, their care and the eventual outcome of that care (see Nursing Care Plan 29.1).

Nursing Care Plan 29.1 The Mead model

Name: Mr H **DOB**: 10/12/30 **Date**: 24/05/06

DIAGNOSIS: Repair of abdominal aortic aneurysm (AAA), ischaemic heart disease, peripheral vascular disease, respiratory failure, acute renal impairment

24 HOUR SUMMARY

Second day postop following AAA repair: respiratory function improving, continues on dopamine for renal impairment

Assessment	Day/night	Goals and planned care
RESPIRATORY SIMV: 10 × 700, ASB: 20, PEEP: 5, F_iO_2: 0.6 S_aO_2: 95–97%, RR: 15–20 Air entry R=L, quiet bases Minimal obtained on tracheal suction ABGs: PO_2 9.6, PCO_2 6.2		*Goal*: To optimise gaseous exchange and tissue perfusion *Plan*: Continue with ventilatory support; assist with physiotherapy and the clearance of secretions; position for optimal lung expansion; repeat ABGs
CARDIOVASCULAR HR: 95–110, irregular with ventricular ectopics BP: 180/95–210/100 Temperature: 37.5–38°C K+: 4.3, Hb: 8.9 Peripherally cool, feet mottled with pedal pulses present		*Goal*: To promote and maintain cardiovascular stability *Plan*: Monitor vital signs hourly, reporting any abnormalities; control hypertension with GTN infusion; transfuse with 2 units of RCC; continue with antibiotic therapy; monitor K+, 12-lead ECG
RENAL Hourly urine output: 25–55 mL/h CVP: +12–14 cm Maintenance fluid running at 30 mL/h + previous hour's urine output, slight peripheral oedema Urea: 12.5, Creatinine: 210 Dopamine infusion: 4 mg/mL, at 3 mL/h		*Goal*: To optimise renal function and maintain adequate hydration *Plan*: Record hourly urine output; continue with dopamine infusion at 3 mL/h; monitor urea and electrolytes; involve renal physicians if necessary; continue with maintenance fluids as prescribed
NEUROLOGICAL GCS: 9, PEARL, size 3 Sedated on midazolam 2 mL/h (1 mg/mL) Morphine at 3 mL/h (1 mg/mL) Pain score: 0–1 Sedation score: 3		*Goal*: To maintain neurological integrity and maintain pain-free *Plan*: Assess neurological status at regular intervals; monitor sedation and pain scores hourly; continue with sedation and analgesia as is

Continued ▶

Nursing Care Plan 29.1 The Mead model *(Continued)*

NUTRITION/GI 4-hourly NG aspirates minimal, on free drainage 50–85 mL/h bile-coloured fluid, no bowel sounds present, blood sugars: 6–12 mmol/L, i.v. antacid prescribed BD, no bowel movements	*Goal*: To optimise nutritional support and maintain GI integrity *Plan*: Aspirate NG tube 4-hourly; discuss on ward round about commencing enteral feeding as per protocol; monitor blood sugars 4–6-hourly, assessing the need for insulin therapy
HYGIENE/MOBILITY/WOUND CARE Pressure areas intact, feet mottled, especially left big toe, mouth dry due to open mouth breathing, eyes slightly sticky, tolerates side lying, abdominal wound left intact, minimal leakage	*Goal*: To promote and maintain personal hygiene and maintain skin integrity *Plan*: Give all care as required; assess pressure area score daily; assess wound and re-dress as per wound care protocol
PSYCHOSOCIAL Mr H appears to be a very anxious man. His wife and their two sons and their families keep in close touch and visit on a regular basis	*Goal*: To minimise the stress/anxiety of the ICU environment *Plan*: Offer adequate reassurance and encouragement and explain all procedures prior to them being carried out; keep Mr H's family well informed as to his condition

ABG, arterial blood gases; ASB, assisted spontaneous breathing; CVP, central venous pressure; ECG, electrocardiograph; F_iO_2 inspired oxygen fraction; GCS, Glasgow Coma Scale; GTN, glyceryl trinitrate; HR, heart rate; K+, potassium; NG, nasogastric; PEARL, pupils equal and reacting to light; PEEP, positive end-expiratory pressure; RCC, red cell concentrate; RR, respiratory rate; SIMV, synchronised intermittent mandatory ventilation.

PROGRESS/EVALUATION REPORT

Day: Tuesday	**Time**: 19.30	**Night**	**Time**
Ventilatory settings unchanged; gaseous exchange slightly improved, maintaining S_aO_2 95–97%; spontaneous respiratory effort minimal 2–5 breaths; tracheal secretions now mucopurulent; specimen sent to bacteriology Tolerated manual hyperinflation with physiotherapy HR remains irregular, rate 100–135; BP 180 systolic/90 diastolic; continues on a GTN infusion; remains pyrexial; antibiotics discontinued; WBC up to 12.6 Transfused 2 units of RCC; 12-lead ECG shows AF, started on i.v. digoxin; K+ checked at 16.00: 3.9 Peripheral circulation remains the same; seen by the surgeons who seem content with his progress Urine output: 65–100 mL/h, on dopamine 3 mL/h CVP: + 10 to + 14 cm; remains slightly oedematous peripherally; maintenance fluids as before; urea and creatinine remain elevated; renal physicians to be consulted GCS 9, PEARL size 3; morphine at 3 mL/h and midazolam at 2 mL/h; responds to speech, and will obey commands NG aspirates nil; commenced on enteral feed at 25 mL/h, to continue as per enteral feeding protocol; blood sugars stable; i.v. antacid discontinued; no bowel movements All care given as required; pressure areas intact; abdominal wound left exposed, as no leakage Mr H requires a lot of reassurance Mr H's wife and sons visited this afternoon for a short while; they seemed pleased with his progress			

The aim of using this care plan format is to provide a structured framework for application of the nursing process (assessment, planning, intervention and evaluation) and to document this in such a way as to help others to find out about a patient's individual care easily, without working through less relevant information, much of which is documented elsewhere, e.g. 24-h chart, drug prescription chart. The development of the Mead model for nursing demonstrates that the nurse should be free to select from a model those elements that are appropriate to a specific type of patient care.

For further reading on nursing models in ICU, see Robb (1997).

MEETING THE PHYSICAL NEEDS OF THE CRITICALLY ILL PATIENT

RESPIRATORY NEEDS AND CARE

Intensive care units became established when life could be supported and maintained by means of artificial ventilation and therefore the care of ventilated patients is paramount to intensive care nursing (Woodrow 2001). While many disease processes may lead to the need for mechanical ventilation (see Box 29.1), it is most clearly indicated in the treatment of patients with severe respiratory failure who do not respond to conventional forms of medical treatment. Mechanical ventilation is the artificial support of or assistance with breathing when adequate gaseous exchange and tissue perfusion can no longer be maintained (see Ch. 3). Modern ventilatory equipment and techniques enable therapy to be directed specifically at a wide range of respiratory disorders and can do far more than just maintain vital functions.

Box 29.1

Causes of respiratory failure

Acute respiratory failure without respiratory distress
- Central airway obstruction
- Decreased level of consciousness
  - — head injury
  - — sepsis
  - — drug overdose
- Neuromuscular pathway impairment
  - — Guillain–Barré syndrome
  - — myasthenia gravis
  - — postoperative diaphragmatic paralysis
  - — trauma
- Cardiovascular impairment
  - — acute myocardial infarction
  - — cardiogenic shock

Lung parenchymal disease
- Asthma
- Pneumonia
- Adult respiratory distress syndrome (ARDS)

Acute or chronic respiratory failure
- Exacerbation of chronic obstructive airways disease (COAD)
- Chronic neuromuscular disease

Adapted from Weilitz (1993).

Nursing priorities and management

Goal: to ensure optimal gaseous exchange and tissue perfusion.

Plan:

- monitor and maintain safe ventilatory support
- assist with physiotherapy and the removal of tracheal secretions
- wean from ventilatory support when appropriate.

Monitoring respiratory function and maintaining safe ventilation

It is the nurse's responsibility to understand both normal and abnormal respiratory function, therapeutic modes of ventilation, how to maintain safe ventilatory support and how to respond appropriately to any problems that might occur. Ashworth, in 1990, suggested that advanced technology is only as good as those who use it and Woodrow (2001) states that nursing care should focus on the person rather than the machines.

29.1 Describe the general principles of respiratory physiology.

Ventilators

Consideration of the patient's specific needs and diagnosis will determine the most appropriate mode of ventilation. Positive pressure ventilators are those most commonly used, and the positive pressure, volume-controlled ventilator is that most widely seen in general ICUs. This type of ventilator exerts positive pressure on the airway, delivering a predetermined volume of gas and allowing limits to be set for pressure and time. Specific considerations in the choice of ventilator include:

- the delivery of accurate predetermined oxygen concentrations of 21–100%
- a variety of modes (see Table 29.1)
- the delivery of preset volumes, despite lung characteristic changes
- the facility to monitor respiratory variables
- the appropriate alarm limits with electrical and gas safety features and a back-up system
- minimal circuit resistance allowing effective spontaneous breathing modes
- cost and user-friendliness
- reliable sterilisation and maintenance of the ventilator parts (Berston & Soni 2003)
- the use of heated bacterial filters
- the effective and safe provision of humidification and nebulised drugs.

Modes of ventilation are as follows (see Table 29.1):

- intermittent positive pressure ventilation (IPPV)
- synchronised intermittent mandatory ventilation (SIMV)
- biphasic positive airway pressure (BiPAP)
- assisted spontaneous breathing/pressure support (ASB/PS)

Table 29.1 Modes of mechanical ventilation

Mode	Advantages	Disadvantages	Uses
IPPV — also referred to as volume control, it delivers a preset volume of air at a certain rate regardless of the patient's own attempts to breathe (Berston & Soni 2003)	Complete control over ventilation; improves CO_2 elimination and improves oxygenation	Provides only full ventilation; sedation and/or paralysing agents required for the patient to tolerate it; barotraumas; decreases cardiac output; water retention; atelectasis; reduced lung compliance	Failure of ventilation (e.g. neuromuscular disease) To facilitate CO_2 excretion To reduce cerebral blood flow in patients with cerebral oedema secondary to head injury To reduce the work of breathing in patients with cardiorespiratory failure (Hillman & Bishop 1996)
SIMV — the patient's positive pressure breaths are synchronised with the inspiratory effort. If no inspiration time is sensed, a mandatory breath is delivered at a predetermined interval (Hinds & Watson 1996)	Provides both partial and full ventilation support; minimises mean airway pressure; allows spontaneous unassisted breathing; synchronises positive pressure breaths with the patient's effort (Hillman & Bishop 1996)	General hazards of artificial ventilation	As above, SIMV provides the most therapeutic mode of ventilation
BiPAP is a pressure controlled system similar to CPAP with periods of deflation, can range from full ventilation to pure spontaneous breathing (Hormann et al 1994)	It allows the patient to breathe more comfortably through invasive ventilation conditions, improving lung conditions and reducing damage associated with barotraumas	Initially used only for weaning. Is now recognised as suitable irrespective of the degree of pulmonary failure or underlying disease	Significantly reduces the need for sedatives and can be delivered non-invasively like CPAP
ASB/PS — not found on older models of ventilators, this mode senses each breath and assists breathing with a preset amount of positive pressure	Aids the transition from ventilation support to spontaneous breathing; can be used on its own or in conjunction with ventilator breaths (SIMV mode)	Does not control ventilation	Facilitates weaning Used to encourage spontaneous breathing
PEEP occurs when, instead of allowing airway pressures to reach atmospheric pressure between breaths, an end expiratory pressure is applied, enabling diffusion of more O_2 from the alveoli into the pulmonary capillaries and thus optimising gaseous exchange. Not used on its own (Hillman & Bishop 1996)	Improves oxygenation; recruits alveoli for ventilation	Decreases venous return; decreases cardiac output; can cause pulmonary barotraumas; decreases extrathoracic organ blood; increases the work of breathing; pulmonary overdistension	Patients with ARDS, LVF, pulmonary oedema, atelectasis or profound hypoxaemia may benefit greatly from the addition of some PEEP
CPAP is an option which delivers gas to the airways at a constant pressure, allowing for inspiratory pressure as well as providing PEEP. Can be used on its own	Recruits alveoli; low intrathoracic pressures compared with full ventilation; improves oxygenation; increases lung compliance; decreases the work of breathing; decreases cardiac preload and can be delivered via the ventilator or through a face mask, avoiding the need for intubation	Potentially has the same disadvantages as PEEP and artificial ventilation; however, pressures are lower and so, therefore, are the risks	Used to support spontaneous breathing

ARDS, acute respiratory distress syndrome; ASB/PS, assisted spontaneous breathing/pressure support; BiPAP, biphasic positive airway pressure; CPAP, continuous positive airway pressure; IPPV, intermittent positive pressure ventilation; LVF, left ventricular failure; PEEP, positive end-expiratory pressure; SIMV, synchronised intermittent mandatory ventilation.

- positive end-expiratory pressure (PEEP) — used as an adjunct to IPPV, SIMV and ASB/PS
- continuous positive airway pressure (CPAP).

Weaning modes (in order of decreasing ventilatory support), as indicated above, are:

- SIMV/ASB
- BiPAP
- ASB
- CPAP.

During the weaning phase, patients may alternate between these modes until they are able to cope continually on a reduced mode, ultimately achieving spontaneous breathing.

Assessment of respiratory function

This focuses heavily on physical examination and together with the patient's underlying medical condition, age and weight, will determine the prescribed mode of ventilation. Monitoring and maintaining safe ventilation is crucial and, once the patient is intubated (see Ch. 28) and receiving ventilation support, constant and thorough observations are required as there are many associated complications (see Box 29.2) (Hillman & Bishop 1996, Juniper & Garrard 1997).

Nursing priorities for maintaining safe ventilation

Chest auscultation This should be performed at the start of a shift, as a baseline, and thereafter at the discretion of the nurse. It can offer a wealth of information about the patient's air entry — from an expiratory wheeze requiring treatment with a bronchodilator, to areas of reduced air entry due to secretion retention, consolidation or pulmonary oedema. Using a systematic approach, this can spotlight trouble early and assure appropriate intervention (Cox & McGrath 1999).

Maintaining a patent airway This involves endotracheal suctioning and while it is essential to keep the airway clear of secretions, it is also just as important not to oversuction and thereby cause unnecessary trauma, irritation and hypoxia (Wood 1998, Day et al 2002).

Humidification The oxygen used to ventilate the patient must be warmed, humidified and filtered artificially as the endotracheal tube bypasses the natural processes of the nasal passages. Exposing the lungs and airways to cold gas has a number of potentially harmful effects: it can increase mucus viscosity, depress ciliary activity and obstruct the airways due to the build-up of the tenacious secretions. Temperature-controlled water humidifiers may be used; however, disposable heat moisture exchange filters (HMEF) are now more widely seen, primarily because they are cheaper, disposable and reduce the risk of infection (Beaumont 1998).

Ventilator and endotracheal (ET) tubes The ventilator tubes must not be allowed to become kinked which would reduce the desired respiratory effect. Patient comfort must be balanced with the safe and secure position of the ET tube in the patient's mouth. This is achieved by tying a crepe bandage or non-allergic adhesive tape, to decrease the risk of raised intracranial pressure in the case of a patient with a head injury, around the patient's mouth, in order to prevent movement of the ET tube. Care should be given to the pressure prevention and the position of the ET tube can be changed daily to facilitate this. Ventilator tubes must not be allowed to drag, pulling on the ET tube and thereby applying pressure to the lips. Ventilators usually have an 'arm' which will support the weight of the tubes. It is important that the tubes slope downward from the patient towards water traps, so preventing water from condensation entering the ET tube and the lungs. When turning the patient, care should always be taken to ensure that ET and ventilator tubes are guarded and supported.

Endotracheal cuff pressures These need to be checked regularly using an endotracheal cuff manometer. While cuff pressures of 30 mmHg are recommended, pressures of 17–23 mmHg have been shown to be adequate. Complications arising from prolonged excessive ET cuff pressures include tracheal oedema, loss of mucosal cilia, ulceration, ruptured tracheo-oesophageal fistula, stenosis, necrosis, sore throat and hoarseness (Wood 1998). Prevention of these complications is part of the rationale behind re-siting the airway and the fashioning of a tracheostomy after 12–14 days of oral intubation.

Level of sedation If patients are too alert, when the mode of ventilation used prevents/reduces their opportunity to trigger a break, e.g. IPPV, they may fight against the work of the ventilator, so preventing the desired therapeutic treatment being carried out; in these cases, sedation becomes necessary. Other patients may clamp down on the tube, preventing ventilation and clearance of secretions. It is also not uncommon for patients to bite through the ET tube completely. On the other hand, oversedation will inhibit patient progress, if weaning from the ventilator and spontaneous breathing are the goals. Maintaining the appropriate balance in sedation is important.

Box 29.2

Potential complications of mechanical ventilation

- Damage to the airways/lung parenchyma
- Barotrauma, tension pneumothorax, disconnection/occlusion of the endotracheal tube
- Mechanical failure
- Subcutaneous emphysema
- Hypo/hyperventilation
- Pulmonary oedema/pleural effusions
- Nosocomial hospital acquired infection (HAI), consolidation
- Low cardiac output
- Cardiovascular depression
- Arrhythmias
- Water retention
- GI haemorrhage, aspiration of stomach contents, paralytic ileus
- Impairment of CNS, kidneys and liver function
- O_2 toxicity
- Altered body image
- Sleep deprivation
- Tracheal injury

Ventilator observations Continual observations should include the patient's colour to check if well perfused or cyanosed; oxygen saturations (S_aO_2); level of consciousness, i.e. if on sedation, whether drowsy due to CO_2 retention; and chest movements, i.e. are both lungs being ventilated? It is essential that the fraction of inspired oxygen (F_iO_2), the prescribed ventilatory setting, the expired minute volume, the patient's tidal volume, airway pressures and respirations (spontaneous and ventilator breaths) are all recorded hourly allowing for continual respiratory assessment and the early detection and treatment of any problems.

Vital signs Changes in a patient's vital signs can immediately indicate problems with ventilation. Blood pressure, heart rate and rhythm, temperature, and respiratory rate and pattern should all be closely monitored.

Arterial blood gases (ABGs) Regular analysis of ABGs (see Ch. 3) will most accurately reveal a patient's respiratory progress or deterioration and the adequacy of ventilatory support.

Inhaled nitric oxide (NO) administration Nitric oxide has a powerful and often beneficial vasodilatory effect on the body (Woodrow 1997). It is used in ICU primarily to treat pulmonary hypertension, a known feature of acute respiratory distress syndrome (ARDS). For intensivists, its therapeutic properties of dilating pulmonary vasculature, reducing pulmonary vascular resistance and optimising gaseous exchange are of major significance. However, it is often seen as a last resort, as its potential toxicity necessitates that nurses responsible for its safe delivery are fully aware of the doses and dangers associated with its use, both to patient and staff; nitric oxide can form nitrogen dioxide, a highly toxic environmental pollutant. Closed suction systems should therefore always be used (Ismail-Zade & Oduro-Dominah 1997, Powroznyk & Latimer 1997, Woodrow 1997). There is no evidence that NO improves final outcome.

Assisting with physiotherapy and the removal of tracheal secretions

Physiotherapists are invaluable members of the multidisciplinary team. Their main role, in relation to the respiratory needs of the critically ill patient, is to aid the clearance of tracheal secretions, so preventing alveolar collapse, atelectasis or consolidation of the lungs, and generally optimising ventilatory efficiency through good positioning, manual hyperinflation and ET suctioning. Modern physiotherapy methods are both prophylactic and therapeutic (Juniper 1999).

Positioning

Depending on where the pulmonary abnormality is, the patient should be positioned to maximise the matching of ventilation and perfusion. In a case of a left lower lobe collapse, it may be helpful to nurse the patient on the right side, thereby optimising the treatment to the affected area. Regularly turning patients will not only assist in the prevention of pressure ulcers but also facilitate pulmonary postural drainage, and adopting a semi-recumbent position may reduce the risk of aspiration and consequently acquired ventilator-associated pneumonia (Woodrow 2000).

When a patient's oxygenation remains poor, despite high oxygen delivery and high PEEP levels, it may be decided to turn the patient to the prone position. Studies have shown that significant and dramatic improvements in arterial blood oxygenation can be achieved through the use of the prone position (Thomas 1997, Gosheron et al 1998, Ball et al 1999), especially in the treatment of patients with ARDS. For patients with ARDS, fluid tends to fill the alveoli, predominantly in the posterior lung bases, due to the effects of gravity and the usual supine positioning. These patients exhibit improved oxygenation when positioned prone because this position allows increased perfusion of the better ventilated antero-apical regions. Physiotherapy will be severely limited in this situation.

Once positioned and ready for physiotherapy with the most affected lung uppermost, manual hyperinflation (hand ventilation) is likely to be the method adopted, unless the patient's condition proves too unstable to tolerate it.

Hand ventilation (manual hyperinflation)

This is a manual form of positive pressure ventilation which is not without severe adverse effects (see Box 29.3). It is used primarily to stimulate a cough in patients with either a poor or absent cough reflex, or when there is atelectasis or excessive bronchial secretions. It may also be necessary when there is a ventilator fault, or more obviously during cardiopulmonary resuscitation, or as part of the treatment of those with raised intracranial pressure. It may also be the method used during short transfers from theatre to ICU (Robson 1998).

Endotracheal suction

Together with hand ventilation, ET suctioning is a procedure used to facilitate the clearance of secretions when a patient's normal cough mechanism is either inadequate or disrupted, e.g. where there is underlying respiratory or neurological disease or when the cough reflex is suppressed by sedation, muscle relaxants or anaesthetic agents during IPPV. Its purpose is the removal of pulmonary secretions, thereby avoiding any of the problems associated with their retention, such as increased airway pressures, pneumothorax,

Box 29.3

Some adverse effects of hand ventilation

Respiratory effects
- Pneumothorax
- Loss of the effect of PEEP
- Bronchospasm
- Decreased respiratory drive
- Rebreathing CO_2

Cardiovascular effects
- Decreased blood pressure due to decreased venous return caused by the IPPV of hand ventilation
- Increased blood pressure due to inadequate sedation or inadequate hand ventilation
- Vagal stimulation (causing bradycardia)

Box 29.4

Potential hazards of endotracheal suctioning

- Tracheal mucosal damage
- Hypoxaemia
- Atelectasis
- Arrhythmias
- Infections
- Excessive coughing
- Stress response
- Pain
- Aspiration of stomach contents

cardiovascular instability, lobar consolidation, ventilation–perfusion mismatch, pneumonia, hypoxaemia and atelectasis (Day et al 2002).

Endotracheal suction can produce complications and carries with it hidden risks (see Box 29.4). In order to minimise these risks, certain principles should be adhered to; these are discussed in Chapter 28. Infection control measures may necessitate that closed suction systems be used to minimise risk to both staff and patients.

For further reading on performing endotracheal suction, see White (2001).

Weaning from ventilatory support

Weaning is the term employed for the gradual transition from mechanical to spontaneous ventilation (self-ventilation). It should be individually tailored and begun as soon as it is established that the patient is physically capable of maintaining respiration. Often nurse-led, weaning is most successful when the underlying clinical condition predisposing the patient to require ventilation support has first been corrected. Such factors as a disturbed acid–base balance, electrolyte abnormalities, arrhythmias or altered state of consciousness may severely hinder the chances of successful weaning.

Before attempts are made to wean a patient, certain criteria must be met (Crocker 2002, Martensson & Fridlund 2002). These are:

- a stable physiological status
- a stable psychological status
- an adequate nutritional status.

The main underlying principle in weaning is that of 'minimising the work of breathing'. Box 29.5 sets out how this may be done.

Close monitoring is essential during the weaning process. Should signs of poor tolerance to weaning be evident (see Box 29.6), ventilation support may need to be resumed.

29.2 Discuss the measures used to wean a patient from ventilatory support.

Extubation

When spontaneous respiration is successfully maintained, the next step is the removal of the ET tube, a procedure known as extubation (see Box 29.7). Prior to this procedure, ABGs, oxygen saturations, tidal volumes, respiratory rate and pattern, vital signs, any evidence of tiring, and the presence of a gag reflex together with a strong cough reflex must all be reviewed. Extubation should not be considered unless the patient can cough, swallow and protect the airway, and is sufficiently alert to cooperate. If possible, a planned extubation early in the day is ideal, with more staff on duty. Emergency equipment should be available in case rapid reintubation is necessary.

Box 29.5

Minimising the work of breathing in relation to weaning from ventilatory support

The nursing aims should be to:

- Prepare the patient psychologically
- Treat the underlying disease
- Reduce airway secretions
- Position for optimal lung expansion
- Reverse bronchospasm
- Maintain haemoglobin levels within normal limits
- Maintain cardiovascular stability
- Correct fluid and electrolyte imbalances
- Limit CO_2 production
- Maintain arterial blood gases within normal limits (all other aspects considered)
- Ensure optimal nutritional support
- Facilitate sleep
- Ensure neurological integrity
- Optimise pain control.

Box 29.6

Indicators of poor tolerance to weaning

- Respiratory rate increases, exceeding 45/min, or 10 above the baseline, climbing over three consecutive half-hours
- Heart rate increases, exceeding 130 beats/min
- Hypoxia develops
- Hypercarbia develops
- Conscious level deteriorates
- Systolic blood pressure increases or decreases 20 mmHg
- Diastolic blood pressure increases or decreases 10 mmHg
- Poor tidal volumes (250–300 mL)
- Significant arrhythmias
- Significant changes to arterial blood gas analysis
- Shallow breathing/use of accessory muscles
- Desaturation (S_aO_2 decreases to an unacceptable level)
  - 100–95%: acceptable
  - 95–90%: acceptable*
  - 90–80%: requires to be treated*
  - 75%: life-threatening
- Cyanosis
- Profuse sweating
- Altered breath sounds

*Depending on past medical history, e.g. COAD.

Box 29.7

Extubation procedure

1. Position the patient well, preferably as upright as possible, for optimal lung expansion.
2. Explain the procedure to the patient, as this will minimise anxiety and maximise cooperation.
3. Any sedation in use should be discontinued prior to extubation as it may hinder successful unassisted spontaneous breathing.
4. Clear the airway, both oral and tracheal, via endotracheal (ET) suction.
5. Deflate the cuff on the ET tube, cut the tape securing the ET tube, repeat ET suction and removal of the suction catheter, and then remove the ET tube.
6. Immediately substitute ET tube with an appropriate percentage of O_2 via a face mask.
7. Be aware of the patient's vital signs.
8. Record oxygen saturations with the face mask in situ.
9. Clear any oral secretions.
10. Ask the patient to cough and encourage regular deep breathing post-extubation.
11. Listen, by auscultation, to air entry.
12. Pain control may need to be reassessed following extubation, especially in the case of postoperative patients.

Adapted from Rippe et al (1995) and Hinds & Watson (1996).

CARDIOVASCULAR NEEDS AND CARE

The cardiovascular system is a closed system with haemodynamic pressures existing within the heart and arterial system. Pressure changes occur because of altered circulating volume, vessel resistance or blood viscosity and because of changes in the efficiency of the cardiac pump. In intensive care settings, monitoring systems are essential in order to evaluate any potentially fatal physiological derangements and to allow timely treatment to correct any abnormalities. The cardiovascular system can be monitored by the measurement of volume, flow, pressure and resistance in different areas. Chapter 18 covers haemodynamic monitoring and should be referred to in relation to this section.

Nursing priorities and management

Goal: to maintain haemodynamic stability and optimal perfusion.

Plan:

- monitor heart rate and rhythm
- monitor arterial blood pressure
- monitor central venous pressure
- monitor pulmonary artery pressure
- monitor temperature.

Monitoring heart rate and rhythm

The amount of information which can be gleaned from a three-lead ECG and, more importantly, a 12-lead ECG must never be underestimated and a sound understanding of the heart's electrical activity facilitates this. Cardiac arrhythmias are commonplace in patients in ICU. In general, hypoxia, shock, electrolyte abnormalities, sepsis, vagal stimulation from ET suctioning, irritation from central venous or pulmonary artery catheters, and medication are responsible for the majority of cardiac arrhythmias; however, some will be the result of myocardial ischaemia in patients with underlying heart disease. Accordingly, where possible, the nurse needs to be aware of any cardiac impairment the patient may have. Monitoring should be continuous, to enable early detection and prompt treatment of underlying problems. For details on the conduction pathways of the heart, arrhythmias and their management, see Chapter 2.

Monitoring arterial blood pressure

Patients admitted to the ICU generally have an arterial line inserted for the accurate measurement of arterial blood pressure and the provision of easy access to arterial blood for blood gas analysis. Common sites for the insertion of arterial lines are (in order of preference):

- radial artery
- brachial artery
- femoral artery
- dorsalis pedis artery.

(See Ch. 18 for information on the insertion of arterial lines.)

Arterial blood pressure monitoring is necessary:

- in those patients who are haemodynamically unstable, requiring inotropic support
- for those who have cardiopulmonary failure
- when a non-invasive blood pressure is unobtainable.

Together with the systolic and diastolic arterial pressure, the mean arterial pressure (MAP) is also recorded. This gives the measurement of perfusion pressure over the majority of the cardiac cycle. A MAP of 65–85 mmHg is generally the acceptable range. Below 50 mmHg is not desirable as it is inadequate to perfuse vital organs and tissues. Complications associated with arterial lines can and do arise (see Box 29.8).

Monitoring central venous pressure (CVP)

Central venous access is generally preferred over peripheral access, with the obvious benefit of being able to assess the patient's circulating blood volume as well as allowing the administration of intravenous medication that can only

Box 29.8

Complications associated with arterial lines

- Infection/potential sepsis
- Haemorrhage due to disconnection of the line
- Air embolism
- Vascular occlusion/thrombosis (distal circulation should be assessed regularly)
- Ischaemia
- Poor reading
- Spasm of the artery

be infused centrally, i.e. all inotropes, specific antibiotics/antifungals and certain electrolyte supplements. Monitoring the CVP also allows for the assessment of the tone of the vascular system and the ability of the right side of the heart to accept and expel blood, itself influenced by left ventricle function (see Ch. 18 for the insertion, reading and care of CVP). The trend of readings, along with other clinical information, is more important than any one reading on its own.

Monitoring pulmonary artery pressure

A pulmonary artery catheter is an important tool in the care of the critically ill patient, enabling the rapid treatment of potentially life-threatening cardiac dysfunctions. It enables the assessment of the functioning of the left ventricle and very often becomes part of the monitoring profile in situations causing either circulatory failure or acute respiratory failure. Its use is considered when information is required about fluid status, cardiovascular function or oxygen delivery (Bridges 2000). It provides information which guides the therapy of those patients on mechanical ventilation, circulatory assist devices or inotropic medication (see Ch. 18 for information on insertion of and care of pulmonary artery catheters).

The pulmonary artery wedge pressure (PAWP), or 'wedge', gives a more accurate indication of the fluid status of the patient. Elevated PAWPs may arise as a result of volume overload, left ventricular failure (LVF), mitral stenosis or regurgitation and cardiac tamponade, whereas abnormally low readings may relate to hypovolaemia.

The frequency of haemodynamic measurements depends on the patient's condition and, as with all invasive monitoring, actions should be supported by clinical findings (see Box 29.9).

Doppler monitoring

Oesophageal Doppler monitoring is now increasingly favoured in ICU, primarily because it offers a reduced risk of morbidity and mortality in comparison to the pulmonary artery catheter, as it is less invasive. An ultrasound probe is placed in the oesophagus running parallel with the descending aorta. The Doppler then measures the velocity of the blood flow in the descending aorta (Edwards 1998).

Box 29.9

Haemodynamic cardiac profile — normal readings

- Pulmonary artery pressure (PAP)
  - — systolic: 15–25 mmHg
  - — diastolic: 8–15 mmHg
- Pulmonary artery wedge pressure (PAWP): 6–12 mmHg
- Cardiac output (CO): 4–8 L/min
- Cardiac index (CI): 2.5–4.2 L/min per m^2
- Systemic vascular resistance (SVR): 900–1600 dyn/s per cm^5 (this measurement relates to the resistance to flow in the whole systemic circulation)
- Mixed venous oxygen saturations (S_vO_2): 65–75%

Adapted from Coombs (1993).

This form of monitoring is not suitable for all types of patient. It is most useful as a guide in deciding when, what and how much fluid replacement to give in cases of hypovolaemia. The pulmonary artery catheter may still be required for absolute measurements of CO, PAWP, S_vO_2 and SVR (see Box 29.9), especially in cases of severe sepsis.

29.3 How could an atypical pneumonia cause multisystem failure in a 65-year-old woman admitted to ICU following a respiratory arrest in a medical high-dependency unit? Discuss her nursing care and what haemodynamic monitoring may be necessary.

Inotropic medication

A pulmonary artery catheter is often inserted in order to determine inotropic therapy, as it clarifies whether there is a pressure problem, i.e. reduced blood pressure, a problem with the flow, i.e. decreased cardiac output, or a problem with oxygen delivery and consumption. Cardiac contractility can become impaired, either as a direct result of cardiogenic shock, or secondary to hypovolaemic and septic shock. In such cases, inotropic medication such as adrenaline, dopamine and dobutamine, which improve cardiac contractility, are frequently used to support the patient until such time as definitive treatment is administered or the patient recovers (Hillman & Bishop 1996). Administration is always via a central vein and the effects of inotropic therapy are monitored closely. Different combinations of inotropic medication may be advocated in order to achieve the desired effect. It is common practice to titrate inotropic therapy against MAP, generally aiming for a MAP of between 65 and 85 mmHg; inotropic medication is always titrated down 1 mL at a time before discontinuation.

Monitoring temperature

Despite a wide variety of heat-producing metabolic processes and the range of ambient temperatures to which the human body may be exposed, core body temperature is maintained with remarkable stability. However, critical illness can disturb temperature control, producing body temperatures at either end of the spectrum, i.e. hypothermia (<35°C) or hyperthermia/hyperpyrexia (<38.5°C) (Ch. 22 explores temperature maintenance in depth).

For further reading on the management of hypothermia, see McGowan (1999).

RENAL/FLUID BALANCE NEEDS AND CARE

The kidneys are very sensitive organs and it is not uncommon for an abrupt decline in renal function to occur in the presence of other systemic illnesses. This is particularly so if the cardiovascular or respiratory systems become compromised. Renal function is especially susceptible to the effects of underperfusion and hypoxaemia. In the critically ill patient, acute renal failure (ARF) is a relatively common complication resulting from severe hypotension or drug toxicity, or more frequently as a consequence of overwhelming sepsis and multisystem organ failure (MSOF). However, it is usually multifactorial. According to Hinds and Watson (1996), 'ARF can be defined as a sudden (and usually reversible) failure of the kidneys to excrete the waste

products of metabolism, and may be broadly categorised as prerenal, renal or postrenal'. The treatment of ARF is predominantly one of support until recovery occurs.

29.4 Discuss the key regulatory functions of the renal system.

Nursing priorities and management

Goal: to maintain indices of renal function within the patient's own normal limits.

Plan:

- monitor and maintain optimal fluid and electrolyte balance
- provide necessary and appropriate renal replacement therapy.

Monitoring and maintaining optimal fluid and electrolyte balance

In the susceptible patient, the primary goal must always be the prevention of renal impairment. This involves knowledge of the causes of ARF and meticulous monitoring and assessment of the patient. The causes of ARF fall into the three categories mentioned above: prerenal, renal and postrenal (see Ch. 8, p. 388); the first two are largely responsible for the development of ARF, but elements of all three may coexist in the critically ill patient. ARF can be divided into phases, or stages (see Ch. 8, p. 388), as follows:

- the onset phase — the time between the precipitating episode and oliguria or anuria developing
- the oliguric phase (diminished urine output) — can last from 7 to 21 days
- the diuretic phase — characterised by an increase in urine output over several days
- the recovery phase — follows the gradual improvement of kidney function and usually occurs over 3–12 months.

Systemic manifestations may accompany the development of renal insufficiency, as outlined in Box 29.10 (Henke & Eigsti 2003).

Nursing priorities in monitoring and maintaining optimal fluid and electrolyte balance

Urine output In addition to the monitoring of all fluid intake, hourly urine output volumes must be recorded, together with an accurate 24-h fluid balance, of all fluid gains and losses. While a urine output of 400 mL or less (oliguria) over a 24-h period is indicative of ensuing renal failure, it is also acknowledged that ARF can occur in the absence of oliguria (non-oliguric ARF).

Urea and electrolytes Daily assays of urea and electrolytes will indicate the degree of renal insufficiency present. Urea, creatinine and some electrolyte levels rise with developing ARF, leading to varying degrees of metabolic acidosis. It should be noted, however, that elevated urea on its own may indicate, merely, that the patient is dehydrated.

The nurse must know the normal plasma values for urea, creatinine and the more common electrolytes and the significance of any deviations, as some electrolyte abnormalities can produce life-threatening arrhythmias.

Box 29.10

Systemic manifestations of acute renal failure

Respiratory
- Pulmonary oedema
- Suppressed cough reflex
- Kussmaul respiration (see Ch. 5, part 2)

Cardiac
- Congestive cardiac failure/overload
- Arrhythmias
- Uraemic pericarditis

Vascular
- Hypertension
- Fluid overload, increased CVP, decreased urine output
- Electrolyte imbalance
- Metabolic acidosis

Haematopoietic
- Anaemia (as a result of reduced erythropoietin production)
- Coagulopathy (platelets have a reduced life span due to the uraemic toxins)
- More prone to infections (as a result of uraemic toxins)

Neuromuscular
- Electrolyte imbalance
- Uraemic encephalopathy

Gastrointestinal
- GI bleeding
- Nausea
- Uraemic halitosis
- Bowel changes

Skin integrity
- Purpura rash (due to coagulopathy)
- Yellowness (uraemia)
- Dry skin (due to decreased sweat production as a result of uraemic toxins)

Fluid therapy Intravenous fluid therapy should be considered carefully in the management of the critically ill patient. This is particularly so in conditions of sepsis, ARDS or systemic inflammatory response syndrome (SIRS). In such situations, the permeability of capillary endothelial cells increases and the vessels become 'leaky', allowing large protein particles to pass into the interstitial space and thus reducing the capillary osmotic pressure. This facilitates the movement of water together with further protein molecules into the interstitial space, depleting intravascular volume and impairing gaseous exchange. This results in peripheral oedema and, within the lungs, results in pulmonary oedema, causing hypoxaemia and consequently diminished oxygen delivery and consumption by peripheral tissues. Vascular volume must be restored. The three main groups of volume-expanding fluids are crystalloids, colloids and blood:

- Crystalloids are made up of non-ionic solutes such as sodium chloride added to water; they do not contain oncotic particles and will therefore eventually move out of the vascular compartment (see Ch. 20). These fluids, unlike colloids, are cheap to produce and are not associated with immunologically mediated reactions.

- Colloids, which contain oncotic particles, generating oncotic pressure, are mainly confined to the intravascular space, at least when first administered.
- Blood and blood products also exert an oncotic pressure due to the large protein particles they contain and so are less likely to contribute to interstitial oedema.

Clinical assessment A careful clinical assessment is necessary, observing for signs of worsening pitting oedema, notably at the ankles and sacrum. Chest auscultation may reveal widespread coarse crackles and suggest fluid overload and pulmonary oedema.

Cardiovascular status directly affects renal perfusion. It is recommended that the MAP is above 60 mmHg for renal perfusion to be ensured (Kishen 2002). Regular monitoring of the CVP, cardiac output and PAWP will indicate whether fluid input or inotropic support is required. The presence of peaked T waves is suggestive of a rising plasma potassium level.

Nephrotoxic medication The use of nephrotoxics, e.g. gentamicin and non-steroidal anti-inflammatory drugs (NSAIDs), should be avoided in those with impending renal failure or in those whose renal function is precarious (Hillman & Bishop 1996).

Immediate management of diminishing renal function

- Optimise fluid balance either by giving a fluid challenge if vital signs indicate hypovolaemia or by using diuretic therapy if there are clinical signs of fluid overload. Furosemide, a potent loop diuretic, is the drug of choice.
- Correct electrolyte imbalances as necessary.
- Maintain haemoglobin within the normal range.
- Assess nutritional input, with particular attention to appropriate protein and carbohydrate content. Generally, nutritional support is provided via the enteral route unless otherwise contraindicated. The dietitian will make an important contribution to the team approach to care.
- Remove any known causative factors, e.g. nephrotoxic drugs.
- Exclude obstruction, e.g. make sure that the urinary catheter has not become blocked with sediment.

If this is not enough to resolve renal impairment, then continuous renal replacement therapy (CRRT) will be required.

Renal replacement therapy

In unresolving ARF, the management focuses on supportive renal replacement therapy and the control of metabolic derangements arising from renal failure. Rapid commencement of CRRT is essential in situations where the patient is severely hyperkalaemic, grossly overloaded or suffering from uraemic complications or pericarditis, or where ARF has been drug induced. Forni and Hilton (1997) assert CRRT to be an effective and efficient way of controlling the problems caused by ARF and, while not providing a 'cure', it enables the critically ill patient to be supported pending recovery from the underlying disease process or injury.

Caring for patients with CRRT is deemed part of the professional practice of experienced nurses working in the ICU. They require a thorough knowledge of the reasons for its use, the equipment involved, the problems that can arise and how to respond to them.

Haemofiltration

Traditionally, the recognised form of treatment for critically ill patients with ARF was peritoneal dialysis or haemodialysis. However, dialysis has not always produced a beneficial outcome as haemodialysis often induces severe hypotension and peritoneal dialysis impairs ventilation. For some decades now, there has been increasing use of a less aggressive form of renal replacement therapy — haemofiltration. This is a relatively straightforward form of CRRT by which excess fluid and solutes are removed by passing the patient's blood through a haemofilter. By creating a positive pressure gradient within this haemofilter, fluid removal from the blood by ultrafiltration is facilitated. For the clearance of solutes, a large amount of fluid must be filtered. To prevent dehydration, replacement fluids must be carefully monitored (Urwin & Fletcher 2000, Urwin et al 2001).

Continuous venovenous haemofiltration (CVVH) This is generally the mode of choice in haemofiltration, as it allows the slow, steady removal of fluid volume. It also gives the venous system time to compensate for fluid lost from the interstitial spaces. Most importantly, it avoids the rapid shift of solutes and electrolytes, thereby preventing the risk of cardiovascular instability. It is the only safe line of treatment in the management of ARF in those with haemodynamic instability and/or MSOF, where the removal of fluid and waste products is vital. A further advantage of CVVH is that it does not require arterial access. Access for CVVH is via a double-lumen catheter, often referred to as a Quinton line. This line is inserted into a main vein — the femoral, subclavian or internal jugular. When not in use, the lumens of this line are injected with heparinised saline to maintain line patency and prevent clot formation and the release of emboli.

Molecular adsorbent recycling system (MARS) is a membrane-based blood purification system, also referred to as bioartificial liver support. It works directly with the CVVH in supporting liver function in severe liver failure, providing time for detoxification, hepatic regeneration or donor availability, and is used in patients with fulminant hepatic failure (FHF), e.g. after paracetamol and other drug overdoses (Karnik & Freeman 1998, Stange et al 2002).

Nursing responsibilities in haemofiltration

Fluid balance Accurate measurement of input and output of fluid is essential, and renal replacement therapy is reviewed daily by the renal physicians. The nurse responsible for the patient should adjust filtration rates in accordance with the medical prescription.

Vital signs The recording of vital signs is imperative. At the start of CVVH, the patient's blood pressure may fall, as blood is removed from the circulating volume. However,

this can be pre-empted and is readily corrected by giving volume expanders.

The patient's temperature is also altered. It is generally believed that body temperature drops by 1°C with CVVH in process. It is therefore not uncommon for a patient to become moderately hypothermic. To prevent this, replacement fluid should be warmed to a suitable temperature. It should be noted that CVVH may mask developing sepsis, as a recorded temperature of 37°C may equate to a patient temperature of nearer 38°C.

Urea, electrolytes and ABGs Regular assessment of urea, electrolytes and ABGs is necessary in order to assess acid–base balance. Electrolyte supplements are often required and potassium is usually given in replacement fluid being administered via the filter. Initially, no potassium may be required as hyperkalaemia may be the very reason for commencing haemofiltration. Other electrolyte supplements such as calcium and phosphate can be administered intravenously or nasogastrically. Lactate-free filtrate solute is also available when lactate acidosis is a problem.

Monitoring the activated clotting time (ACT) The ACT is the time it takes for a small sample of blood to clot. It is of particular importance if the patient is receiving heparin as anticoagulation therapy while on the haemofilter. Heparin, the anticoagulant of choice, is administered to prevent clotting of the extracorporeal circuit (Urwin et al 2001). Patient coagulation, and therefore the demand for heparin, will vary greatly depending on the underlying disease process. However, a concentration of 250 IU/mL at a rate of 1–6 mL/h is normally administered. Some patients will not be able to tolerate the effects of heparin, as it is known to disrupt the intrinsic coagulation cascade and promote platelet aggregation. This is seen particularly in liver failure. In such cases, prostacyclin can be used as it preserves platelet function and number. It does, however, have strong side-effects, noticeably vasodilatation, causing facial flushing and significant hypotension. ACT is not required with prostacyclin as the normal clotting process is not so severely altered.

Preventing infection Preventing infection and maintaining asepsis are vital. Patients on haemofiltration are often immunocompromised and therefore are more susceptible to infection. Residual catheterisation is performed every 2–3 days, preventing stasis of urine in the bladder, a potential source for infection. If urine volume is 250 mL or more, the catheter is normally left in situ, as this can be indicative of the return of renal function.

Patient safety Maintenance of patient safety is the nurse's responsibility. If access is via the femoral vein, the limb should be carefully observed to ensure optimal perfusion is maintained (Woodrow 1993). Furthermore, the prevention of air emboli, infection or haemorrhage, as a consequence of heparin use, should be borne in mind.

Psychological care Providing psychological support and reassurance to the patient receiving CVVH is all-important, true indeed for any procedure carried out on the critically ill patient. Extended body image is an issue not widely written about, but some, e.g. Smith (1989), have studied its implications in relation to the critically ill patient with particular reference to the ventilation tubing and dialysis lines. The nurse responsible for the patient undergoing CVVH must be aware of and sensitive to this issue.

High-volume haemofiltration (HVHF) and haemodialysis

When a patient's stability is restored, HVHF or haemodialysis may then become an option. It facilitates the rapid clearance of waste products over a period of 3–4 h. Daily, or alternate-day, treatment may be necessary until the kidneys recover completely. Full renal recovery is entirely possible in patients with no prior history of renal impairment.

NEUROLOGICAL NEEDS AND CARE

A number of conditions predispose critically ill patients to altered states of consciousness. These include (Goldhill & Withington 1997):

- intracranial pathology, such as intracranial haemorrhage, cerebral hypoxia, tumours and abscesses
- systemic disease affecting the cerebral blood supply or oxygenation, such as sepsis, metabolic encephalopathy, hypoglycaemia, hepatic failure (hepatic encephalopathy), renal failure, pancreatitis, respiratory failure or hypo/hyperthermia
- exogenous agents, such as drugs and toxins, and drug withdrawal.

Neurological functioning is an important part of the overall clinical assessment and continuous care of those being nursed in the ICU. The use of a standardised neurological assessment tool such as the Glasgow Coma Scale (GCS) is essential, enabling early detection of any deterioration and facilitating prompt treatment (see Ch. 28). In addition, invasive neurological monitoring of intracranial pressure (ICP), which facilitates the monitoring of the cerebral perfusion pressure (CPP), is often indicated in patients who demonstrate a GCS of 8 or less and/or a grade 3 or 4 encephalopathy (see Box 29.11). As with the majority of clinical observations, it is the trend that is of greatest significance when monitoring ICP and CPP.

Nursing priorities and management

Goal: to maintain neurological status.

Plan: monitor neurological function.

Box 29.11

Grades of encephalopathy

1	Mild confusion, poor concentration, but fully coherent when awake
2	Increasingly confused, disoriented, yet remains rousable
3	Very drowsy, may be agitated or aggressive when roused to command
4	Responsive to painful stimuli, not rousable to command. May display signs of pupil and limb changes, abnormal breathing and extensor plantars

Monitoring neurological function

The Glasgow Coma Scale is the standard tool used in assessing neurological function. It is an objective way of measuring levels of consciousness (LOCs) and is set out in detail in Chapters 9 and 28. However, Price et al (2000) looked at the appropriateness of the GCS in ICU and concluded that it has limited use as an assessment tool as many therapeutic interventions, such as ventilation, may obscure the real LOC.

Cerebral function analyser monitor (CFAM) This comprises a visual display unit and printer which allows the continual monitoring and display of cerebral activity. This activity is picked up by five electrodes: two are situated over each hemisphere and one ground electrode allows both hemispheres to be compared. This system is better than the conventional EEG. It is used continuously by the bedside to assess whether the patient is appropriately sedated and commonly used with patients receiving paralysing agents in order to detect whether or not they are having seizures.

Computed tomography (CT) scan In relation to neurological functioning, CT scanning is usually performed in order to detect cerebral haematomas, oedema, infarctions, atrophy, hydrocephalus and tumours.

ICP monitoring Intracranial pressure is the pressure exerted by the intracranial contents against the skull. Normally, brain tissue constitutes 80%, cerebrospinal fluid (CSF) 10% and blood volume 10% of the intracranial contents. It becomes necessary to monitor the ICP in the critically ill when a patient displays signs of raised ICP manifested as severe encephalopathy (see Box 29.11). For patients who do not progress any further than a grade 1 or 2 encephalopathy, the prognosis is good. Severe head injuries remain the most common cause of raised ICP, but it may also occur in patients presenting with problems such as hepatic encephalitis due to fulminant hepatic failure (Hawker 1996), increasingly seen nowadays as the consequence of paracetamol overdose.

For a case study on paracetamol poisoning, see Leighton (1995).

ICP monitoring can be used to help minimise neurological damage in those patients predisposed to neurological problems, as such monitoring will demonstrate neurological changes before they present clinically and thus greatly assist clinical observation. For further discussion of raised ICP, see Chapter 9 (p. 406).

Cerebral perfusion pressure (CPP) The value of monitoring the ICP is that it allows the CPP to be calculated. This is done by subtracting the ICP measurement from the mean pressure of circulating blood within the cranial cavity (i.e. CPP = MAP – ICP). Generally the aim is to maintain CPP above 70 mmHg, thus preventing underperfusion of the cerebral tissue.

Jugular bulb oximetry (S_jO_2) This is an uncommon invasive monitoring system, but may be used to provide information about global cerebral oxygen consumption (Chatfield & Rees-Pedlar 2001).

The immediate management of elevated ICP

The level at which treatment of raised ICP will be necessary depends on the patient's condition, but is often set at around >15 mmHg. Medication of choice includes mannitol 20% initially and then subsequent administration of furosemide, which both enhances its effect and produces a faster diuresis. It is important to be aware of the patient's renal status prior to administration of these medications, i.e. is there a significant degree of renal impairment? In order to counteract any sudden electrolyte changes due to induced diuresis, plasma protein substance (PPS) is also part of the treatment protocol. This line of treatment can be considered at 4- to 6-hourly intervals. If ineffective, barbiturate therapy may be necessary. Barbiturates exert their effect on ICP by reducing cerebral oxygen consumption and thereby producing vasoconstriction and reduction in ICP. Another useful agent is thiopental which lowers ICP by reducing metabolism to a minimum as well as lowering blood pressure by reducing venous and arterial tone, thus reducing cerebral perfusion (Stanley & Hancox 2001).

Nursing activities and ICP

- ET suction should be carried out only as required, i.e. in response to secretions. Retention of secretions will increase ICP, just as frequent suctioning can be detrimental. The maintenance of adequate ventilatory support is essential as hypercapnia and hypoxia will increase cerebral vasodilatation, causing raised ICP. It may be necessary to continually monitor the end-tidal CO_2 (Frakes 2001).
- Secure the ET tube with adhesive tape, thus not restricting cerebral drainage.
- Ensure good head alignment, elevating the head of the bed to promote cerebral drainage.
- Keep all nursing procedures to a minimum.
- Check pupils hourly and following all nursing and medical procedures.
- Maintain an accurate fluid balance chart. Monitor and be aware of electrolyte levels, e.g. both hypo- and hypernatraemia can contribute to raised ICP.
- Prevent cerebral ischaemia and maintain CPP above 60 mmHg.
- Provide adequate nutritional support. Patients with ICP problems are often in a hypercatabolic state.
- Assess the need and extent to which pressure area care is appropriate.

29.5 Describe the nursing care of a patient following an overdose of tricyclic antidepressants.

SEDATION AND PAIN CONTROL

Nursing priorities and management

Goal: to maintain the optimal level of sedation and pain control.

Plan: assess the need for sedation and analgesics.

Assessing the need for sedation and analgesics

Pain has been identified as a major problem for patients in the ICU. Pain is a subjective experience and the control

of pain will require regular assessment and clear documentation. The challenge is to provide the most appropriate form of pain relief. Pain control is covered extensively in Chapter 19 and therefore this section will focus primarily on the assessment of sedation required.

Most patients admitted to the ICU will, at some point during their stay, require sedation and/or analgesics (Arbour 2000). Views and practice have changed considerably over the years from the belief that patients should be heavily sedated and unaware of their surroundings to the current preferred state of lighter sedation while maintaining an optimal state of comfort (Shelley 1998). Many units now operate some form of sedation protocol. Patient comfort may be achieved by creating a supportive environment, through constant reassurance and explanation prior to all procedures, together with the maintenance of some sort of diurnal rhythm. However, medication may be required to produce the respiratory depression necessary to facilitate adequate ventilation, to aid tolerance of the presence of the ET tube or to decrease anxiety in general. Shelley (1998) suggested that patient comfort is a better term than sedation, as sedation is only one of the desired effects.

Sedation and analgesics can be administered continually or as a bolus, the prescribed regimen being tailored to the needs of each patient. The nurse must constantly assess the sedation level (a number of sedation scaling systems exist — see Box 29.12) and therefore should display a sound knowledge of the issues surrounding sedation in the ICU, i.e. sensory overload, sensory deprivation, ICU psychosis and psychological support. The goal of sedation is to decrease anxiety, fear and restlessness and to increase cooperation and compliance. Optimal sedation should enable the patient to be rousable on stimulation but able to sleep/rest when undisturbed — keeping the patient comfortable is a balance between under- and oversedation (Shelley 1998).

Patient comfort

Four main groups of drugs can be enlisted to enhance patient comfort:

Sedatives Benzodiazepines are probably the most commonly used medications in ICUs, with midazolam used widely. Its has sedative, anxiolytic and amnesic properties and has a short half-life. However, it is largely hepatically metabolised and renally excreted and therefore could accumulate should these organs be impaired (Bion & Oh 2003).

Box 29.12

Sedation scale

0	Asleep, no response to tracheal suction
1	Rousable, coughs with tracheal suction
2	Awake, spontaneously coughs or triggers the ventilator
3	Actively breathes against the ventilator
4	Unmanageable

From Cohen & Kelly (1987).

Propofol, administered either as a bolus or continuous infusion, has anaesthetic properties and is commonly used to sedate patients who require short periods of mechanical ventilation. It is widely used as it provides a controllable level of sedation which is easily maintained and recovery is rapid, allowing weaning from the ventilator to progress.

Analgesics Morphine provides safe analgesia but should be used with caution in those with liver and renal impairment. NSAIDs and local analgesics in the form of nerve blocks may also be considered.

Alfentanil is a valuable analgesic used in the ICU, especially when short-term supplementation is required. It is short-acting with a short half-life.

Neuromuscular blocking agents The use of these agents has been reduced, partly as a result of the more effective use of sedatives, but also because of improved ventilator design. A muscle relaxant will be administered initially to most patients admitted to ICU, in order to facilitate intubation and line insertion, e.g. suxamethonium has a rapid onset and offset action, but is not suitable for prolonged administration (Goldhill & Withington 1997). Longer administration may be required to aid ventilation control, reduce O_2 consumption in patients who have developed ARDS, and lower ICP in head injury — in such cases, a neuromuscular blocking agent such as atracurium is often used.

Antidepressants (e.g. amitriptyline) Antidepressants are often prescribed in those showing depressive behaviour, often patients who have been critically ill for weeks, where weaning from the ventilator is slow, or those with previous depressive illness. As well as improving mood, antidepressants can help to normalise the sleep pattern.

For further reading on sedation and the critically ill patient, see Kress et al (2002).

NUTRITIONAL/GASTROINTESTINAL NEEDS AND CARE

The nutritional status of patients in hospitals has been the topic of much research over the years. It is well recognised that critical illness in general is associated with a massive increase in catabolic hormone production leading to a rise in basal metabolic rate. If not addressed appropriately, malnutrition in such patients can contribute to immunosuppression, increased postoperative complications, delayed wound healing and consequently longer stays in hospital, all of which may adversely affect their outcome (Leary et al 2000a,b). Chapter 21 covers nutritional support thoroughly and should be studied in relation to nutrition and the critically ill.

It is now believed that the gut has an extremely important and active role to play in the treatment of the critically ill patient (Singer & Carr 1996). Well recognised for its role in absorbing and digesting nutrients, the gut also has a vital function as a barrier to microorganisms and endotoxins. This defence mechanism is preserved by the normal epithelial cells and is supported by a series of immunological mechanisms. In the critically ill, this barrier is often severely

compromised and as a result the bowel, which acts as a reservoir for organisms, facilitates the process of gut translocation of bacteria. This practice allows the transfer of endotoxins and pathogens into the portal and systemic circulation and may add to the risk of sepsis (Leary et al 2000a,b). Consequently, it is imperative that, where possible, optimal gastrointestinal function should be maintained. In the past, nutritional support was often not considered an immediate priority in the management of critically ill patients, but it is now widely acknowledged that early assessment and optimal nutritional support are vital components in the overall treatment of such patients and where possible such nutritional support should be via the enteral route (Maitnel & Blackburn 2003).

Nursing priorities and management

Goal: to minimise weight loss and maintain normal gastrointestinal (GI) function.

Plan:

- establish nutritional support
- maintain GI integrity.

Establishing nutritional support

Nurses are responsible for assessing nutritional needs, administering nutritional therapy, monitoring its effects and complications, and evaluating its effectiveness. There are basically two clinical routes for maintaining nutritional support: parenteral and enteral (see Ch. 21).

Parenteral nutrition

In the past, parenteral nutrition (PN) was the accepted form of nutritional support for the critically ill. However, evidence now suggests that using the parenteral route may not only increase the risk of sepsis from complications associated with its administration (see Ch. 21), but also, because gut function is not maintained, result in mucosal atrophy and the facilitation of bacterial translocation (Buckley & McFie 1997, Maitnel & Blackburn 2003). Microorganisms and endotoxins cross into the blood, resulting in sepsis. Systemic inflammatory response syndrome (SIRS) follows and can lead to multisystem organ failure, as illustrated in Figure 29.1.

PN, which requires administration via a large central vein, is an unnatural method of feeding, however justified, in certain situations, where the use of the gut is either impossible or inadequate. Because of the well-recognised complications arising from PN administration, as well as its cost, enteral feeding is preferred in the treatment and support of the critically ill patient.

Serum electrolytes Monitoring electrolyte levels to prevent imbalances is essential. This in fact pertains to both routes of nutritional support, but is especially the case in PN. It is necessary to check regularly the patient's blood glucose level, monitoring for hypo/hyperglycaemia and consequently assessing the need for insulin therapy. Patients requiring inotropic therapy in the form of adrenaline also need their blood sugar levels monitored closely, as adrenaline, especially at higher doses, affects the utilisation of glucose from the cells. Insulin resistance is frequently a

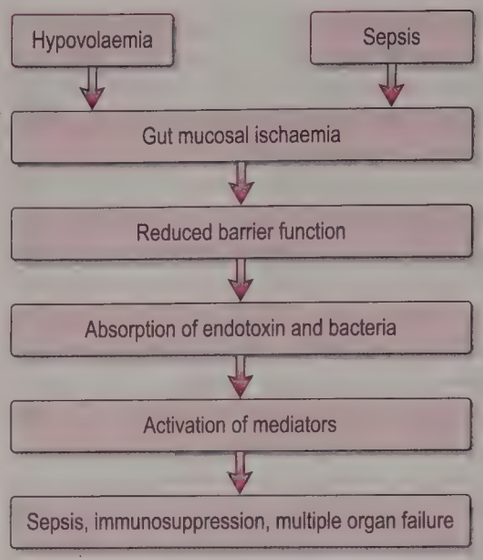

Fig. 29.1 The role of the gut in multiple organ failure.

feature of critical illness and studies have concluded that the use of insulin to maintain blood sugar levels no higher than 110 mg/dL reduces morbidity and mortality in critically ill patients in the ICU, irrespective of whether or not they had a history of diabetes mellitus (Van den Berghe et al 2001, Bradley 2002).

Enteral nutrition

Besides being relatively inexpensive and safe to use (Leary et al 2000a,b; see also Ch. 21), enteral nutrition (EN) offers a protective effect on the GI tract and should be utilised early and often, reducing the risk of bacterial translocation and maintaining mucosal integrity. EN is also believed to maintain the autoregulation of blood flow to the gut. Most patients in the ICU can be fed enterally, the only absolute contraindication being true gut failure. Relative contraindications include bowel anastomosis distal to the feeding tube, pancreatitis or small bowel disease. Gut function may be decreased and an ileus may develop as a result of IPPV or the use of opiates; however, the small bowel retains motility and absorptive functions in most critically ill patients. Feeding is usually via the nasogastric or nasoenteral route — nasoduodenum or nasojejunum — however, a jejunostomy tube may be fashioned.

For further reading on nasogastric intubation, see Dougherty & Lister (2004).

Feeding via the enteral route On introducing enteral feeding, a protocol should be followed and this, together with competent nursing practice and perseverance, will enable most critically ill patients to be fed by this method. Lack of bowel sounds is not a contraindication to enteral feeding (Leary et al 2000a,b). As patients who are ventilated often swallow less air than normal, therefore reducing their main source of gas, bowel sounds do not always correlate with gastric absorption. The feed should be administered using an infusion pump at a constant rate, helping to reduce the incidence of diarrhoea, and nasogastric aspiration carried out every 4 h to monitor feed absorption. A number of standard formula feeds exist and, while usually satisfactory for most patients, special feeds may be required to

meet the excessive metabolic demands of the critically ill. Some examples of special properties are:

- high-protein, low-osmolarity feeds
- fibre/bulking agents
- low-carbohydrate, high-fat content — for those producing too much CO_2, inhibiting weaning from the ventilator
- low-protein, high-calorie content with reduced potassium — for those with renal or liver impairment
- constituents targeted specifically at critically ill patients — e.g. multiple trauma, sepsis, general states of catabolic stress — include omega-3 fatty acids and glutamine. Glutamine, in particular, is thought to increase the gut's ability to accept nutrients during critical illness (Verity 1996), enhancing gut mucosal integrity. This enables proliferation of both lymphocytes and macrophages, correlating with a boost in the immune system.

29.6 Identify physiological changes caused by inadequate nutritional support.

Maintaining GI integrity

As well as providing nutritional support, the assessment and alleviation of GI problems must be given due consideration. These can range from delayed gastric emptying, abdominal distension, diarrhoea or constipation to the presence of stress ulcers (see Ch. 4).

Delayed gastric emptying

This may be alleviated through the use of a wide variety of pharmacological agents, e.g. metoclopramide which will stimulate gastric emptying and erythromycin which has been demonstrated to increase gastric motility (Bradley 2001a, Oudemans-van Straaten 2003). In extreme cases, when pharmacological agents are not enough, feeding via a distal tube, e.g. into the jejunum, may be considered. In this way the need for gastric emptying integrity is bypassed.

Abdominal distension

This is associated with the malabsorption of enteral feed and, in this case, feeding should be reduced or stopped for a few hours and the enteral feeding regimen reviewed.

Diarrhoea or constipation

This is not uncommon in the critically ill patient. However, it cannot be assumed automatically to be the result of enteral feed intolerance. Many factors can induce diarrhoea, not least antibiotic therapy or infection, *Clostridium difficile* being a common causative agent.

Rarely is feeding stopped because of feed-induced diarrhoea. On occasions, contamination of the feed may be the root cause, highlighting the need for an aseptic technique during the handling of feeding equipment. At the other end of the spectrum, it is also necessary to review the need for aperients.

Stress ulceration

This may develop due to damage to the mucosal layer, often during a period of ischaemic anoxia as part of a shocked state (see Ch. 28). In addition, impaired production of gastric mucus, reduced epithelial renewal, disturbed acid–base balance, reflux of bile acids and the presence of uraemia all predispose the patient to gastric ulceration (Bradley 2001b, Tucker & Dexter 2003).

Enteral feeding acts as prophylaxis; however, in patients being supported by PN, prophylactic medication should be prescribed. Antacids and H_2-receptor blockades are thought to be equally effective as prophylactic agents for stress ulcers.

HYGIENE AND MOBILITY NEEDS AND WOUND CARE

Caring for the critically ill patient requiring mechanical ventilation is both a medical and nursing challenge. Many patients in the ICU setting are fully dependent on the provision of all care. Meticulous nursing care is required in order to maintain optimal body tissue integrity and organ function. Individualised care tailored to the needs of the patient is a prerequisite with regular assessment and evaluation of the effectiveness of care chosen.

Nursing priorities and management

Goal: to provide optimal personal hygiene and to maintain skin integrity.

Plan:

- maintain personal hygiene, preventing infection
- maintain skin integrity and promote wound healing
- promote and maintain normal tone, power and movement of the musculoskeletal system.

Maintaining personal hygiene and preventing infection

Personal hygiene

Assisting with the maintenance of personal hygiene not only promotes comfort and dignity, but also represents an opportunity for thorough assessment of the patient, including skin integrity, any potential sites of infection, e.g. inflamed cannula insertion sites, and the peripheral circulation. The nurse should maintain the dignity of the critically ill patient at all times.

Oral hygiene

Most seriously ill patients will encounter oral problems, some specific to the disease and others associated with the medication. There is, for example, an increased risk of mouth ulcers, dry, cracked oral mucosa or yeast growth in those with diabetes mellitus, acute or chronic breathing difficulties and thyroid dysfunction.

Furthermore, with the use of certain antibiotics, diuretics or morphine and procedures such as intermittent suction, the potential for oral hygiene problems is heightened. Knowledge of the factors which contribute to poor oral health is important in order to maintain hygiene (Thurgood 1994) (see Ch. 15 for further detail on oral hygiene).

Eye care

Eye care is a very necessary procedure for those patients who are unconscious, paralysed or sedated, who lack a blink reflex, have an inability to close their eyes or who experience

dry eyes. Eye care facilitates maintenance of healthy eyes, comfort and the prevention of infection (Lloyd 1990).

Effective eye care is vital to prevent particular ocular complications such as:

- exposure keratopathy — incomplete closure of the eyelid
- dry eyes
- infection, e.g. conjunctivitis
- 'ventilator eye' (oedematous eyes); for explanation, see below
- corneal ulcerations.

(Ch. 13 discusses the disorders of the eye in depth.)

The critically ill patient is more susceptible than most patients to developing ocular problems, for the following reasons:

- Mechanical ventilation leads to the retention of body fluid, which in turn leads to increased venous pressure, producing oedematous eyes, often referred to as 'ventilator eye' (Lloyd 1990).
- Medication used during intubation can lead to raised intraocular pressure, predisposing the patient to ocular damage.
- Paralysing and sedating agents prevent patients from carrying out important physiological eye protection mechanisms. The blink mechanism is diminished, whereby tears are no longer effectively dispersed over the eye, if indeed they are produced at all. Tear production and dispersion are important in the prevention of infection and the maintenance of the structural integrity of the eye. In addition, those patients being ventilated artificially are at risk of eye infections arising from poor ET suctioning procedures, whereby cross-contamination from droplets sprayed out of the ET tube during suction can occur.
- The side-effects of some drug therapies are known to contribute to dry eyes, including atropine, antihistamines and tricyclic antidepressants.
- The patient who is critically ill will often be immunocompromised and thus more susceptible to infection. As with all procedures pertaining to patient care, strict and thorough handwashing must be maintained.

Maintaining skin integrity and promoting wound healing

A sound knowledge of the factors involved in successful wound healing and those that adversely affect its progress are necessary (see Ch. 23). The main types of wound encountered in the ICU are surgical wounds (see Chs 23 and 26), traumatic wounds and pressure ulcers (Chs 23 and 30).

For further reading on the effect of septic shock upon wound healing, see James (2001).

Pressure ulcers

Prevention is always better than cure and this is certainly the case when it comes to pressure ulcers. However, with the critically ill patient, the main priority is ultimately to maintain haemodynamic stability and optimise ventilation, and in some cases this may be jeopardised by turning or rolling the patient. Therapeutic beds are regularly required for the maintenance of skin integrity. Recent years have witnessed many developments in the design of specialised beds, from temperature regulatory devices to beds specifically for cardiac or respiratory patients providing rotation and percussion, as well as devices to assist with the movement of patients and the nursing of patients in the prone position.

There is also a risk of tissue damage due to pressure from equipment, such as an ET tube pressing on the lip, a tightly taped three-way tap or tube pressing on the skin, or even an overinflated tube cuff, which has been shown to cause necrosis through the tracheal wall to the oesophagus.

Pressure ulcers may delay recovery, pose increased infection risks and entail much discomfort for the patient. Assessment of the patient's risk of developing a pressure ulcer should be undertaken daily using a standardised tool such as the Waterlow pressure sore prevention/treatment policy (see p. 851).

Promoting and maintaining normal tone, power and movement of the musculoskeletal system

As well as regularly positioning the patient to optimise air entry, ventilation and maintain skin integrity, passive and active exercises should be carried out. In patients who have limited movement or who are unable to move at all, a regimen of passive movements can be implemented which will progress to active/assisted movements as the patient's condition improves. This can counteract effects of bed rest, e.g. deep venous thrombosis (DVT), contractures and foot drop.

MEETING THE PSYCHOSOCIAL, CULTURAL AND SPIRITUAL NEEDS OF THE CRITICALLY ILL PATIENT

PSYCHOSOCIAL NEEDS

Anyone who becomes critically ill is first and foremost a person; 'patient' is only one of their current subsidiary roles in life. It is sometimes difficult to remember this when immersed in life-saving procedures on the body of someone unknown.

Critical illness may be caused by trauma, infection or other pathophysiological state, possibly complicated, at least initially, by major surgery, and may affect any, or all, of the body systems and vital organs. Malfunction of one organ or system is likely to affect others and progress to multiple organ failure. Patients may be fully conscious and able to talk and move, or totally unconscious and/or paralysed. Each person has a unique combination of age, gender, personality, ethnic origin, social and cultural background, general health and other experiences, which may result in different physical and psychological responses (Clark 1987).

Nursing priorities and management

Goal: to support the patient psychologically, interacting in order to minimise the stress of the ICU environment.

Plan:

- provide adequate information, reassurance and encouragement
- prevent sensory overload or sensory deprivation
- maintain natural biorhythms/sleep patterns.

Providing adequate information, reassurance and encouragement

Nichols (1993) identified informational care, emotional care and counselling as the essential components of good psychological care in illness. All are dependent on optimal communication. Similarly, 'reassurance' and 'encouragement' are often identified as important to nursing, particularly in intensive care, but they are often not defined in practical terms. The difficulties of communicating with intubated patients and the theoretical reasons why communication is essential have long been known, e.g. Ashworth (1980). Good communication may enable patients to see monitoring equipment as helpful rather than frightening, even if they do not always remember being told about it. Support for each patient is most likely to be optimised when nurses, visitors and the patient collaborate to achieve effective and sensitive communication.

For further reading on maintaining confidentiality and information giving, see Lissemann (2000).

Preventing sensory overload/sensory deprivation

The sensory environment of an ICU is abnormal, compared with the environment in which people usually live, and can be disturbing even to those who are healthy. The sounds of ventilators, tracheal aspiration, equipment warning signals, the movement of trolleys and the like all combine to provide an auditory environment which may both bewilder and provoke anxiety. Patients may also experience other unusual stimuli, such as bright lights and strange equipment, and sensations of heat or cold, of being handled by other people, and of being attached to tubes and wires. There may also be a fear of falling out of bed during a change of position while paralysed, discomfort from tapes holding the ET tube in situ, and pain. Sometimes there is a lack of body privacy and a sense of humiliation. Boredom, powerlessness and fear that essential machinery might fail are commonly reported (Offord 1998, Bemun et al 2003).

Critically ill patients may suffer sensory overload or sensory deprivation, or a combination of both. Many years ago, Goldberger (1966) identified five areas of investigation related to sensory alteration which bear mention here:

- reduction of stimulus input variables — an absolute reduction in the variety and intensity of stimuli
- reduction of stimulus variability — the quantity of stimuli is the same but there is reduced patterning, imposed structuring and homogeneous stimulation. When light is diffuse, sound is muffled and body sensations are non-distinct and difficult to interpret; this is referred to as perceptual deprivation
- social deprivation — isolation from people and familiar environment
- confinement — immobilisation or restriction of movement
- increased sensory input — input via a number of senses at greater intensity than normal.

All of these can be found in individual or collected accounts of the experience of critically ill patients, as can accounts of nightmare auditory and visual hallucinations, delusions and paranoid feelings about staff and the environment (Heath 1989).

Patients may also experience depersonalisation, disturbed body image and extension of body boundaries, so that they regard machinery such as the ventilator as part of themselves (Smith 1989). One factor which is important in determining a patient's responses to a critical care environment is the nature of the human environment. Psychological as well as physical stimuli can be stressful and cause physiological reactions that may be harmful to critically ill patients. Such stimuli may result from deficiencies in the human environment. Nurses are an important part of the sensory and human environment of patients, and vice versa. Nurses affect the internal environment and responses of patients, and are in turn affected by them (Ashworth 1980). Many ex-patients say that a caring staff member, usually a nurse, who they trusted, was essential to their confidence and sense of security.

For further reading on nurses' experiences of assessing and dealing with patients' psychological needs, see Price (2004).

Psychological and behavioural problems

Mental health problems in the ICU can be divided into three categories:

- organic brain disorder, e.g. dementia, delirium
- psychological reaction to illness, i.e. depressive illness
- previous mental illness.

Delirium is common among critically ill patients within the general ICU setting; postanaesthetic states, hypoxia, systemic infections, drug intoxication, alcohol withdrawal and metabolic derangement also contribute to states of delirium. Symptoms vary considerably and, prior to medical intervention, the patient should be assessed clinically, establishing haemodynamic stability and, where possible, the probable cause of delirium (Roberts 2001).

Haloperidol is usually the medication of choice but should not be given before first assessing the patient's vital signs, clinical condition and the underlying cause of their behaviour.

Maintaining natural biorhythms/sleep

Human beings have biological or circadian rhythms that are normally related to the sleep/wake cycle, including fluctuations in body temperature, blood pressure, heart rate and plasma levels of various hormones (see Ch. 25).

In ICUs, there is always a concern that activity and lighting may be more or less constant because of the need for constant observation and frequent treatment, leading to lack of sleep for patients and disturbance of their biological rhythms, and also contributing to the sensory–perceptual alterations and delirium known to affect a considerable

proportion of critically ill people. Diminishing the amount of light, noise and disturbance as far as possible at night can help to minimise such potential problems. It is clear that nursing requires the application of sound knowledge, judgement and skill. Practice must be sensitive, relevant and responsive to the needs of the individual and nowhere more so than when preventing sleep deprivation.

CULTURAL NEEDS AND SPIRITUAL CARE

Nursing priorities and management

Goal: to meet the spiritual and cultural needs of the patient and family.

Plan: ensure that the spiritual beliefs of the patient and family are upheld.

Spiritual health relates to having a sense of meaning, hope and purpose in life, not simply to having a religious faith. Cultural and personal values are relevant to purpose in life and should be considered in assessment and care.

Some critically ill patients lose hope and 'give up', ceasing to fight for life, particularly when ill for days or weeks, and this can contribute not only to their current physical and emotional experience but also to the outcome of the illness. Anything a nurse can do, either directly or with the help of the patient's family or friends, to help the patient draw on their usual resources and sources of support must be helpful (Hupcey 2001). Helping people to continue the practices important to them in life can enable them to do so, and there are a variety of ways of doing this. Many former patients have indicated that faith can be an important part of a person's life and a comfort in a crisis (Ashworth 1987).

The role of family and friends

Family and friends play an important role in relieving social isolation, depersonalisation and disorientation for patients. Yet family and friends are unable to be of maximum help to patients unless they themselves are assured of any necessary help from the nurses in the form of access, information and emotional support. Nurses have a great influence on the extent to which family and friends can support the sick patient during intensive care, after transfer to a ward and then home. Some of the major expressed needs that have been identified from a number of studies are the need to reduce anxiety, the need for information, the need to be near the patient and the need to be helpful.

For further reading on the needs of family members of ICU patients, see Wilkinson (1995).

SUMMARY

Care of the critically ill patient is a diverse and ever-expanding field, as medicine and technology collaborate to support patients through life-threatening situations. It is often viewed only as a highly technical arena. However, the same general principles of care apply, be it in an ICU, a general hospital ward or the community setting. To be effective, nurses must have a sound knowledge and understanding of physiology and other sciences, of how the body works in health as well as in illness; of technical equipment and its functions and of how people behave in, and respond to, health and illness. The expertise, however, is to be able to use this knowledge to generate competent skills and the judgement necessary to achieve the best possible outcomes for patients and their families.

This chapter has only touched on some of the fundamental concerns surrounding the nursing care of the critically ill patient. It has to be said that, as medicine strides forward to maintain life in increasingly fragile states, it does indeed create its own ethical dilemmas, and while it is not possible to cover these issues in this chapter, it is important to consider the ethical implications that critical care nursing may encounter.

INTRODUCTION

Imagine for a moment having lost everything: your loved ones; your home and possessions, including mementoes from the past; your health and ability to function normally; your appearance — in other words, yourself. This not infrequently occurs when people are victims of a house fire.

Most people are burned more than once in their lifetime but few have any conception of the horror associated with severe burns injury. Extensive burns injury is catastrophic, both physically and psychologically, for the patient and their family. It is also one of the most challenging and arduous types of injury to treat. In order to help the patient and their family to achieve optimum function, the responsibility of care must be distributed throughout the multidisciplinary team. However, the nurse, being the only professional in 24-h attendance, will play an especially important role. Nurses also attend to many patients whose burns are not extensive, providing care in the community, in emergency departments (ED) and in general surgical wards. This chapter aims to provide information which will help the nurse care for patients with burn injuries in any of these settings.

PREVENTION OF BURN INJURIES

Burns are frequently described in the literature as being among the most serious of injuries because of the long-term problems which are often associated with them. Advances in treatment and improved facilities have led to a reduction in mortality rates, but the morbidity resulting from burns is such that prevention must be viewed as the responsibility of all health care personnel.

One of the main aims identified in the constitution of the International Society for Burn Injuries (ISBI 1979) is 'to disseminate knowledge and to stimulate prevention in the field of burns'. Many studies have since emphasised that, in order to be effective, burn prevention programmes should involve assessment of the incidence of burn injuries, followed by planning, implementation and evaluation of appropriate interventions (Liao & Rossignol 2000).

Assessment

This includes identifying the extent of the problem, its causative agents and any predisposing factors.

The extent of the problem

Department of Trade and Industry data (1999) revealed that, in the UK, 112 000 people attend emergency departments annually suffering from the effects of burn injuries, with a further 250 000 presenting at GP services; approximately 7765 people require hospital admission and 211 people die each year as a result of burn injury. However, due to advances in treatment, burn mortality rates have fallen over the last two decades (Pereira et al 2004). Although statistical data on burn mortality are generally available, the incidence of burn morbidity is difficult to estimate. Van Loey et al (2001) identify the problem as being substantial in terms

of the ensuing psychological and physical difficulties experienced by the patient.

Causative agents

Studies report that either scalds or flame burns are the most common type of burn injury. Contact burns (from touching hot objects) also have a high incidence. Chemical and electrical burns occur less frequently.

The Office of the Deputy Prime Minister (2003), which is responsible for collating fire statistics, identifies the most common cause of death in domestic fires as careless handling of fire and hot substances, mainly smokers' materials. Non-fatal burn casualties result from the misuse of equipment or appliances, most commonly cooking appliances (see Case History 30.1). In the case of scalds, the electric kettle is recognised as a major cause of injury, usually in children of pre-school age (Sheller & Thuesen 1998). Hot water in plumbing systems is also a considerable cause for concern in countries where there is no legislation governing the upper limit of plumbed water temperature. Although many authorities advocate a temperature of 50°C (which would take 2–3 min to cause a burn), because of altered sensation and reduced mobility in older people, this figure has been reduced to 43°C in residential accommodation for older people (Stone et al 2000) (see Box 30.1 for advice on reducing the risk of scalds).

Predisposing factors

Epidemiological studies identify toddlers as being at greatest risk of burn injuries, with scalds accounting for most of these. Adult high-risk groups include those with epilepsy (Josty et al 2000) and those who smoke tobacco, drink alcohol in excess and take prescribed psychotropic medications (Duggan & Quine 1995) (see Case History 30.2). Haum et al (1995) found that patients with positive blood alcohol levels had a significantly higher fatality rate than those with negative blood alcohol levels. Older people have also been identified as being more susceptible to burn injury and as having a higher mortality rate following injury (Sarhadi et al 1995). Studies agree that males of all ages are at higher risk than females.

The common denominator of predisposition to burn injury appears to be a combination of reduced awareness of danger and decreased mobility.

CASE HISTORY 30.1
Ms C

Ms C, aged 24, returned home after a night out with her friends and, feeling hungry, decided to have some chips. She put the chip pan on the stove, leaving the fat to heat whilst she got ready for bed. Smelling smoke, she rushed back to the kitchen to find the saucepan in flames. In her panic she tried to douse the flames by smothering them with a dry towel, which promptly caught fire. She then remembered to put the lid on the saucepan and turn off the stove. Her screams alerted the neighbours, who phoned for an ambulance. Ms C was rushed to the nearest casualty department, where, on examination, she was found to have a total of 8%, mainly superficial, burns to her hands, forearms, chest and face.

Box 30.1

Reducing the risk of scalds

- Water does not have to be close to boiling point to cause severe injury.
- A cup of freshly made tea or instant coffee takes 20 min to reach a temperature which will not damage the skin and 15 min if milk is added (Mercer 1988). The same study found that the contents of a newly boiled kettle containing 1.5 L of water will take 1 h to reach a safe temperature.
- Water at a temperature of 66°C will cause a full-thickness scald after 2 s contact and, at 60°C, after 6 s (Moritz & Henriques 1947). Walker (1990) and Adams et al (1991) advocate the reduction of plumbed hot water temperatures to 50–55°C, and to 43°C in residential accommodation for older people (Stone et al 2000).
- Setting the hot water thermostat to a lower temperature will help to reduce fuel bills.

CASE HISTORY 30.2
Mr M

Mr M, aged 47, regularly abused alcohol and was a heavy smoker. One evening, after a bout of heavy drinking, he fell asleep, dropping his cigarette onto the horsehair sofa on which he was resting. The material smouldered, but did not immediately burst into flames or produce toxic fumes. Mr M was lying on his left side with his right hand resting on the sofa. He was eventually found by his brother, who dragged him off the sofa, extinguished the flames and called for an ambulance. On admission to the burns unit, Mr M was found to have sustained full-thickness burns to the left side of the face and chest. There was no circulation through his left hand and arm (which required above-elbow amputation) and the fingers of his right hand were burned down to the bone. The total body surface involved was estimated at 20%.

Planning and implementation

Planning for a burns prevention programme must be realistic. While it is impossible to modify certain risk factors, e.g. gender and age, having identified the groups most at risk, it should be possible to alter some of the related predisposing factors.

In the past, burn prevention programmes were based on education of the public, but recent studies indicate that, on its own, this is not an effective method.

McLoughlin (1995) recommended the use of the 'public health model' which considers three factors: the host or person at risk, the agent and the environment. With regard to the host, Adams et al (1991) found that recognition of potential danger did not alter the behaviour of adult high-risk groups. There are already numerous health education campaigns aimed at persuading the public not to smoke and to drink alcohol in moderation. It seems unlikely that those who do not comply would be influenced by the knowledge that smoking and drinking increase their risk of burn injuries. Tones and Tilford (2001) point out that, unlike

the promotion of commercial products, which is based on enhancing pleasure, promising immediate gratification, health promotion usually urges people to stop doing something which they find pleasurable in the hope of long-term benefit. They also state that the public have a right not to be unreasonably frightened. Blatant shock tactics are therefore considered unacceptable and are likely to make people 'switch off'. More subtle, but potentially potent, messages may be conveyed, e.g. by incidental reference in popular television series.

Identification of the burn agent or energy source results from epidemiology studies. The agent may be a result of poor design of equipment, such as the hot water jug which has a higher centre of gravity than a kettle, or a stove or radiator which produces a high surface temperature. Once the problem has been recognised, modification of design may be sufficient to eradicate the danger.

Product modification may be carried out voluntarily by manufacturers; however, legislation is often required. Since 1990, it has been against the law to sell new or re-upholstered soft furnishings which are padded with foam that is not combustion-modified or which are covered with fabric that does not resist ignition tests for both smouldering cigarettes and match-like flames. Currently, cigarettes contain an additive which allows them to smoulder for 28 min, and in many developed countries there is interest in introducing a regulation to reduce the ignition propensity of cigarettes (Harper & Dickson 1995, McLoughlin 1995).

Previous legislation and regulations include the prohibition of the sale of highly flammable children's nightwear and the requirement that all new gas or electric fires and radiant oil-burning stoves are fitted with a fireguard which passes British Standards specifications.

With regard to the environment, probably the greatest single factor in reducing death and injury by fires in the home has been the introduction of smoke detectors/alarms. In North America, their installation into both new and established domestic properties is legally required. In the UK, legislation is more arbitrary and installation into established properties is voluntary. Because of their sensitivity, smoke detector alarms may be set off by cooking fumes, e.g. burning toast, and there have been numerous reports of people consequently removing the batteries from smoke detectors from properties where they have been installed. Some detectors have a temporary 'silence' button which may solve the problem of false alarms; however, as the ceiling is the recommended site for mounting, the detector may be out of easy reach.

It must be recognised that the groups at highest risk of injury from burns, i.e. older or disabled people, may be less able than others to buy the new, safer soft furnishings and heating appliances. Smoke detectors may be bought for as little as £5, but their fitting, although simple for the able-bodied, may be impossible for older or disabled individuals.

Health care workers, therefore, not only have a responsibility to disseminate information on the prevention of burn injuries, but also must work closely with other interested groups such as the Fire Brigade, The Royal Society for the Prevention of Accidents (see 'Useful websites', p. 1027) and both local and national government offices in order to lobby for more effective legislation and regulations. Nurses working in the community have the opportunity to observe the environment and to give specific advice relating to burns prevention.

For further information on prevention and health promotion, see Ewles & Simnett (2003) and Sidell et al (2003).

FIRST AID TREATMENT OF BURNS

Burn injuries result from the transfer of energy from a source of heat to vulnerable tissues. The higher the temperature of the heat source and the longer it is in contact with the tissues, the greater will be the destruction.

The first priority of first aid treatment is to remove the individual from the source of heat. If the causative agent is electricity, it is important to switch off the supply, if possible, or to use non-conducting material to rescue the person.

Frequently, there is a continuing source of heat in the form of the individual's clothing, which may be on fire or saturated by a hot liquid. The most effective way to remove this continuing heat source is to throw cool liquid, which is neither flammable nor corrosive, over the affected material, thus dousing the flames or reducing the temperature of the scalding liquid. If no such cool liquid is immediately to hand, rapid removal of hot saturated clothing will arrest the heat transfer. Where clothing is on fire, it is important to stop the person running around as this will fan the flames. The person assisting should lie the victim on the ground and use heavy material such as a coat or blanket to smother the flames. If chemicals are the causative agent, prompt sluicing with copious amounts of water will dilute the strength of the agent and limit the penetration of the chemical into the skin, where it will continue to cause damage for many hours. Hojer et al (2002) demonstrate the advantage of taking this universal first aid measure rather than taking time searching for specific neutralising agents. In the clinical situation, a useful means of identifying whether a chemical is acid or alkaline is to apply a Multistix, normally used for urine testing, as this will give a pH reading.

Having taken steps to remove the heat source from the skin, the next measure is to cool the superheated tissues. The easiest means of doing this is to place the affected part in cold water. For the face, however, cold soaks should be applied. The application of ice or chilled water below 5°C is contraindicated, as Sawada et al (1997) found that this was associated with increased likelihood of tissue damage, possibly due to vasoconstriction. There is no doubt that continued cooling helps to reduce pain from the burn wound, but if a large area of the body surface is involved there is a risk of hypothermia.

Ellis and Rylah (1990) advised against using cold soaks or ice packs during the transfer of patients to hospital, especially if the journey was to take some time. For example, a 10-year-old girl sustained 12% burns on her back when her shirt-tail came into contact with a gas flame. Her brother, with whom she was playing, threw the contents of a jug of lemonade over the flames; then she was placed in a bath by her mother, who repeatedly scooped cold water over the burned area. She then wrapped her daughter in a clean sheet and took her to the local hospital. From there, the child was transferred to a specialist unit, a journey of more than 1 h. During the period of transfer she was lying prone on

a stretcher lined with incontinence pads, absorbent surface up. The escorting nurse carried out the instructions, which were to continually irrigate the saline soaks which had been placed on the girl's back with cold saline from a cool-pack. When the patient arrived at the specialist unit, the rectal temperature was recorded at 34.8°C. Tsuei and Kearney (2004) have noted a high mortality rate related to trauma patients who have a core temperature of less than 35°C at the time of their admission to hospital. Fortunately, in the case described, the child survived. Patients with extensive burns clearly have problems in retaining body heat. The use of space blankets or other heat-retaining coverings is advised during the period of transfer.

Many burns units in the UK are now advising that the temporary wound dressing of choice is polyvinyl chloride film, e.g. clingfilm (Lawrence 1996a). The reasons for this are as follows:

- the film is sterile on the inner rolled surface
- it does not adhere to the wound surface and cause pain on removal
- it conforms closely to the body contours and excludes air, thus reducing pain
- a succession of personnel can view the wound without removal of the transparent film.

This kind of material is often available in the home but, if not, a clean cloth should be used as a temporary cover. The use of ointments, lotions and powders should be avoided as they may change the appearance of the wound and thus impair the assessment of the burn.

Practice and treatment room nurses often see people with severe sunburn that, unsuccessfully self-managed, has become infected. This can also happen with other types of burns, as in Case History 30.3.

To summarise, first aid treatment of burn injuries consists of:

- separating the individual from the source of injury
- immersion of the affected part in cold water for 10 min or application of cold soaks to the face
- application of polyvinyl chloride (cling) film or a clean cloth to the wound; cold soaks may be used for wounds which are not extensive.

ASSESSING THE SEVERITY OF BURN INJURIES

The majority of patients with burn injuries do not require hospital inpatient care. The UK National Burn Injury Referral Guidelines (2001) recommend that when deciding whether to refer patients to a burn unit, consideration should be given to the complexity of the burn injury rather than simply to the size of the burn wound. The categories of patients for whom admission or referral to a regional burns unit is advisable include:

- those under 5 years or over 60 years
- those whose burns exceed 5% of the body surface area
- those with burns on functionally important areas such as face, hands, feet, perineum, joints or flexor surfaces
- those with electrical or chemical burns
- those with infected wounds or evidence of infection
- those with small, full-thickness burns which would benefit from early excision and grafting
- those whose injury limits their capacity to care for themselves at home
- those with associated injuries, e.g. smoke inhalation, crush injuries, fractures
- those with other medical conditions, e.g. epilepsy, diabetes mellitus, cardiac limitation
- where there is doubt, either suspected non-accidental injury or uncertainty about the depth of the burn.

For patients who do not fall into any of these categories, relief of pain and local treatment of the burn wound are generally all that is required. Both interventions will be described later in the chapter (see p. 1022).

The UK guidelines also suggest that in the post-acute phase of burn injury, practice nurses and district nurses should refer patients whose burn has not healed within 14 days, as any resulting scarring may have significant impact on the subsequent physical and psychological rehabilitation of the patient.

Assessment of the severity of the burn injury involves estimation of:

- the extent of body surface area involved
- the depth of tissue damage
- the probability of associated respiratory tract injury.

Knowledge of the circumstances of the accident, e.g. whether electricity was involved, and information about the individual's general health and domestic situation will help in deciding whether the patient may, or may not, be managed by the primary health care team.

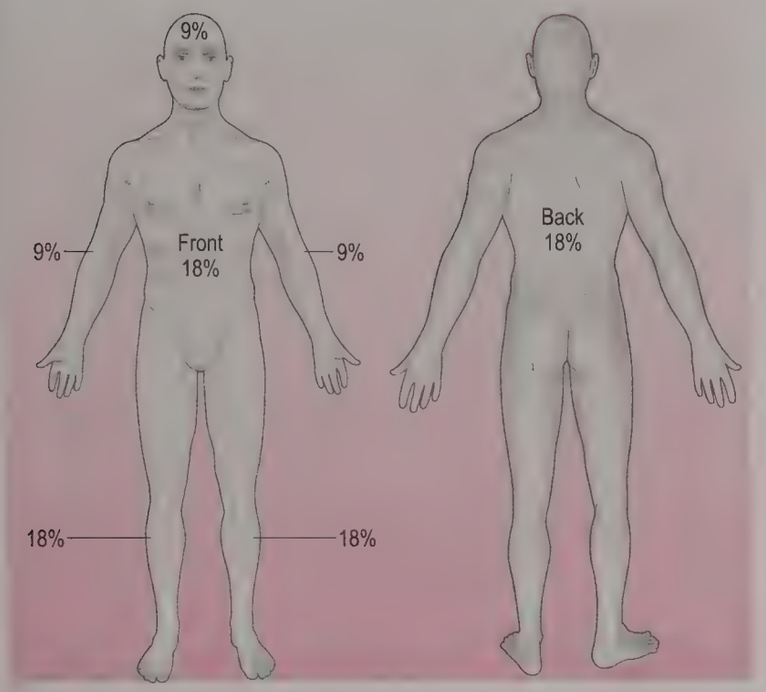
CASE HISTORY 30.3
Miss K

Miss K, aged 53, suffers from diabetes and lives alone. One morning she awoke to find that she had blistering on her left lower leg. She assumed this had been caused by contact with her hot water bottle. As there was no pain, she did not contact her doctor but dressed the burn herself, using an antiseptic cream and a bandage. A week later she attended the local health centre as the wound was now very inflamed and producing pus.

Extent of burn

Whenever body tissues are traumatised, the inflammatory response is stimulated, resulting in increased circulation to the area (hyperaemia) and increased movement of fluids from intravascular to interstitial compartments. If this occurs in a small area, i.e. over less than 5% of the body surface, the effects are localised. However, when a larger percentage of the body surface is injured, there is a massive shift of fluids into the tissues with a corresponding reduction in circulating volume. It is generally accepted that children with burns involving more than 10%, and adults with burns of more than 15%, of body surface area will suffer from hypovolaemic shock unless there is prompt intravenous replacement of fluid (see Ch. 18).

In order to estimate the percentage of body surface affected, the simplest and most easily remembered method is the long established 'rule of nines' introduced by Wallace



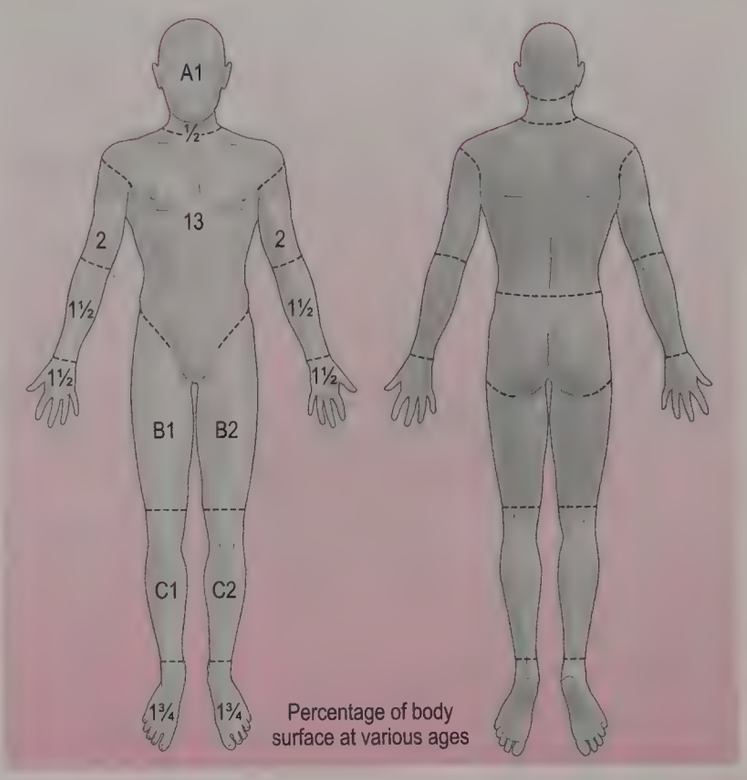


Fig. 30.1 Wallace's rule of nines.

Percent of areas affected by growth

	0	1	5	10	15	Adult age
A = ½ head	9½	8½	6½	5½	4½	3½
B = ½ one thigh	2¾	3¼	4	4¼	4½	4¾
C = ½ one leg	2½	2½	2¾	3	3¼	3½

To estimate the total of the body surface area burned, the percentages assigned to the burned sections are added. The total is then an estimate of the burn size.

Fig. 30.2 The Lund and Browder burn chart.

in 1951 (see Fig. 30.1). In this method, the head and upper limbs each equal 9%, while the anterior trunk, the posterior trunk and the lower limbs each equal 18%. The remaining 1% is usually applied to the perineum. Another rapid approximation of the percentage can be made by using the palmar aspect of the patient's hand (with fingers together) as 1% of the body surface area.

The rule of nines should never be used for estimating burn percentage in young children as it does not allow for the different proportions of head and lower limbs in infants and toddlers. Under the age of 1 year the child's head equals 19% of the body surface area and the lower limbs are correspondingly smaller. A more accurate chart which allows for the changing proportions of different age groups and which shows percentages applicable to smaller, more specific areas of the body surface is the Lund and Browder (1944) burn chart (see Fig. 30.2). This is generally in use in specialist units and is available in EDs throughout the country.

Burn depth

The depth of a burn influences the rate at which the wound will heal spontaneously. The longer the wound takes to heal, the greater the probability of infection and the worse the scarring and loss of function (see Ch. 23). There are a number of methods of classifying burn depth. In the UK, the most popular is to differentiate between partial-thickness and full-thickness skin destruction. Partial-thickness burns involve the epidermis and part of the dermis. Full-thickness burns destroy the epidermis and all of the dermis. Full-thickness burns may also involve deeper structures such as fat, muscle and bone. Partial-thickness burns are classified as 'superficial' or 'deep', depending on the amount of dermis involved. As a general rule, deep partial-thickness and full-thickness burns require surgical enhancement of healing in the form of skin grafting.

As may be seen from Figure 30.3, the more superficial the injury, the greater the number of surviving epithelial sources from which cells will undergo mitosis and migrate across the wound surface; thus a more superficial burn heals more rapidly and causes less wound contraction. The effects of superficial partial-thickness burns and full-thickness burns are described below and in Table 30.1.

Superficial partial-thickness burns

These burns are very painful as the sensory nerve endings are stimulated by the injury or exposed to air. They are characterised by oedema, blister formation and serous exudate where the blisters burst. The blistering results from the increased permeability of the capillary walls, with fluid leaking into the interstitial spaces and from the wound surface. This fluid collects into blisters beneath the non-germinating layers of the epidermis. Heat radiates from the wound surface due to arteriolar dilatation and increased blood flow and as part of the inflammatory response. This also causes the typical bright pink appearance of the wound, which will blanch on pressure. On removal of the pressure the hyperaemia is restored.

Full-thickness burns

These burns are painless, as the sensory nerve endings have been destroyed. There is no blister formation and the

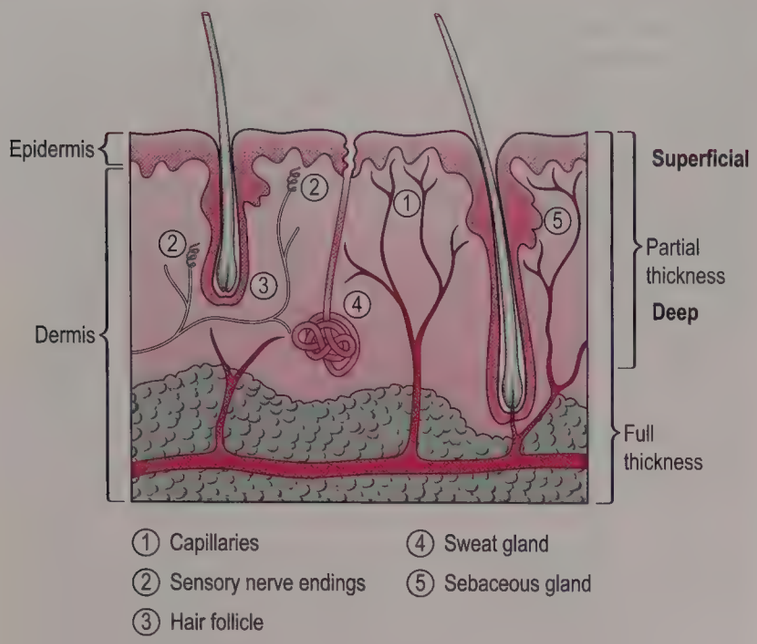

Fig. 30.3 Classification of burn depth.

wound surface is dry. There is no overt oedema, the wound surface is cool to the touch and the colour may be white, brown or bright red with no blanching on pressure. These characteristics are all due to the fact that there is no surviving circulation within the dermis. The brown or red colour is due to the release of haem pigments from destroyed red blood cells. The area may appear translucent with thrombosed vessels being apparent. It is important to recognise that there is an inflammatory response in the deeper tissues affected, but this is masked by overlying necrotic tissue. High temperatures (>60°C) cause coagulation of the tissue proteins and water is lost from the cells, interstitial spaces and blood vessels, resulting in a degree of contraction of the affected tissues. Destruction of the dermis renders the skin inelastic and the texture becomes firm and leathery. This destroyed tissue is known as eschar (see Box 30.2).

Box 30.2

Escharotomy

Where full-thickness burn injury occurs circumferentially around a limb, the combination of a firm inelastic eschar and the covert inflammatory response in the subcutaneous tissues will cause compression of the deeper structures, especially the blood vessels. Incisions through the eschar to allow decompression are carried out by the surgeon and are termed escharotomy.

Escharotomy may also be carried out when full-thickness burn injury of the chest and upper part of the abdomen inhibits rib or diaphragmatic movement, causing respiratory difficulty.

Nursing note. Monitoring of circulation to distal parts of limbs involved or of respiratory ease is required when full-thickness burns are suspected in either site.

Deep partial-thickness burns

As the depth of destruction in this type of burn is between those of superficial partial-thickness and full-thickness burns, the presenting signs and symptoms are between the extremes in sensation, blistering, temperature and colour.

Problems in assessment

The assessment of burn depth is not an exact science, although much work has been carried out to make it more so in recent years. The use of a hypodermic needle to test for

Table 30.1 Indications of burn depth

Depth	Signs and symptoms	Related anatomy/physiology
Superficial partial-thickness burns	Very painful	Sensory nerve endings in the dermis are stimulated by the injury and/or exposed to air
	Oedema, blister formation, serous exudate where blisters have burst	As a result of the inflammatory response, the capillary walls are more permeable and fluid leaks into the interstitial spaces of the dermis, collecting below the non-germinating layers of the epidermis or exuding from the wound surface
	Wound surface warmer than unburned skin	Also due to the inflammatory response; arteriolar dilatation causes increased blood flow
	Wound appears bright pink and blanches with pressure	Due to increased blood flow. Pressure greater than capillary blood pressure occludes the flow of blood
Full-thickness burns	Painless, no sensation	Sensory nerve endings in the dermis are destroyed
	Wound surface dry. No blistering	Cessation of blood flow through dermal capillaries
	No overt oedema	Necrosis of dermis renders it inelastic
	Wound surface cooler than unburned skin	Cessation of blood flow through dermal capillaries
	Wound colour may be white, brown, translucent showing thrombosed vessels, or bright red (does not blanch on pressure)	Cessation of blood flow through dermal capillaries. Brown or red appearance is caused by release of haem pigments from destroyed red blood cells

pinprick sensation was first described by Bull and Lennard-Jones (1949), and Settle (1996) admits that, although not an absolute test for viability, it is still useful. Pape et al (2001) found that laser Doppler imaging may be used successfully in aiding assessment of burn depth; however, this option is not readily available outwith specialist burn units. Frequently, assessment of burn depth is dependent on the visual characteristics of the wound, the information given regarding the circumstances of the accident, the agent involved and the first aid measures carried out.

Burn-associated respiratory tract injury

Inhibition of respiratory function may result from thermal injury to the skin of the trunk and neck. Covert oedema formation below the leathery, inelastic eschar of circumferential full-thickness burns causes pressure on the deeper structures. In deep burns of the neck, this may cause compression of the trachea and, if there is involvement of the chest and upper abdomen, will inhibit expansion of the thoracic cavity. Decompression by escharotomy will be required (see Box 30.2).

Inhalation of smoke and hot toxic gases is frequently associated with burn trauma. The potent synergistic effects of burns and smoke inhalation are noted by Beeley and Clark (1996), who state that for victims of smoke inhalation who are unburned and alive on arrival at hospital the mortality rate is low, whereas for those who are also burned the mortality rate associated with the extent of burn is substantially increased.

The main causes of inhalation injury are:

- intoxication and hypoxaemia
- thermal damage to the airways
- respiratory tract injury due to irritants.

Intoxication and hypoxaemia

Intoxication and hypoxaemia most commonly result from inhalation of carbon monoxide and/or hydrogen cyanide produced by burning plastics.

Carbon monoxide (CO), produced by the combustion of carbon and organic materials in a limited oxygen supply, has an affinity for haemoglobin many times that of oxygen. Therefore, following inhalation of CO there is displacement of oxygen on the haemoglobin molecules and the production of carboxyhaemoglobin (COHb) with resulting generalised hypoxia. The symptoms of CO poisoning are related to the concentration of the inspired gas and to COHb levels and are recognised as mild headache, dizziness, confusion, irritability, nausea, vomiting and fainting. At higher levels there will be convulsion, coma, respiratory failure and death. Diagnosis is suggested by the typical cherry pink appearance of the patient and confirmed by checking COHb levels. The formation of carboxyhaemoglobin can be reversed by the administration of high concentrations of oxygen.

Hydrogen cyanide is rapidly absorbed through the lungs and binds readily to the cytochrome system, inhibiting cell function and resulting in metabolic acidosis. It causes loss of consciousness, neurotoxicity and convulsions. However, over a period of time it is gradually metabolised by the liver enzyme rhodenase (Australia & New Zealand Burn Association Ltd (UK) 1996).

Thermal damage

The upper airway may be damaged by the inhalation of hot gases, hot vapours or combustible gas mixtures. Mucosal oedema will narrow the lumen of the airway. The diagnosis is suspected where there is a history of explosion, burns of the face, singed nasal hairs, erythema and ulceration of the oropharynx. Hoarseness and inspiratory stridor may present later. As signs of upper airway obstruction may take several hours to become apparent, constant supervision is required.

Hot, dry air seldom causes burns of the airway below the level of the epiglottis as the respiratory tract has an excellent heat exchange capability. Injury to the lower airway is most commonly caused by inhalation of toxic chemicals.

Inhalation of irritant chemicals

The combustion of various materials produces a wide spectrum of irritant chemicals, including chlorine, ammonia, formaldehyde and phosgene. The extent of the resultant damage to the respiratory system will be determined by the density of the smoke and the duration of exposure. Patients who are asleep or under the influence of drugs or alcohol at the time of the fire will tend to have a longer exposure time, as will those who have restricted mobility, e.g. older or disabled people.

When irritant chemicals bound to carbon particles settle on the respiratory endothelium, the following reactions occur:

- the inflammatory response — this causes increased secretions and narrowing of the lumen of the trachea, bronchi and bronchioles
- inflammation of the alveolar capillary membrane — this interferes with gaseous exchange, and capillary exudate will leak into the alveoli
- bronchospasm — this causes further narrowing of the lumen of the airway
- chemical denaturation of all protein, which leads to:
  - — necrosis and ulceration of the epithelial tissue, with an increase in cellular debris
  - — cessation of ciliary activity, inhibiting removal of secretions and cellular debris
- loss of surfactant production by type II alveolar cells.

Surfactant normally lowers the surface tension of the walls of the alveoli, thus preventing collapse, and also prevents the transudation of fluid from capillaries into the alveoli. Loss of surfactant production will therefore lead to atelectasis (see Ch. 3).

In summary, the pathophysiological results of the inhalation of irritant chemicals may include tracheobronchitis, pulmonary oedema, atelectasis and airway obstruction. These are frequently compounded by infection.

In cases where the patient survives long enough for admission to hospital, the respiratory damage related to inhalation of smoke may take several hours or even days to become manifest. Suspicion should be aroused where:

- the fire occurred within an enclosed space, especially at night
- there is a history of exposure to smoke, especially if the patient required bodily rescue
- the patient's breath and clothing smell of smoke

- there is inflammation of the conjunctivae
- carbon particles are present in clothing, wounds, nose, mouth and sputum.

Other injuries

The appearance of a patient with extensive burns may be so visually dramatic as to distract the assessor from checking for other, less obvious, injuries. Fractures, internal injuries and spinal cord damage may have been sustained, especially if the burn was a result of a road traffic accident, an explosion or high tension electricity, or if the patient jumped from a burning building.

THE PATIENT WITH EXTENSIVE BURNS

Early problems and nursing care

The patient with extensive burns has multiple problems, the relative urgency of which will vary during the perhaps very prolonged period following injury. There is increasing awareness that extensive burn injury causes a systemic inflammatory response syndrome (SIRS) in which there is widespread disorganisation of the immune system, eventually resulting in multiple organ dysfunction syndrome (MODS) (Sparkes 1997). Sparkes attributes this to a lipid protein complex associated with burned skin.

During the first 36–48 h, however, the most life-threatening problem, except where inhalation injury is present, will be burn shock. The subject of shock is covered in Chapter 18, but a summary of events which have particular relevance to burns injury is given here (see Table 30.2).

The initial physiological response to a burn injury results in plasma loss from the circulation (see p. 1022). This is accompanied by:

- *Gross oedema* of the affected tissues.
- *Hypovolaemia* — as in all types of shock, this results in decreased circulation to the skin, muscle and internal organs. Cerebral and coronary perfusion, being of greatest priority, are temporarily maintained.
- *Haemoconcentration* — unlike the hypovolaemia which results from haemorrhage, the loss of plasma alone from the intravascular compartment causes an increase in the ratio of blood cells to plasma in the circulation, a raised haematocrit. This increases the viscosity of the blood, further reducing the flow through the capillaries.

In addition to suffering from burn shock, the patient may be emotionally shocked, in great pain and have extensive destruction of the skin and, possibly, deeper structures. There may be associated injuries, especially inhalation of smoke, and a pre-burn illness may be present.

Haemoglobinuria may develop in patients who have been badly burned. This is described in Box 30.3.

Table 30.2 Pathology and related clinical features of burn shock

Pathological condition	Clinical signs and symptoms
Hypovolaemia	Thirst Rapid, weak pulse Hypotension Peripheral and splanchnic vasoconstriction
Peripheral vasoconstriction	Pale skin and mucosa Extremities feel cold Patient complains of feeling cold
Reduced perfusion of kidneys	Oliguria, anuria Impairment of renal function Metabolic acidosis Renal failure may occur
Red cell haemolysis	Haemoglobinuria Renal failure may occur
Reduced perfusion of lungs	Rapid, shallow breathing Air hunger — gasping
Reduced perfusion of gastrointestinal tract	Reduced absorption and intestinal stasis Vomiting, loss of electrolytes Paralytic ileus, lack of bowel sounds Bacterial translocation through mucosa
Hypoxaemia/electrolyte imbalance	Restlessness, disorientation, confusion May lead to coma and death

Box 30.3

Haemoglobinuria

This is a potential complication of extensive burn injury which may result in acute renal failure.

As haemoglobin has the molecular weight of 68 000 mmol, it may be filtered through the glomerulus and pass into the renal tubules. Under normal circumstances, haemoglobin is not free in plasma, because when erythrocytes degenerate they are processed by the mononuclear phagocytic system. If pathogenic haemolysis does occur intravascularly, the haemoglobin is usually combined with the plasma protein haptoglobin, a mechanism for iron conservation, which forms a molecular complex too large to pass through the glomerulus.

However, if intravascular haemolysis is extensive, there will be exhaustion of the haptoglobin and therefore free haemoglobin will be present in plasma. The reason why haemolysis occurs in extensive thermal injury appears to be more complicated than the direct effect of heat on the erythrocytes (Yuan et al 1988). Studies indicated that one of the mechanisms involved is the release of toxic oxygen metabolites, e.g. superoxide and hydrogen peroxide from activated neutrophils (Hatherill et al 1986). The red blood cell changes include increased osmotic fragility and decreased membrane deformability (Endoh et al 1992). Brady et al (1996) noted that there is uncertainty as to the means by which free haemoglobin, and myoglobin from damaged muscle, causes damage to the renal tubules and suggest that it may be due to metabolites of the compounds, other toxins from red blood cells/muscle or the coexistence of other renal insults such as hypovolaemia.

The emergency department

To those unfamiliar with burns, the patient with extensive burns may not appear to be critically ill. The loss of plasma from the circulation is less rapid than haemorrhage from ruptured vessels and the patient may appear quite well. Inexperienced staff should consult with the regional burns unit to ensure that treatment is appropriate to the severity of the injury.

The Australia and New Zealand Burn Association Ltd (UK) (1996) identifies the following principles of primary assessment and management by medical personnel:

A Airway maintenance and cervical spine control
B Breathing and ventilation
C Circulation; cardiac status, with control of haemorrhage if present
D Disability, neurological status
E Exposure with environmental control; evaluation of extent and depth of injury, including removal of jewellery and keeping the patient warm
F Fluid resuscitation; i.v. fluid replacement, including introduction of a urinary catheter for monitoring output, and insertion of a nasogastric tube.

These are followed by X-ray of the cervical spine, chest and pelvis to exclude associated injury.

After life-threatening conditions have been excluded or treated, the secondary survey should be commenced. This includes a patient history, description of incident and complete examination.

Except in instances where nurses are specially educated, the role of nursing staff is to assist with the above procedures, to support the patient and their relatives and to keep meticulous records of fluid balance and of medications given.

Transfer of the patient with extensive burns

The patient should be prepared for transfer with the application of a temporary wound dressing, preferably clingfilm, and covered with a space blanket or layers of ordinary blankets. As described earlier, there is a high risk of hypothermia, especially during transfer, and wet dressings should not be used. If there are airway problems the patient must be accompanied by an experienced nurse, as well as by a member of the medical staff. Monitoring of vital signs and maintenance of the intravenous fluids are usually carried out by the nurse. The speed of travel is frequently rapid, which will make the task of monitoring and recording fluid balance and vital signs very difficult; nonetheless these records are important and, along with the ED file, should be given to the staff of the burns unit on arrival.

Admission to a regional burns unit

The burns unit staff are usually informed in advance of the imminent admission of a patient with extensive burns. The time between their notification and the actual arrival of the patient, depending on the distance from the referral centre, is used to prepare the environment and the necessary equipment.

Reception of the patient

When the patient arrives at the unit, they should be greeted sensitively and orientated as to place, as many regional burns units receive patients from a wide catchment area. One nurse should be designated to receive the patient from the escorting nurse. Where possible, the patient should be reassured and given a simple explanation of what is being done at every stage of the admission procedure and thereafter, throughout their stay in the unit. The appearance and smell of the burn wounds may be very upsetting, not only for the patient but also for inexperienced staff. It is important for staff to appear calm and confident, thus helping to reassure the patient.

The receiving staff must wear protective clothing, e.g. waterproof gowns, plastic aprons or tabards and gloves. This is to protect staff against contact with wound exudate and blood and the patient against wound contamination (Weber et al 2004).

The patient should be received into a single room warmed to a temperature of 28°C, as heat loss from the inflamed wounds, in addition to evaporative heat loss from the wound exudate, can be extensive.

Maintaining the airway

If the patient has inhalation injury, endotracheal intubation and assisted ventilation may have been instituted in the ED or may be required at the time of admission to the unit. In any case, all nursing care and observations relative to this treatment must be carried out (see Ch. 3).

Constant observation of respiratory rate and ease, and of the colour of unburned skin and mucosa, must be carried out and recorded. Humidified air or oxygen administered by face mask or nasal catheter may be required.

Weighing the patient

If possible, an accurate body weight in kilograms should be obtained as this is one of the baseline measurements on which the volume of fluid replacement is calculated. Estimation of weight is sometimes carried out but, unless the person doing so is experienced in this, gross over- or undertransfusion may result. In many units the patient is weighed on a special bed or sling, still covered in the blankets and temporary dressings used for the transfer; these are then gently removed and the patient laid on and covered with sterile sheeting, e.g. linen, foam or clingfilm. The original coverings are then weighed and their weight subtracted from the total in order to get a naked weight. It is important to record the weight immediately as the exact figure may easily be forgotten, especially if there is a great deal of activity in the room.

Wound assessment

The medical staff will estimate the depth of the burn wounds and chart their position and extent. Colour photographs may also be taken for recording purposes. In addition to being useful baseline records of wound appearance and distribution, the photographs may, with the patient's permission, be used in evidence in criminal or civil proceedings. Whilst the wounds are exposed, the nurse can take swabs for bacteriological examination from each wound site, e.g. right hand, left hand, chest, neck. This reduces the possibility of wound contamination and the discomfort

and possible loss of dignity suffered by the patient during repeated removal of the coverings. The initial wound swabs usually show no bacteriological contamination but provide a useful baseline for further monitoring. The wounds are then covered with a temporary dressing. Specific care will be carried out once the patient's condition has been stabilised.

Bacteriology swabs from nose and throat are also obtained in order to identify commensals which may act as wound pathogens.

Analgesics

It is unusual for patients to complain of pain at this stage, even if their wounds are of partial thickness. If pain is felt, however, intravenous analgesics, usually in the form of morphine, are administered by infusion pump, giving an initial dose and then at an hourly rate of 20–30 mcg/kg. The intramuscular route is never used if the patient is in shock, as the medication will not be absorbed owing to the peripheral vasoconstriction.

Intravenous fluid replacement

Once an accurate body weight has been obtained and the percentage area of the burn estimated, the medical staff will calculate the volume of intravenous therapy required. There are a number of different formulae in current use but most depend on these two parameters for calculation of the volume to be infused. Regulation of the rate of flow and recording of the volume transfused, as well as care of the intravenous site, is the responsibility of the nurse. A volumetric intravenous pump provides accuracy for the infusion of volumes required in each period which may be very large.

Monitoring urine

If this has not been carried out in the ED, an indwelling urinary catheter is passed, the bladder emptied and the urine volume measured. A specimen is tested for specific gravity and analysed using a Multistix. The appearance is noted. A urimeter which allows hourly measuring and sampling whilst maintaining a closed system is attached to the catheter. Settle (1996) emphasised the importance of monitoring renal function through regular, frequent measurement of volume and composition of the urine. A volume of 0.5–1.0 mL/kg body weight hourly is generally accepted as indicating that intravenous fluid replacement is satisfactory, although urine concentration, measured by specific gravity or osmolality, must also be estimated in order to assess renal function.

The appearance of the urine is monitored for indications of haemoglobinuria (see Box 30.3) and, if this is present, for indications that it is diminishing. It is important that the nurse inform the medical staff at the first indication of haemoglobinuria, as it is usual for a solution of sodium bicarbonate and an osmotic diuretic, e.g. mannitol, to be prescribed in order to clear the pigments.

Monitoring vital signs

Pulse If the patient is shocked, the pulse will be rapid and weak. This, combined with generalised oedema, can make manual counting very difficult and mechanical aids such as the pulse oximeter are normally used. It should be remembered, however, that the pulse oximeter will only give pulse rate.

Blood pressure Where all four limbs have been burned, it is not usual practice to record blood pressure. Indeed, even if one limb is unaffected it has been considered more important to ensure effective intravenous replacement than to repeatedly constrict the vessels with a blood pressure cuff. Bainbridge et al (1990), however, found that it is possible to monitor mean arterial pressure by using oscillometric automatic blood pressure monitors with the cuff applied over bulky dressings and this method is useful for monitoring blood pressure in limbs with burns.

The routine measurement of central venous pressure or arterial pressure is not recommended in most UK burns units because of the risk of systemic infection associated with such invasive techniques, especially if the site of entry of the catheter is close to the burn wound. Settle (1996) advised that invasive monitoring should be employed if there has been a delay in starting fluid replacement or if severe respiratory, renal or cardiac impairment exists. However, Schiller and Bray (1996) found that the routine use of the pulmonary artery catheter in patients with extensive burns facilitated optimum levels of fluid replacement and was associated with a significant decrease in overall mortality.

Temperature A good indicator of the state of peripheral perfusion is the difference between core and shell temperatures (see Ch. 22, p. 813). In the normal person, under warm conditions, the temperature of a toe is 1–4°C lower than rectal temperature, but in the patient suffering hypovolaemic shock the vasoconstriction is such that the difference may be as much as 15°C. Temperature monitoring is usually facilitated by the use of thermistor probes in preference to the repeated insertion of a rectal thermometer. In some units, a specially designed probe is inserted into the external auditory meatus in preference to using the rectum (see Ch. 22, p. 820). If thermistor probes are not available, it is possible to gauge the shell temperature by feeling the temperature of the peripheries, especially the toes or the tip of the nose.

In addition to monitoring the difference between a normal core temperature and changes in the shell temperature, measuring the core temperature will, of course, also indicate a trend towards hyperpyrexia or hypothermia (see Ch. 22).

Oral intake

Because of the reduction in gastrointestinal tract perfusion which results from hypovolaemia, it is necessary to restrict the volume of oral fluids initially, even if the patient is very thirsty, until it has been established that there is no nausea or vomiting. If there is persistent vomiting, a nasogastric tube is passed and is either allowed to drain freely or aspirated hourly before small amounts of water are given. In some units, a nasogastric tube is passed routinely in all patients with burns greater than 35% of the body surface. However, studies have shown that early (within 6 h) introduction of intragastric feeding is beneficial in reducing both gastrointestinal ulceration (Raff et al 1997a) and mortality (Raff et al 1997b).

Box 30.4

Complications of burn injuries

In some patients with extensive burns, recovery from the initial injury may be complicated by severe episodes of conditions such as severe sepsis, adult respiratory distress syndrome (ARDS) and/or disseminated intravascular coagulation (DIC), causing them to fluctuate between a satisfactory and a critical condition, perhaps for many weeks. This is especially distressing for the relatives who are trying to cope with the altered appearance of their loved one and who can be given no assurance of eventual recovery; their hopes are raised and dashed repeatedly by their own observations of the patient's condition. Less life-threatening complications include gastrointestinal ulceration and haemorrhage, systemic infection of the respiratory system or urinary tract, wound infection, and wound contraction and scar formation.

Patient behaviour

In addition to recording clinical measurements as described above, it is useful for the nurse to keep a record of the patient's behaviour, noting for example, restlessness, confusion, distress or apathy, as these, along with the measured recordings, will give a more complete picture of the patient's condition. If there is cause for concern, monitoring of neurological status is facilitated by use of the Glasgow Coma Scale (see Ch. 28).

The post-shock phase

After the first 36–48 h following injury, the fluid in the interstitial spaces is reabsorbed into the circulation and, although there is continuous fluid loss through exudate and evaporation from the wound surface, there is normally no longer a need for intravenous replacement of fluids. Unless complications arise (see Box 30.4), the intermediate stage of management will have been reached.

Nursing management during the intermediate stage of burn injury recovery follows the basic principles of burn care whatever the extent of body surface involved. Thus nursing priorities include:

- pain relief (see p. 1022)
- hydration and nutrition
- prevention of infection and local wound care
- psychosocial support for patients and relatives (see p. 1025).

Hydration and nutrition

Until wound closure is complete, there will be continuous loss of the water, protein and electrolytes which comprise the wound exudate (see Ch. 20). In addition, nutritional requirements will be increased because of the elevation in the metabolic rate resulting from trauma, as well as the cellular requirements of wound healing. In patients whose burn area is less than 20% of the body surface, oral intake of a normal diet, perhaps supplemented with high-protein, high-calorie drinks, should be all that is required. However, dietary intake should be monitored to allow assessment by the dietitian and the patient should be weighed weekly. The patient should be encouraged to take fluids and the fluid balance should be monitored and charted.

In more extensive burns, metabolic requirements will be greatly increased, making enteral nutrition via a nasogastric tube necessary. As a fine-bore tube is used to facilitate patient comfort and reduce trauma, there may be difficulty aspirating gastric contents to ensure correct placement; X-ray confirmation of the position of the tube will therefore be required. There are a number of proprietary preparations of enteral feeds available and the dietitian will prescribe the type, volume and rate of administration for each individual. Many manufacturers of enteral feeds produce their own giving sets and volumetric pumps; their instructions should be followed in the use of this equipment. Diarrhoea, nausea and vomiting may complicate enteral feeding. Raff et al (1997a) advise that, rather than commencing with diluted feeds, patient tolerance is best developed by introducing the feed at a slow rate and gradually increasing this until the required rate is reached. If there is a problem with using the nasogastric route, percutaneous endoscopic gastrostomy (PEG) may be performed; Kreis et al (2002) found that the placement of PEG tubes through wound areas did not precipitate wound complications. Parenteral nutrition is reserved for patients who are unable to achieve adequate nutrition by the preferred enteral route (see Ch. 21) because of the danger of infection associated with the introduction of central lines; peripheral lines are usually impractical because of the limited availability of peripheral veins.

Prevention of infection

Both non-specific and specific mechanisms of the immune system are impaired in patients with extensive burns (see Ch. 16).

Because of the large areas of skin destruction and the presence of exudate and necrotic tissue, burn wounds rapidly become colonised with bacteria. It has been found that most of the bacteria are acquired from other contaminated patients or equipment in the ward or unit and therefore meticulous attention must be paid to the prevention of cross-infection (Tredget et al 2004) (see Ch. 16). When possible, the patient should be nursed in a single room and standard infection control precautions implemented. Once the patient's wound becomes colonised with an organism, it will soon be found on their bedclothes, personal clothing and on the surface of dressings. Protective clothing must be worn whenever the patient is attended to; this normally consists of plastic tabards or water-resistant gowns. Disposable water-resistant gowns are expensive but are necessary in the care of patients with major burns, as bodily contact between nurse and patient extends well beyond the confines of an apron when handling and moving procedures are carried out or when dressings are being changed. The wearing of masks and caps is usually not necessary, except when the wound is exposed. Gloves should be worn during any direct contact with the patient and the immediate surroundings; clean rather than sterile gloves may be used for most procedures, apart from those requiring an aseptic technique. Adherence to good handwashing practice requires frequent emphasis (Weber et al 2004).

The bacteriological status of the wounds should be monitored regularly by obtaining wound swabs during dressing changes.

THE BURN WOUND

As for any wound, the aim of management is to provide the optimum environment for the natural healing processes to take place (see Ch. 23). However, most burn wounds involve larger areas of the body surface than is common in other types of wound and this presents many problems in wound management.

Most burn wounds exude copious amounts of fluid. This is evident in superficial partial-thickness wounds from the outset. In deeper wounds, the surface is initially dry and, depending on the depth of tissue destruction, it may take days before the eschar becomes saturated with fluid leaking from the damaged capillaries in the deeper tissues. The volume of exudate has been calculated to be as much as 5200 g/m^2 per day in some burn wounds (Lamke et al 1977) and the evaporative water loss may be as much as 20 times the rate of that from normal skin (Quinn et al 1985).

Unless the superficial partial-thickness burn wound becomes infected, or is subjected to further trauma, it should re-epithelialise in 7–10 days. As migration of the epithelial cells occurs, the exudate will gradually diminish. Bayley (1990) described the major aim in burn wound care to be obtaining wound closure as soon as possible. In order to meet this goal, management must entail:

- meticulous cleansing and debridement of devitalised tissue in order to prevent infection
- facilitating re-epithelialisation or granulation in preparation for any necessary wound grafting
- reducing scarring and contractures
- promoting patient comfort.

Pain relief

It is generally agreed that patients with burns experience the greatest pain during therapeutic procedures (Patterson et al 2004). Pain-relieving strategies used in wound care include:

- the administration of morphine and other similar opioids timed to ensure optimum cover during the procedure
- patient-controlled analgesia by inhalation methods, e.g. Entonox
- relief of anxiety through explanation, and if necessary hypnosis and other psychological coping strategies.

The degree of discomfort the patient experiences will be strongly related to the skill of the dresser and to their ability to recognise and appreciate the individual's pain threshold and tolerance (see Ch. 19). Examples of useful pain assessment tools are given in Chapter 19.

Wound cleansing and debridement

The following procedures must be carried out using strict aseptic technique. If carried out correctly, they can be very time consuming and, where wounds are extensive, will require a number of staff. In some units, patients with extensive burns will have dressings changed under general anaesthesia with the involvement of a full surgical team.

A number of different methods are currently in use for burn wound cleansing. As long as the wound surface comprises non-viable tissue, the method of choice may be to use saturated gauze or foam pads, although physical cleansing is contraindicated in wounds which are granulating or epithelialising. Depending on the size and site of the wound, less traumatic methods include irrigation via a syringe, showering or immersion in a special tub. There is still debate over the type of solution to be used. Although the use of warmed sterile normal saline is generally advocated for wound cleansing, a survey of UK burns units established that antiseptics such as chlorhexidine acetate and povidone–iodine are also used for the initial cleansing of burns; however, as no rationale is given for the use of the antiseptics, it is best to adhere to local policy (Edward-Jones et al 2000). What is important for both patient comfort and to limit heat loss, especially when the wounds are extensive or on the trunk, is to ensure that the solution used is warmed to body temperature.

Following cleansing, loose devitalised tissue is trimmed using sharp scissors. Specialists vary in their approach to the management of blisters: Flanagan and Graham (2001) advise that they be left intact, whereas DuKamp (2001) advocates this approach only if the blister does not restrict joint movement, recommending aspiration of the blister with a needle and syringe in this instance. In contrast, components of blister fluid have been found to inhibit the healing process (Rockwell & Erlich 1990) and to promote wound contraction (Wilson et al 1997). It would therefore appear that evacuating the fluid from intact blisters, allowing the 'roof' of the blister to come into contact with the wound surface and act as a biological dressing, is the most logical approach. However, all authors agree that this subject warrants further research and investigation.

As hair harbours bacteria, it should be clipped short in the area of the wound and a surrounding margin of approximately 5 cm. Shaving is not advised as it can be painful and cause further wound trauma. Long hair which may encroach on the wound should be restrained with elastic bands or adhesive tape.

Promotion of re-epithelialisation or granulation and the prevention of wound contamination may be facilitated either by exposing the wound or by applying dressings.

Exposing the burn wound

This method is currently most commonly used for burns of the face and occasionally for burns of the perineum. The aim of the exposure method is to provide a dry, intact scab under which re-epithelialisation will take place. Relevant nursing management is described in the section dealing with burns of the face (see p. 1023).

Dressing the burn wound

One of the main problems presented by the burn wound is the copious amount of exudate it produces. This strongly influences the choice of dressing material used. Many modern materials are designed to create the optimum environment for healing, i.e. warmth and moisture, whilst removing excess exudate. This may be accomplished by highly absorbent materials, such as alginates, hydrocolloids or hydrophilic foams, or by materials which allow rapid transmission of water vapour. These types of dressing can

be used successfully in burns which are of a relatively small area, but a substantial margin must be in contact with unburned skin to prevent leakage of exudate. Thus their use is often not feasible for large wounds.

For extensive burns, no material has yet been found to exceed the benefits of conventional dressings (Lawrence 1996b). These comprise an inner layer of mesh, usually impregnated with paraffin or water-miscible cream, which may or may not provide a base for antibacterial agents; layers of cotton gauze (Fowler 1994); cotton wool or Gamgee. The materials may be retained with cotton conforming bandages, or on the trunk by stitching or stapling. The aim of conventional dressings is to allow exudate to filter through the layers and for water to evaporate from the surface of the dressing, thus preventing maceration of the wound. It is important, therefore, that the surface of the dressing is not occluded with a non-porous material, such as many of the adhesive tapes used to retain bandages. Other non-porous materials which may come into contact with the surface of the dressing include plastic mattress and pillow covers; such contact should be avoided by the use of foam wedges, slings and special mattresses or beds. If the outer surface of the dressing does become moist, the outer layers only are changed under aseptic conditions. To change the whole dressing unnecessarily exposes the burn to contamination from the atmosphere and may disrupt healing if the innermost layer has become adherent.

The frequency of scheduled dressing changes depends on the depth and state of the wound and on the properties of any medication incorporated in the innermost layer. Superficial partial-thickness burns may have their dressings left undisturbed for 7–10 days, the estimated time of healing, unless there are indications for investigating the wound, such as signs of infection. More frequent changes, daily, every second day or twice weekly are required in deeper burns as the presence of necrotic tissue increases the likelihood of bacterial growth. In such cases, antibacterial agents are normally used. For many years, silver sulfadiazine cream, in the UK Flamazine, was a popular antibacterial application for burn wounds throughout the developed world. However, because of its tendency to change the appearance of the wound and to macerate non-viable tissue, making surgical excision difficult, silver sulfadiazine with cerium nitrate (Flammacerium) is used as an alternative. In addition to its antibacterial effects, Sparkes (1997) found that cerium nitrate inhibits the release of toxins from the burn eschar. Interest is also being expressed in other silver-containing wound products including Aquacel Ag (Caruso et al 2004) and Acticoat (Dunn & Edward-Jones 2004).

The ideal wound cover is the patient's own skin in the form of an autograft which 'takes' to provide wound closure. Other types of skin graft, i.e. from other humans, an allograft, or from animals, a xenograft, provide only temporary cover except in the case of identical twins. Sheets of epidermal cells (keratinocytes) may be cultured from the patient's own skin but it may take some weeks before sufficient material is available and research indicates that, for optimum survival and growth when applied to the wound, they require a collagen-based carrier (Shakespeare 1993). Loss et al (2000) have now successfully demonstrated effective results using Integra, a bilaminate skin substitute, with cultured epidermal autografts.

Care of burn wounds prior to skin grafting

The necrotic tissue has to separate from the wound bed before granulation tissue, suitable for skin grafting, is produced. This process of separation may take many weeks and is aided by judicial trimming of loose slough at each dressing change. In relatively small wounds, the process may be accelerated through the use of hydrogels or hydrocolloids.

Surgical removal of necrotic tissue may be carried out, usually within the first 4 days following injury. The tissue is either excised with a scalpel or shaved down to a viable (bleeding) surface with a skin grafting knife. This procedure can result in extensive blood loss, and multiple transfusions may be required. The freshly prepared wound bed is usually skin grafted immediately, but if the bleeding is difficult to control, the skin grafts will be harvested and stored in order that they can be applied without a second operation, usually within the following 48 h.

A skin graft 'takes' by the ingrowth of capillaries from the wound into the graft, a process which takes only a few days. This will be disrupted if there is any blood, serum or pus preventing contact between graft and wound. Other factors which can cause disruption of the graft include any shearing of the graft/wound interface and the presence of β-haemolytic *Streptococcus*, group A (*Strep. pyogenes*) which produces streptokinase, an activator of plasmin which is fibrinolytic. Sometimes the surgeon will choose not to apply a dressing to a newly grafted area. Nursing staff will be responsible for ensuring that there is no collection of fluid under the graft. This is done by gently rolling a rolled-up swab from the centre to the margins of the graft, thus expressing any blood or serum. An aseptic technique is employed and great care is required to prevent the graft shearing on its bed.

The skin graft donor area is a very superficial wound and, as a result, can be very painful. For the first 48 h or so it produces large amounts of bloodstained exudate and is usually dressed with calcium alginate followed by a conventional dressing, which is managed in the same way as that covering a superficial partial-thickness burn. The speed of re-epithelialisation depends on the depth of dermis removed along with the epidermis but is normally between 10 days and 2 weeks.

Ideally, the dressing is left intact until it falls off. Injudicious early investigation will cause further trauma, delay healing and lead to risk of infection.

The alginate dressing dries out as epithelialisation occurs but readily regains its gel consistency when soaked with normal saline.

Care of special areas

The face The most common method of managing facial burns is that of exposure. Bulky absorptive dressings which extend well beyond the wound margin are liable to encroach on the facial features, which should not be covered.

The face becomes very oedematous and the head should be elevated as soon as the patient's condition allows. Drying out of the exudate is encouraged in order to produce a thin scab. The longer the wound exudes, the greater is the build-up of serum; this will produce a thick crust which may never completely dry out and is more likely to crack.

Rapid drying may be facilitated by regular aseptic application of well wrung-out saline swabs which quickly absorb the exudate and are then removed; barely damp material absorbs liquid more effectively than dry material. Careful use of a hair dryer on a cool setting will also speed the drying process but care should be taken that the patient is able to achieve complete closure of the eyelids before such air flow is directed at the face.

Once the scab has formed, it will be similar to a cosmetic face mask and greatly restrict facial movement. Because of this it is usual practice in some units to apply a thin layer of liquid paraffin to facial burns (Hudspith & Rayatt 2004), in particular to the areas around the eyes and mouth, as mobility of these areas is most important The resultant stickiness may allow adherence of debris and it is important to cleanse these areas gently with saline on a regular basis.

Oedema of the periorbital region can cause closure of the eyelids. This is very frightening for the patient, who may think the blindness is permanent. The nurse should warn the patient that eyelid closure may occur but reassure that the swelling will lessen in a few days. Eye drops or ointment will be prescribed in order to reduce the possibility of conjunctivitis. The use of artificial tears will make the patient more comfortable.

Oedema of the lips may cause eversion of the oral mucosa, which should not be allowed to dry out. The skin of the lips should be kept lubricated with yellow soft paraffin and care must be taken when oral hygiene is performed. The use of a soft toothbrush, by patient or nurse, will help to maintain normal mouth care and, if the patient is unable to eat, regular mouthwashes should be given. If oral intake is allowed, the patient may experience difficulty in drinking from a normal cup; a feeding cup with a spout is preferable to using a straw as the patient may find it difficult to exert just the right pressure to allow suction without collapsing the straw.

Oedema of the ears may cause them to jut out at right angles to the head, making them more susceptible to further trauma. If the pinna produces exudate, this is liable to trickle into the external auditory meatus, where it will collect and dry out at the level of the ear drum, reducing the patient's ability to hear. This may not be detected until some time later, in which case it may prove very difficult to evacuate the plug. It is easy to avert this problem by inserting a small piece of gauze just at the opening of the meatus to absorb the exudate, changing it as necessary. The ears may be dressed lightly with a conventional dressing or have gauze spread with an antibacterial ointment, e.g. Flamazine, gently applied. The ears will be very painful when touched and it is useful to elevate the head slightly off the pillow, using either a well-padded foam ring or a foam wedge, as this will reduce the possibility of the ears coming in contact with the pillow.

The lower nostrils should be kept free of exudate build-up by regular cleansing with a dampened cotton bud. If exudate dries on the nasal hairs, the crust will occlude the nostrils and its removal will be very painful indeed. This problem may be prevented by the application of a light smear of soft yellow paraffin just inside the nostrils.

The beard in male patients also becomes incorporated in the crust as it grows. This does not usually present problems until the scab is separating from the newly epithelialised facial skin; in the case of deep burns, the hair follicles will be destroyed and no hair growth will occur. Once the scab starts to lift it may be rehydrated using a moisturising lotion or hydrogel; this causes swelling of the scab, which will then no longer fit the contours of the face, and softens it to allow painless removal. Many men prefer to keep their beard for a time, but if they wish to be clean-shaven, the use of an electric razor is preferable as it causes less trauma to the skin.

Scab removal As the scab lifts on the rest of the face, loose areas should be trimmed with care. There may be a strong temptation on the part of both nurse and patient to remove as much as possible, as the satisfaction of revealing nice pink skin can prove irresistible. However, it must be borne in mind that removing adherent crust causes trauma and may increase the possibility of scar formation. Newly epithelialised skin needs to be moisturised regularly with a bland cream to keep it from drying out (see Box 30.5).

Box 30.5

Care of newly healed skin

Care of newly healed skin consists of washing with mild soap, rinsing well, patting dry and applying a moisturising cream. Newly healed skin does not produce sufficient sebum to prevent it from drying out nor cracking on the surface; neither does it produce enough melanin to prevent burning if exposed to sunlight. It must therefore be protected by covering with clothing or by high protection factor sun creams for at least a year.

The hands Burns involving the majority of the hand are most commonly treated by the application of polythene bags or gloves, with or without the addition of an antibacterial cream, in order to facilitate movement and thus prevent joint stiffness and allow the patient a degree of independence. Because the polythene does not allow evaporation of water, the wound environment is very moist and the non-burned skin will become macerated. As large volumes of exudate will collect, it is usual, before applying the bag, to apply several layers of gauze around the wrist to absorb some of the exudate. The bags should be changed on a daily or more frequent basis, and the hand gently cleansed at each change. Minor burns to the hand are treated with lighter dressings, which should not restrict mobility.

Limbs In order to reduce oedema formation, burned limbs are elevated and exercised on a regular basis, unless freshly laid skin grafts preclude movement.

Joints Wound contraction is an integral part of the healing process, but excessive contraction leads to dysfunction and deformity. As flexor surfaces are more liable to contract, joints must be correctly positioned, with compensatory hyperextension especially of the wrists and neck. Physiotherapy should be carried out regularly, with adequate analgesic cover, to maintain a full range of movement of all joints. However, splinting may be necessary to arrest or correct contracture formation.

Scar formation

Scar formation is part of the maturation phase of the healing process. In wounds healing by secondary intention, the scar often appears red and is raised above the level of the surrounding skin (hypertrophic). Hypertrophic scarring is a well-known complication following burn injury and the resulting disfigurement causes great distress. The most common means of prevention is the application of external pressure, usually effected by the use of specially designed elasticated garments which can be made to fit any anatomical part. The garments should be worn, apart from bathing and skin care, for 24 h/day; treatment should continue for at least 9 months and a pressure of at least 24 mmHg is necessary for the treatment to be effective. Patients are provided with at least two sets of garments, which are alternately washed and worn.

Elastic garments are not very effective for applying pressure to concavities on the body surface, especially on the face around the nose and mouth. For treatment of these areas, a rigid, or semi-rigid, transparent face mask can be made. One technique which does not rely on pressure to reduce the hypertrophy and redness of scars is the use of silicone gel sheets (Mustoe et al 2002). These need to be retained in place with light bandages or adhesive tape and must be removed regularly for washing as they are reusable for a few applications. The sheets are relatively expensive and tend to be used only when problems arise in pressure therapy. A cheaper and more practical method described by Davey (1997) is the use of adhesive tapes such as Mefix applied directly onto florid scars, with the application of Silastic elastomer on areas when early thickening is detected.

PSYCHOLOGICAL EFFECTS OF BURN INJURIES

The disfigurement and impaired function which result from wound contracture and scar formation are generally accepted as the major sequelae of burn injuries, causing great distress and psychological problems for the patient and their loved ones. This, however, describes the long-term view and does not take into account that, for the patient and their family, the psychological effects start at the time of injury.

Partridge (1990) gives a graphic account of his experiences when he sustained burns in a road traffic accident and notes that 'being on fire is unforgettable, you will recall those seconds with crystal clarity for the rest of your life'. Many patients voice their relief at being alive in the immediate period following the accident, but as the implications of their injury sink in, their emotions and behaviour may begin to go through a series of changes.

Bereni-Marzouk et al (1981) described four psychological phases experienced by patients hospitalised following burn injuries:

- critical
- stabilisation
- recovery
- pre-discharge.

This categorisation will be adopted in the following discussion of the problems commonly encountered by individuals with burn injuries.

The critical phase

During the early stages of treatment, the patient will be preoccupied by bodily feelings and by the care provided by nursing and medical staff. If the wounds are extensive and complications arise, the patient will require constant attendance, perhaps for lengthy periods of time, which may result in intensive care psychosis (see Ch. 29, p. 1007). Topf et al (1996) emphasised the need for nursing staff to be aware of the harmful effects of the experience of intensive care, and the importance of providing communication and controlling environmental factors in order to promote sleep and sensory balance. Nightmares associated with the accident are common at this stage, as are fears of dying. A constant presence, reassurance and reorientation may be necessary.

Stabilisation

When the patient reaches this stage, anxiety related to survival is replaced with fears for the future, both short and long term. In the short term, stress is related to anticipation of pain and many patients become depressed or are hostile towards the nursing staff. They may regress in their ability to cope with activities of living and demand care and attention. This is perhaps the most difficult phase for the unit staff to cope with. Pain control helps to reduce patient anxiety related to wound care, and physiotherapy and monitoring of pain should continue throughout the period of hospitalisation.

Although there is a tendency to expect that there will be more pain the greater the injury and that pain will reduce in time, in their study Choiniere et al (1989) found no correlation between pain scores and the time elapsed following injury, or between pain scores and size of burn.

Longer-term anxieties include the fear of disfigurement and of losing function and former roles. Nursing staff can help the patient come to terms with their changed situation by being honest and supportive and allowing them to grieve. The first look in the mirror should not be accidental but a planned occasion with the patient making the choice whether to be alone or to be accompanied by nursing staff or loved ones. Although the patient may have some idea of their changed appearance from watching the reactions of visitors, the true extent of disfigurement may only be seen on first looking in a mirror. Some patients have glimpsed their reflection in the spectacles of attendant personnel, in darkened windows or in plate glass doors and later reported that they were able to deny their appearance, attributing it to a flaw in the glass.

If the hands are not injured, the patient may gauge contour and textural changes through touch, but the reality of their changed appearance will still be a great shock.

Manifestations of hostility may range from refusal to cooperate with treatment, through cursing and swearing, to actual bodily assault. Sometimes the hostility is directed only towards certain nurses and the patient may manipulate the situation to create discord among the staff. Care should be planned to ensure a consistent approach by all staff and it may be necessary to reallocate staff. If the patient's behaviour is uncooperative to the extent that it will interfere with recovery, behaviour modification techniques may be in

order. A contract may be drawn up specifying the type of behaviour expected of the patient and describing the rewards which will be given or withheld accordingly.

Regression in physical ability may also be managed by behavioural modification, with the patient being set easily achievable tasks, such as pouring a drink from their own water jug and being encouraged to feel a sense of achievement on doing so. Many patients regress when there is a sudden, unexplained reduction in the amount of nursing care they receive. Explanation about their improving condition, and patient involvement in identifying needs and planning the reduction of care can help to alleviate this problem.

Recovery

This phase is marked by the patient beginning to rediscover former interests and pleasures. The patient may, for example, take more notice of the activity in the unit and of the other patients. When possible, mixing with the other patients should be encouraged; the patient's involvement in small tasks, such as distributing newspapers, will also aid independence and self-esteem. When disfigurement is highly visible, such as on the face and hands, the patient may not wish to mix with others and will require a great deal of support from staff as well as from family and friends. Griffiths (1989) offered the following list of coping strategies which the nursing staff can explore with the patient:

- Do not give in to fear.
- Learn to control fear and anxiety.
- Practise positive self-talk.
- Concentrate on relevant pieces of information.
- Do not interpret discomfort as rejection.
- Find your own way of acknowledging the disfigurement.
- Congratulate success.

The pre-discharge phase

Patients frequently experience ambivalence about leaving the safe confines of the unit where they are known and accepted. The actual discharge may be graduated by the introduction of progressively longer visits home and by giving the patient the opportunity to discuss the pleasures and problems encountered. Williams and Griffiths (1991) emphasise the patient's need for practical advice in the form of staff-led discussions during the period prior to or immediately following discharge from hospital in order to reduce the psychological sequelae of burn injuries. Liaison with the primary health care team will ensure continuity of care, and involvement of the social work department and occupational therapists in the community will provide financial and practical help in the resumption of home life.

After discharge

It is possible that the patient will need to return to hospital for clinic appointments and, later on, for plastic surgery to improve appearance and function, a process which may involve many operations over a number of years. Many patients suffer long-term psychological problems including depression, anxiety and other post-traumatic stress symptoms. In 2001, Van Loey et al, in a survey of European hospitals, found that the provision of continuing support was inadequate and there is no evidence that this has improved with regard to the NHS; it would therefore appear that there is a growing need for voluntary groups such as Changing Faces (see 'Useful websites').

No matter how high the standard of care provided, the patient who suffers extensive burns may never return fully to their former physical or emotional functioning — a fact which can only serve to emphasise the need for greater effort in the field of burn prevention.

INTRODUCTION

Cancer touches all of us at some stage in our lives — personally, through friends, acquaintances or the media. It is a disease with a profound effect on every aspect of life, whether physical, psychological, social or spiritual. There are two principal reasons for this. First, cancer is still associated with suffering and death. Second, despite improvements in cure rates, many uncertainties persist concerning the nature and causes of cancer and the methods of prevention and cure. This uncertainty serves to perpetuate various myths and fears surrounding the disease, some of which are described in Box 31.1.

31.1 (a) What words come to mind when you think of the word 'cancer'?
(b) Ask the same question of a few friends, or a member of your family. How do their responses compare with yours?
(c) Is their overall attitude one of optimism or of pessimism?

Cancer is a serious social problem, costing much in human and financial terms. One in three people in the UK risk developing cancer in their lifetime, with one in four deaths being attributable to cancer, which has now overtaken heart disease as the UK's number one killer (SHS 2005, Cancer Research UK 2005a,b). Globally, by 2020, there are likely to be 20 million new cancer patients each year, double that identified by Oliver in 1999. While statistics appear to present a bleak picture, people in the UK are surviving cancer, with death rates falling since the 1970s (Kmietowicz 2004). This provides clear evidence for a more positive approach by nurses and other health professionals, which will foster realistic hope in their patients. With existing knowledge and advancing technology, the WHO cancer programme hopes to prevent up to 50% of cancers in the next 20 years (Sikora 1999).

Before reading further, consider your own knowledge and attitudes towards cancer by carrying out the following exercise.

31.2 Consider the following statements. Decide whether they are true, partly true, or false:

(a) Everyone with cancer dies from the disease.
(b) Cancer is the cause of the highest number of deaths per year in the UK.
(c) Cancer is the result of a person's lifestyle.
(d) Cancer is hereditary.
(e) Certain personality types are more prone to cancer than others.
(f) Some forms of cancer are contagious.
(g) Most persons with cancer are disfigured in some way by the disease.
(h) Cancer patients can enjoy many years of normal, productive life.
(i) A cancerous growth is a collection of cells that are foreign to the body.
(j) The side-effects of all cancer treatments are particularly severe.
(k) Everyone with cancer suffers pain at some point during the disease.

Oncology as a specialty

Since the mid-1990s, cancer has been a high priority on the UK political and health care agenda in response to variable patterns of care and the then relatively low survival rates in comparison with mainland Europe. Several fundamental changes have been made to the organisation and provision of cancer services initiated by the publication of the Calman–Hine/Calman report (DH 1995). The vision of the Calman report was to focus care around the patient and their family, care being delivered in specific designated cancer centres and cancer units by coordinated services in

Box 31.1

Sociohistorical perspectives

In medieval times, cancer was believed to be contagious, caused by lack of cleanliness and even by a form of demon possession (Nery 1986).

Society

The cultural legacy of historical beliefs is the aura of fear and shame that surrounds the disease even today. Skott (2002), using patient narratives, from a sociocultural perspective, examines the highly metaphorical language in which the cancer disease process and treatment are described — such as the cancer 'eating' away tissues or of an 'invasion' by an 'alien army' of 'colonising' cells.

This tendency to view cancer symbolically is also evident in the causes to which many patients attribute their disease, ranging from divine retribution to a stressful life event, a fall or physical blow, dirt or, very commonly, personal failing (Walker 1990).

Cancer stigma

Stigma is a process of negative social judgements (Flanagan & Holmes 2000) which, according to seminal work by Goffman, 'reduce the person in our mind from a whole and usual person to a tainted and discounted one' (Goffman 1963). This is illustrated in a recent study where patients with lung cancer perceived that others held the belief that they were 'dirty', 'disgusting', 'blameworthy' and automatically assumed to be smokers. One individual imagined others viewing him as a 'leper' (Chapple et al 2004).

For individuals with cancer, insurance cancellations or refusal, job discrimination and problems with reintegration into school or the workplace are manifestations of the persistent social stigma of cancer.

In favourable circumstances, most people are not conscious of these underlying social attitudes. However, a person with cancer may soon become painfully aware of the degradation and isolation which accompanies the disease. Family and friends may struggle to maintain a supportive relationship, as excessive fear and dread may give rise to avoidance or overprotective behaviour.

Analysis of media coverage reveals a tendency to emphasise the tragic nature of cancer (Macmillan Cancer Relief Fund 1999). However, the media are in a powerful position to provide accurate, balanced and comprehensive sources of information to replace such negative attitudes with a more realistic public awareness. Cancer still remains a relatively taboo subject, as anyone who tries to discuss it in social gatherings will discover.

Patients and their families bring these attitudes and beliefs into their cancer experience. Assessment of their perception of the situation is an essential first step in the provision of supportive care.

partnership with each other. The report recommended a seamless service, integrating primary, secondary and tertiary care, with real commitment to psychosocial as well as medical needs. It also provided the opportunity to think about cancer control, early screening and detection programmes.

Building on this framework, subsequent policy documents have influenced the progression of cancer services (DH 2000a,b, SEHD 2003). Comprehensive long-term strategies have been developed to shape cancer services, looking at all aspects of the patient's cancer journey, promoting high standards of equitable care and investing in equipment and the cancer workforce. Cancer networks have been identified as the organisational model for implementing these strategies, through the development of shared protocols and pathways of care, and the promotion of working partnerships between health professionals, the voluntary sector, local authorities and users of the service across a geographical area (Kunkler 2000). Mapping the patient's journey allows everyone involved to see the process from the patient's perspective, thus providing continuity and avoiding fragmentation of care.

There is acknowledgement of the need for investment in education, research and professional development for all health care professionals and for the promotion of core skills in communication, teamwork and palliative care. Students and newly qualified health care professionals need to understand the multidisciplinary nature of cancer management within and outside the hospital, appreciating the roles of all those providing patient care (DH 1995, RCN 1996a,b).

These initiatives clearly demonstrate the value of the nurse in cancer care and recognise the need for specialist cancer care education (DH 2000c, RCN 2003). With the development of the roles of the advanced nurse practitioner and nurse specialist, it is imperative that the expertise required of all nurses at ward level and in primary care is not forgotten.

The cancer process

The process of cancer or carcinogenesis has many stages and occurs over time. Cancer develops when cells grow and divide uncontrollably outside the normal cell regulatory mechanisms. These cells have no specific tissue function, but are able to spread from the site of origin to distant tissues. In the last three decades, molecular biology has made great progress in unravelling the steps involved in this process of cell transformation and is improving our ability to classify, diagnose and treat cancer. There still, however, remain many unanswered questions.

A critical component in understanding the cancer process and rationale for treatment is a knowledge of the structure and function of cells, the role of DNA and the reproductive cell cycle; for further reading, see Martini (2004) or Tortora & Grabowski (2005).

When a cell divides, a chain of chemical signals controls the process. The links are proteins such as growth factors, receptors, cytoplasmic message-carrying proteins and cell nucleus regulatory proteins. Specific genes in the cell DNA express these proteins during protein synthesis. The basic cause of cancer is damage to one or more of these genes. Such damage may occur from either errors in DNA replication during mitosis or exposure to environmental agents. In the transformation to a cancerous growth, there is a progressive series of mutations of genes regulating cell division and differentiation.

Exciting research into these cell regulatory genes has recognised that 'proto-oncogenes' promote cell division ('on switch') and 'tumour suppressor genes' inhibit cell division ('off switch'). One such tumour suppressor gene, p53, is

now recognised to have mutated in at least 50% of human cancers (Brown 1999). Normally, the protein from a p53 gene halts the cell cycle in the G_1 phase at a control checkpoint before DNA replication occurs. This allows the cell to repair any DNA damage identified. If, however, genomic damage is excessive, the cell undergoes a programmed cell death (apoptosis). For this reason, p53 is often referred to as the 'guardian of the genome'. When p53 mutates, cells do not repair defective DNA and continue to replicate. Changes in p53 are not a direct cause of cancer, but cells lacking p53 are at high risk of malignant transformation (Yarbro 2000, Lee & Yielding 2003). Cancer cells therefore grow in an erratic and uncoordinated way because of an alteration in cell regulatory mechanisms. As tumours grow by repeated cell divisions, their rate of growth is often defined in terms of 'doubling time'. Tumours vary greatly in their doubling time but, contrary to popular belief, their growth is not as rapid as that of certain normal tissues. For a tumour growth to exceed 1 or 2 mm, it requires a blood supply for survival; therefore a capillary network from the surrounding host tissue is initiated by proteins or angiogenic factors, e.g. fibroblast growth factor (FGF) and tumour necrosis factor (TNF) (Fidler 1997, Franks & Teich 1997).

At any one time, a tumour consists of a mixture of cells, some dividing or growing, some dying or dead. Tumour cells appear to have the capacity to develop various strains within one tumour, each with different properties and, unfortunately, different levels of resistance to anticancer treatments.

Tumour pathology

Malignant and benign tumours The word 'cancer' is a general term used to describe all malignant neoplasms, i.e. a new growth of tissue, or tumour. A tumour may be benign or malignant, although this distinction is not always clear. Brain tumours, for example, may be benign in nature, e.g. meningioma, but because of their location within a limited space may prove to be fatal.

Benign tumour cells are usually well differentiated, i.e. they resemble the host tissue, are slow growing and do not invade surrounding tissue or form metastases in distant tissue. Once removed, they rarely recur. Malignant tumours have the opposite properties, albeit to varying degrees. A malignant tumour poses a threat to life mainly because of its ability to proliferate destructively into surrounding tissue and to metastasise to other parts of the body.

The molecular biology of cancer is profoundly changing the approach to identifying cancer by tissue analysis (histology). A definitive cancer diagnosis is made by the examination of tissue and cell (cytology), samples under a microscope combined with molecular technology such as DNA analysis and immunohistochemistry (IHC). This technology aims to identify tumours by recognising unique molecular alterations occurring in specific tumour types and provides a more sophisticated method of classifying tumours (Harris 2005). IHC, for example, has been invaluable in determining a primary tumour (Costa & Cordon-Cardo 2001).

Identification of the steps involved in carcinogenesis has led directly to the discovery of molecular tumour markers (see Table 31.1). Among the cancers for which molecular diagnostics has had the greatest impact is chronic myeloid leukaemia (CML). The marker of this disease is the Philadelphia chromosome, which is detectable in 95% of cases (Pasternak et al 1998). In addition to diagnosis, prognosis has in many cases been enhanced by the identification of such markers. For example, in 20–30% of breast and ovarian tumours, the oncogene HER-2/neu is overexpressed and is a reliable indicator of poor prognosis (Loud et al 2002). The protein expressed by this gene has now become a therapeutic target to improve treatment outcomes.

Histology reports therefore communicate both diagnostic and prognostic information by referring to the degree of differentiation of tumour cells, their capacity to invade, the degree of vascularity (blood supply) and now the molecular analysis. Well-differentiated tumour cells bear considerable resemblance to the original tissue in structure and function.

Table 31.1 Examples of molecular genetic markers used in cancer diagnosis and prognosis

Cancer	Genetic marker	Principle application
Chronic myeloid leukaemia	Philadelphia chromosome t(9;22)(q34;q11) [BCR/ABL]	Primary diagnosis, detection of residual disease after treatment
Non-Hodgkin's lymphoma: Follicular	t(14;18)(q32;q21) [BCL2/IGH]	Primary diagnosis, detection of residual disease after treatment
Burkitt's	t(8;14)(q24;q32)	As above
Neuroblastoma	MYCN amplification	Prognosis
Breast cancer	HER2-neu/ERB2 amplification	Prognosis
Familial cancers Breast	BRCA1, BRCA2	Diagnosis of hereditary predisposition
Colon	APC, MSH2, MLH1	As above
Wilms' tumour	TP53 mutation	As above
Retinoblastoma	RB mutation	As above

These tumours are usually slower growing and are less likely to spread (metastasise), usually responding well to treatment. Undifferentiated cells, however, are very different from the original tissue, almost unrecognisable. These tumours grow and disseminate more rapidly, and may be more resistant to treatment.

Tumours may be classified, not only by their biological behaviour, but also traditionally by their tissue of origin. Most tumours retain sufficient characteristics of the normal differentiated cell to allow recognition of the type of tissue from which they were derived which is the basis for the classification of tumours by tissue type (see Table 31.2). Tumours of one organ may be of various tissue types with differing behaviours and prognoses. For example, an adenocarcinoma of the lung behaves in a much less malignant way than small cell carcinoma of the lung, the latter carrying a much poorer prognosis.

Cancer is therefore not one disease but many, each type behaving in a very different way. This must be taken into account in all discussions about cancer and in all relationships with cancer patients.

The spread of cancer (see Fig. 31.1)

The term 'carcinoma in situ' refers to a cancer before it has become invasive. The exact manner in which invasion occurs is unknown but is thought to be due partly to physiological changes occurring in tumour cell membranes which reduce their adhesion to other cells. Tumours also produce proteolytic enzymes (protein-dissolving), which may assist the invasion of normal tissue. Malignant cells also seem to lose 'contact inhibition', failing to recognise their boundaries and to cease growth on meeting a different tissue type. For example, tumours of glandular lung tissue may continue invasion through the pleura to the chest wall. Once local invasion has occurred to any degree, metastases may develop in distant tissue. Metastatic spread (dissemination) may occur in one of four ways:

- via the lymphatic system
- via the bloodstream
- via serous cavities
- via the cerebrospinal fluid (CSF).

Lymphatic spread Tumour cells may invade the lymphatic vessels and grow in clumps and cords, establishing themselves en route in local lymph nodes. This is termed 'regional spread'. It eventually causes lymph node swelling, which may be painful, and may prevent local tissue fluid drainage, causing lymphoedema, for example, in the affected arms of some patients with breast cancer. Ultimately, distant lymph nodes may also be involved.

Table 31.2 Classification by tissue type of malignant tumours

Tissue of origin	Malignant tumour
Epithelial	**'Carcinoma'**
Squamous: surface epithelium, cell lining covering body cavities, organs and tracts	Squamous cell carcinoma, e.g. lung, skin, stomach
Glandular: glands or ducts in the epithelium	Adenocarcinoma, e.g. breast, lung, colon
Transitional cells: bladder lining	Transitional cell carcinoma, e.g. bladder
Basal cells: skin layer	Basal cell carcinoma ('rodent ulcer')
Liver	Hepatocellular carcinoma
Biliary tree	Cholangiocarcinoma
Placenta	Choriocarcinoma
Testicular epithelium	Seminoma, teratoma, embryonal carcinoma
Endothelial cells	Angiosarcoma
Mesothelial: covering the surface of serous membranes	Mesothelioma, e.g. pleura, peritoneum
Connective tissue	**'Sarcoma'**
Bone	Osteosarcoma
Cartilage	Chondrosarcoma
Fatty tissue	Liposarcoma
Fibrous tissue	Fibrosarcoma
Lymphoid tissue	Lymphomas
Bone marrow	Leukaemias, e.g. ALL, CML
Muscle	**'Myosarcoma'**
Smooth muscle	Leiomyosarcoma
Striated muscle	Rhabdomyosarcoma
Cardiac muscle	Cardiac sarcomas
Neural	
Meninges	Meningeal sarcoma
Glia	Glioblastoma multiforme
Neurones	Neuroblastoma, medulloblastoma
Germ cells	
Testes or ovary	Teratoma, germ cell

ALL, acute lymphoblastic leukaemia; CML, chronic myeloid leukaemia.

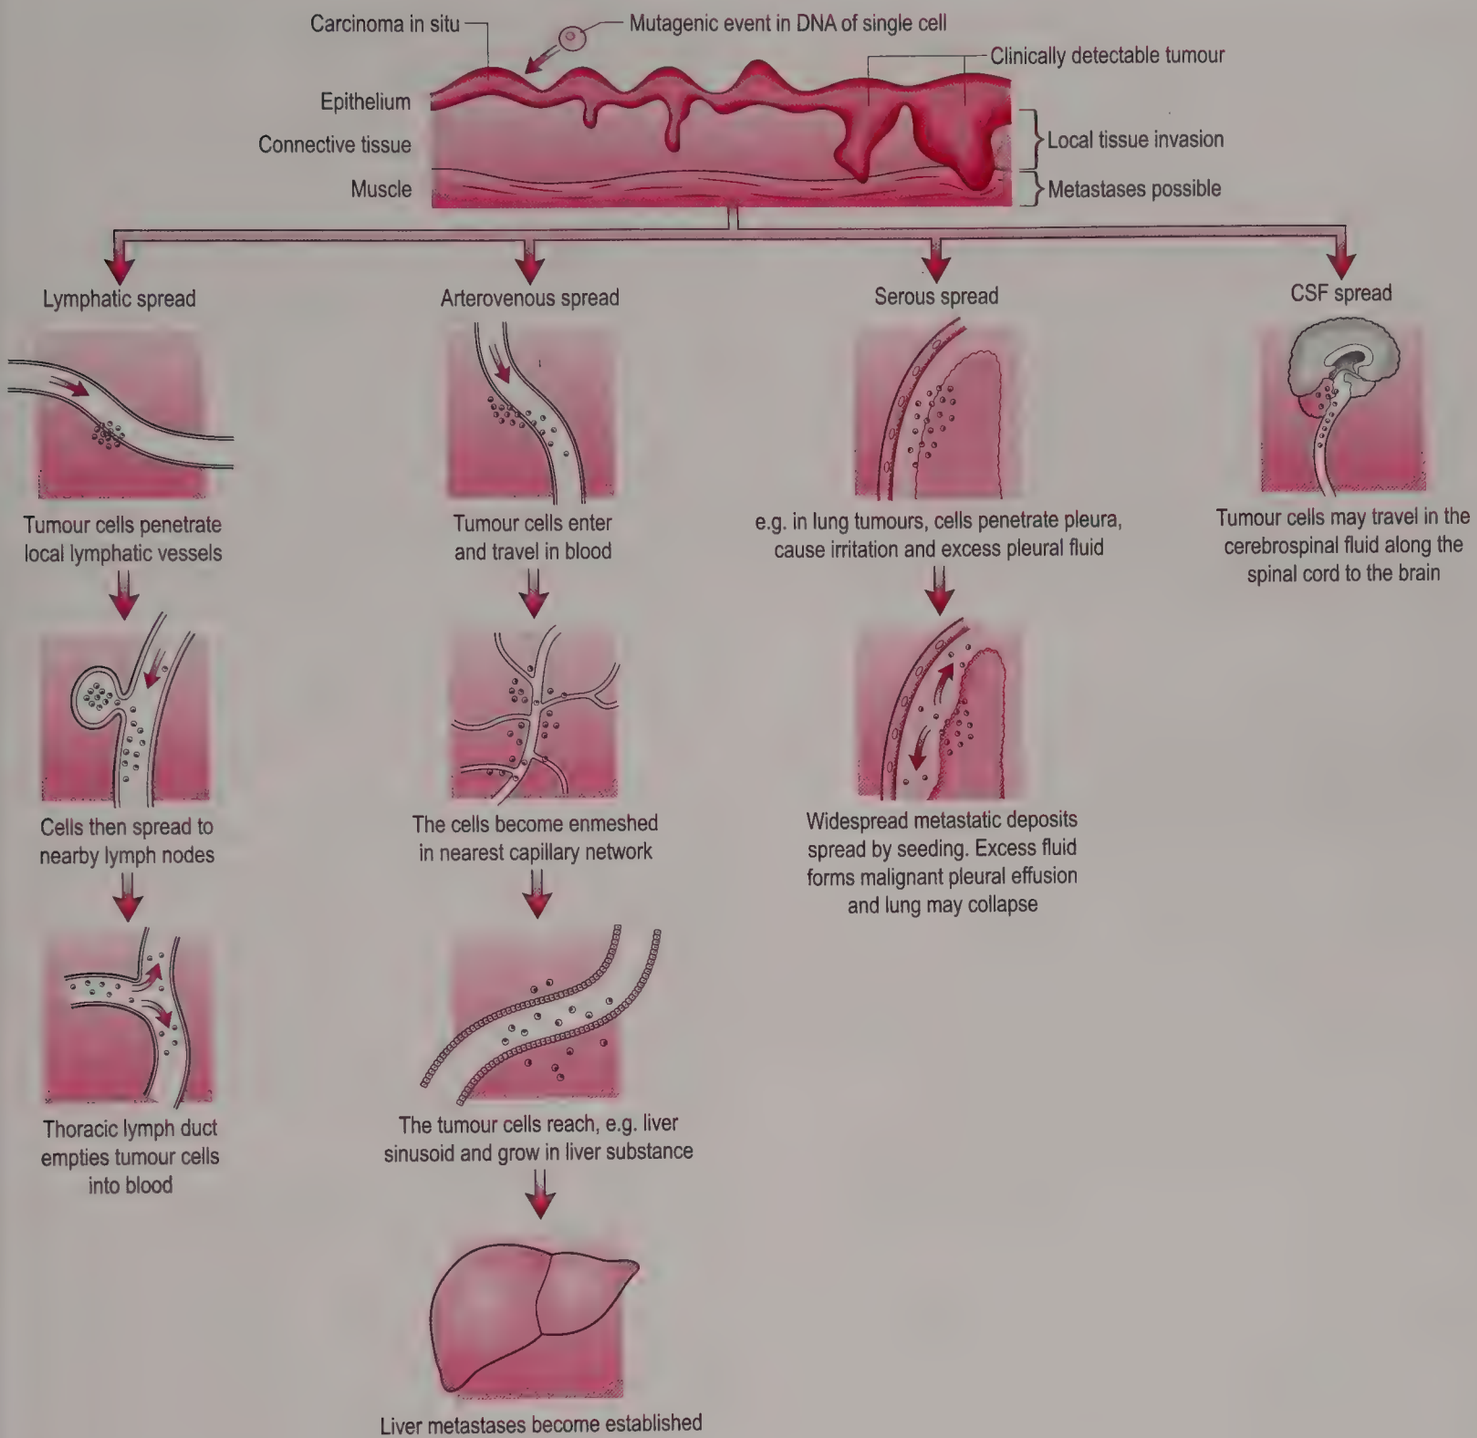

Fig. 31.1 The cancer process.

Arteriovenous spread Tumour cells enter blood vessels near the primary tumour or are shed into the blood via the thoracic lymph duct. They then become enmeshed in the next capillary network they encounter. Hence cancer of certain organs has a certain pattern of spread; gastrointestinal tumours, for example, typically spread via the portal venous system, initially to the liver.

Serous cavity spread Serous membranes, e.g. the pleura or the peritoneum, may be invaded by tumours, either locally from the primary tumour or from nearby metastases. Resulting irritation causes excess serous fluid to be produced, which can distribute cancer cells widely in the serous cavity. This process is called 'seeding'. The excess fluid forms malignant pleural effusions or ascites.

CSF spread Similarly, tumour cells may spread directly in the CSF. Some brain tumours metastasise along the spinal cord in this fashion.

The most common sites of metastatic deposit are the lungs, bones, brain and liver. Two-thirds of patients develop metastases; in half of these, dissemination occurs before diagnosis, and often even before symptoms arise.

The effects of cancer

The manifestations of cancer depend directly or indirectly on the location, size and type of tumour involved and on

the extent of any metastases. The medical and nursing problems associated with cancers of particular body systems are covered in preceding chapters.

Direct tumour effects Symptoms may be due to the following direct tumour or metastatic effects.

Occupation of limited space Because it takes up space within the body, the tumour can cause the following effects:

- obstruction of ducts and tracts, e.g. the oesophagus, causing dysphagia
- compression of major blood vessels, e.g. tumours at the apex of the lung or metastatic mediastinal lymph nodes may compress the superior vena cava, causing ischaemia, oedema of the head, neck and right arm, and dyspnoea
- compression of neighbouring tissues and organs, e.g. brain metastases may cause pressure and local oedema, which can compromise brain function and level of consciousness, depending on the area of brain tissue involved
- pressure on regional nerves, causing pain and/or paralysis, e.g. metastases in the spinal vertebrae may compress the spinal cord and result in pain or loss of sensation and paralysis from the level of the lesion downward (spinal cord compression, one of the significant oncological emergencies)
- invasion and replacement of normal tissue, e.g. gastric tumours often spread diffusely across the gastric mucosa, compromising digestive function.

Haemorrhage Tumours may invade small local blood vessels, causing chronic bleeding and anaemia. Occasionally haemorrhage may be sudden and fatal, as when a major blood vessel such as the carotid artery is eroded.

Ulceration Tumour tissue growth may outstrip local blood supply, causing necrosis, or ulceration, of part of the tumour and adjacent normal tissue. This ulceration may be internal or external. Advanced breast tumours may result in surface ulceration. Due to their appearance, these lesions are often termed 'fungating'.

Infection This is very common, being seen as the cause of death in 50% of patients with metastatic cancer. Increased susceptibility to infection is caused by malnutrition, cancer treatments and, sometimes, by metastatic invasion of the bone marrow, compromising haemopoiesis. Eroded or ulcerating tumours are prone to local infection, which may then become systemic.

Metabolic imbalances These are numerous and tumour-specific and, in advanced disease, may become widespread. Tumours of the pancreas may cause disturbance in glucose metabolism. Liver metastases may alter ability to metabolise essential medication and renal tumours cause progressive renal failure, leading to fluid and electrolyte imbalance.

Hypercalcaemia is a common and serious manifestation of advanced cancer of the breast, bone, lung and kidney and is caused by bone destruction due to metastases or by the tumour's production of substances causing bone dissolution.

Indirect tumour effects These are sometimes termed 'paraneoplastic' effects (or syndromes) and may be the presenting features before diagnosis in 10–15% of patients (Haapoja 2000). Early detection is important as these symptoms can often be ameliorated even when the primary tumour cannot be controlled.

The syndromes result from the secretion of substances, usually proteins, by the primary tumour or its metastases. These substances include hormones, growth factors, cytokines, antibodies and other immune products, which indirectly result in a multitude of disorders (see Fig. 31.2).

Almost all patients with cancer will experience at least one paraneoplastic effect. For example, approximately two-thirds of cancer patients suffer some degree of cancer cachexia. This complex syndrome has been termed 'a physical fading of wholeness' (Costa 1977). It involves progressive and extreme weight loss and muscle wasting. The resulting weakness can be very severe and death may eventually ensue due to exhaustion of the respiratory muscles. This is most common in patients with gastrointestinal and lung tumours. The causes are multifactorial; however, research has demonstrated increased basal metabolic rate and disturbed fat, protein and carbohydrate metabolism, with accompanying anorexia, altered digestion and absorption of nutrients (Tisdale 2000, Inui 2002).

Prognosis and the cause of death The risk of disease recurrence cannot be discounted with certainty until a period of several years has elapsed. This length of time depends on the type of cancer and varies from 3 to 20 years, so for practical purposes a limit of 5 years is often used to estimate survival rates. The term 'cure' is, however, used cautiously; most health care professionals prefer the phrase 'complete remission'. However, these concepts are often open to interpretation, creating ambiguity and lack of understanding (Chapman et al 2003). It is therefore important for health care professionals to clarify their meaning for patients.

This uncertain outlook can probably be explained by the fact that malignant cells, which are often undetectable by current diagnostic techniques, frequently persist despite treatment and in time cause local recurrence of the tumour and/or metastases. Many factors intervene, however, such that no patient's prognosis can be calculated with certainty.

It may seem obvious that any of the effects of cancer (described on p. 1033) may result in or contribute to death. While this is the case, the immediate cause of death is often uncertain, and in these situations it is generally presumed to be the subtle interplay of the failure of different body systems. The issue of whether or not cognitive and emotional states can influence long-term survival remains controversial, with evidence so far being inconsistent (Petticrew et al 2002). However, Brown et al (2003) suggest that the cancer diagnosis and physical effects of the disease may predispose to distress which, if maintained over time, enhances disease progression.

It is now widely accepted that quality of life in cancer patients may be improved by psychological interventions (Meyer & Mark 1995, Goodwin et al 2001). Prolongation of life, however, is more controversial, but this has opened up an area known as psycho-immunology. There has been increasing speculation in the psychosocial literature on whether intervention groups can lead not only to good outcomes with respect to mood but also to improved chances of survival (Fox 1995, Greer 1995). Preliminary evidence from research by Spiegel et al (1989) and Fawzy

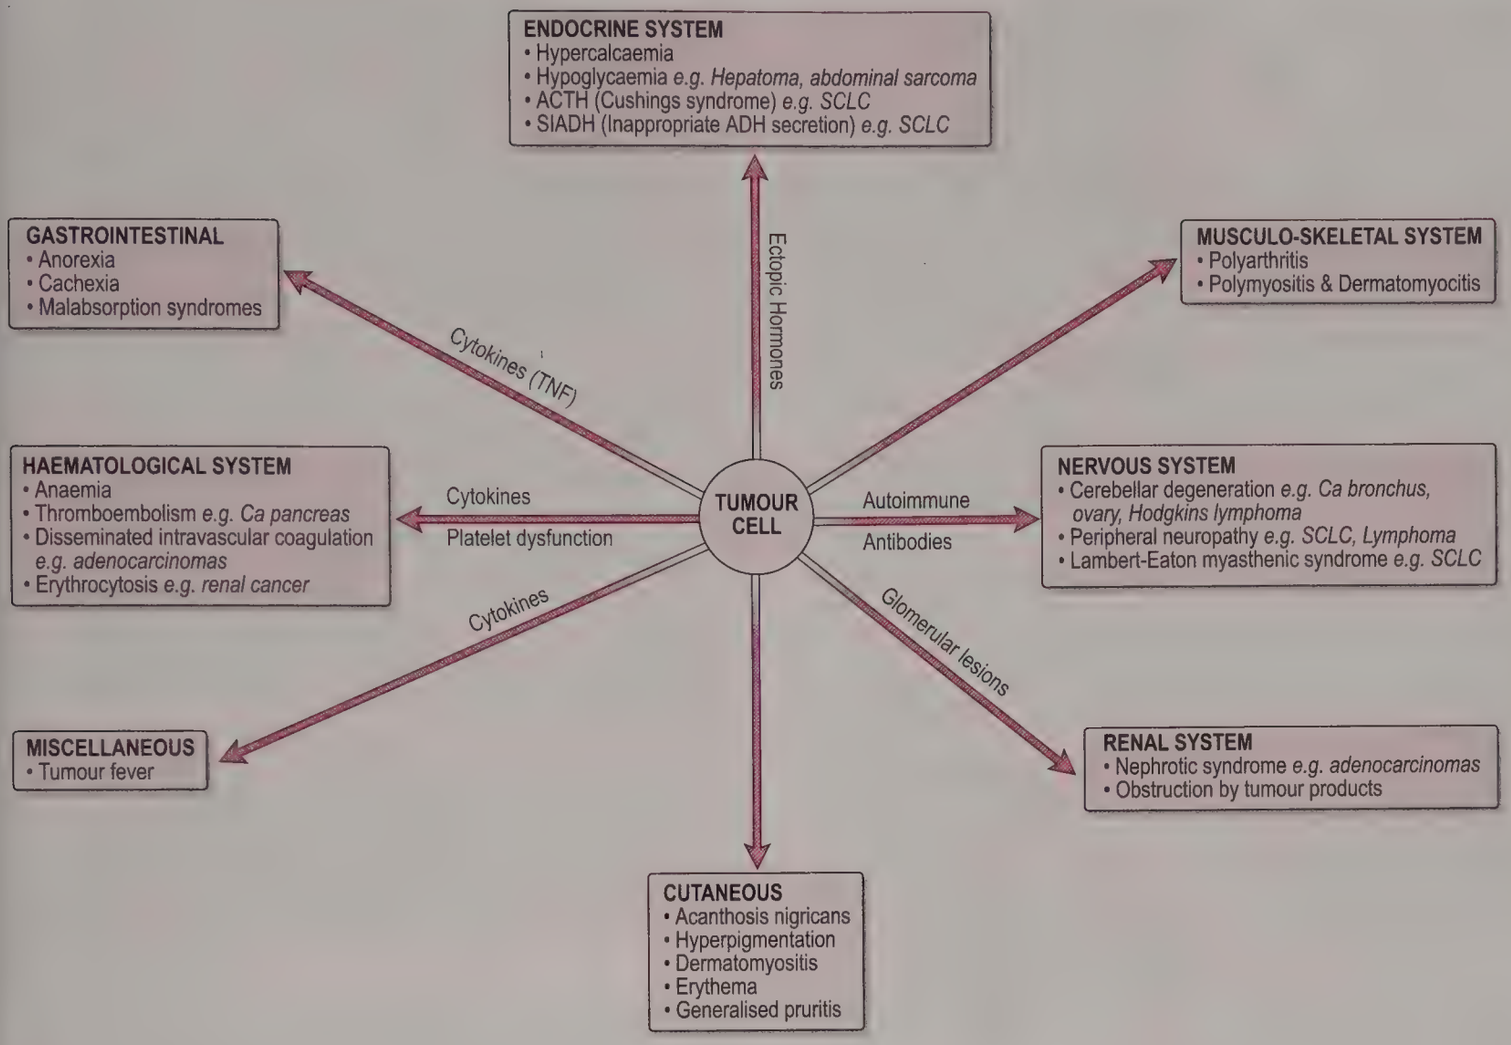

Fig. 31.2 Paraneoplastic syndromes. (Adapted from Haapoja 2000.)

et al (1993) indicated that cancer support groups may foster positive changes in immune function, which may influence tumour growth rate, thus promoting survival. However, at the 10-year follow-up, the survival benefits of the intervention had weakened, though not entirely disappeared. It is difficult to prove this type of relationship, and attributing physical deterioration to the patient's emotional state is not justified (Petticrew et al 2002). Research has also indicated that social deprivation and life crises may have a negative impact on prognosis (Barraclough 1998). A good social support system and elements of spirituality and religious belief appear to be consistent predictors of improved quality of life (Creagan 1997). As the expected time of death is often uncertain, a specific prediction of prognosis is therefore unwise and may even lead to loss of hope.

31.3 Consider patients you have cared for who have died from cancer. Do you know what was the immediate cause of death? Ask a doctor involved if you are unsure. Is the doctor certain of this cause? Were psychological and social factors important?

31.4 It is common for relatives to want to know the details and exact cause of death of the patient. Discuss with other students why you think this need is so common. Relate any experiences of being with the recently bereaved. What do you think is the nurse's role in the face of this uncertainty? What are the ethical issues involved?

Epidemiology of cancer

Epidemiological studies have given rise to theories about the possible causes of different forms of cancer and hence to strategies for cancer prevention and for the screening of high-risk population groups for early-stage, treatable disease. Figure 31.3 shows the incidence of the 10 most common causes of cancer mortality in the UK.

In the developed world, populations are ageing and age is one of the major risk factors for developing cancer. More than 65% of all people diagnosed with cancer are over 65 years old (Cancer Research UK 2005a). Although cancer is very rare in children, it is now the most common cause of death (after accidents) in those under 15 years, despite the fact that childhood tumours respond to treatment far more readily than those in adults (Cancer Research UK 2004a).

For a discussion of the specialist treatment of paediatric and adolescent cancer care, see Baggott et al (2002).

The incidence of cancer in the UK is one of the highest in the Western world (see Ch. 35). Predominantly, cancer is a disease of the rich, although the pattern is shifting and many developing countries will triple their cancer incidence over the next decade (IARC/WHO 1998, Parkin et al 2002).

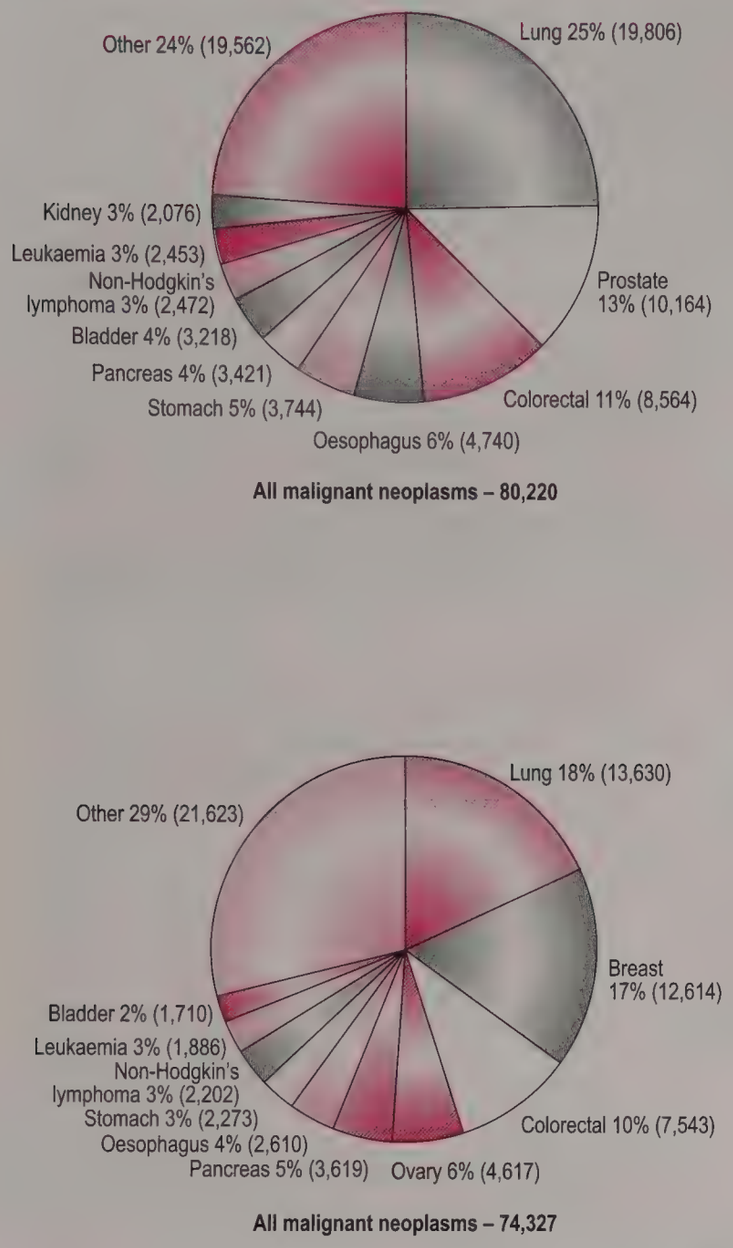

Fig. 31.3 The 10 most common causes of cancer deaths in the UK in 2003. A: Men; total number of cancer deaths = 80 220. B: Women; total number of cancer deaths = 74 327. Variations in the cancer mortality between the sexes reflect, as well as anatomical differences, different behavioural and environmental factors. Although lung cancer represents 22% of all cancers, there is a downward trend which reflects the fall in tobacco consumption since the first two World Wars. However, as smoking increases, particularly among teenage girls, and without effective tobacco control measures, this decreased mortality may be reversed in the future. (Reproduced with permission from Cancer Research UK 2005.)

The greater incidence in Western society may be partly attributed to the more sophisticated screening, diagnostic and reporting procedures. Also with the eradication of smallpox, polio and other diseases, life expectancy is greater. Western diet, industrial pollution and behaviours such as smoking and excessive alcohol consumption are chief environmental causes of cancer.

Geographical variations in the incidence of cancer provide fascinating clues to the causes of the disease. In Mozambique a high incidence of liver cancer is thought to be associated with aflatoxin from mould found on stored peanuts. Since the introduction of more appropriate storage practices, the incidence of liver cancer has been falling (Souhami & Tobias 2005). The Japanese have a low incidence of breast cancer but a high incidence of stomach cancer. However, within one or two generations, Japanese immigrants to Hawaii showed the American pattern of a high incidence of breast cancer and a moderate incidence of stomach cancer (Haenszel & Kurihera 1968). This seminal study and other similar studies indicate that geographical variations in cancer incidence are attributable to environmental rather than genetic factors; however, there may be an interaction with genetic disposition.

Epidemiological investigation of genetic predisposition to cancer is growing rapidly as developments in molecular biology make it possible to study genetic markers in large populations. The completion of the Human Genome Project (see Box 31.2) is accelerating the discovery of such markers (Peters et al 2001, Loud et al 2002).

Box 31.2

Human Genome Project

In the mid-1980s, it was first suggested that the fundamental problem of cancer could be addressed by studying the sequence of the entire human genome. Initiated in 1988, the specific aim of the International Human Genome Project (HGP) was to map the estimated 50 000–1 000 000 genes determining the sequence of nucleotides that make up the human genome. With the initial sequencing and analysis now complete, demonstrating 30 000 genes, the availability of this information is helping to unlock biological processes, allowing the translation of this knowledge into cancer care. Major opportunities are developing for identifying those at risk of developing cancer and the ability to detect cancer early (screening), and for more effective cancer treatments (pharmacogenetics).

From its inception, it was recognised that acquiring and using genetic knowledge would have profound implications for both the individual and society. Therefore, the analysis of the ethical, legal and social implications associated with the availability of this information is a major component of the HGP.

A series of articles highlighting the explosion of information and technology in this genetic revolution and its implications for oncology nursing are detailed in 'Further reading' (p. 1070) and include Calzone & Masny (2004), Greco & Mahon (2004), Jenkins (2004), Kwitkowski & Daub (2004), Loud & Hutson (2004), Lowrey (2004), Rieger (2004) and Vadaparampil et al (2004).

The causes of cancer

Most cancers develop through the interaction of genetic and environmental factors and it is difficult to separate the two completely. Although all cancers have a genetic origin at the cellular level, this does not mean all cancer is inherited. Genetic is a general term used when discussing genes or chromosomes. Genetic changes or mutations may be either *somatic* (acquired) or *germline* (inherited).

- *Germline mutations* are those present in the egg or sperm of a parent that can be passed to the offspring through

fertilisation. The mutation is present in every cell of the body.
- *Somatic mutation* is when an individual body cell, postconception, acquires a gene alteration. If not repaired, the mutation is passed on to all future cells through mitosis. These clonal changes are unique to the cells in that particular tissue and are not inherited.

Many questions remain to be answered regarding the exact mechanisms involved in the cellular mutations that lead to cancer. However, epidemiological studies have identified certain causative factors, termed 'carcinogens'. Knowledge of identified carcinogens is essential for:

- the development of prevention and screening strategies
- the provision of accurate information for patients, allaying the myths surrounding cancer causation.

Carcinogenesis is multifactorial and factors may enhance or inhibit the process. Stages include:

- *initiation* — a mutagenic event occurs in the DNA of a single cell; this may, for example, be radiation-induced
- *promotion* — repeated exposure to carcinogenic agents may or may not cause this initiated cell to proliferate to form a tumour.

A long latency period may exist between carcinogen exposure and cancer development. Carcinogenic factors and substances can be divided into those that are intrinsic and those that are extrinsic to the individual.

Intrinsic factors

Heredity Inherited cancers contribute 5–10% of all cancers. Several genes have now been identified that are responsible for predisposing individuals to develop certain cancers. For example, childhood tumours such as retinoblastoma are due to inherited chromosomal abnormalities. Cancers that occur with increased frequency in families are components of various hereditary cancer syndromes, e.g. hereditary non-polyposis colon cancer (HNPCC).

Cancer susceptibility genes such as BRCA1 and BRCA2 have been identified in breast and ovarian cancer. Women who inherit a mutation in these genes may face a 50–85% lifetime risk of developing breast cancer including an increased risk for ovarian cancer (Calzone & Biesecker 2002). Testing for these particular genes and others is now available commercially. (See Ch. 6 for more details regarding genetics and the implications for individuals with cancer).

Hormones Excessive amounts of certain hormones are thought to promote some tumours. Early menarche, late menopause and nulliparity are all associated with a high incidence of breast cancer, implying that prolonged exposure to oestrogen is a causative factor (Toniolo et al 1995). Results of the Million Women Study (2003) in the UK have confirmed that use of combined oestrogen plus progesterone hormone replacement therapy (HRT) increases the risk of breast cancer. This risk increase is duration dependent, declining when HRT is discontinued and, by 5 years, the risk level is the same as that of a non-user (Million Women Study Collaborators 2003). Endometrial cancer risk increases with exposure to 'unopposed' oestrogen, i.e. oestrogen only HRT, obesity, the sequential use of oral contraceptives and a late menopause. High levels of gonadotrophins are associated with an increased risk of ovarian cancer (Henderson & Bernstein 1997) and high testosterone levels have been related to prostate cancer (Ross et al 2003).

Immunity Individuals with impaired immunity are more prone to cancer than others; for example, people with AIDS have a high incidence of Kaposi's sarcoma (see Ch. 37). This does not mean that cancer is an infectious disease. Immunosuppression may predispose to certain infections, which may then contribute to the cancer process.

Pre-existing disease Any tissue subjected to constant irritation or to some disease process has an increased susceptibility to malignant change. Hence, ulcerative colitis may precede colonic carcinoma.

Age The rising incidence of cancer with age is thought to be attributable to:

- prolonged exposure to carcinogens
- decreased resistance to carcinogens
- hormonal changes that occur with age.

Extrinsic factors

The fact that 70% of cancers occur in epithelial cells that are constantly exposed to external, ingested or inhaled substances implies that extrinsic factors related to lifestyle and the environment are important in carcinogenesis. These factors may be considered under the following headings:

- physical agents
- chemical agents
- viruses
- diet.

Physical agents

Radiation is known to cause cellular mutations and cancer. Survivors of the atomic bomb explosions in Hiroshima and Nagasaki experienced a high incidence of leukaemia and skin cancer. Early research has shown an apparent increase in the incidence of leukaemia among the children of fathers working in the nuclear industry, possibly due to germ cell mutations (Gardner et al 1990). Repeated exposure to therapeutic doses of radiation is not thought to be harmful, although stringent precautionary regulations should be followed for the protection of all exposed workers. Therefore, it is not routine discharge of radioactivity by the nuclear industry that should be feared, but rather the catastrophic event, such as occurred at Three Mile Island in 1979 and at Chernobyl in 1986. In the former accident, radioactive noble gases were released into the atmosphere. By the worst estimate, there will be one radiation-induced cancer death in the 2 million people living around the reactor. Chernobyl, however, released much of its radioactive core into the atmosphere and will account for an increase of 2–3% in related cancer deaths (Hall 1997).

UV light There is overwhelming evidence that repeated exposure to solar UV light is the primary cause of basal and squamous cell carcinoma. Data establishing a direct causal relationship with sunlight are more complex, but suggest a promotional role of sunlight in the cause of

melanoma. Fair-skinned or freckled individuals who are unable to manufacture sufficient protective melanin are particularly at risk (see Ch. 12).

Chemical agents Ninety per cent of all lung cancer cases can be attributed to tobacco smoking. The temporal relationship between smoking and lung cancer was defined in the 1950s by studies undertaken by Doll and Hill (1954). Cigarette smoking has now clearly been identified as a major cause of cancers of the mouth, pharynx, larynx, bladder and pancreas, whilst contributing to many others. Risk is more dependent on duration of smoking than on consumption. Smoking 20 cigarettes a day for 40 years is eight times more hazardous than smoking 40 cigarettes a day for 20 years. People who stop smoking even well into middle age avoid most of their subsequent risk of lung cancer and stopping before middle age avoids more than 90% of the risk attributable to tobacco (Peto et al 2000). It is also evident that non-smokers are at risk from exposure to other people's smoke: one-quarter of lung cancer cases in non-smokers are estimated to be due to passive smoking (Trichopoulus et al 1981, DH 1998a,b, IARC 2004).

Excessive alcohol, ingested over long periods of time, contributes to cancers of the mouth, pharynx, oesophagus and liver. Those who drink spirits as opposed to wine and beer and those who smoke as well as drink are particularly at risk (see Ch. 36).

Many other chemicals, whether inhaled, ingested or absorbed through the skin, have been shown to cause cancer. Lung cancer in non-smokers is most prevalent in large cities where traffic fumes and chimney smoke raise atmospheric levels of polycyclic hydrocarbons, the same chemicals present in cigarette smoke.

Other carcinogenic chemicals present occupational hazards. Some of these, but by no means all, are now subject to government control or ban. These controlled substances, and associated cancer sites, include:

- asbestos (lung, mesothelium and larynx)
- vinyl chloride (liver)
- certain chemical dyes (bladder)
- arsenic (lung and skin)
- some hardwood dusts (nasopharynx).

Viruses Although cancer is not contagious, viral infections account for one in seven human cancers worldwide (Poeschla & Wong-Staal 1997). The Epstein–Barr virus causes a systemic infection that may precede Burkitt's lymphoma, a malignant disease common in parts of Africa. Patients with chronic hepatitis B are more susceptible than others to liver cancer. The human papilloma virus, which may be sexually transmitted, is associated with cervical cancer and *Helicobacter pylori* is estimated to cause 60% of cases of stomach cancer in the USA (Cole & Rodu 2001).

Diet Epidemiological studies that isolate diet as a causal factor in the development of cancer are extremely problematic to undertake. Nevertheless, dietary factors have been implicated as a major cause of the high incidence of cancer in the West. Countries where the average diet is high in fat and protein appear to have a high incidence of breast cancer, and low-fibre diets are thought to contribute to bowel cancer. Some food additives have been found to be carcinogenic and have been removed from the market, although many others have not yet been fully investigated.

Cancer prevention and screening

Prevention of human cancers is a major focus of research and education. The principal hope lies in the rigorous application of prevention and screening programmes. The goal of primary prevention is to reduce the risk of the healthy population developing cancer. Secondary prevention aims to detect early-stage, curable, cancer. Primary prevention is therefore the most effective and economic method of controlling cancer.

Nurses now have a much wider role, incorporating health promotion, health education and disease prevention as well as the care of those who are ill. This wider role is reflected in their initial and post-basic education. Many health visitors, district nurses and practice nurses working in community health centres offer innovative health promotion programmes, as well as screening for ill-health. Antenatal care, well-woman or well-man clinics, family planning centres and other health screening clinics all provide opportunities for the promotion of cancer prevention. In clinical practice, nurse specialists are now incorporating cancer awareness and prevention in their roles, with many involved in local and national initiatives such as cancer site-specific awareness weeks and health promotion in schools.

Primary prevention

Primary cancer prevention is true health promotion and includes such activities as:

- identifying risk factors in individuals or groups
- counselling high-risk individuals to promote behaviour modification
- genetic screening
- implementation of new cancer prevention programmes, e.g. smoking cessation, healthy eating.

Walker (1990) argued that cancer prevention programmes that use fear of the disease to motivate compliance may be counterproductive. Media reporting of cancer risk development requires cautious interpretation and should be put into perspective by reference to the original studies on which they are based. It is important to remember, for example, that substances that are carcinogenic in animals are by no means always so in humans. Moreover, everyday exposure to some of the substances implicated is so minimal as to make risk insignificant. Some of these media scares do little to promote health; fear of cancer, after all, is one of the most common reasons why people avoid screening or fail to present with symptoms.

Health promotion programmes Box 31.3 lists actions that people can take to reduce their risk of cancer. Arguably, observing these guidelines will result in a healthier lifestyle with a low risk of many health problems including cancer. Health promotion programmes should explore practical and realistic ways of assisting people to integrate such generally healthy behaviours into their daily lives.

Box 31.3

Lifestyle and cancer — how to reduce your risk

Two-thirds of all cancers are linked to lifestyle and could be prevented.

- Breathe clean air. Stub out cigarettes — the longer you give up cigarettes, the more you reduce your cancer risk.
- Drink sensibly — all alcohol in moderation following recommended guidelines.
- Eat healthily — a diet low in fat and rich in fruit, vegetables and fibre.
- Be active — exercise moderately for at least 30 min five times a week. Avoid being overweight.
- Protect yourself in the sun — don't burn and follow recommended advice for protection.
- Take care with chemicals or radiation exposure — follow Health and Safety instructions.
- Be body aware — know your body and what is normal for you.
- Know the early signs of cancer — see your doctor about unusual lumps, moles, bleeding or other persistent symptoms.
- Go for screening — early changes can be picked up and the chance of successful treatment maximised.
- Practise safe sex — using a condom decreases the chance of passing on a virus.

Adapted from Cancer Research UK (2002).

Health education programmes have some measure of success (Ewles & Simnett 2003). The Community Intervention Trial for Smoking Cessation (COMMIT) funded by the National Cancer Institute (NCI) was designed to test the effectiveness of a 4-year community-based intervention programme to help smokers achieve and maintain cessation. The programme had a positive effect on light to moderate smokers, but no significant impact on the heavy smokers' group (COMMIT Research Group 1995). These results are both positive and disappointing. However, it has provided important information regarding future cessation programmes. Dissemination of knowledge, it appears, is not in itself sufficient to motivate changes in behaviour.

Several government publications have taken on 'The Cancer Challenge', with measures to promote a 'pro-health' culture (Scottish Office 1999, DH 2000a, SEHD 2003). Projects have been developed to assist smokers to quit, particularly in areas with high levels of deprivation, prisons, the army, and working men's clubs. Political action has included a comprehensive ban on tobacco advertising, reduction of smoking in public places and the workplace, the setting up of new 'stop smoking clinics' and a smokers helpline, nicotine replacement patches and bupropion (Zyban) available on prescription, as well as a major health education campaign in schools aimed at preventing youngsters from starting to smoke (DH 2000a, SEHD 2003).

Through working partnerships with the community and the food industry, strategies to promote healthy eating include a national 'Five a Day' programme, improving accessibility to affordable fresh fruit and vegetables, and advocating five portions of these daily. The national School Fruit Scheme ensures that fruit is available each day at school for children 4–6 years of age. However, if an impact is to be made, continuing legislation is required regarding the control of tobacco sales, occupational exposure to carcinogens and regulation of food additives.

Attitudes Many factors other than knowledge deficit are known to affect a person's health attitudes. Psychologists have developed a Health Belief Model (Strecher & Rosenstock 1997) to predict an individual's preventive health behaviour and account for some of the factors which determine attitudes to health and illness.

The Health Belief Model states that an individual feels vulnerable to a disease if they believe they are susceptible to developing it and believe the disease to be serious. Preventive action will be taken only after the individual has balanced the benefits of that action against its physical, psychological and financial costs (Fernsler & Miller 2000).

Despite being taught about the risks of smoking, teenage smokers may consider themselves to be young and healthy and therefore not 'at risk'. Young people in general are motivated by short-term rather than long-term rewards. Smoking in some subcultures and families is associated with attributes such as maturity or rebelliousness, which the young person and their peer group may value. Later, the physical addiction to nicotine becomes a coping mechanism for life's stresses and social deprivation. For such people, possible avoidance of lung cancer is not worth the cost of surrendering the immediate gratification and social status offered by smoking.

Clearly, consideration of the wider causes of individual behaviour would lead those involved in health promotion to an awareness of the social and political action necessary. Most cancers are more common in lower socioeconomic groups than in more affluent groups, yet uptake of preventive and screening services is lower in the former. The causes of social deprivation need to be considered alongside individual behaviour. Preventive services must be readily accessible and based on the expressed needs of the community, e.g. on the principle of client-centred care (DH 1998c).

The concepts of health and ill-health are open to wide interpretation. An essential aspect of communication is that everyone understands and attaches the same meaning to language used. If adherence to health care programmes is to be achieved, nurses need to understand an individual's personal health beliefs and how information is interpreted (Wilkinson 1999).

31.5 Using the Health Belief Model, consider the factors that would be taken into account by a community or practice-based nurse working in liaison with an area health promotion officer in devising a cancer prevention programme in the following community health centres:

(a) An inner city practice in which 50% of the population are first- and second-generation immigrants from the Indian subcontinent. The remaining 50% consist of students in rented housing, young professional people in their first jobs and homes, and workers in a local petrochemical industry.

(b) A new town practice covering a large area of farmland. The new town housing estates accommodate a large percentage of single, unemployed parents. The nearest large hospital is 20 miles away.

Discuss this as a group. Also consider how community nurses in each centre might incorporate cancer prevention into their practice.

Secondary prevention: screening

The prognosis of patients with most types of cancer is very much improved if the tumour is detected at an early stage. Often, complete cure can be assured if pre-cancerous tissue can be identified and treated, as in the case of cervical intraepithelial neoplasia (CIN).

Cancer screening issues The development of accurate and cost-effective methods of screening at-risk sections of the population is problematic for several reasons. The test must have both a high degree of sensitivity, reducing the risk of false-negative results, and specificity, reducing the psychological trauma and expense of treating false-positive results. It must be possible to identify an at-risk group, otherwise the cost of screening becomes prohibitive. Finally, and most problematically, it must be determined whether detecting the cancer type at an early stage will actually prolong life (Segnan et al 2004). In the case of small cell lung cancer, for example, early detection with existing tests would simply mean that patients would have an earlier knowledge of their diagnosis, but still live for the same number of years (see Ch. 3).

Two standard screening methods concern cancers affecting women:

- breast cancer screening
- cervical screening.

Breast cancer screening Despite recent debates about the quality of over 40 years of trials, it is generally agreed that there is a clear benefit and reduction in mortality from breast cancer from screening women over the age of 50 years by mammography every 2 years (IARC 2002). Accepted screening techniques include mammography and clinical breast examination, although Baxter (2001) has concluded that breast self-examination is of no benefit in routine screening. Controversy still surrounds the value of screening women of 40 years or younger, consequently professional clinical judgement and a woman's choice should guide decision-making. The denser breast tissue of premenopausal women makes mammograms difficult to interpret in this age group. In future, genetic screening and new technologies such as digital mammography may be of benefit.

Cervical cancer screening Cervical cancer is among the most common of female cancers in developing countries. Since the introduction of the Pap (Papanicolaou) smear test over 20 years ago, there has been a steady decline in mortality rates in the UK (Cancer Research UK 2005b). New guidelines in the USA suggest that smears should be taken from 3 years after the onset of vaginal intercourse, which for some women in the UK is below the age at which screening is offered, i.e. 25 years (Smith et al 2003). However, some GPs may offer early screening as part of their consultation with women regarding sexual health.

Initially, uptake of the service by groups at highest risk, i.e. women over the age of 40, of lower socioeconomic status and in minority ethnic groups, was poor. Barriers to cervical screening include lack of sensitivity and trust in health professionals; possible feelings of guilt and embarrassment may be exaggerated by judgemental attitudes, a lack of privacy and supportive care in clinics (Fitch et al 1998). It is important for staff working in screening services to have well-developed interpersonal and communication skills to alleviate any fears or anxieties. In addition, clinic schedules should allow time for giving support.

Intervention strategies based on individual respect, health care provider relationships and inclusion of significant others may increase adherence to cancer screening guidelines (Steven et al 2004). For example, the recent provision of culturally sensitive information to women in minority ethnic groups has been successful, as evidenced by improved service uptake (DH 2000a).

There has been controversy regarding the reliability of screening tests and accurate detection of abnormal smears. However, the introduction of liquid-based cytology, and the potential to detect human papilloma virus in the same sample, are thought to reduce the number of inadequate smears (Uyar et al 2003).

Screening for other cancers Screening programmes for other cancers are now under scrutiny, including:

- colon cancer
- prostate cancer
- ovarian cancer
- lung cancer.

Colon cancer The natural history of colon cancer with the relatively long time from biological onset to the development of cancer makes it a good candidate for screening. A UK pilot for colorectal cancer screening tested the value of the faecal occult blood (FOB) test for early detection and mortality reduction (Scholefield et al 2002) and, as a result, a national bowel screening programme is to begin in 2006 (Birmingham 2004). Further trials are also being conducted looking at the role of flexible sigmoidoscopy in diagnosis (Boyle et al 2003). The proposed screening interval is 2 years for those aged 50–69 years. Campaigns by Colon Cancer Concern have been initiated to promote a greater awareness of the early warning signs of colon cancer. Emerging future technologies to improve sensitivity include virtual colonoscopy and DNA testing of stools.

Prostate cancer There is at present no consensus regarding the most appropriate screening method. There are three main screening modalities: digital rectal examination (DRE), serum prostate-specific antigen (PSA) and transrectal ultrasonography (TRUS). There are wide ranges in the estimates of sensitivity and specificity. Interest in PSA (a blood test) emerged in the late 1980s when it was shown that, post-prostatectomy, previously abnormal PSA levels reduced by half (Catalona et al 1991). However, PSA may be elevated in men with non-cancerous conditions. There is currently no evidence that prostatic screening improves clinical outcomes; in fact, there are issues of uncertainty surrounding the appropriateness and type of treatment for

men with early-stage prostatic cancer, since it has a long asymptomatic latency period. It is therefore important to consider that there might be an adverse psychological impact as a result of prostate screening although, for those men at risk, it may provide some reassurance (Cantor et al 2002).

To address some of these concerns, a prostate risk management programme has recently been introduced which sets out initiatives to improve men's understanding of the benefits and limitations of PSA testing (NHS Cancer Screening Programme 2004). Working in conjunction with CancerBACUP (see 'Useful websites'), a booklet explaining the PSA test has been produced.

Ovarian cancer Transvaginal ultrasound and detection of a raised cancer antigen (CA125) in the blood provide two possible techniques for the screening of ovarian cancer. However, as with PSA, CA125 may be elevated in non-malignant conditions. A UK collaborative trial of ovarian cancer screening (UKCTOCS) aims to answer the question of whether or not early detection will save lives. The effectiveness of different screening technologies will be examined and a report is expected in 2010.

Women known to have a high familial risk of developing ovarian cancer are offered annual screening as part of a national familial ovarian cancer screening study.

Lung cancer It has been shown that low dose spiral CT scanning can identify lung cancer in high risk but asymptomatic individuals (Gohagan et al 2005). Whilst this may be a useful screening test, evidence is required to substantiate a link with decrease in mortality.

Screening in the future With the discovery of susceptibility genes, cancer prevention will become a more prominent area of cancer care. The provision of psychological support during screening and for decision making regarding treatment in cases with a positive diagnosis requires considerable knowledge, skill and sensitivity on the part of nurses and team colleagues.

31.6 Consider the role of (a) school nurses and (b) occupational health nurses in the primary and secondary prevention of cancer. Try to arrange to spend a day with one of these practitioners, and identify the elements of their role which could be further expanded to fulfil this function.

CASE HISTORY 31.1(A)

D

D, a 22-year-old student, discovered a testicular swelling but chose to ignore it, initially because he misinterpreted it as a sports injury, and later because he felt embarrassed. Nine months later he presented to the student health centre because he was becoming breathless far more readily than usual and suffered a constant backache. These symptoms were due to lung metastases and referred pain caused by metastases in the para-aortic lymph nodes.

CASE HISTORY 31.1(B)

D *(cont'd from Case History 31.1(A))*

D was admitted to a surgical ward, where a biopsy under anaesthesia was performed. A frozen section taken for histology showed a testicular teratoma. A left orchidectomy was then performed.

Following postoperative recovery, D was taken to an oncology ward for staging. D lived too far away to travel to the department each day, otherwise the necessary tests could have been performed while he was an outpatient. The tests were carried out and their results were as follows:

- chest X-ray: showed multiple lung metastases
- thoracic CT scan: confirmed lung metastases
- abdominal CT scan: showed a large para-aortic lymph node and no liver metastases
- blood samples for full blood count, urea, creatinine and electrolytes, liver function and tumour markers (AFP and HCG).

These tests showed that D had stage IV testicular teratoma; however, even extensive disease is curable with cisplatin-based chemotherapy (Souhami & Tobias 2005). Accordingly, this was the treatment course chosen.

Creatinine clearance is calculated from the serum creatinine to establish baseline measurements for subsequent assessment of any nephrotoxicity induced by platinum compounds.

CASE HISTORY 31.2

Mrs F

Mrs F is 45, married and has three grown-up children. She is very health conscious and presents herself every 3 years for a cervical smear at the occupational health centre of her workplace. On this occasion, she is informed that her smear is positive. Subsequent colposcopy reveals carcinoma in situ, i.e. a pre-invasive cancer of the cervical cells that is curable by cone biopsy or laser therapy.

MEDICAL INTERVENTION AND THE NURSE'S ROLE

Diagnosis and staging

Patients present with cancer in a wide variety of ways. Consider the different physical and psychosocial care needs of the three patients in Case Histories 31.1–31.3.

Patients may present at any point in the disease process, ranging from the premalignant to the metastatic phase. Staging is the process whereby the extent of the disease is established; this involves a varied number of tests for each patient (see the appropriate chapter for a given tumour site). Diagnosis and staging are carried out in a variety of settings, depending on the patient's presenting signs and symptoms. This process can be long, complex and tedious for the patient, raising many issues of uncertainty. However, accurate staging of the extent of the disease is vital for the following reasons:

- Certain modes of treatment are known to be effective at specific disease stages. For example, thoracic surgery for Mr H (see Case History 31.3) would be inappropriate given the dissemination of his disease. Staging spares the human and financial cost of inappropriate treatment.
- Prognosis can be estimated according to the disease stage and cell differentiation (see p. 328).

CASE HISTORY 31.3

Mr H

Mr H is a 76-year-old widower. A heavy smoker, he has suffered from chronic bronchitis for 30 years. His respiratory symptoms have seemed more troublesome lately, but it is pain in the ribs and back (due to bone metastases) which finally cause him to consult his GP. These pains are initially considered to be arthritic in nature, causing further delay in the eventual diagnosis of disseminated small cell bronchogenic carcinoma.

- Staging information is valuable for cancer research, for statistical analysis and in considerations of the patient's eligibility to enter a trial of a new treatment.

The TNM system

The most common internationally used method of defining disease stages is the TNM system (Sobin & Wittekind 2002), in which:

- T denotes the size or extent of local invasion of the primary tumour
- N refers to the spread to local lymph nodes
- M refers to the presence of metastases.

Box 31.4 illustrates the use of the TNM system in carcinoma of the lung. Some types of cancer — usually those that are disseminated at presentation — cannot be effectively staged with the TNM system and have necessitated the development of other systems. Box 31.5 shows the staging system generally used in the UK for testicular tumours. During the course of their illness, patients may be restaged in order for their response to treatment, or the extent of disease recurrence, to be assessed. Case History 31.1(B) illustrates the experience of staging for a patient with testicular cancer.

Psychological impact of diagnosis and staging

Confirmation of diagnosis It is very common for patients to be aware that they have cancer before they are told formally of their diagnosis. This awareness derives from their experience of symptoms, tests and, in some cases, surgery and from the non-verbal communication of staff or relatives. How to inform patients in *full* of their diagnosis, and when this should be done are ongoing issues of ethical debate (see Box 31.6).

Even if they suspect their diagnosis, patients often cling to hope or use denial as a coping mechanism (Stephenson 2004). These are the early emotional reactions experienced by people facing any actual or potential life crisis or loss, as described by Kübler-Ross in her seminal text (1973).

For further reading, see Niven (1999).

For most patients, confirmation of their fears comes as a devastating shock; this is often followed for varying periods by a normal stress reaction, which may include anxiety, depression, insomnia and poor concentration. This stressful time is one of great emotional confusion, during which the individual attempts to adjust to a shattered world. Relatives and friends also experience a conflict between their desire to be supportive and their fear of impending change and loss. The following words summarise the feelings of one patient immediately after she was told of her diagnosis (Evans 1989):

> *Then he mentioned cancer. I suddenly went numb, rooted to the spot. The only thing that I could think of was that I was going to die. With that one word he had shattered my well-ordered world. I felt my life was closing in on me. I wanted to cry but the tears would not come. I wanted to laugh but it was not funny. Shock and fear invaded my*

Box 31.4

Summary of the TNM staging system for lung cancer

T (primary tumour)

TX	Positive cytology only
Tis	Carcinoma in situ
T1	Tumour ≤3 cm in diameter. No proximal invasion
T2	Tumour >3 cm in diameter, within 2 cm from carina or invading the visceral pleura or partial atelectasis
T3	Tumour of any size extending into the chest wall, diaphragm, pericardium, mediastinal pleura or within 2 cm of carina, total atelectasis
T4	Tumour of any size with invasion of mediastinal organs or vertebral body, malignant pleural effusion

N (lymph nodes)

N0	Nodes negative
N1	Positive nodes in ipsilateral hilar nodes
N2	Positive ipsilateral, mediastinal and subcarinal nodes
N3	Positive contralateral mediastinal or hilar nodes, scalene or supraclavicular nodes

M (distant metastases)

M0	No metastases
M1	Metastases present

The disease is then staged using the above information, as follows:

Stage IA	T1	N0	M0
Stage IB	T2	N0	M0
Stage IIA	T1	N1	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
Stage IIIA	T1–3	N2	M0
Stage IIIB	T4	Any N	M0
Stage IV	Any T	Any N	M1

Adapted from Sobin & Wittekind (2002).

Box 31.5

UK staging system of testicular tumours

Stage I	Tumour confined to testes
Stage II	Pelvic and abdominal lymph node involvement
Stage III	Mediastinal and/or supraclavicular lymph node involvement
Stage IV	Distant metastases, e.g. lung

Box 31.6

Informing patients of their diagnosis: ethical considerations

Two ethical principles are central to the discussion of whether it is always right to tell a patient the whole truth about their diagnosis: these are the principles of autonomy and of beneficence (for a fuller discussion, see Thomson et al 2000).

Autonomy

Patients have a right to autonomy, or self-determination. They cannot make decisions about their treatment or the future if they are not fully aware of their diagnosis. However, research has suggested that denial as a coping mechanism is sometimes necessary for the preservation of well-being during a crisis, allowing an individual time to mobilise the resources to cope with the seriousness of their disease (Moyer & Levine 1998). Unlike 30 years ago, patients are now normally told their diagnosis, with a discussion of prognosis — often a medical uncertainty — and the level of information is tailored to the individual's needs. There is no evidence to suggest that acceptance correlates positively to survival in cancer (Creagan 1997, Spiegel 2001).

Beneficence

The principle of beneficence obligates health care professionals to prevent harm and 'do good' for their patients. It may seem obvious that to tell lies or withhold the truth is wrong. Patients may suffer severe psychological problems if they continue to feel unwell despite the optimistic messages they receive from others, and may even blame themselves for their symptoms. They may also lose trust if and when they discover the 'conspiracy'.

Discussion

The matter is seldom as simple as the choice between lying and truth-telling, and each case must be considered individually. Relatives may ask that their family member be protected from the *whole* truth. However, respect for the patient's autonomy should, whenever possible, override such a request, but the relatives and patient need to be supported when such information is given, and their issues and concerns addressed.

Tension can arise within the health care team when medical staff fail in their responsibility to disclose appropriate information to those patients who clearly wish to know more. Other staff — nurses in particular — who spend more time with patients become frustrated in their attempts to meet the psychological needs of individuals who lack awareness of the reality of their situation. There must be an open staff forum for the discussion of such problems.

In most cancer centres, the issue is not whether, but how and when, to inform patients of diagnosis and prognosis. A study by Schofield et al (2003) shows that practices linked to lessening anxiety include preparing the patient for a possible cancer diagnosis, having significant others present at diagnosis, being given as much information as desired in understandable language, having questions answered, talking about feelings and being given reassurance. It would seem appropriate that a nurse is present at such discussions because they can follow up the conversation and help the patient to strike a balance between realistic hope and the acceptance of reality.

mind. Did I really hear correctly what he had said? I wondered what on earth I was going to do. I turned to my husband and looked into his eyes, hoping to find the much needed help and support. All I could see was my own disbelief, horror and fear mirrored back at me. I knew I was on my own.

At the same time, this patient expressed relief at having a label for her symptoms and knowing that treatment could now proceed.

Disease recurrence The discovery that the disease has recurred after a symptom-free period may provoke even greater psychological disturbance, for the patient's hopes of cure have been disappointed. In any event, most newly diagnosed or re-diagnosed patients will be anxious to proceed with treatment as soon as possible, and many will become frustrated with the staging process. The period of waiting for test results, whether at initial diagnosis or at recurrence, is one of great anxiety; the patient is often afraid of the verdict but nonetheless desperate to know it.

Psychological support Aside from providing the necessary nursing care prior to and following each test, the nurse must act as communicator. It is important to know why each test is being performed and what it will entail for the patient so that explanations and reassurance can be provided. Findings suggest that a substantial proportion of the lay public do not understand phrases often used in cancer consultations. For example, in one study, only 52% understood that the phrase 'the tumour is progressing' was not good news and less than a third understood what was meant by 'seedlings' (Chapman et al 2003). The nurse, acting as facilitator, should ensure that the doctor explains test results and their significance to the patient as soon as possible. Many fears for the future, both rational and irrational, arise at this time. These need to be discussed openly, and it is the nurse who is most suitably placed to do this.

31.7 (a) Consider D's needs for information and emotional support during the staging process (see Case History 31.1(B)). Devise a care plan showing how you would meet these needs.

(b) Mr H (see Case History 31.3) has been discharged home following palliative radiotherapy to his ribs and spine. One day he asks his district nurse how long it will be before his strength returns. Consider the other questions he may be implying by asking this. What information would the nurse need and what might be the reply?

Aims of treatment

Cancer treatments can be described in terms of the following categories:

- curative — often termed 'radical' treatment
- palliative — given with the intention of controlling the disease and distressing symptoms.

The transition from radical to palliative therapy need not be presented to the patient as a major or sudden change of direction, as this may lead to feelings of abandonment and hopelessness. Often, several forms of treatment are given in combination; this is termed 'multimodal therapy'. Usually one therapy is the primary therapy while the others

are termed 'adjuvant' therapies, as in the case of adjuvant radiotherapy following breast surgery.

Response to treatment

Changes in the size of a tumour following treatment are termed 'response rates'. These may be *complete* — the tumour has disappeared; *partial* — the tumour has decreased by at least 50%; *minimal or stable* — there is very little change in tumour volume; *progressive* — 25% increase in tumour volume. A good tumour response does not necessarily prolong the patient's survival, but it may, in any event, significantly improve quality of life. Unfortunately, cancer treatments can have considerable side-effects, which may seriously reduce quality of life. Thus, the decision to treat a patient must be based upon a careful balancing of the costs and benefits of treatment and should, ideally, be taken jointly by the health care team and the patient.

Treatment modalities

The principal forms of cancer treatment are:

- surgery
- radiotherapy
- chemotherapy – both cytotoxic chemotherapy and biological response modifiers (BRM).

Surgery

Surgery is the oldest form of treatment for cancer and remains the most successful method of achieving long-term survival for patients with various types of localised tumour. Surgical removal of tumours of the skin (non-melanoma), thyroid gland, uterus, colon and rectum (early stage) are associated with an excellent chance of cure. Certain other tumours, particularly those disseminated at presentation such as small cell carcinoma of the lung, are inoperable.

Surgical procedures are not always performed with curative intent. Surgery may be used adjuvantly with other treatments, e.g. in the resection of diseased bone after radical chemotherapy for osteosarcoma. Palliative surgery can improve the quality of the patient's remaining life; for example, a stent insertion or bypass of the common bile duct can be performed to relieve jaundice in cancer of the head of the pancreas or in cholangiocarcinoma.

Psychological support Surgical techniques, pre- and post-operative nursing care, and the psychological problems associated with undergoing surgery are discussed in Chapter 26. The patient with cancer has all of the usual problems of the surgical patient to contend with, together with the stigma of cancer and the fear and uncertainty of an unknown outcome. Frequently, it is during the perioperative period on a general surgical ward that the patient is told of the diagnosis. There is a need for the nurses on these wards to be aware of the particular problems and needs of the cancer patient.

Radiotherapy

Radiotherapy is the use of ionising radiation to destroy cancer cell populations. Approximately half of all patients with cancer receive radiotherapy during the management of their disease.

Radiation physics and biology are complex topics, which are subject to intense research and development. More comprehensive accounts can be found in Dow et al (1997) and Faithful & Wells (2003).

There are two kinds of radiation:

- particle radiation, e.g. alpha particles, beta particles, electrons, protons, neutrons which have a mass, limiting their depth of penetration
- ionising electromagnetic radiation, i.e. gamma (γ) rays and X-rays — these are similar to light, radio or microwaves, but have a very much higher energy level and are deeply penetrating.

Alpha particles are of low energy; they can be absorbed by a sheet of paper and are too weak to kill cancer cells. Electrons are of higher energy and can penetrate anything up to the density of wood. In radiotherapy, electrons are used to treat superficial areas located a few centimetres underneath the skin, for example as a 'booster' treatment to the scar line postoperatively in breast cancer to prevent local recurrence. Gamma rays are short, very powerful waves that require lead or concrete to absorb them. They are emitted from the nuclei of radioactive elements, e.g. caesium and cobalt, and are able to penetrate deeply into the body tissues (Hilderley 2000).

The most common form of radiotherapy now is the X-ray. These rays are artificially generated when a stream of electrons bombard against tungsten metal targets, releasing energy in the form of X-rays.

Radioactivity Understanding ionising radiation requires a basic understanding of atomic and molecular structure. All matter is made up of atoms, which consist of a central nucleus containing positively charged protons and uncharged neutrons, orbited by negatively charged electrons, equivalent in number to the protons. The negatively charged electrons (–) orbit the nucleus, being held in place by the attractive force of the positively charged protons (+); hence a stable state is maintained (see Fig. 31.4).

However, as the number of protons increases, an excess number of neutrons are required in order to hold the nucleus together. This imbalance causes the spontaneous disintegration of the nucleus with an associated emission of charged particles and radiation energy.

Some elements exist in a variety of states, depending on the number of neutrons in the nucleus. These are termed the isotopes of an element. Two isotopes of iodine, for example, are ^{127}I and ^{131}I. The latter is a radioisotope, i.e. it is unstable, because the nuclei of its atoms have a disproportionate number of neutrons. Radioisotopes may be naturally occurring, such as radium-226 (^{226}Ra), which is now seldom used in radiotherapy, or artificially manufactured by bombarding elements with neutrons in a nuclear reactor, e.g. cobalt-60 (^{60}Co).

The effects of radiation Cellular response to radiation is not yet fully understood. Radiation causes ionisation of atoms and molecules. The main target of radiation is DNA, which is altered *directly* by ionisation of its own molecules or *indirectly* by changes in the chemical environment of the cell, caused by ionisation of other molecules, particularly

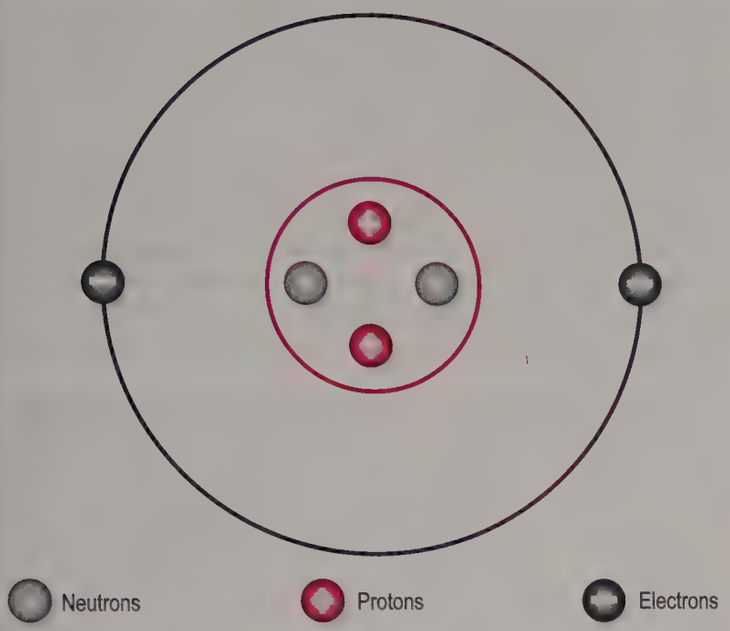

Fig. 31.4 The stable atom. The nucleus of this atom is stable because the number of neutrons and protons are in balance. The neutrons counteract the electrostatic forces pushing the protons apart.

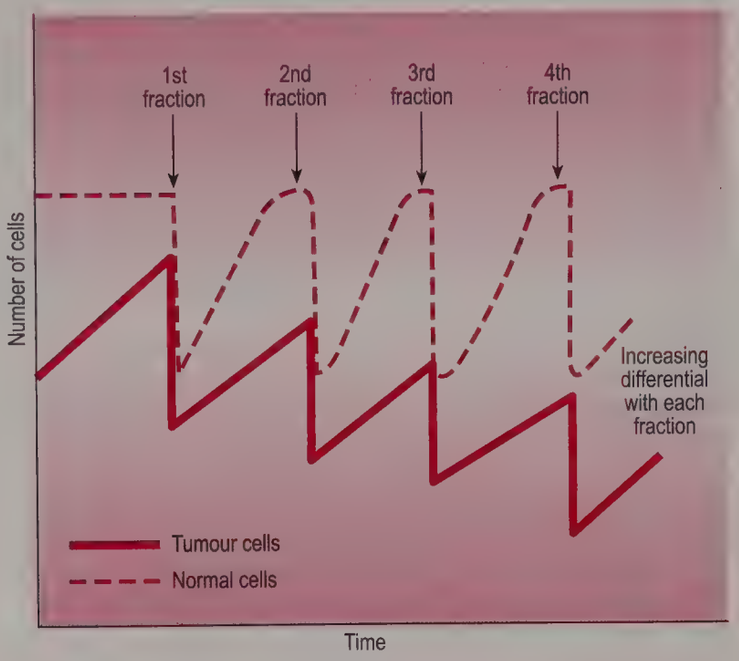

Fig. 31.5 The difference between normal and tumour cell kill and recovery in radiotherapy. Normal cells have the capacity to recover to their previous population level more rapidly than malignant cells. Therefore, successive treatments given after normal cell population recovery but before malignant cell population recovery will result in minimal damage to normal tissue but successive reductions in tumour size.

water. The latter results in a free radical in the cell, a very reactive atom with an unpaired electron, which triggers chemical changes. This ultimately stimulates a chain of events that leads to biological damage, irreparably damaging DNA, which retards cell metabolism and causes cell death. Cells are therefore more sensitive to radiation-induced damage at certain phases of the cell cycle, e.g. G_2 and M phase.

To revise your knowledge of the cell cycle, see Martini (2004) or Tortora & Grabowski (2005); for further information regarding the radiobiological basis of radiotherapy, see Adamson (2003).

Radiosensitivity of a given tumour is closely related to cell proliferation activity. As malignant cells are constantly dividing, they are all radiosensitive, although to varying degrees. Unfortunately, rapidly dividing healthy cells, such as those of the skin, the epithelium of the gastrointestinal and urinary tracts, the gonads and the bone marrow, are also vulnerable to radiation damage; this accounts for the unwanted side-effects of radiotherapy. Figure 31.5 explains the difference between the radiation responses of tumour cells and normal cells. In theory, all tumour cells could be eradicated by radiotherapy. However, the often narrow difference between the dose required to produce lethal damage to the tumour and that which causes irreversible damage to normal tissue (therapeutic ratio), makes it difficult to achieve optimal dosing without causing unacceptable side-effects.

Radiotherapy is prescribed as an 'absorbed dose'. The unit used is the gray (Gy), where 1 Gy = 1 joule as absorbed by 1 kg of body tissue. The dose prescribed will vary, depending on several factors such as the volume and site of the area to be treated, sensitivity of the surrounding normal tissue, radiosensitivity of the particular tumour and also treatment intent, i.e. curative or palliative.

Sources of radiation Radiotherapy is given in a variety of ways, according to tumour type and stage and, occasionally, the patient's condition. Teletherapy (from the Greek téle — 'far'), sometimes called 'external beam therapy', is the most common method of treatment. Brachytherapy (from the Greek brachys — 'short') is administered via radioactive sources placed within a body cavity or tumour bed.

Teletherapy External beam radiotherapy is administered by machines, which are categorised according to the level of energy of radiation produced and depth of penetration (kilovoltage, orthovoltage, megavoltage, cobalt machine). The 'linear accelerator' or 'linac' is the predominant teletherapy equipment in use throughout the world. Machines delivering lower voltages are still used to treat superficial lesions, such as skin carcinomas. The total prescribed radiation dose, if administered in one session, may be far too toxic to normal tissue and possibly even fatal to the patient. Hence treatment is often administered in daily 'fractions' of the total dose, so as to take advantage of the four Rs of radiobiology — repair, reproduction, redistribution and reoxygenation. Repair of sublethal cell injury generally occurs within 24 h, but possibly in as little as 30–90 min. Normal cells can therefore repair between daily doses of radiation. Tumour cells may do so initially but become less capable as treatment is protracted.

The standard fractionation schedule is a daily single dose five times a week. Alternative fractionation schemes continue to receive attention as the search continues to achieve greater cell kill and tumour control. Two strategies have been developed involving multiple fractions per day: hyperfractionation and continuous hyperfractionation accelerated radiotherapy (CHART). Hyperfractionation is

the use of several smaller than standard doses given two to three times daily. The accumulative daily and total doses are usually greater than for conventional treatment. Accelerated hyperfractionation refers to an overall shortened treatment time, achieved by increasing the number of fractions per day, treating continuously including weekends. In both approaches, 6 h between doses must be allowed for repair of sublethal damage from the first dose before the second is given (Saunders et al 1997). CHART has significantly better tumour control but implementation requires considerable changes in working practice (Adamson 2003).

The patient's initial visit to the department involves a planning session (simulation) which, if complex, may necessitate more than one visit. Extreme accuracy in devising the unique plan for each patient is vital, the aim being adequate dosage to the tumour and minimum exposure of healthy tissues and organs. Localisation of the tumour is made using an X-ray simulator which mimics the treatment machine, and information from CT or MRI scans. This information is then used by the planning computer staff to determine a beam configuration that conforms precisely to the target organ or site. Patient immobilisation is important, particularly for patients with head and neck tumours. A close fitting individualised Perspex shell is made in the mould room, which is worn throughout treatment. Some individuals may find this claustrophobic.

Intensity modulated radiation therapy (IMRT) harnesses the latest advances in digital, diagnostic imaging, information processing and beam-shaping technologies to enable clinicians to determine and deliver an optimal treatment plan whereby beams can be shaped to avoid surrounding tissue (Staehelin 2003).

In most centres, the treatment field, or reference points, are marked out on the patient's skin using small permanent tattoos. Traditionally these had been defined using ink marks, which were not to be washed off.

Brachytherapy This form of treatment is less common than teletherapy. It is the temporary or permanent placement of a radioactive source (isotope), either in close proximity to or within a tumour. It offers the advantage of delivering a continuous dose of radiation to a specific tumour volume. The most common methods used include interstitial implants, intracavitary treatment and systemic therapy. In an interstitial implant, the radioactive source is contained in the form of a needle, seed, wire or catheter that is implanted directly into the tumour (e.g. iridium — breast, prostate, head and neck cancer). In intracavitary treatment, the radioactive source is placed directly into the body cavity by remote control and held in place by a prepositioned applicator (e.g. caesium — cervical, endometrial, vaginal and lung cancer). In systemic therapy an unsealed radioactive source is given orally or intravenously (e.g. iodine — hyperthyroidism).

Stereotactic radiotherapy has been developed to deliver a precise dose of radiotherapy to a small area (millimetres). It is a complex and highly specialised treatment, initially used for the treatment of benign brain tumours of poor surgical risk.

For more details of stereotactic radiotherapy, see Kreth et al (1995); if caring for patients receiving brachytherapy, refer to a specialist text, e.g. Dow et al (1997) or Faithful & Wells (2003).

Radiotherapy treatment intent may be:

- curative (radical)
- adjuvant/long-term control
- palliative.

The goal of radiotherapy in early stage cancer is curative as in the treatment of radiosensitive tumours such as skin cancer, Hodgkin's lymphoma, cervical cancer, cancer of the larynx and seminoma (germ cell tumour, testicular in origin). Treatment is often lengthy with considerable side-effects but the good prognosis for long-term survival makes it worthwhile.

Adjuvant radiotherapy Radiotherapy is commonly used as adjuvant treatment to ensure local control, usually either pre- or postoperatively, or, increasingly, with chemotherapy e.g. breast, prostate, colon and rectal cancer.

For those cancers in the later stages where cure or eradication is not possible, local control ranging from months to years may be the treatment goal. Usually more than one treatment modality is advocated. In order to improve the therapeutic ratio, concurrent radiotherapy and chemotherapy regimens are being used. Chemotherapeutic agents such as cisplatin, 5-fluorouracil (5-FU), doxorubicin or mitomycin C are given alongside radiotherapy in cancers of the cervix, anus, head, neck and lung to achieve a greater cell kill.

Palliative radiotherapy constitutes 50% of all radiotherapy treatments given (Blyth et al 2001) and involves a shorter course of treatment at much lower doses than either radical or adjuvant therapy. Its aim is to achieve symptom relief with minimum side-effects, ensuring that quality of life is maximised. Again, radiotherapy is effective primarily in the control of local problems, such as local recurrence of breast cancer, pain, compression of adjacent structures by metastases and bleeding, e.g. haemoptysis in carcinoma of the lung or rectal bleeding in carcinoma of the rectum. Spinal cord compression and superior vena cava obstruction, for example, often present as emergencies, and the treatment is usually immediate radiotherapy.

Large field radiotherapy Occasionally, radiotherapy is given to much larger areas of the body. Total body irradiation is used for some patients with leukaemia to eradicate all tumour cells from chemotherapy-resistant tissues. This treatment must be followed by bone marrow transplant to restore bone marrow function (see Ch. 11). Hemi-body (half body) radiation provides effective palliation for patients with extensive bone metastases, as are common, for example, in prostatic cancer.

The decision making and planning surrounding any course of radiotherapy involve a team approach. Informed consent is essential as is patient and carer education. Incorporation of the principles of physics, radiobiology, dosimetry, treatment technique, anatomy, physiology, psychosocial and patient/family care requires a multidisciplinary approach.

Radiation protection There is much fear and misconception amongst both professionals and lay people about the dangers of radiation exposure. Indeed, radiation is potentially extremely hazardous, and exposure to high doses can cause all of the side-effects itemised in Table 31.3, together

with cell mutations that may lead to carcinogenesis, or to congenital abnormalities if pregnant women are exposed.

Every institution dealing with radiation is legally obliged to appoint a radiation protection officer, to follow stringent guidelines for radiation monitoring to provide education for staff and patient protection. If these are adhered to, radiation damage risk is negligible. Staff most at risk are those working constantly with unsealed sources. Staff working in areas of potential radiation exposure should wear badges in which radiographic film records exposure if it occurs.

31.8 Arrange to visit a radiotherapy department. Where is it located in the hospital, how is it designed, and why? Ask what types of machine are in use and what kind of treatment each is used for. Ask who the radiation protection officer is, and ask to see a copy of the local policy. Try to imagine how a patient might feel arriving at the department for their first treatment. Compare your impressions with that of another student.

Side-effects of radiotherapy Side-effects occur when normal tissue is irradiated. Manifestation of side-effects varies greatly from patient to patient, depending on the location and amount of tissue being irradiated, the dose and its fractionation, and the patient's physical and psychological state. Treatment techniques are constantly being developed to improve accuracy of delivery and minimise side-effects. Patients may suffer from systemic side-effects such as fatigue, lethargy, nausea, anorexia and headaches. Such a cluster of symptoms, termed 'radiation sickness', may be due to the circulation of tumour breakdown products. In general, however, radiotherapy affects only those tissues in the area being irradiated. For example, a patient receiving treatment for bladder carcinoma, as opposed to radiotherapy to the brain, will not lose the hair on their head.

Side-effects may be 'early' (acute), occurring 10–14 days after commencement of treatment, continuing for a period of weeks following treatment completion. Long-term or 'late' side-effects usually present 18 months to 2 years after treatment. Acute problems manifest in areas of rapid cell growth and division and are usually reversible. The nursing management of the most common of side-effects forms a major part of the nursing role in the radiotherapy department and is discussed in Table 31.3.

Late side-effects occur as, due to DNA damage, slowly dividing cells fail to replicate. Problems are most often a consequence of damaged vasculature and are usually permanent. Examples include the distressing symptoms of fibrosis of the lung, chronic bowel inflammation, and lymphoedema resulting from lymph node damage. Monitoring of late side-effects is important for patients attending follow-up outpatient clinics.

Psychological and supportive care Radiotherapy patients are often perceived as the self-caring 'walking wounded'. Their needs are often less obvious as treatment is mostly on an outpatient basis with the added stress of daily travel to and from the department (Wells 1998a). It is important to remember that radiotherapy treatment is not always an isolated event but usually precedes or follows other forms of cancer treatment. Although it brings its own problems and side-effects, its impact needs to be considered in the context of the patient's overall experience. That experience may be affected by existing psychosocial, physical and functional needs related to other existing disease or to financial or social constraints. A particularly vulnerable time for a patient is at the end of treatment, when side-effects are often at their peak and professional support is not always accessible. Patients may experience considerable uncertainty and vulnerability (Wells 1998b).

Myths and fears As Rotman et al (1977) pointed out several decades ago, few therapeutic modalities in medicine induce more misunderstanding, confusion and misapprehension than radiotherapy. Several studies over the years have shown that patients have many fears and anxieties, with some experiencing psychological distress, and more often than not feeling they are given insufficient information pre- and post-treatment (Eardley 1985, Poroch 1995, Mills & Sullivan 1999). A seminal study carried out in the 1970s found that more than 60% of patients receiving radiotherapy experienced mild to moderate anxiety or depression prior to starting treatment. Many expressed fears related to the machines, the radioactivity and being burned or scarred (Peck & Boland 1977).

For many patients, the news that they are to receive radiotherapy comes soon after knowledge of their diagnosis when they are already coping with multiple stressors and feelings of loss. Myths and fears compound these stresses. Hammick et al (1998) examined patients' knowledge and perceptions of radiotherapy and radiation. Outside of medical usage, radiation was commonly perceived in terms of the atom bomb. Media coverage often highlighted problems in terms of overdosages, burns and permanent damage. From observations in clinical practice it is apparent that media reports do influence patients' anxiety levels regarding treatment. This became evident at the time of publicity surrounding patients belonging to RAGE (Radiation Action Group Exposure), where women had developed long-term toxicity as a result of radiotherapy to the brachial plexus following treatment for breast cancer. Health care professionals need to be aware that patients may have many anxieties following public information releases and that it is important to place these reports into perspective. As Mackenzie (1996) points out, it is not surprising that patients find it confusing that radiation, which is known to cause cancer (e.g. following Chernobyl in 1986), can be both curative and survivable.

The nurse's role Nurses can do much to alleviate the patient's fears and anxieties, helping to make the experience of radiotherapy more tolerable. Supportive care relies on the understanding of the impact of cancer and its treatment viewed from the perspective of the patient. A thorough needs assessment is fundamental to enable effective interventions to support the patient and their family throughout treatment. Dennison and Shute (2000) piloted a simple checklist for use in the outpatient setting to identify quickly issues of concern for patients regarding their illness, treatment, symptoms, finances, social support and relationships. Outpatient nurses reviewed the completed checklists prior to the consultation so that appropriate support and specialist referrals could be initiated. As a result, patients found that communication and relationships with staff improved, allowing them greater involvement in their care.

Table 31.3 Nursing management of the side-effects of radiotherapy

Irradiated body part/organ	Radiation effect	Nurse intervention	Rationale
General	Fatigue	Forewarn patients of the likely occurrence during and after radiotherapy. Provide appropriate information about the experience and pattern of symptoms	To foster independence, encouraging energy-saving activities
		Assess and promote self-care strategies. Refer to appropriate allied health care professional as necessary	To prevent feelings of social isolation, low mood and to decrease anxiety levels
		Assess baseline fatigue levels prior to treatment starting	To monitor changes over time and need for further intervention
		Check for physical, biochemical and psychological causes of fatigue	Electrolyte imbalances/anaemia may be corrected. Appropriate psychological support can be given
		Encourage patients to maintain a daily record of fatigue levels and the relationship to activities	Enhances the ability to control activities or plan ahead, goal setting and prioritising
Skin Particularly areas where the skin is thin, moist, e.g. skin folds, axilla, groin, breast and perineum. Fair skin is especially sensitive	Three-stage reaction: 1. Erythema: redness, heat, itchiness	No metal-containing skin preparations	Metal may intensify radiation reactions
		Gentle washing with warm water and gentle drying, no rubbing	Friction causes irritation. Ink marks must not be washed off
		Application of simple moisturiser, e.g. aqueous cream	Soothing and minimises friction, keeps skin supple
		If itchy, an antihistamine cream may be prescribed. Apply 1% hydrocortisone	To alleviate discomfort and itch
		Avoid exposure to the sun and extremes of heat and cold	UV light may intensify any reaction
		Encourage non-constrictive clothing in lightweight, natural fabrics: no tight or elastic clothing	Reduces sweating and friction
	2. Dry desquamation: dryness, scaliness, tight feeling, pain on movement	1% hydrocortisone or lanolin cream (centres vary in their recommendations)	Soothing emollient and/or anti-inflammatory
		Expose skin to fresh air or cool fan	Cooling has a short-term analgesic effect
		For moderate to severe reaction, or if skin folds involved, consider application of hyperfix, ensuring it is removed with baby oil	Preventive measure and promotes wound healing as is permeable. Removing with oil ensures the skin is not damaged
	3. Moist desquamation: blisters, loss of surface epithelium, pain, susceptibility to infection. Occasionally progresses to necrosis	A break in treatment may be required	To prevent further skin breakdown and discomfort
		Analgesics	
		Observation for signs of infection	Infection exacerbates skin damage and may become systemic
		Use of hydrogel/hydrocolloid/ alginate dressings	To promote wound healing
		Dressing plan: assessment, dressings, evaluation using wound care principles	To record any changes, evaluating the effectiveness of the intervention applied
Scalp	Alopecia (in treatment field only). Loss of any body hair occurs from weeks 2–3	Reassure the patient that hair will usually grow back in 2–3 months, although it may be of a different texture and colour	Hair loss poses a very stressful threat to body image, especially for women
		Organise provision of a wig	
		Wearing of scarf/turban at night	Prevents distress of hair on pillow
Brain	Cerebral oedema (within week 1 of treatment): altered mental state, restlessness, irritability, headaches, nausea, ↑ BP, ↓ P, ↓ respirations, ? raised intracranial pressure (see Ch. 9)	Administer prescribed steroids	Anti-inflammatory
		Observe and report alterations in mental status	Enables prompt medical intervention
		Ensure patient safety	

Table 31.3 Nursing management of the side-effects of radiotherapy *(Continued)*

Irradiated body part/organ	Radiation effect	Nurse intervention	Rationale
Mouth	1. Mucositis due to damaged, sloughed oral mucosa. Opportunistic infection may ensue, e.g. *Candida albicans*	Comprehensive dental review prior to treatment	To identify potential infection risks and carry out any necessary dental work, giving time for wound healing
		Regular use of an oral assessment tool	To monitor any changes, evaluating interventions
		Teaching and encouraging frequent routine systematic oral hygiene, initiated prior to treatment if possible	To reduce the amount and severity of mucositis and encourage compliance. Also to minimise the risk of infection
		Use of a soft toothbrush, fluoride toothpaste and regular normal saline mouthwashes	To minimise damage to the oral mucosa and prevent build-up of plaque
		Use of antibacterial/antifungal preparations, e.g. chlorhexidine, nystatin	To prevent or treat infection
		Regular analgesics: topical, e.g. benzydamine, and systemic including opiates	Oral pain is excruciating and always to the forefront of consciousness
		Use of cellulose film-forming agents to line the mucosa, e.g. Gelclair	Forms a thin protective film which relieves pain and discomfort
		Observe for signs of dehydration and inadequate nutrition, liaising with the dietitian (NCI 2003)	Prompt parenteral hydration and dietary supplements or enteral feeding may be commenced
	2. Xerostomia (dry mouth) due to altered salivary gland function. May be permanent. Causes difficulty in chewing, swallowing and talking	Frequent mouth rinses with normal saline and sodium bicarbonate	Comforting, aids swallowing, buffering of oral environment
		Frequent sips of water	Lubrication of mucosa
		Use of artificial saliva	
		Moist soft diet	Easier to tolerate
		Avoidance of spices, alcohol, smoking, extremes of temperature	These are mucosal irritants
	3. Taste changes due to xerostomia and damaged tastebuds	Assist patients to experiment with other foods	To maintain nutritional intake
	4. Dental decay due to xerostomia and radiation gingivitis	Pre-treatment dental referral	Any caries will be exacerbated by radiation and form foci for infection
		Avoidance of high sugar content foods and fluids	Sugar alters natural slightly alkaline pH of mucosal environment and demineralises teeth
Neck area	1. Pharyngitis, laryngitis, causing pain, hoarseness, loss of voice, dry cough and occasionally respiratory stridor	Discourage smoking	Mucosal irritant
		Encourage patient to rest voice	
		Observe respiratory status and colour	Medical intervention in the form of steroids or even a tracheostomy may be necessary
		Linctus as a cough suppressant	Prevents mucosal irritation caused by coughing
		Topical analgesics prior to food, e.g. aspirin gargles, anaesthetic throat spray; systemic analgesics	Promotes comfort and aids swallowing
	2. Oesophagitis (upper one-third) causing dysphagia	Maintain nutrition. Soft diet, referring to the dietitian for supplements. Avoid irritant foods, strong alcohol and smoking	These patients are often already malnourished
Thorax	1. Oesophagitis (lower two-thirds) causing 'heartburn'	As above; also administer antacids prior to food. Some antacids also contain topical anaesthetics	Lines oesophagus and prevents pain and trauma of swallowing and from gastric acid reflux

Continued

Table 31.3 Nursing management of the side-effects of radiotherapy *(Continued)*

Irradiated body part/organ	Radiation effect	Nurse intervention	Rationale
Thorax *(cont'd)*	2. Pneumonitis due to inflammation of bronchioles and alveolar lining. May cause dyspnoea, productive cough and haemoptysis	Discourage smoking Observe for signs of infection: pyrexia, purulent sputum Oxygen as prescribed (see Ch. 3) Assessment and management of breathlessness (Corner et al 1995)	Irritant Enables prompt commencement of antibiotics Patient comfort and integrated approach to managing this distressing symptom
	3. Dyspepsia, nausea and vomiting (less severe than with abdominal radiation)	(see below)	
Abdomen and pelvis	1. Nausea and vomiting due to inflammation of gastrointestinal epithelium; also a generalised radiation reaction	Encourage a small meal 3 h before treatment and light snacks after Regular antiemetics: systematically try various kinds and routes Distraction/relaxation techniques Monitor fluid and food intake	Some patients are unable to eat after treatment due to nausea Regular administration required to prevent and relieve nausea There may be a contributing psychological factor in nausea (Holmes 1996) To avoid dehydration
	2. Diarrhoea, possibly accompanied by rectal bleeding	Maximise privacy Administer antimotility medication as prescribed Low-residue, bland diet, low fat Observe for dehydration Maintain high fluid intake Observe perianal skin: gently apply barrier cream after washing if necessary	 Better tolerated by damaged mucosa Avoid dehydration To prevent skin excoriation
	3. Cystitis due to inflammation of urinary tract. Predisposition to urinary tract infection	Encourage high fluid intake (3 L daily) Encourage and/or assist with personal hygiene Regular collection of urine specimens for microbiology	Prevents stasis of urine and sloughed epithelium Helps prevent ascending urinary tract infection Enables prompt antibiotic treatment of urinary tract infection
	4. Altered sexual function (degree depends on exact treatment site and dosage)	Psychological support and counselling Include partner in discussion if patient wishes Assess the need for psychosexual counselling	Loss of any degree of sexual function is very threatening to most people's self-image; opportunity to talk this through is vital To gain understanding and support and minimise body image problems To maintain a healthy relationship and sexuality
	Men: Erectile dysfunction (usually temporary)	Psychological support May need referral to erectile dysfunction clinic for discussion re: access to vacuum constriction devices, penile prosthesis, pharmacological intervention	To explore possible options to help with erectile difficulties
	Sterility (usually permanent)	Offer sperm banking if appropriate	To enable sperm to be used for artificial insemination
	Decreased sexual desire/libido	Monitor hormone levels Testosterone replacement therapy Patient/couple education and psychological support	To improve libido and promote healthy sexuality

Table 31.3 Nursing management of the side-effects of radiotherapy *(Continued)*

Irradiated body part/organ	Radiation effect	Nurse intervention	Rationale
	Women:		
	Sterility (if ovaries are irradiated). May be temporary or permanent	Advise continued contraception during and for several months after treatment	Fertility is not always immediately affected and any pregnancy may not be viable
	Dyspareunia due to vaginal fibrosis and dryness	Advise use of water-based vaginal lubricant	To promote comfort and ease of penetration
		Use of barrier contraceptives, e.g. condom during intercourse	There may be a burning sensation associated with semen and this will help to decrease irritation
		Education and use of vaginal dilators during (if tolerated) and for up to 2 years after treatment	To prevent vaginal stenosis and post-coital bleeding, facilitating future sexual intercourse and internal examination
	Loss of libido	Patient/couple education and psychological support, sensitively explaining that this is usually temporary	To maintain healthy sexual relationships
	Premature menopause (if ovaries irradiated)	Inform of possibility and potential menopausal symptoms Discuss possible strategies in managing the hot flushes, osteoporosis, etc. Hormone replacement therapy should be discussed with the individual in light of media highlighted risks and benefits	To help women manage menopausal symptoms

Supportive care may also involve simple behavioural strategies such as simply being there, actively listening, talking, preserving the patient's individuality and providing information (see Research Abstract 31.1). Forming a relationship with the patient and answering questions have also been shown to have a positive effect on patients' coping strategies (Poroch 1995, Hinds & Moyer 1997).

Information is seen as crucial, relieving anxiety and promoting a sense of control (Poroch 1995, Mills & Sullivan 1999, Van der Molen 1999). Nurses are responsible, therefore, for becoming accurately informed themselves — about radiotherapy in general, and about each patient's individual treatment plan and likely side-effects in particular.

Studies indicate that patients tend to prefer verbal information backed up with written material (Slevin et al 1996, Hammick et al 1998). Good practice advocates that written information should be accompanied by verbal explanation wherever possible. The last few years have therefore seen the development of a comprehensive patient information strategy by support agencies such as CancerBACUP, Macmillan and Tenovus (see 'Useful websites'), alongside telephone information helplines and publication of in-house material. Managed clinical networks are also involved in the development of information, ensuring patients receive accurate information at the appropriate time across all care settings. The use of other methods of providing effective information such as audio and visual tapes is also being explored (Hagopian 1996, Harrison et al 2001). The media have been shown to be important contributors to knowledge and to help with decision making, although some sources are trusted more than others (Balmer 2005). The internet has many sites providing high quality information and in this latter study was seen as a valuable tool.

Studies have also shown that the vast majority of patients want as much information as possible to enable them to prepare for treatment, decrease their fears and anxieties, and increase their understanding of treatment. Information requested includes:

- how treatment works
- the effectiveness of treatment
- likely side-effects
- preventive and self-care strategies
- impact of treatment on their lives and their families (Fieler et al 1996, Barnett et al 2004, Skalla et al 2004).

With so much emphasis on information and ever-increasing resources, it is not surprising that some patients report informational overload, problems with retention and confusion (Skalla et al 2004). A patient-centred approach is therefore vital, with information being tailored to the individual's needs.

Nurses in Europe, in comparison with their American colleagues, have been slower to realise their contribution to radiotherapy care. However, this is changing. Both nurses and therapy radiographers are developing advanced practitioner roles through which innovative approaches to care are increasingly evident. The central components of these roles include assessment, education, knowledge, prevention of side-effects, psychosocial support, liaison with other health care professionals and rehabilitation. Employment of both nurse specialists and therapy radiographers to provide information and counselling

RESEARCH ABSTRACT 31.1

Support is regarded as an essential aspect of nursing care, enabling patients to cope with stressful situations. A Canadian qualitative study explored how patients and their caregivers describe their experiences and perceptions of support during radiotherapy treatment. Twelve patients and five family caregivers were interviewed whilst the patient was receiving radiotherapy or 4–6 weeks post-treatment.

Both patients and caregivers repeatedly described support as ordinary, everyday words and deeds. Three main types of support were encountered: 'being there', 'giving help' and 'giving information'. Forms of support included being encouraged where possible to take part in everyday life, for example:

- going out for a coffee or walk, help with shopping, gardening, etc. (physical)
- being encouraged to verbalise fears, concerns and feelings, providing diversions and laughter (emotional)
- support through the prayers of family, friends and congregations (spiritual).

Interestingly it was family and friends who were perceived to be the main source of support for all types, also shown more recently by Wengstrom and Haggmark (2001), whereas nurses provided a professional source of support in providing information and advice.

Support also appeared to be related to the way in which it was given rather than meeting a specific need. Nurses who were seen to be making an effort were noticed and appreciated. Participants also commented that support was most likely to be of value if it occurred in the context of a relationship.

These findings illustrate that support is a multifaceted concept as perceived and interpreted by patients. Although this study was small, it highlights that nurses are able to provide support beyond that which is informational and affirming. As the authors point out, provision of support promotes feelings of self-worth, maintains identity and ensures that the person is treated as an individual rather than just a patient receiving radiotherapy.

Hinds C, Moyer A 1997 Support as experienced by patients with cancer during radiotherapy treatments. Journal of Advanced Nursing 26: 371–379

services, practitioner-led review and follow-up clinics, telephone follow-up and nursing interventions for side-effects can make a positive contribution to patient care (Colyer & Hlahla 1999, Campbell et al 2000, Collins 2001). The future holds many challenges for nurses, radiotherapists and oncologists working together in this field towards a collaborative, coordinated and supportive approach to care.

For further reading on supportive care in radiotherapy, see Faithful & Wells (2003).

31.9 Use the above information together with supplemental reading to devise an explanation of external beam radiotherapy and its effects that would be suitable to give to a patient prior to treatment. Draw upon available patient literature, such as that published by CancerBACUP (see 'Useful websites'), and your own impressions during your visit to the radiotherapy department. Avoid technical terms and emotive words such as 'burn' or 'blast', and bear in mind that patients need to know what they will actually experience.

Systemic treatment: chemotherapy

The word 'chemotherapy' literally means 'treatment with chemicals' and therefore can refer to any form of medication therapy.

Cytotoxic (literally 'poisonous to cells') chemotherapy involves the use of medication to disrupt the cell cycle and thus ultimately kill malignant cells.

How cytotoxic chemotherapy works Cytotoxins are termed 'antiproliferative'; like radiation, they are toxic to dividing cells, both healthy and malignant. There are many different types of cytotoxic agents, which have various modes of action and therefore work at different phases in the cell cycle.

For a description of the cell cycle, see Tortora & Grabowski (2005).

Cytotoxic drugs are usually classified according to their chemical structure, cell cycle activity and primary mode of action. The classic categories include:

- alkylating agents
- antimetabolites
- antitumour antibiotics
- plant alkaloids.

The action of each of these is described in Box 31.7.

Modes of cytotoxic chemotherapy treatment Cytotoxic chemotherapy differs from radiotherapy in that it is a systemic rather than a localised treatment modality. It is therefore particularly useful for the treatment of haematological malignancies, which are usually disseminated or metastatic in nature. These drugs were first identified in the 1940s, and their use has since become widespread. Despite their great potential, results have been disappointing to date because it has been mainly the rarer tumours that have responded well. Childhood leukaemia is particularly responsive, with approximately 70% of children being cured. Complete responses are also being achieved in adults with Hodgkin's lymphoma. Very few solid tumours are as responsive, the exception being some childhood tumours and testicular teratoma, in which cure rates of 80–90% have been achieved. However, these potentially curable malignancies represent a mere 5% of patients with cancer (Souhami & Tobias 2005).

Adjuvant and palliative chemotherapy For the most part, chemotherapy is used:

- as the sole, or most important, treatment
- as a means of reducing the size of the tumour to aid the success of subsequent surgery or radiotherapy, i.e. 'debulking' of tumours, such as those of the head, neck and bladder
- following radiotherapy or surgery to eliminate remaining tumour cells or micrometastases; adjuvant

Box 31.7

Classification of cytotoxic agents

Alkylating agents
Alkylating agents are highly reactive and are cell cycle non-specific. Their primary mode of action is to join together or cross-link the two strands of DNA, preventing them from separating and therefore replicating. Cyclophosphamide is an example of a cytotoxic which acts in this way. Another group of alkylating agents are platinum-based compounds, e.g. cisplatin and carboplatin, which cause interstrand and intrastrand linkages.

Antimetabolites
These are cell cycle specific, exerting their effect in the S phase. They are structural analogues of normal intracellular metabolites essential for cell function and replication and so are used to disrupt cellular metabolism. Methotrexate, for example, inhibits the enzyme necessary for the conversion of folic acid to folinic acid. Folinic acid is necessary for the formation of purines and pyrimidines, components of DNA. Folinic acid rescue, in the form of folinic acid replacement, is necessary 12–24 h after the administration of methotrexate to prevent the death of too many healthy cells. Other antimetabolites include 5-fluorouracil (5-FU) and cytosine arabinoside.

Plant alkaloids
Many plants and plant extracts continue to be screened to identify new cytotoxic agents. To date these include the vinca alkaloids, taxanes and topoisomerase inhibitors.

Topoisomerase inhibitors (etoposide, teniposide, irinotecan and topotecan) interfere with DNA replication by binding to DNA and the topoisomerase enzymes. Mitotic inhibitors include vincristine, vindesine and vinblastine, which are cell cycle specific acting in the mitosis phase. They bind to microtubule proteins, blocking spindle formation and preventing cell separation. The taxanes (docetaxel and paclitaxel), on the other hand, promote assembly of the microtubule which results in a very stable microtubule that is non-functional.

Antitumour antibiotics
Some classes of antibiotic have been found to be cytotoxic. In general, they are cell cycle non-specific and interfere with DNA function, although several other mechanisms of action may occur, such as alteration of the cell membrane or inhibition of certain enzymes. The most widely used is doxorubicin because it has a broad spectrum of activity; others include mitoxantrone and bleomycin.

Cytotoxic agents are constantly being researched and developed. There are several which do not fit into the above categories and whose action may not be fully understood.

postoperative chemotherapy is commonly used for cancer of the breast or ovary to improve disease-free survival

- to treat a relapse after initial treatment
- for palliation of symptoms — some tumours are partially chemoresponsive, so that treatment may relieve symptoms and improve the quality of, and possibly lengthen, life
- for investigation of the usefulness of a new medicine.

Combination chemotherapy, which uses a variety of agents, has been found to be far more effective than single-agent chemotherapy. At any given time, the cells of one tumour will be at different phases of the cell cycle: a combination of agents acting on those various phases will therefore kill more cells than a single agent. A lower dose of each agent is given, thus reducing the side-effects of each. Tumour cells unfortunately have the capacity to acquire resistance to single agents, and therefore giving intermittent high doses of drugs, alternating drugs and minimising the intervals between treatments are the major factors used to prevent acquired drug resistance.

Administration of chemotherapy Chemotherapy is usually given in 'intermittent' doses, sometimes called 'pulses' or 'cycles', the principle being similar to that of fractionation in radiotherapy. Chemotherapy is toxic to rapidly dividing healthy cells, although these have the capacity to recover more quickly than tumour cells. A graph similar to Figure 31.5 could be drawn to illustrate this principle. Hence, most chemotherapy is organised into 'regimens', sometimes called 'protocols', particularly if the treatment is part of a research trial.

Chemotherapy may be administered systemically or regionally and by several routes.

Systemic chemotherapy The goal is to provide a concentration of the drugs that is sufficient to achieve a therapeutic cytotoxic effect without causing too much toxicity to normal cells. Routes of administration include oral, subcutaneous, intramuscular and intravenous. Intravenous administration may be delivered either as a 'bolus' or infusion. Continuous infusions may be delivered using a medication delivery pump via a vascular access device (VAD) such as a skin-tunnelled catheter (STC), a totally implanted port (TIP) or a peripherally inserted central catheter (PICC).

These devices have permitted safe and reliable access to the venous system and patients are now able to spend longer periods at home while receiving continuous infusions of chemotherapy. The development of such devices has enhanced the lives of cancer patients but their use poses challenges for patients and health care professionals. Concerns include psychosocial issues, care of the device to prevent potential complications, and management of any complications which may occur. Some of these complications may be life threatening and require immediate and effective intervention.

For more information about VADs, see Weinstein (2001). This text covers appropriate usage, insertion techniques and the management of associated complications, both common and rare.

Regional chemotherapy The goal of regional chemotherapy is localisation of effects by delivering chemotherapy drugs directly into blood vessels supplying the cavity containing the tumour or into the tumour itself. Such routes include intrahepatic, intra-arterial, intrapleural, intraperitoneal and intrathecal.

Many patients receive chemotherapy as outpatients, on a day unit, and so need a considerable amount of support and teaching in order to be able to cope with the side-effects they experience at home. There is agreement that this

Box 31.8

Safe administration of chemotherapy

Cytotoxic agents can be dangerous if they are not handled appropriately. A joint proposal to develop national guidelines for the administration of chemotherapy was initially funded by the NHS Executive (1995). From this, the Royal College of Nursing (1998) and the Scottish Cancer Care Pharmacy Group (2000) have issued guidelines for the safe use of cytotoxic chemotherapy in the clinical environment. These guidelines are to assist practitioners in defining and demonstrating high standards of practice, reducing unacceptable variations.

Extravasation
Some cytotoxic agents, e.g. doxorubicin and vincristine, are termed 'vesicants' and can cause severe burns and tissue damage if they leak from the vein into the subcutaneous tissue. Figure 31.6 shows the possible result of extravasation. If extravasation is suspected, the infusion should be stopped and an experienced clinician informed immediately. There are various antidotes available, but more scientific research is required (for more details, see How & Brown 1998, Jones & Coe 2004, NEIS 2004).

Staff protection
There has been concern for many years regarding the potential exposure and subsequent effects in health care workers. Sufficient scientific evidence exists, however, to support the need for staff handling these medications to do so with extreme caution. It is known that at therapeutic doses these substances can cause carcinogenesis, cell mutations and fetal damage. Staff handling cytotoxic medicines should be educated about exposure risks, safe handling procedures and appropriate clothing, i.e. wearing aprons and latex gloves, as risk management strategies have been shown to minimise exposure (Ziegler et al 2002). More research is required to evaluate occupational surveillance. A register for those at risk should be kept and safe practice needs to be regularly audited. Chemotherapeutic agents should be prepared in a specially designed pharmacy unit (laminar air flow/isolator). Staff should always wear gloves when handling oral preparations and should mop up spillages immediately, using large amounts of water and wearing protective clothing. Spillage kits should be available in all the areas where chemotherapy is administered. On seeing the precautions necessary, patients may be alarmed that such dangerous substances are required to control their disease. They should be reassured that these measures are necessary to protect those who are constantly dealing with cytotoxic agents.

Handling body fluids
Many cytotoxic agents are excreted unchanged in urine and faeces and both should be treated as hazardous for at least 48 h. However, Cass and Musgrove (1992) highlighted that some excreta may be contaminated for as long as 7 days. It is therefore important to wear gloves when handling the body fluids of patients receiving chemotherapy, and also to teach patients and their families to take appropriate precautions.

requires specially prepared chemotherapy nurses to fulfil this role (RCN 1998) (see Box 31.8).

Side-effects of chemotherapy As seen with the examples given in Table 31.4, each cytotoxic agent causes different side-effects, varying in intensity with dosage and method of administration. Nursing management of the potential side-effects requires an in-depth knowledge of the common and uncommon toxicity profiles of each agent given in the regimen (Fischer 2003).

Physical and emotional responses to chemotherapy vary greatly between patients. Studies by Sitzia and Wood (1998) and Tanghe et al (1998) have shown that nurses' interpersonal skills and manner influence patients' coping mechanisms. In both studies, nurses underestimated the distress caused by chemotherapy and overestimated the patients' ability to cope. Nurses reported common side-effects, such as alopecia and nausea and vomiting, as being the most distressing toxicities for patients. However, interestingly, a large number of patients reported more subjective symptoms such as fatigue, mood disturbances, altered appetite and restlessness as a source of distress. These findings have implications for nurses assessing patient side-effects and delivering appropriate therapeutic interventions. The following is a brief summary of some of the potential physical side-effects of chemotherapy.

Myelosuppression is not only the most common dose-limiting toxicity of chemotherapy but also potentially the most lethal. To understand the potential damage that chemotherapy may cause to the bone marrow, it is helpful to review normal blood cell development (see Ch. 11). The suppression of the production of blood constituents by the bone marrow occurs to varying degrees after almost all types of cytotoxic chemotherapy. Cell cycle specific agents (e.g. antimetabolites, natural products) tend to cause a rapid decline to a low point (nadir) in the marrow cells, usually 7–10 days after drug administration, although with some drugs the nadir may be reached earlier. Cell cycle non-specific drugs (doxorubicin, cisplatin) have nadirs around 10–14 days, while the nitrosureas' nadir is 26–30+ days. Such factors need to be considered in the planning of treatment regimens. The resultant three problems of leucopenia/neutropenia, anaemia and thrombocytopenia are far more severe in the case of chemotherapy for haematological malignancies (see Ch. 11). Since the prime function of neutrophils is phagocytosis, neutropenia eliminates one of the body's prime defences against bacterial infection. The longer the nadir period, the greater the frequency and severity of infections which are invasive or due to overgrowth of pathogenic microbes. Thrombocytopenia is usually delayed and, if active bleeding occurs, transfusions of platelets may be given. For all patients, myelosuppression may compound other side-effects such as stomatitis.

In view of the significant problems associated with bone marrow suppression, attention has been focused on the therapeutic use of haemopoietic growth factors such as granulocytic colony-stimulating factor (GCSF) (Cappozzo 2004). Studies have shown that these factors can significantly reduce or prevent myelosuppression induced by chemotherapy (Trillet-Lenoir et al 1993, Gatzemeier et al 2000).

Fig. 31.6 Skin damage caused by extravasation of vesicant cytotoxins. This photograph shows a moderate degree of damage; in some cases there may be nerve and blood vessel damage, progressing to necrosis and requiring skin grafting or even amputation. The key factor in avoiding this situation is vigilant, regular observation of cannulation sites during injection or infusion. The patient should also be asked to report any altered sensation in the area, e.g. coldness, heat, tingling, pain, numbness or swelling. Should extravasation occur, the infusion should be stopped immediately, area marked with a pen, cannula aspirated, a doctor informed and an experienced professional consulted for advice. There is a lack of research to guide treatment for extravasation; however, all centres administering chemotherapy should have a local management policy. For national monitoring, a green card should be completed and sent to the National Extravasation Information Service (Allwood et al 2002, NEIS 2004). It is most important to avoid concentrating only on the affected limb whilst ignoring the stress generated for the patient in this situation.

With the support of GCSF, higher doses of chemotherapy may be given, whilst minimising the effects on the bone marrow.

Therapeutic interventions for myelosuppression are aimed at the prevention and active treatment of infection and bleeding.

Stomatitis/mucositis induced by chemotherapy is significantly associated with myelosuppression and regarded as the main dose-limiting factor in radical treatment regimens (Trotti 2000). It is the result of a two-stage process: First, some cytotoxic agents have a direct effect on the oral mucosa, causing thinning and ulceration within 4–7 days of administration. Patients may experience mild erythema and oedema along the mucocutaneous junction of the lip, mouth dryness and a burning sensation in the lips (Dose 1995). Nausea, vomiting and a reduced food and fluid intake compound this effect, making the mucosa an ineffective barrier to opportunistic infection. Within 10–16 days, myelosuppression causes the already compromised mucosa to be even more susceptible to infection and haemorrhage. Nursing care is similar to that for the patient with radiation stomatitis, described in Table 31.3, see page 1049. Regular thorough assessment and care of the oral mucosa is a vital part of a supportive care strategy (Miller & Kearney 2001). A meaningful and validated assessment tool should be used at least daily and more often if mucositis is severe. It will contain questions about eating, swallowing, pain, erythema and will include an ulceration score (Sonis et al 1999, Eilers & Epstein 2004).

5-Fluorouracil (5-FU) commonly causes mucositis. Oral cryotherapy or sucking on crushed ice during the administration of 5-FU has been shown to reduce the frequency and severity of resulting mucositis. However, further clinical evaluation of this approach is needed (Casanu et al 1994).

The literature suggests many pharmacological regimens for oral care but often the evidence base is weak. Oral care interventions should aim to provide adequate pain relief, prevent or treat infection and promote healing. Advances in molecular biology are again creating new opportunities for novel therapies (Peterson et al 2004).

For further reading, see the series of articles in Seminars in Oncology Nursing 2004, Volume 20(1), by Brown & Wingard; Daniel et al; Eilers & Epstein; Epstein & Schubert; Peterson et al; and Sonis.

Nausea and vomiting induced by chemotherapy can be particularly troublesome, especially with agents such as adriamycin and cisplatin. These drugs activate the chemoreceptor trigger zone (CTZ) in the brain, which in turn stimulates the centre in the brain stem that controls nausea and vomiting. It is important to remember that persistent nausea is often more unbearable than vomiting, which may relieve nausea. The problem may be severe enough to trigger 'anticipatory vomiting' at the sight of the hospital or any stimulus associated with chemotherapy. During the past decade, with the advent of new antiemetics such as the 5-HT_3 antagonists, for example ondansetron and granisetron, the management of chemotherapy-related nausea and vomiting has vastly improved. However, studies continue to show that nurses are markedly underestimating this side-effect and patients report the negative impact such symptoms have on their quality of life (Fawcett & Dean 2004, Grunberg et al 2004, Miller & Kearney 2004). These medications have their own side-effect profile, including constipation and headaches. Steroids such as dexamethasone potentiate the effect of these antiemetics and are most effective in delayed emesis. Again they have their own toxicity profile, such as indigestion, hyperactivity and mood disturbance, and may mask signs of infection in myelosuppressed patients. Relaxation, meditation and sedatives such as lorazepam have also been found to be helpful for some patients.

Alopecia is caused by some agents, e.g. adriamycin, taxanes, topoisomerase inhibitors, and may range from slight thinning to complete hair loss. Several factors contribute to the severity of hair loss including the specific drug, dose and schedule. It usually occurs approximately 2 weeks after therapy has started and is temporary, with hair regrowth occurring about 6 weeks after the completion of treatment.

Table 31.4 Cytotoxic agents and common side-effects

Cytotoxic agent	Action	Common use	Potential side-effects
Capcitabene	Prodrug, antimetabolite	Breast cancer Colorectal cancer	Myelosuppression Mucositis Palmar–plantar syndrome Diarrhoea Mild nausea
Cisplatin	Action uncertain Similar to alkylating agent	Wide spectrum Cancer of the testes, ovary, cervix, endometrium, bladder, head and neck, lymphomas, small cell lung	Severe nausea and vomiting Metallic taste Diarrhoea (HD) Myelosuppression Hearing changes/loss (due to damage to VIIIth cranial nerve) Peripheral neuropathy Renal impairment
Cyclophosphamide	Alkylating agent	Wide spectrum Cancer of the breast, ovary, bladder, small cell lung Acute leukaemias	Nausea and vomiting (HD) Myelosuppression Haemorrhagic cystitis Alopecia (HD) Infertility (especially in men)
Cytosine arabinoside (Ara-C)	Antimetabolite	Acute myeloid leukaemia Acute lymphoblastic leukaemia (low dose may be given subcutaneously)	Severe nausea and vomiting (HD) Myelosuppression Flu-like symptoms Mucositis Corneal ulceration
Doxorubicin (Adriamycin)	Antitumour antibiotic (interferes with nucleic acid synthesis in the S-phase)	Wide spectrum Lymphomas Cancer of the breast, ovary, stomach, sarcomas, small cell lung	Severe mucositis Severe nausea and vomiting Cardiotoxicity (dose limiting) Myelosuppression Alopecia Vesicant if extravasated
Etoposide (Vepesid, VP16)	Mitotic inhibitor arresting cell cycle at G_2-phase	Testicular cancer, small cell lung, lymphoma Acute lymphocytic leukaemia	Myelosuppression Mucositis (HD) Alopecia Hypotension if infused rapidly
Fludarabine (Fludara)	Purine metabolite	Chronic lymphocytic leukaemia Low-grade non-Hodgkin's lymphoma	Myelosuppression Nausea and vomiting Flu-like symptoms Central nervous system toxicities (HD)
5-Fluorouracil (5-FU)	Antimetabolite	Breast, colorectal and GI, head and neck cancers	Myelosuppression Diarrhoea Mucositis Mild nausea Vein discoloration
Irinotecan (Campto, CPT-11)	DNA topoisomerase inhibitor, spindle poison	Colorectal cancer	Myelosuppression Nausea and vomiting Alopecia Delayed diarrhoea Acute cholinergic syndrome
Methotrexate	Antimetabolite (folic acid antagonist)	Wide spectrum Breast cancer Osteosarcoma Choriocarcinoma Acute lymphocytic leukaemia Non-Hodgkin's lymphoma	Myelosuppression Diarrhoea Mucositis Mild nausea Renal failure (HD)

Table 31.4 Cytotoxic agents and common side-effects *(Continued)*

Cytotoxic agent	Action	Common use	Potential side-effects
Paclitaxel (Taxol)	Plant alkaloid Tubulin spindle poison	Ovarian and breast cancer	Myelosuppression Alopecia Hypersensitivity — urticaria, abdominal cramping, rash, anaphylaxis Peripheral neuropathy; numbness, tingling and loss of function Myalgia/arthralgia — joint and muscle pains
Vincristine (Oncovin)	Vinca alkaloid Spindle poison, blocks mitosis in M-phase	Wide spectrum Sarcoma, lung, breast cancer Acute lymphocytic leukaemia Lymphoma	Myelosuppression Alopecia Peripheral neuropathy; numbness, tingling and loss of function Vesicant if extravasated

HD, high dose.

Hair may grow back a different texture and colour, to which patients should be alerted. Patients should be offered the choice of a wig before they experience hair loss in order to enable close matching to their own hair. Promoting a positive self-image by offering advice to minimise hair loss and about the use of fashion accessories is important, as the psychological impact of alopecia should not be underestimated (Munstedt et al 1997, Batchelor 2001).

Scalp cooling techniques have been developed with varying degrees of success (Macduff et al 2003, Massey 2003). Earlier scalp cooling techniques involved wetting the scalp and applying ice packs, but more sophisticated refrigeration systems are now available which offer a more uniform cooling at a constant rate (Protiere et al 2002, Massey 2003). Observations from clinical practice suggest that scalp cooling can slow down the rate of hair loss when used with single-agent drugs with a short half-life at low dosages, e.g. adriamycin, cyclophosphamide, docetaxel. It may also be effective with such regimens as FAM (5-fluorouracil, adriamycin, mitomycin C) and CMF (cyclophosphamide, methotrexate, 5-fluorouracil).

Sexual dysfunction may occur due to vascular changes and hormonal imbalance. Amenorrhoea and menopausal symptoms may be induced due to ovarian failure and follicle destruction. Women under 35 years of age have a greater chance of resumption of the menses on completion of treatment; however, this may not occur for 6–12 months.

Infertility may occur, depending on the agent, its dosage, the patient's age and gender, and other as yet unknown factors. Infertility may be temporary or permanent. Alkylating agents such as cyclophosphamide, chlorambucil and the nitrosurea compounds are certain to induce infertility. This variability must be stressed when patients are informed about potential side-effects. Barrier methods of contraception are encouraged, as the exposure of an unborn fetus to cytotoxic agents may result in deformities or an unviable fetus (Chasle & How 2003).

In certain circumstances, some patients may receive counselling for sperm banking or oocyte harvesting. These options raise emotional and ethical dilemmas which may compound patients' existing stress concerning their diagnosis and treatment. This is an area of nursing that provides new challenges in terms of psychological support for patients and their partners.

Other side-effects It is not possible to address all the potential side-effects of chemotherapy in this chapter. However, apart from the more common ones mentioned above and those in Table 31.3, it is important to remember the more generalised effects, e.g. fatigue, anorexia, general malaise, mood disturbances and lack of concentration. Ream and Richardson's (1999) nursing research focused attention on fatigue and the need to develop positive interventions such as energy conservation.

For further information, see Holmes (1997) and Dodds (2001).

Biological response modifiers

Biological therapy, often referred to as the fourth treatment modality, involves the therapeutic use of substances known to occur naturally in the body. Most of these are involved in some way in the immune response, controlling cell-mediated and humoral responses; hence some of these new developments are termed 'immunotherapies'. The theory behind these new treatments is that it may be possible to manipulate the immune system such that it recognises tumour cells as antigens and causes the body to reject them.

Biological therapies were prematurely hailed as 'miracle cures' for all cancer types. In fact, the response of the immune system to tumours has been found to be far more subtle and complex than the response to microbes, and results have been far from dramatic. Nevertheless, several substances, mostly created by recombinant DNA technology, have been developed. Although research is still at a very early stage, tumour response, however transient, has been achieved for some cancer types.

Cytokines are substances released from an activated immune system. Interferon α_{2a}, for example, is an activator of natural killer cells and protects host cells against viruses. It has been found to maintain remission in hairy cell leukaemia and is being used with some success in certain

patients with renal cell carcinoma and AIDS-related Kaposi's sarcoma. Side-effects include flu-like symptoms and mood disturbances, which may be very unpleasant. Other similar substances include tumour necrosis factor (TNF) and interleukin 2.

Haemopoietic growth factors include GCSF which stimulate the proliferation of leucocytes. Used appropriately, these factors may reduce the number or degree of myelosuppressive episodes, prevent treatment delays and allow high doses of treatment to be given (stem cell transplantation). Erythropoietin is another stimulating factor used in the treatment of anaemia. The number of blood transfusions may be reduced and symptoms of fatigue minimised, thus enhancing quality of life.

Monoclonal antibodies A limiting factor in effective cancer therapy is its current lack of specificity. During the 1980s, significant strides were made in the field of antibody therapy, which promotes specific targeting of cells through an antigen–antibody response. Tumours have been found to possess antigens on their surface, and monoclonal antibodies to these antigens can now be manufactured in laboratories. Examples of monoclonal antibodies used in the clinical setting are rituximab (MabThera) and trastuzumab (Herceptin). Rituximab is directed against the CD20 antigen expressed in over 90% of B cell lymphomas and chronic lymphocytic leukaemia (CLL). Trastuzumab is directed against the human epidermal growth factor HER2-neu (c-erb2) proto-oncogene. In clinical studies, HER2 protein overexpression and gene amplification have been associated with a higher frequency of tumour recurrence and a reduction in overall survival time. Trastuzumab is presently used as a single agent for the treatment of women with metastatic breast cancer whose tumours overexpress the HER2-neu protein. Trials are ongoing to determine its value in the adjuvant setting (Miles 2001).

Cancer vaccines Based on the antibody–antigen response mechanism, several vaccines have been developed for use in melanoma and trialled with encouraging responses. A cancer vaccine for the human papilloma virus (HPV16 and 18), a risk factor for cervical cancer, has recently been developed with positive trial outcomes (Harper et al 2004). More research is required in this area to determine the therapeutic value of such vaccines (Mitchell 1998).

Side-effects These therapies have quite different toxicity spectra from those of chemotherapy, such as flu-like syndromes with patients frequently experiencing fever, chills, headache, malaise, arthralgia and fatigue, severe enough to be dose-limiting factors. These symptoms can disrupt and impact on a patient's lifestyle quite significantly. It is important for nurses to be aware of this in order to support their patients, initiating appropriate interventions such as premedication and energy saving techniques.

For further reading, see the following comprehensive articles on new biological cancer treatments in Seminars in Oncology Nursing 2003, Volume 19(3), by Gale; Liu; Mautner & Huang; Muehlbauer & Schwartzentruber; and Schmidt & Wood.

31.10 Choose a patient who is about to receive combination chemotherapy. Find out whether the doses or medications in the regimen are low or high. List the side-effects you may expect to see and those that actually occur. For information, consult the manufacturers' instructions, your hospital pharmacy cytotoxic manual and texts on chemotherapy, e.g. Holmes (1997), Allwood et al (2002) and Fischer (2003).

Psychological support during systemic therapy (see Box 31.9). There is increasing recognition, supported by research, that chemotherapy, particularly the highly toxic regimens, can cause short- and long-term side-effects that can lead to psychological distress and thus affect an individual's quality of life (Amir & Ramati 2002, Del Mastro et al 2002). In a recent study in Scotland, nurses reported that patients were often anxious, distressed or frightened and emphasised that patients required individualised, clear information about their disease and treatment. Psychological, social and financial support for themselves and their families was also seen to be important. Nurses perceived that patients required more psychological support at the beginning and at the end of treatment, which may be difficult times for patients. The importance of talking and providing information was seen as an essential intervention for meeting patients' psychological needs (Arantzamendi & Kearney 2004). As with radiotherapy, the key to effective support for these patients is an understanding of the impact of chemotherapy on the patient and their family, a thorough needs assessment and an individualised plan of care.

Nurses in most oncology centres and some cancer units have their own patient caseload where care priorities include assessment of treatment toxicities, cannulation, administration of bolus and intravenous chemotherapy, and

Box 31.9

Chemotherapy: the patient's perspective

The need for information and emotional support during chemotherapy varies according to the patient's perception of the treatment. The following responses by patients to the discovery that they required chemotherapy (cited in Tierney et al 1989) reflect this variability.

Negative feelings

I can't tell you how terrified I am ... it's like being put into a dark room ... you've no idea what to expect and you're really frightened.

The word 'chemotherapy' sends shivers up my spine — you hear so much about how awful it is.

Mixed feelings

I do want it, but I don't. I feel really nervous ... Butterflies in my tummy all the time ... and then I tell myself not to be silly ... You'll manage, I say.

Positive feelings

I'm making myself feel positive because I intend to do everything possible to survive. That never occurred to me before ... the idea of survival ... but your priorities change when you are faced with a disease like this.

coordinating the chemotherapy/BRM regimens in collaboration with the clinician. The continuity of care engendered by this approach allows a trusting supportive relationship to be built between nurse and patient.

A more recent development in the UK is home chemotherapy. Specialised nurses, who may be hospital- or community-based, deliver chemotherapy to patients in the comfort of their own homes (Watters 1997). Some projects are nurse-led pilot schemes, others are being set up in collaboration with intravenous access companies in the private sector (Pattison & Macrae 2002).

31.11 The patient receiving palliative chemotherapy may find travelling exhausting and feel that staying at home is far preferable to spending precious time in hospital. With new services developing to include chemotherapy administered in the patient's home, what potential problems can you foresee for the patient, the family and the nurse? On balance, do you think this is a worthwhile and cost-effective scheme?

Non-cytotoxic chemotherapy

Agents other than cytotoxic drugs are used to control, but as yet not to cure, cancer. Tumours that arise in tissues under the control of hormones have been found to respond to hormone manipulation. This may mean surgical removal of the ovaries (oophorectomy) or testes (orchidectomy) to reduce the growth stimulus to tumours of the breast or prostate provided by oestrogen and testosterone, respectively. In the last 30 years, similar control has been achieved by the use of medication such as tamoxifen. Tamoxifen blocks the action of oestrogen by binding to oestrogen receptor sites on the tumour cells. However, more recently, tamoxifen has been superseded by the use of aromatase inhibitors such as anastrozole in post-menopausal women. They work on the cancer cells differently from tamoxifen, not by blocking the effect of oestrogen, but by preventing its production.

Steroid hormones, such as prednisolone and dexamethasone, are also widely used, the former in conjunction with cytotoxic medication as primary treatment, usually for lymphomas, and the latter for its anti-inflammatory action in symptom control and the control of emesis.

Symptom control forms a major part of both the nursing and medical roles in oncology (see Ch. 33).

Clinical trials

Despite an enormous amount of worldwide investment in research, cancer remains on the whole an incurable disease.

Most cancer centres are involved in multiple research trials, and nurses should be familiar with the format of these trials in order to understand the implications for patients and for their nursing care and to consider the ethical dilemmas which arise around all experimental therapy.

Following laboratory testing, new treatment methods are tested on consenting patients by means of a series of trials termed phase 1, 2 and 3 trials. During phase 1, the maximum tolerable dose is established and information is obtained about the drug's toxicity profile; phase 2 trials discover which type of cancer is most responsive; and finally, phase 3 trials discover the extent to which the treatment improves survival. In phase 3 trials, patients from the target group are randomly selected to receive either the new treatment or the best established one. Survival rates are then compared.

New approaches to established radiotherapy and chemotherapy treatments are constantly being tested in this way. In addition, some centres are involved in trials of totally new modes of treatment.

Complementary therapy

As treatment outcomes of conventional medicine are uncertain, and as cancer may become a chronic illness affecting every area of life, there is increasing interest in complementary therapies. Based on the connection between body and mind, these therapies focus on a more 'holistic' approach to health in which the individual is encouraged to take control of their own life, both mentally and physically. Such therapies include homeopathy, acupuncture, therapeutic touch, massage, aromatherapy, relaxation techniques, yoga, hypnotherapy, nutrition, self-help groups and stress management.

Little research exists to justify the use of any of these therapies as alternatives to orthodox treatments (Fitch et al 1999) and evidence for the value of complementary therapy is conflicting. However, evidence is accumulating that some interventions may contribute positively to both psychological and physical health outcomes. Data from eight randomised controlled trials in a Cochrane Review of the use of massage and aromatherapy for symptom relief in patients with cancer found short-term benefits. The authors conclude that longer follow-up studies are required to determine whether these benefits persist (Fellowes et al 2004).

Recent discoveries of neurotransmitters connecting the brain, body and immune system suggest a physiological basis for improved outcomes. It is also possible, however, that the extra time, attention and caring mediated by therapists in the course of complementary treatments are factors in the patient's feeling of well-being. It is well established that, when patients feel in control, they have better coping skills, emotional well-being, physical health, immune function and, most importantly, experience subjectively a better quality of life (Gerits & De Brabander 1999, Henderson & Donatelle 2003, Link et al 2004).

It is important that health professionals respect an individual's beliefs and choices, recognising the potential benefits of a combined approach to cancer treatment. In order to avoid potential harm, only certified practitioners with knowledge of interactions or contraindications should deliver complementary therapies. Recent surveys confirm that a substantial proportion of patients are using herbal medicines, which have the potential to cause adverse reactions (Werneke et al 2004, Molassiotis et al 2005). For efficacy and safety, it is helpful for patients and clinicians to discuss any planned complementary therapy.

NURSING PRACTICE IN CANCER CARE

The cancer nurse

Cancer and its treatment have a unique impact on an individual's life. Although the physical problems experienced by cancer patients may be similar to those of patients with many non-malignant conditions, the combination of these

problems with the chronic nature of cancer, the highly toxic effects of treatment and the profound psychological impact of the disease mean that cancer nurses require specialised knowledge and skills. Cancer nursing as a specialty has been in existence for many years in the UK and is continually developing. The last decade has recognised the increasing diversity of the role of the cancer nurse and the particular contribution in providing seamless care throughout the cancer journey. Key skills in cancer nursing are those that help the cancer patient and their carers to adapt to the reality of living with cancer while maximising quality of life.

Hospital–community liaison

Cancer is a chronic illness characterised by remissions, exacerbations and progressive physical changes. More patients with cancer are living longer. Health professionals caring for cancer patients should view care as a continuous process whether it takes place in the hospital or in the community setting. Supporting the patient through the cancer journey requires the skills of all members of the multiprofessional team in conjunction with the patient and family. If care is to be a truly continuous process then the importance of sharing the care between hospital and community must be acknowledged (Owen & Black 1996). Shared care protocols, a relatively new concept in cancer care, came about in response to the recognition of unfulfilled needs of patients receiving active treatments at home, e.g. immunotherapy or continuous chemotherapy infusions. Such protocols promote the philosophy of continuity of care between hospital and community. Effective communication and discharge planning are essential to optimal care. Without proper coordination and integration of services, the cancer patient's 'journey' through the health care system can be a bewildering and demoralising experience. The example of Mr A in Case History 31.4 illustrates the need for good discharge planning and liaison between hospital and community nurses.

Cancer patients spend most of their lives at home, interrupted by short hospital admissions. As a result, much of the psychological and physical adjustment to cancer takes place at home. Community initiatives and services are set up to support patients, their families and other carers from diagnosis to terminal illness, helping patients in decision making and achieving optimal independence and quality of life.

Cancer care in any setting can be very satisfying; it can also be stressful and nurses working in this specialty need to develop healthy and effective coping strategies (see Box 31.10).

Cancer care in the community

Community nursing staff are involved in cancer care during five phases:

- prevention programmes
- diagnosis
- treatment-related support
- rehabilitation following initial cancer treatment
- palliative care.

GPs, practice nurses, community nurses, liaison nurses and health visitors are generally involved in prevention schemes. Some health visitors may visit patients recently discharged from hospital in order to assess how they and their families are coping and their needs for care and emotional support. District nurses coordinate and carry out a needs assessment for patients throughout their time in the community. In some areas, new initiatives are being developed to support patients in the community at diagnosis and during treatment with the introduction of community cancer care nurses with specialist oncology knowledge and skills (Gorman et al 2000). Towards the later stages of the disease, symptoms may become more problematic and place more strain on carers; at this stage, Macmillan, Marie Curie or community palliative care nurses who have close links with the hospice and hospital-based palliative care teams, may become involved. These nurses have specialist skills in managing complex symptoms, providing psychosocial support and planning care in conjunction with the

CASE HISTORY 31.4

Mr A

Mr A, a 58-year-old head teacher, is married with two children: a daughter in Australia and a married son with two small children who lived nearby.

He presented to his GP with urinary hesitancy and frequency. Examination and subsequent referral to a urologist revealed a T3 adenocarcinoma of the prostate (a locally invasive tumour with no metastases). A biopsy of the tumour and a bone scan were performed with Mr A as an outpatient. Mr A opted for 4 weeks of radical radiotherapy rather than a prostatectomy. Because he lived in a small town 50 miles away from the nearest radiotherapy department, he became an inpatient, going home at weekends. During his recovery at home, a health visitor visited twice.

Two years later, 1 week after his retirement, rib pain necessitated a further bone scan. This showed metastatic deposits in the ribs and spine. At Mr A's local hospital, a bilateral orchidectomy was performed to reduce hormonal stimulation of tumour growth. Mr A was then readmitted to the radiotherapy department. One week of palliative radiotherapy and the commencement of opiate analgesics enabled discharge and 6 months of reasonably independent life.

However, a fall whilst Mr A was gardening resulted in the collapse of the third thoracic vertebra, with resultant severe pain and paraplegia due to spinal cord compression. High dose steroids initially, emergency radiotherapy and intensive physiotherapy restored some function, but Mr A was now confined to a wheelchair and had no bladder or bowel control.

Mrs A was fit and very determined to cope at home with the help of her son and his wife. Prior to Mr A's discharge, the community occupational therapy department oversaw the installation of a wheelchair ramp, bath aids and a hoist in the A's bungalow. District nurses visited regularly and referred Mr A to social services to provide support with washing and dressing. The Macmillan nurse provided psychological support and complex symptom management, linking Mr A in with the local hospice.

Within 6 weeks a further admission, this time to the local hospital, was necessary due to hypercalcaemia, which was treated with intravenous bisphosphonates for several months. Gradually Mr A's condition deteriorated and he was generally too weak to get out of bed. District nurses now visited him twice a day, and the Macmillan nurse visited regularly for pain and symptom control. It was arranged for Marie Curie nurses to care for Mr A at night, in order to give the family a rest. Mr A died peacefully at home with his family.

Box 31.10

Stress in cancer nursing

In 1988, Speck stated that the most important ethical choice made by cancer nurses is whether or not to engage in 'an intense, personalised involvement' with their patients in response to human need. A degree of emotional involvement is inevitable, and even necessary, to achieve excellence in cancer care. But such involvement, particularly as it may be terminated by the patient's death, results in considerable occupational stress. This emotional involvement is simultaneously a great asset and a point of vulnerability for nurses (Cunningham 2000).

The picture that emerges from the research and literature related to stress, burnout and the emotional labour of cancer nursing is mixed (Magnusson & Robinson 2000). A focus group found that patient care or contact was the greatest source of job satisfaction for cancer care workers. Oncology was felt to be a special environment because of the type of relationship established with patients and their families. However, over a third of participants demonstrated high levels of emotional exhaustion and low levels of personal accomplishment (Grunfeld et al 2005).

The constructive expression of emotions is as important as stress control. Establishing an environment of trust and mutual respect where it is safe to admit to colleagues feelings of inadequacy, grief and guilt, and even personal fears about cancer and death, is beneficial in relieving stress. Such support should also be provided on an organised basis in the form of support groups and counselling services, as formal support groups are often catalysts for social support, problem solving and task sharing (Tschudin 1996). Reflective practice, clinical supervision and mentorship are also important concepts that enable and empower individuals within their nursing practice.

Nurses continue to describe emotionally charged areas of care as being the most difficult and stressful; however, Wilkinson et al (2002) have shown that an integrated approach to communication skills improves nurses' expertise in this area.

An active life and supportive relationships outside of work are also vital in maintaining a realistic perspective on life. Without external interests, it may be easy for the nurse to imagine that cancer is far more prevalent than it is. Fields et al (1997) introduced stress reduction therapies such as a 10-minute massage, listening to music, visual imagery and social support group sessions and found that nurses experienced increased vigour and decreased anxiety and fatigue.

A commitment to continuing education by nursing management is essential in stress control. However, as Tschudin (1996) concludes: 'nurses themselves need to take on more direct responsibility for their own psychological care', and in campaigning for support and education.

district nurse and other members of the primary care team. The fostering of links with the Macmillan service as early as possible, when a patient is still able to discuss their hopes, fears and goals, assists in the establishment of a supportive relationship (see also Ch. 33).

The role of the district nurse The role of community staff is one of partnership with the patient and their family, who constitute the main 'unit of care'. Providing information, support and advice is often as important as assistance with physical care.

Another major role of the district nurse involves co-ordination of the primary care team and integration of statutory and non-statutory services. Because of the nature of cancer, the need for these services is considerable. The statutory services available include all of those necessary for the care of the chronically ill in the community (see Ch. 32).

Non-statutory services in the community Non-statutory services for cancer patients are particularly comprehensive in their provision and include the following.

Support and self-help groups Such groups can reduce the isolation of the cancer experience. The sharing of feelings and experiences provides emotional support, fosters hope and encourages a sense of self-worth and purpose. Many local groups exist for patients and/or their carers.

Support and information centres Empowerment of individuals, thereby allowing them to help themselves, is the basis of psychoeducational intervention programmes advocated by Fawzy et al (2000). Information, emotional support, relaxation and stress management are provided in thoughtfully designed environments for those affected by cancer, including carers, partners, relatives and friends. Programmes have been developed to provide opportunities for people to live and cope with a cancer diagnosis. Maggie's Cancer Caring Centres and Macmillan Information Centres are just two examples. Many other UK cancer support centres provide similar assistance and access to complementary therapists.

Counselling services Counselling may be necessary to assist the patient and their family to adapt emotionally to cancer and can help to relieve anxiety and depression. The Cancer Counselling Trust provides this service by telephone and in person and CancerBACUP advises about other local counselling services.

Financial aid The Cancer Relief Macmillan Fund (CRMF) can provide financial aid to meet the cost of aids, appliances, heating, bedding, holidays and other special needs.

Nursing services The Marie Curie organisation provides nursing staff, including a night nursing service, to allow carers some respite or sleep.

See 'Useful websites'.

Nursing frameworks for cancer care

No one framework or model of nursing can be suitable for every cancer patient or care setting. Integrated care pathways are an example of a framework which aims to integrate evidence-based practice through a documented plan of anticipated care for a group of patients with a particular diagnosis or set of symptoms. Each professional involved in the patient's care has a clearly defined role and the plan of care leads each patient towards a desired goal (Middleton & Roberts 2002). In palliative care for example, the Liverpool Care of the Dying Pathway transfers a hospice model of care into other health care environments (Ellershaw & Wilkinson 2003).

It is important to adapt and combine models and approaches to provide a workable framework of care for each patient.

Family coping

A cancer diagnosis can have a drastic effect on the patient's family and loved ones in the following ways:

- Cancer can disrupt patterns of familial and other interpersonal interaction. Those who are close to the patient are usually perplexed as to how to relate to the person in the most helpful way. Reactions vary from overprotection and excessive vigilance to distancing behaviour and even the complete breakdown of relationships. Many patients, especially in the early stages of the disease, may feel that they have to be the strong one emotionally, supporting and holding the family together. Under such strain it is no wonder that cancer can, and does, precipitate partnership and marital breakdown. Most at risk are those whose relationship is already unstable. In a study by Barraclough (1998), however, a majority of married people stated that they actually felt closer to their partners in the few months following a cancer diagnosis.
- Cancer disrupts planning for the future. An experience with cancer may last for many years. The uncertainty involved disrupts family plans and dreams for holidays, retirement, parenthood and so forth. Roles within the family change, particularly if the patient is a breadwinner or parent. Such change is stressful and can undermine the patient's sense of self-worth and purpose. Loss of income and increased expenditure due to the illness can create financial strain.
- Cancer alters the interaction of the family with external groups. Patients and their families may become isolated as a result of the social stigma of cancer, financial hardship and any residual disability. For some, however, involvement in self-help groups and cancer charities expands social interaction.

Nursing interventions After assessment of family dynamics and needs, the following nursing interventions may help to alleviate some of the above problems:

- Providing regular information about the patient's status and plans for care, preferably facilitating open communication between the patient and their family, which is associated with lower anxiety levels (Edwards & Clarke 2004). Shared information helps to promote a positive attitude and improves adaptation and communication within the hospital setting and at home.
- Encouraging relatives to express their feelings of fear, loss, guilt and exhaustion.
- Encouraging realistic, mutual goal-setting, e.g. the timing and planning of holidays.
- Encouraging family members to adapt the patient's role within the family to maintain a sense of belonging and worth, e.g. by exchanging physical tasks for clerical ones.
- Referring families promptly to the social work department for financial assistance and, if necessary, rehousing.
- Recognising signs of exhaustion in carers, giving them 'permission' to take time off and arranging respite care or hospital/hospice admission for the patient if necessary.
- Encouraging continued social involvement, suggesting appropriate activities if necessary.
- Suggesting referral to a psychologist or marriage guidance counsellor if family relationships appear to be breaking down.

Nutrition

In most societies, food and drink have sociological, psychological and cultural significance. They are an important source of enjoyment and social interaction with adequate nourishment symbolising health and well-being. Up to 85% of cancer patients, due to a variety of complex factors, are malnourished (Shaw 2002).

Cancer cachexia (see p. 1034) is a multifaceted syndrome not yet fully understood (Inui 2002). The associated weight loss can have a very negative effect on a patient's body image and sexuality; it represents a major source of concern for both patient and family, often acting as a barometer of the patient's condition.

Malnutrition in cancer patients is associated with a poor prognosis, reduced response to anticancer treatments and prolongation of treatment side-effects (Holmes 1996). Causes of malnutrition and weight loss in cancer patients include the following:

- Reduced food intake due to:
  - — anorexia: due to multiple causes, e.g. release of cytokines such as TNF and interleukin-1 are thought to delay gastric emptying, thus delaying digestion, suppressing the appetite and causing satiety (Shaw 2002)
  - — taste changes: may occur in any cancer patient (Foltz 2000); they are most common following radiotherapy to the head or neck due to destruction of salivary tissue. These changes involve a lowered threshold for bitter tastes, and therefore aversion to meat; raised threshold for sweet tastes, and hence many foods taste bland and 'cardboard-like'; alteration of the taste of tea and coffee
  - — early satiety: metabolic abnormalities directly related to tumour burden may result in early satiety, a premature feeling of fullness, usually progressing over the day
  - — other symptoms: such as pain, nausea, vomiting and drowsiness
  - — physical difficulties: due to oral prostheses or badly fitting dentures; also to the tumour and treatment, e.g. oesophageal obstruction, chemotherapy-induced mucositis
  - — anxiety and depression.
- Malabsorption due to:
  - — resection of tumours of the gastrointestinal tract, leading to decreased enzyme production and increased transit time
  - — impairment of nutrient absorption resulting from chemotherapy and abdominal radiotherapy.
- Excess expenditure of nutrients, due to:
  - — in many patients, raised basal metabolic rate, partly due to the demands of the tumour

— excessive loss of body protein due to vomiting, diarrhoea, haemorrhage, oedema, and exudates from stomas, fistulae and ulcerations.

Nursing interventions Actions that the nurse can take to help the patient overcome or manage difficulties with eating and drinking include the following:

- Use at regular intervals of a screening tool such as MUST (malnutrition universal screening tool) to assess the patient's current nutritional status and potential for further deterioration (Malnutrition Advisory Group 2003). Weekly weighing is adequate; more frequent weighing may cause the patient to become anxious and demoralised by continued weight loss.
- Identifying the major factors that contribute to the nutritional deficit.
- Referring 'at-risk' patients to a dietitian.
- Referring to a speech and language therapist those patients with an identified swallowing or aspiration problem.
- Referring to an occupational therapist to assist with functional or practical difficulties.
- Referring to a social worker for a care package to assist with shopping and meal preparation.
- Enlisting the help of relatives and friends to offer the patient's favourite foods whilst respecting autonomy. However, it is important to explain that there are very real reasons for the patient's reluctance to eat. Provision of dietary information, recipes and self-care measures may be helpful.
- Offering frequent, small, high calorie attractive meals and snacks throughout the day; negotiating with the catering department for flexibility in portion size and for a supply of nutrient-rich foods to be kept at ward level.
- Encouraging patients to take fluids in the form of high-energy drinks; discouraging drinking at mealtimes, to avoid early satiety.
- Decreasing satiety by the avoidance of high fat foods which delay gastric emptying; the use of prokinetics, e.g. metoclopramide, may promote gastric emptying.
- Reassuring the patient that taste changes are to be expected and may disappear in time; offering taste-enhancing herbs, spices, marinades (unless mucositis a problem) and alternatives to tea and coffee.
- Supporting the patient if there is further weight loss despite sufficient calorie intake, due to disruption of normal metabolism.
- Using gentle exercise, relaxation or modest amounts of alcohol to stimulate the appetite.
- Controlling other symptoms. Antiemetics and analgesics, topical and systemic, should be administered 30 min before meals.
- Encouraging regular mouthwashes before and after meals.
- Providing dietary supplements which may be nutritionally complete supplements, or calorie supplements. These may be fruit juice, milk or yoghurt based. Research into the use of fish oils as a nutritional supplement may prove useful for the future (Barber 2001).
- Eliminating nauseating environmental stimuli at mealtimes, such as bedpans, odours and disturbing procedures.
- If intake is consistently inadequate and/or weight loss continues, commencing other forms of feeding: nasogastric if absorption is adequate; parenteral if not.
- Once the patient is well, encouraging a healthy, well-balanced diet, similar to that recommended for preventing cancer (see Box 31.3). It is also important to assist patients to make an informed choice by providing appropriate information regarding the nutritional value, ease, practicality, availability and cost of alternative diets.

Expressing sexuality

Following treatment for cancer, up to 50% of patients who were sexually active before the illness report some reduction in sexual interest or activity (Barraclough 1998). Health care professionals in general fail to take the initiative in addressing their patients' sexual problems within the context of treatment for chronic and life-threatening illness. The reticence of some nurses may be due to embarrassment, but a lack of relevant knowledge and counselling skills has also been reported (Guthrie 1999, White 2002).

Sexuality involves more than sexual intercourse. It includes self-image in relation to gender, role behaviour within a partnership, and many forms of love and affection between partners. Partners are also affected by the experience of cancer and in some cases report higher levels of psychological distress and psychosexual concerns than patients (Carlson et al 2000). A cancer patient's sexuality may be altered for many reasons, including:

- the physical effects of the tumour, e.g. lesions of the spinal cord may interfere with the nerve pathways necessary for sexual sensation or motor function
- symptoms caused by the tumour, e.g. pain, immobility, nocturia, dysuria, rectal bleeding and fatigue can all contribute to a decrease in desire for sexual intimacy
- the physical effects of treatment, e.g. hormone manipulation may alter sexual function; surgery may alter the anatomy, for example a prostatectomy may cause pelvic nerve damage resulting in impotence; pelvic irradiation may reduce vaginal lubrication causing dyspareunia, i.e. painful intercourse
- body image problems, e.g. postmastectomy or following stoma formation; less obvious changes may also contribute, e.g. varying degrees of weight loss or hair loss
- anxiety and depression related to the cancer diagnosis resulting in low self-esteem.

Nursing interventions The nurse can provide support for the cancer patient experiencing problems with the expression of sexuality in the following ways:

- Initiating discussion in order to give the patient 'permission' to voice their concerns. Once the discussion is initiated, the patient will indicate whether or not they wish to pursue the topic.
- Anticipating problems before treatment: explaining how long they will last and that they are to be expected; describing measures that can be used to relieve them

(see Table 31.3 for examples of interventions for radiotherapy patients).
- Opening discussion with non-threatening subjects such as contraceptive advice or the alterations in partnership roles due to illness. This will aid progression to potentially more personal issues.
- Discovering and using the patient's own language in relation to their sexuality.
- Ensuring that anxiety and depression are treated and body image problems addressed. Severe body image problems may require de-sensitisation therapy by a psychologist.
- Involving partners in discussion and physical care as appropriate.
- Facilitating the privacy of couples in hospitals.
- When appropriate, discussing ways in which a couple may share sexual pleasure that does not involve intercourse. CancerBACUP and Cancer*Index* provide information that describes such methods (see 'Useful websites').
- Referring patients and partners with severe problems for psychosexual counselling as appropriate.

Communicating

From the cancer patient's perspective, patient-focused communication can be the most important aspect of treatment, in part because of its capacity to exacerbate or allay the fear that often accompanies cancer (Fallowfield & Jenkins 1999). Communication encompasses three areas of activity, which may be described as:

- cognitive — the giving and receiving of information
- emotional — the feeling and expression of psychological responses
- spiritual — the expression and feeling of thoughts relating to existential issues beyond the self.

Although this division can help in identifying specific nursing activities, the three areas are interrelated. Providing information in a sensitive, caring manner affords emotional support, and many people do not consciously make the distinction between the emotional and spiritual dimensions.

Cognitive activity The patient's need for information in relation to diagnosis and treatment has been examined in earlier sections of this chapter. To this discussion the following observations may be added:

- Knowledge is power: power that enables independence, choice, autonomous decision making and realistic goal-setting for patients and their families. Information promotes the patient's sense of control over their life.
- Studies of patients' perceived needs rank information as a key component for coping with cancer (Peck & Boland 1977, Eardley 1986, Van der Molen 1999).
- Lack of information can deepen a depressive reaction to a cancer diagnosis.
- Specific information about diagnosis and prognosis can encourage active participation by patients in their own care, and in fact generates rather than negates hope (Cassileth et al 1980, Skalla et al 2004).
- Patients have traditionally expected their needs for information to be met by doctors, and their needs for support to be met by nurses. However, in practice, particularly with the evolution of specialist nurses, this is changing. Patients will choose the person they wish to obtain information from depending on their needs.
- Studies show that patients seldom take the initiative in seeking information, mainly because staff appear busy and unavailable (Wells 1998b).
- Nurses, by their behaviour and non-verbal communication, may indicate they are too busy to answer questions at that particular time. They may also feel they lack the information the patient is seeking, or fear that information-giving may lead to an emotional unburdening by the patient, for which they may lack the personal resources necessary to cope.
- Patients and their families need information on the cause of the cancer, the possible course of the disease, treatment options, the role of the health care team, available services and sources of further information.
- Patients vary greatly in their desire for, and receptivity to, information. For example, patients who actively deny their cancer are unlikely to listen to information about community nursing support on discharge, and patients with a fatalistic attitude may not be interested in information about self-help groups or complementary therapy.

Nursing interventions The following advice may assist the nurse to meet the patient's communication needs:

- Be equipped with the information that the patient needs. Be assertive in obtaining this information from other members of the health care team so that a consistent 'story' is given to the patient.
- Be present at as many interactions between the patient and the doctor as possible. Afterwards reinforce messages and ensure that the patient has understood.
- Find out what the patient already knows and has been told, and what they want to know. In general, follow the patient's agenda.
- Discover the patient's principal fears and give information to correct any misconceptions.
- Bear in mind that when receiving information most people remember only three specific points; the first three points made are those most likely to be remembered.
- Avoid jargon: 'your white cell count will fall', for example, may mean nothing to most patients. Information about how they will feel and what they will experience is most important to patients.
- Document information given, together with an estimation of the patient's retention and reaction.
- Be prepared for the patient to forget or deny receiving the information given.
- Reinforce verbal information with written information. CancerBACUP and many oncology centres produce patient literature on a wide range of subjects.
- Be prepared for information-giving to lead to emotional issues. Allow time for this or promise to return at an arranged time — and do so.
- Give the patient and their relatives the same information. Give each the opportunity to receive this information both together and separately, so that

personal anxieties can be expressed privately and within the family group.

Emotional activity Enabling patients and their families to cope with the emotional impact of cancer demands effective listening skills and is an essential component of counselling (see Box 31.11). The following considerations should be borne in mind by the nurse in addressing the cancer patient's emotional needs:

- During any stage of the disease, the cancer patient is suffering the effects of various actual or potential losses. These may include loss of a body part or function, loss of self-image, loss of work or leisure activities, loss of family or social role, loss of control over life, loss of goals and dreams for the future and, ultimately, loss of life itself. Loss is the predominant factor in all sadness and depression.
- There are many uncertainties involved in cancer; uncertainty leads to anxiety.
- While the majority of cancer patients adjust emotionally and cope reasonably well with loss and uncertainty, several studies document the prevalence of psychological distress and even psychiatric illness among this client group (Maguire 1985). A study by Zabora et al (2001), examining the prevalence of psychological distress in 14 cancer sites (n = 4496), found the overall prevalence rate of distress to be 35.1%.
- A great deal of this emotional turmoil, anxiety and depression passes undetected and unrelieved (Fallowfield et al 2001). Rates of depression have been reported to be as high as 75% in several psychiatric studies (Mathieson & Stam 1995). Maguire (1985) calculated that only one-fifth of patients with severe emotional problems were helped effectively. Subsequent research has focused on prediction and early detection of affective disorders, through screening and improving communication skills of health professionals as well as therapeutic interventions (Maguire 1995).
- Emotional support is not a luxury in nursing care. Emotional distress may result in somatic symptoms such as confusion, immobility, insomnia and pain. As previously suggested, long-term distress may exacerbate disease progression (Brown et al 2003).
- The growth of complementary therapies in cancer care represents a recognition that healing is a much wider concept than that of cure; indeed, healing can take place even in the absence of a medical cure. Healing involves psychological adaptation to living with cancer, a process of coming to terms with one's situation.
- Patients' reactions to cancer vary greatly, depending on personality, past experience and learned coping strategies.

Nursing interventions The following strategies can be employed to give patients support as they adjust emotionally to their illness and treatment:

- Many patients cover up a great deal of their distress and assume that nurses do not have time to listen to them. Be alert to clues to this distress, such as constant information-seeking, manipulative behaviour and unrealistic goal-setting.
- Give the patient 'openings' to state what is on their mind, e.g. by concluding an information-giving session by asking them how they feel about the information, or by remarking upon a worried or sad expression.
- Do not be afraid of saying the wrong thing. A desire to understand and an attitude of concern are the important factors (Hinds & Moyer 1997).
- Learn and apply interviewing techniques used in counselling, e.g. reflecting back a patient's question or statement. This gives the patient the chance to realise what has been said and to expand on it, and the nurse time to reflect on what is meant. Constant reflection of questions, however, will irritate patients. Once the

Box 31.11

Communication skills: an example

This is an example of how one nurse offered her support to a young woman with acute leukaemia and her family. Notice the importance of following the patient's agenda and responding to the situation as it developed, rather than imposing a preconceived structure for communication (cited by Benner & Wrubel 1989):

While waiting for confirmation of the diagnosis, I did a lot of listening. I listened to the expression of shock, fear and guilt. I did not negate their concerns or try to offer false assurances.

It was clear that one of the most useful things I could do for this distraught family, who were in a strange and overwhelming place, was to assist them, little by little, in gaining control over their experiences. This involved helping them to anticipate and be prepared for what was to come, for how it might feel or look physically or emotionally. It also involved helping them to continue in their usual roles as much as possible, and engaging them in the decisions affecting Lara's care.

Although she knew that she had less than a 50% chance of survival, Lara concentrated on the here and now: the pain associated with frequent i.v.s, bone marrows and lumbar punctures; the embarrassment of hair loss; the isolation from her friends; and the nausea and vomiting associated with her chemotherapy. I followed her lead by responding to her immediate concerns.

I used a variety of approaches in working with her, depending on what kind of day she was having. Sometimes we would just joke around; other times we would talk about more serious issues — not just her illness but her personal life, as well as my own.

I was always open with her, accepted her feelings, and never made light of them. I did not assure her that 'it would get better soon' or that 'I knew how she must be feeling' because I truly did not know whether she would get better or how she actually felt.

Lara was just plain miserable. All I could do with her was listen, acknowledge how awful it must be, and honestly say that she must feel like crying. Permission to cry was all she needed to let the tears flow. One day, she looked me directly in the eyes and said, 'I'm so sick, am I going to die?'. Although it was a matter of seconds before I answered, it seemed like hours as my mind groped for the right words. I did not avert my gaze and answered from my heart: 'I'm afraid Lara, you are so sick that you could die'.

patient's main concerns have been established, it may be time to give direct answers.
- Resist giving 'pat' answers and false reassurances. Many of the dilemmas faced by cancer patients have no ready solution. Do not be afraid to admit that answers cannot be given to all the patient's questions about the future. Try, however, to leave the patient with some hope: help the patient to identify something positive in their situation on which to focus.
- Assist the patient to identify realistic goals in order to foster hope. These goals should originate from the patient but often need an objective person to identify them. Examples may be the goal of fighting the disease, of living until a daughter's wedding or returning to work part-time.
- A certain degree of worry and sadness is to be expected. Be alert to signs of disabling anxiety (somatic stress symptoms, lack of concentration, feelings of panic) or depression (a 'flat' mood, an exaggerated feeling of guilt and self-blame, suicidal ideation). If these are noted, refer the patient to a psychologist or psychiatrist. Anxiolytic and antidepressant medication and various forms of psychological therapy may be required before other forms of counselling therapy can be effective (Strong et al 2004).
- Patients may react to their disease with denial, anger, bargaining, depression and acceptance (Kübler-Ross 1973). Counselling cannot force the patient to move from one stage to another, but it does allow them to express feelings and perhaps make progress. The nurse should give patients permission to express their feelings in any safe way they choose and should not feel a sense of failure when a patient becomes emotionally distraught. The expression of emotions is therapeutic and is an important part of psychological adaptation.
- Supporting patients and their families through the cancer experience is very demanding emotionally. It is important for nurses to recognise the resultant stress in themselves and their colleagues and to seek and offer active support (see Box 31.10).

Spiritual activity A full consideration of the cancer patient's quality of life must recognise the spiritual dimension of the experience, which might be described, in the most basic terms, as the search for meaning and purpose. Cancer has been described as 'a modern metaphor for human confrontation with existential uncertainty' (Goldberg & Tull 1983). Because spirituality involves the contemplation of things that affect us but lie beyond our control, cancer has the capacity to precipitate a spiritual crisis.

For many in modern society, the spiritual needs for love, hope, creativity and purpose are met in relationships with others and in their engagement with the material world. The person faced with a cancer diagnosis may feel such needs with particular acuity and may be assisted by interventions similar to those described in the section on emotional activity (p. 1065).

For some, whether or not death is imminent, a cancer diagnosis creates a greater urgency to come to terms with concepts of God, the meaning of life, the problem of human suffering and the possibility of an afterlife. For others, religious conviction will provide a framework for such questioning and a vehicle for spiritual expression.

Nursing interventions In acknowledging and addressing the cancer patient's spiritual needs, the nurse should bear in mind the following considerations:

- Spiritual issues are often not expressed as such by the patient. They may be expressed as anger and disbelief, doubts about self-worth, feelings of guilt and a fear of death. These feelings should be recognised as possibly stemming from spiritual questioning. The nurse should listen non-judgementally to the patient's views and acknowledge that some questions can never be answered.
- Patients of all faiths should be assisted to worship according to their custom. Nurses who share the patient's faith may find that a few minutes of shared prayer may be of more benefit than an hour of counselling.
- Even the most religious patients may express feelings of doubt, despair and anger against their God. This does not necessarily mean that they are losing their faith, but could indicate that they are grappling with it. The nurse should acknowledge the patient's distress and, if the patient wishes, enlist the help of a spiritual counsellor or minister.
- Not everyone with cancer is dying. However, almost all cancer patients consider the possibility of death at some point. If patients verbalise this possibility, and the timing is appropriate, they should not be denied the chance to begin the very necessary process of anticipatory grief. At the same time, all reasonable hope for the short-term future should be fostered and the patient's quality of life in the present should be enhanced by all means possible.

New directions for cancer care

Seminal work by Slevin et al (1990) pointed out that those who do not have cancer, whether they are lay people or professionals, have very little concept of the experience of cancer or of how the cancer patient perceives quality of life, their future and the decisions that must be made. Cancer is a chronic illness and more patients are living with their disease than previously. These patients, as survivors, have needs and expectations — physical, psychosocial and spiritual. Cancer patients may survive but they may not necessarily thrive. In this situation, cancer rehabilitation is paramount to support patients in effectively managing their illness on a day-to-day basis.

This millennium will see an increase in self-care, with individuals, families and communities playing a larger role in determining and meeting their own health needs. The internet has empowered patients by providing access to information about their disease and treatment, and opening up communication links with fellow patients. Advances in molecular biology may lead to the identification of high-risk groups and better targeted prevention as well as treatment. New challenges lie ahead for nurses in all fields for role development, research and education to support patients and their families through the cancer experience.

INTRODUCTION

Medicine's traditional cure orientation has long influenced health service development, resulting in chronic illness assuming low priority. In these terms, working with those for whom there is no prospect of full recovery carried little prestige and represented the antithesis of skilled practice. However, the opportunity to focus on care, a concept central to nursing, attests to the importance of nurses' commitment in this area. Changes in demography and morbidity, shifting emphasis to community care and evolving roles mean that nurses encounter in all settings chronically ill people who are living with an array of conditions, occupying differing stages of disease processes and experiencing a variety of life circumstances.

The range of knowledge and skill needed to meet the challenges of promoting and restoring optimum health, in its broad bio-psycho-social and spiritual senses, among this disparate client group cannot be underestimated. Nursing involvement is influenced by the application of a diagnostic label, but directed by what is meaningful to the individual and interdisciplinary input. The role is, therefore, collaborative in nature and must be formulated within context, which includes the nature of chronic illness, its prevalence, its impact on personal experience and functioning, and the relationship between individuals, their carers and care agencies. Perhaps the best place to begin is to consider how chronic illness has been defined.

THE NATURE OF CHRONIC ILLNESS

Terminology

An analysis of the terminology used is an essential starting point for any discussion of chronic illness. Its multifaceted nature means that defining chronicity is extremely difficult. Nevertheless, a number of attempts have been made to describe illnesses that are 'long term and have a profound influence on the lives of sufferers' (Locker 2003). The way in which key terms are applied may reveal assumptions held about the causation and prognosis of enduring conditions and about the individuals who experience them. For example, the North American definition offered by the Commission on Chronic Illness in 1954 (cited by Daly 1993) focuses on disease and refers to chronic illness as being a deviation from the norm, both raising questions as to what constitutes a 'normal' state as well as suggesting that people with such conditions are 'less than normal'. More recently, Curtin and Lubkin (1998) contend that from a nursing perspective:

> *Chronic illness is the irreversible presence, accumulation, or latency of disease states or impairments that involve the total human environment for supportive care and self-care, maintenance of function, and prevention of further disability.*

This reflects growing concern with attending to the whole person within their own context.

'Illness' and 'disease'

It is important to note that some definitions of chronic illness are orientated towards disease rather than illness. A distinction is made between these two terms by some writers such that 'disease' is a medical conception of pathological abnormality as indicated by its presenting features, whereas 'illness' is the subjective response by the individual to feeling unwell (Crumbie & Lawrence 2002, Armstrong 2003). Although it is possible to feel ill without having a disease, and vice versa, 'illness' and 'disease' do not constitute discrete phenomena but, rather, operate at different levels of human experience (Greaves 1996). Their relationship is dependent on the nature and severity of the disease process and on coexisting psychosocial variables. Chronic illness is generally associated with the presence of a protracted disease process which is not amenable to treatment, is responsible for impairment or disability and, so, has a sustained influence on the functioning and lifestyle of the individual. From this perspective, the relationship between disease and illness is characterised by its complexity.

'Impairment', 'disability' and 'handicap'

Biomedical classifications of disease do not necessarily account for the psychological and social consequences which accompany the conditions identified. For example, Dickens et al (2003) consider that depression experienced by women with rheumatoid arthritis is related to social stress, rather than the severity of their physical problems. The terms 'impairment', 'disability' and 'handicap' are commonly employed with reference to chronic illness and are applied in a variety of ways, whether their definitions are stated explicitly or merely implied.

- 'Impairment' is generally used to describe any disturbance of the body's structure and function (Field & Kelly 2003). Impairment may also be influenced by extrinsic factors such as the manner in which the presenting condition is managed. Pressure ulcers, constipation, urinary tract infections and other complications of restricted mobility are examples of these.
- The word 'disability' can be used to identify any long-term or permanent loss or reduction in functional capacity. This may also be defined in relation to behaviour, such as that arising from the individual's inability to perform activities which are expected of them (Nettleton 1995). The level of disability experienced by an individual reflects the severity and duration of impairment, taking into account concurrent disease, illness and the effects of the ageing process. People interested in the study of chronic illness should consider the notion of disability since this presents an opportunity to discuss a range of behavioural responses without concentrating on the diseases concerned. This recognises the reality of disability as something that is lived and experienced physically and psychologically (Marks 1999).
- The term 'handicap' may be applied when limitation of activity persists as a residual effect of impairment, even following rehabilitative efforts to restore function. Handicap stems from extrinsic factors and is not, therefore, merely the presence of disability and impairment, but the social, economic and environmental consequences of these. It is helpful to think of handicap in terms of social disadvantage and deprivation in so far as individuals are prevented from participating in prescribed roles and relationships. Handicap can have different implications for individual experience depending on the way in which social, cultural and economic values are applied to restricted role behaviour (Locker 2003). In this way, 'handicap' can be interpreted as both more and less than 'disability'.

SOCIETAL ATTITUDES TOWARDS ILLNESS AND DISABILITY

Attention is clearly directed towards associations between aspects of lifestyle and some chronic illnesses; for example, smoking is linked with lung cancer and a high dietary intake of saturated fats with coronary heart disease. General awareness of these relationships may result in the individual being judged to be the cause of their own disease and related suffering (Rosenberg 1997). There is also an implication that the individual has failed to respond to preventive health education campaigns. Attribution of personal blame is shown to have a strong moral influence where a link can be alleged between disease and sexual behaviour, such as that between HIV/AIDS and promiscuity (Pitts 1996, Brandt & Rozin 1997). Current beliefs concerning the origin of chronic illness and disability appear, therefore, to reflect a combination of moral ideology and scientific principles.

32.1 Given the association between cigarette advertising and tobacco consumption (Charlton et al 1997, MacFadyen et al 2001) and that tobacco companies appear to be accepting the addictive nature of their products, can individuals be blamed for their behaviour? What other forces influence personal health choices?

Disability and unemployment

The individual's economic survival in a pre-industrial society largely depended on their capacity to engage in physical labour. Those who were restricted by the effects of protracted illness or impairment would thus have had a limited function within their social group. This, together with their likely dependency on others, could result in the perception that disabled people were of less value than their able-bodied counterparts.

In an industrialised society, however, technological developments and diversification of working practices should create opportunities for those with a wide range of disabilities to gain employment. Nonetheless, disabled people seeking to enter the labour market encounter discrimination. It has been argued that the Disability Discrimination Act (1995) has not addressed this because it defines disability using a medical rather than a social model (Reid 1997), is riddled with ambiguity (Jacklin 1997) and does not assure full civil rights (Mahony 1997).

Governmental response to poverty is influenced by the way impoverished people are viewed by other members of society. The assumption that those living with chronic illness experience economic difficulties because their inability to obtain employment results directly from their incapacity

is not held universally. Some believe instead that such individuals are malingerers who choose not to work (Scambler 2003a, Spinney 2003). When this interpretation predominates, programmes for the alleviation of poverty concentrate on motivating individuals by reforming attitudes and implementing workfare-style schemes, so such programmes may appear to be punitive rather than benevolent.

Stigma

As Goffman (1963) points out in his seminal text, the word 'stigma' was originally used with reference to visible signs inflicted with the intent of branding individuals (including slaves or criminals) unfit for participation in normal social interaction. These signs had moral and judgemental implications, such that the disgrace and shame of the stigma assumed more importance than its physical presence (Saylor & Yoder 1998).

The stigma attached to a chronic illness relates to deviation from the perceived norm and depends on the part of the body affected, the degree to which effects of the condition are visible and application of a diagnostic label. To be labelled chronically ill is to be made exceptional and, in many cases, marginalised. People with a chronic illness are engaged in constant effort to make themselves acceptable and their stigmatising condition often assumes primacy in establishing their social identity and relations with others. Case History 32.1 gives some insight into the stigmatisation that may be suffered by an individual with an obvious skin condition. People with less visible conditions such as epilepsy experience 'felt stigma'. Their burden of constantly concealing a discreditable part of themselves in order to pass as normal and avoid being found out is added to by difficulties in gauging which details to share with whom, so that relationships can be maintained (Radley 1994, Pierret 2003). Family members also experience stigma by association and this impacts on their response to the affected individual and their contact with others.

32.2 Have you ever been aware of being embarrassed or uncomfortable when you were with someone with an obvious skin disorder? What were your reactions?

CASE HISTORY 32.1

Mrs I

Mrs I is 44 years old and is employed as a part-time receptionist. She lives in a terraced house with her husband and their three teenage children. Mrs I has had psoriasis for some years, involving much of her body surface.

Although prescribed treatment has controlled features of this condition to some extent, Mrs I has periods of exacerbation. Reddened raised patches sometimes appear on her face, and her scalp is often affected. Medical opinion varies as to whether this is actually due to psoriasis or to seborrhoeic dermatitis. Mrs I feels this distinction to be largely academic because neither condition is curable and the outcome for her remains the same. At present her scalp is covered in a thick, hardened layer of scales. When these areas are detached, her scalp surface weeps and becomes painful. Scales are also deposited continually on her clothing and in her immediate vicinity.

Mrs I finds that living with a skin condition is made more difficult by the reaction of others. She is often conscious that people stare at her and look at her affected skin rather than making eye contact during conversations. Mrs I remembers that when her children were small, one of them tried to prevent her from attending a school play. After a long discussion he admitted that it was because he was embarrassed by her appearance. Mrs I thinks that some people regard her condition to be contagious or to be caused by poor personal hygiene. She considers that this explains why passengers on the bus she takes to and from work rarely occupy the space next to her until the vehicle becomes crowded. Such behaviour still makes her uncomfortable but she has learned to accept it as something she must live with.

Mrs I feels that she has developed effective methods of coping with the problems resulting from her disorder. Since her job involves meeting the public, she has learned to project an outgoing and friendly image which she feels is stronger than the visual impression which her condition creates. She avoids wearing dark clothes likely to make her fallen scales more obvious and purchases her clothing by mail order or from shops which do not have communal changing rooms. She has learned by trial and error which chemicals or cosmetics irritate her skin and excludes them from the household. She takes her own prescribed shampoo to the hairdressers and never uses biological washing powder. Her friends and relations are aware that only selected toiletries are welcome as birthday and Christmas presents. Mrs I has also adapted her treatment regimen to account for exacerbations of her condition. She applies some creams only when she feels that she needs to, rather than at prescribed intervals. As some preparations require careful application due to possible staining of clothes and localised burning (see Ch. 12), Mrs I tries to restrict their use to days when she is not rostered to work. To prevent unnecessary soiling, she reserves specific bed linen for occasions when she needs to leave scalp ointment on overnight.

Public awareness campaigns

Groups have been established to raise public awareness of problems encountered by individuals with chronic conditions. In the USA, veterans of the First World War were successful in exerting large-scale efforts to obtain privileges and opportunities for disabled servicemen returning to civilian life (Dimond & Jones 1987). The amount of popular support such programmes receive depends upon whether the situations to which they are related are viewed positively. This can be illustrated with reference to American veterans of the Vietnam War, who endured stigmatisation by association with a controversial and unpopular conflict (Figley & Leventman 1990).

Other groups draw attention to named conditions and their effects on individual experience. Independent from formal health agencies, these organisations function as a resource for chronically ill people, their families and professionals, lobby to influence health and social policy, and raise funds for facilities and research. Groups operating without the active participation of individuals with chronic conditions risk calling attention to assumed, as opposed to actual need. In addition, activists within the disabled people's movement assert that national fundraising events merely reinforce the notion that an automatic relationship exists between disability and charity. Members of these groups believe that disabled people should avoid passivity and the socialised dependency which results. Their practice of self-advocacy, use of direct action and insistence upon parity rather than charity contrasts sharply with the conventional image of 'the disabled' as recipients of care (see

'Useful websites', p.1093, for the British Council of Disabled People's website).

THE PREVALENCE OF CHRONIC ILLNESS

The prevalence of chronic illness or disease is difficult to establish, given the many definitions and interpretations offered by various agencies. Some indication may, however, be derived from a review of studies which account for such variables as demography and disability. The data are not definitive because reporting and collection methods are inconsistent.

Improvements in public health in the UK during the last century resulted in the near-eradication of some infectious diseases, while others have been largely controlled by vaccination programmes (Galbraith & McCormick 1997). In addition, once contracted, infectious diseases are generally amenable to treatment. Chronic rather than infectious disease therefore remains the major cause of premature death and disability (Griffiths & Brock 2003).

It must not be assumed that infection has been eliminated from Western societies, nor that chronic disease cannot be infectious (Radley 1994). AIDS is the result of infectious disease, yet to contract it means living with a chronic illness.

Patterns of infection are also subject to continual change worldwide. The speed at which this occurs reflects the acceleration of human, social, technical, environmental and population change. This has resulted in the appearance of new diseases, such as severe acute respiratory syndrome (SARS) (Donnelly et al 2003, WHO 2003), and the re-emergence of others. For example, notifications of tuberculosis have risen by nearly a fifth in the UK since 1993 with an increase in drug-resistant isolates and it has become more common than measles or whooping cough (Office for National Statistics 2003a). This is in part due to improvements in the system of notification, but the increase of pulmonary tuberculosis is genuine and associated with socioeconomic deprivation. Almost half of overall notifications are from immigrant communities and are most prevalent among young South Asians (Galbraith & McCormick 1997). Observations such as this have led to members of marginal groups, including political asylum seekers, being viewed pejoratively as the cause of disease and thus a threat to wider society (Pitts 1996). Further, this gives rise to 'port health' thinking, leading to unreasonable fears of infection from abroad and a restrictive view of minority ethnic health issues (Smaje 1995).

The continuing decline in mortality from infectious disease is reflected in an increased expectation of life for all age groups, a trend which is predicted to continue (Charlton 1997). This has implications for the number of people afflicted by chronic disorders because the proportion of the population considered to be impaired or handicapped rises with advancing age. Confirmation of this relationship can be found in data from the annual General Household Survey (GHS) involving a sample of 21 180 people aged 16 years and over (Office for National Statistics 2003b). Respondents were asked whether they had any long-standing illness, disability or infirmity and, if they had, to state whether it served to limit their activities in any way. A long-standing illness was reported by 32% and a limiting long-standing illness by 19%. A comparative measure of acute illness was obtained by enquiring whether participants had limited their usual activities as a result of illness or injury within the 2-week period prior to the interview. Only 14% of the sample fell into this category. The report concludes that in the period 1972–2001, rates of long-standing illness have increased steadily. Although the reporting of such disorders rose from 22% in those aged 16–44 years to 63% in those aged 75 years or more, demographic distribution means that fewer older men were found in this category.

Respondents declaring long-standing illness most frequently identified musculoskeletal, circulatory and respiratory disorders as its source. Among these disorders, musculoskeletal conditions were the most common. Circulatory problems were the second most common form of chronic illness identified; these were reported by 1.9% of adults aged 16–44 years and approximately 33% of those aged 75 years or older. Mortality from these disorders declined during the latter half of the last century (Office for National Statistics 2003a) but still accounted for around 30% of all deaths in England and Wales at the millennium (Griffiths & Brock 2003).

The GHS reveals social inequality in that those connected with routinised and manual occupations were most likely to report long-standing and limiting illnesses. The prevalence of these was also highest among economically inactive respondents. There is striking similarity between the proportions of men and women experiencing various forms of chronic illness, with the following two exceptions among those aged 75 years and above. First, 26% of men stated that they had a long-standing musculoskeletal disorder, compared with 35% of their female counterparts. This could be partly due to the higher proportion of much older women who fall into this age category. Second, 10% of males considered themselves to be suffering from respiratory disease, whereas only 7% of women characterised themselves in the same way. Differences in lifetime smoking behaviour are reflected here, although occupational factors may also be significant (Dunnell 1997).

The number of conditions identified per person increased with advancing age, being 1.3 for those aged 16–44 years and 1.8 for those aged 75 years and above. The findings of these surveys support the notion that, while chronic illness is widespread and involves a variety of conditions, only a proportion of those affected are appreciably disabled. A survey carried out in 1995 on behalf of the Department of Health revealed that, amongst adults aged 16 years and over, serious disabilities were most likely to be caused by arthritis and rheumatism, diseases of the nervous system, particularly Parkinson's disease and multiple sclerosis, and circulatory disease/stroke (DH 1997a).

32.3 Given that chronic illness is so widespread, think again about the meaning of health for different people. Can people with chronic disease be 'healthy'?

Cancer was reported as the cause of their disability by 2% of respondents (DH 1997a). Cancer mortality has fallen during the last 40 years in men under 70 years and women under 50 years of age as a consequence of improved treatment and reduced risk (Swerdlow et al 2001). Data from the GHS show that neoplasms and benign growths are the cause of long-standing illness in 1% of adults.

CASE HISTORY 32.2

Mrs F

Mrs F is 64 years old. She has been widowed for 9 years and has lived with cancer for the last 8. Mrs F can recall clearly the moment when she feels her life changed. She had dropped her soap whilst bathing and, when bending to retrieve it, she noticed a lump in her left breast. For a time it seemed to her that the world stood still, her immediate fear being of the likely diagnosis. Mrs F knew what her course of action should be but she postponed visiting her GP for a week. She felt as though hearing someone else voice her suspicions would make things worse and that somehow the lump would be more real.

Within a short time, Mrs F underwent a series of investigations and a lumpectomy. It seemed that she was on a merry-go-round and could not get off. Each appointment with a hospital department led to another and she joked that her social diary had never been so full. Once surgery was over Mrs F was unsure of herself. Her life was under immediate threat. She did not know how she was supposed to feel or what was normal behaviour in this abnormal situation. The sense of threat lessened as the period between follow-up appointments increased. Despite the surgeon's optimism, Mrs F feared the disease returning. Her medication regimen acted as a constant reminder but as time passed she wondered if she dared to believe that she was safe. Feeling it important to do something to occupy her time, Mrs F enrolled in adult education classes and began work for a local children's charity.

Two years later, further surgery was advised to remove diseased axillary lymph nodes. A course of radiotherapy followed. Mrs F coped by fitting appointments around her charity work but found that her condition was less easy to ignore than before. She was tired, her skin was sore and she found it difficult to use her left arm. Again, the medical team appeared optimistic. Mrs F wondered if they were telling her the truth and found herself looking for clues in their words and mannerisms. She recognised that the disease now posed more problems than ever. Until now she had described herself as healthy.

Mrs F gained some reassurance as the time between follow-up appointments increased as before and scans did not reveal further metastatic spread. The doctors always seemed to define survival in terms of a 5-year period. This assumed great importance for Mrs F. She felt as though it represented an almost magical goal, beyond which her existence was assured. In the meantime she managed her medication regimen and the side-effects of additional treatment. Every previously innocent ache, pain or cough she experienced took on a new meaning. Was it her arthritis, a chest infection or had the disease spread?

Increasing back pain led to Mrs F relinquishing her charity work and to the recent diagnosis of bony metastases. She was offered a place at a hospice day centre but refused. Mrs F felt that accepting it confirmed that the cancer was now bigger than she. She also did not relish making new acquaintances there and then wondering who would be missing when she next attended. Mrs F thought the outcome of her illness was certain but was still unsure of what would happen on the way.

32.4 Read Case History 32.2 and also refer to Chapter 31. Do all cancers result in chronic illness?

FEATURES OF CHRONIC ILLNESS

While analysing the prevalence of long-standing disease is useful in predicting the demand for support services, it gives no indication of the impact of such conditions on daily life. Incongruously, overemphasis on diagnosis and disease entities conceals both the psychological and social problems common to chronically ill people and the uniqueness of each person's experience. In their seminal work, Strauss et al (1984) developed a framework to enable the experience of chronic illness to be understood more clearly and empathically. To provide a basis for this, the seven features of chronic illness outlined below were identified. Only when they are aware of these features can nurses begin to appreciate the profound effect chronic illness has on individuals, their families and health workers.

Chronic illnesses are long-term by nature

The time span for the treatment of acute illness contrasts markedly with that for chronic disease. Once treatment is initiated, the resolution of acute illness is generally achieved within a short period of time and life is resumed as before. The protracted nature of chronic illness results in repeated interactions between individuals and service providers, perhaps over a period of months or years. This leads to individuals gaining familiarity with the organisations providing support and the personnel with whom they come into contact, and has implications for the development of complex social relationships between patients and carers. For example, Curtin and Lubkin (1998) liken chronic illness to an unexpected guest who announces an indefinite stay and becomes part of the household.

Although diagnostic labels often come as a relief, because they explain symptoms and validate individuals' feelings that 'something isn't right' (Locker 2003), labelling also represents a defining moment in the trajectory from person to patient. For example, after being told she had Addison's disease, one woman told of a heightened sense that 'things would never be the same again'.

Adulthood is a dynamic period usually associated with autonomy and control. It is a time of life in which the individual expects to nurture others, rather than to be nurtured. The limitations imposed by illness and a need for protracted care conflict with these expectations and can be damaging to the individual's self-esteem. People with chronic illness may be encouraged to relinquish whatever control they still possess in favour of control by the health professionals (Daly 1993), though this stance has been vigorously questioned, for example in patient-focused rehabilitative care (Wilson 2002). Ironically, failure to accept this may be regarded as active opposition to adopting the role of patient and can result in the individual acquiring a reputation for being 'difficult'. Frequent service usage or long-term admission to hospital do not necessarily enhance relationships between patients and health professionals, despite the opportunity it presents for interpersonal development in the course of continued interactions (Stockwell 1972, Johnson 1997, Jiwa 2000).

Chronic illness is uncertain

Living with chronic illness means living with uncertainty. Obtaining a diagnosis may be a lengthy and complicated process due to the ambiguity of symptoms experienced and insidiousness of onset. Difficulty in establishing a prognosis

with any degree of certainty is also a source of stress for all concerned, since only the progress of the disease itself gives sufficient information to suggest a likely timescale of events for a particular individual (Strauss et al 1984).

Adulthood is also associated with the achievement of socially and culturally specified tasks such as leaving the parental home, finding a partner and rearing a family (Schaie & Willis 2001). The restriction, discomfort and possible dependence which accompany chronic illness may force the individual to forgo these and adopt an alternative lifestyle. Biographical disruption leads to grieving for previously taken-for-granted opportunities, ambitions and loss of self. The difficulty that individuals with a degenerative illness may have in visualising the future is illustrated in Case History 32.3.

Fear of dependence, which in itself causes uncertainty, is a fundamental human concern in cultures valuing self-reliance and economic and physical independence. For instance, following a diagnosis of Parkinson's disease, this problem is shared to an extent by medical staff who must decide how much information to give regarding the likely course of the disorder and difficulties of treatment. Although it is seen as important to provide patients with sufficient data to enable them to exert maximum control over their new situation, doctors question their own professional commitment in situations where purely medical solutions have only a limited effect (Pinder 1992).

Fluctuations in symptoms, and energy to manage them, make it impossible to forecast the occurrence of 'good days' and 'bad days' and this is compounded because a 'good day' can turn abruptly into a 'bad day' and vice versa. Uncertainty is also present because of the inherently episodic nature of many chronic illnesses, in which recurrent unpredictable crises occur, followed by periods of remission or control. Since the onset and duration of these crises cannot be anticipated, individuals and their carers must be vigilant for indications of impending difficulty and ready to respond at any time. Pre-empting the sudden imposition of change results in the restriction and reorganisation of lifestyle. Social uncertainty thus exists for people with chronic illness and their families, who find it difficult to plan their activities in either the long or short term and may be excluded from full participation in community life as a result (Strauss et al 1984). Fluctuation in chronic conditions influences the way in which individuals perceive themselves and are perceived by others. The invisibility of symptoms in some conditions can cause people to question the reality of their experience and those around them to doubt that it exists (Aylett & Fawcett 2003, Foley & Sarnoff 2003). For example, where health workers and family members 'all say "but you look so good for someone who has MS" ... if they can't see it, there really isn't anything wrong with me' (Doss 2002). This also means that the pervasive consequences of living with a protracted disorder are disregarded. Individuals are believed to be directly affected by the disease only when it becomes noticeable, and variation in ability during periods of crisis and remission is misunderstood. Paradoxically, uncertainty can be a positive experience in chronic illness. For example, in Mishel's (1993) study of people receiving renal dialysis, higher levels of uncertainty correlated with adherence to the regimen, while lower levels were related to non-adherence.

CASE HISTORY 32.3

S

S is 28 years old and works as a cook in an independent school for girls. She has been in this employment since leaving college and lives on the premises. Her social life revolves largely around sporting activities, an interest shared with her boyfriend, A.

S was diagnosed as having multiple sclerosis (MS) 2 years ago when she was admitted to hospital following a fall while playing tennis. She had been experiencing difficulty in focusing her eyes for some time but had thought that this was due to overwork. She had also begun to find it difficult to coordinate her movements and became known for dropping and spilling things. These events were explained when the diagnosis was made and S found it strange that she had lived with the condition for so long without realising that something was seriously wrong.

After the diagnosis was confirmed, S felt compelled to search the internet to find out more about the condition and what it would mean to her. She resolved that her approach would be to get on with living despite the disease. Within a short period, however, her balance deteriorated and walking became difficult. She also found that she tired easily. S responded by opting out of strenuous activities. Having valued her physical fitness, she began to experience frustration at her loss of ability and function. She felt as though her body had betrayed her and she did not like to be seen walking with a stick. When S developed frequency and urgency of micturition, she began to avoid visits to public places where toilets would be difficult to reach or where queues were likely.

In private, S found herself increasingly reduced to tears of frustration and despair, believing that no one else could understand her experience. She chose not to share these feelings. She had always been able to manage her life independently and wanted to appear to be continuing to do so. S's boyfriend, A, tried to support her as much as possible, but maintaining a positive stance at all times was hard. His friends advised him not to remain in the relationship, purely because of his concern for S, and his feelings for her were sometimes confused. He wondered if her reluctance to visit public venues was actually her way of avoiding him because she wanted their relationship to end.

S was preoccupied by questions about her future. How long would she be able to continue in her present post? Would it be possible to seek alternative employment? Giving up her job would mean giving up her home. Her parents wanted her to live with them but S was anxious to retain her autonomy and knew that her mother would try to protect her too much. However, it was her future with A that was her greatest concern. S loved him and had hoped that their relationship would lead to marriage. She wanted children of her own and already felt that time was running out. S felt it impossible to confront A about such a commitment, fearing that he would perceive this as pressure to make an immediate decision and that as a result she may lose him altogether. Her sad conclusion was that with MS she could no longer be sure of anything.

32.5 In Case History 32.3, S obviously believes that her life course is being undermined and she has many anxieties about her long-term goals. Anxiety is a distressing experience in itself, but could interfere with her ability to function. If you were caring for S, how would you help her to deal with her situation? What role could an MS specialist nurse have played from the time of diagnosis?

For more information, see Multiple Sclerosis Trust/Royal College of Nursing (2003) and UK Multiple Sclerosis Specialist Nurse Association et al (2003).

Chronic illnesses require proportionately greater efforts at palliation

In view of the remote prospect of effecting a cure in chronic illness, the control of elements which influence quality of life assumes primary importance. More emphasis is placed on palliative measures, e.g. alleviating pain and discomfort, providing symptomatic relief and addressing problems created by the restriction of activity. Palliation is of greater significance than in acute illness because people with long-term disease must learn to live with both the features of their condition and the side-effects of treatment (Strauss et al 1984). The cooperation of patients, their families and close associates is necessary to achieve this. Since symptoms such as constant pain and nausea can compromise the individual's ability to engage in a variety of activities, their treatment is seen as desirable even though it will have little effect upon the disease process.

Decisions as to which palliative measures are selected for individual treatment are influenced by availability, acceptance by the medical profession, their perceived benefit to the patient and financial constraints. Improvements in quality of life following palliation are difficult to measure objectively, and this has implications for the allocation of resources.

Individuals have considerable resources of their own and many use these to try to resolve health problems before seeking professional help or as an adjunct to it, particularly if statutory agencies cannot provide palliation or the side-effects of treatment are unacceptable. The use of complementary therapies is common amongst people who feel that conventional medicine has nothing further to offer (Watkins 1996, Cant & Sharma 1999). This not only represents an assumption of responsibility for their own well-being but a desire to achieve control over unpredictable illness (Montbriand & Laing 1991). Furthermore, in contrast with conventional care, there is a possibility of accessing person-centred treatments which are inherently pleasurable.

Coping strategies can be learned through experience and membership of self-help groups (Field & Kelly 2003). Although self-help groups provide a means of empowering individuals and can complement formal services, they also reflect a subversive readiness to assert the value of experiential knowledge and to question that of medicine (Scambler 2003b). The UK government's 'Expert Patients' initiative stems from a recognition that traditional cure-oriented services have not dealt comprehensively with problems faced by chronically sick people and that partnership enhances self-management, giving patients greater mastery over their lives (DH 2001a). It is intended to introduce user-led training programmes in England and feed these into the forthcoming National Service Framework (NSF) for long-term health conditions and other disease-specific frameworks. Examples of these for diabetes may be found across the UK (DH 2001b, Scottish Executive Health Department 2002, Welsh Assembly Government 2002, CREST 2003).

32.6 In a study exploring attitudes towards patient expertise in chronic illness Thorne et al (2000) found that: 'Whether or not they had any actual expert advice to offer, patients reported that many professionals cling to the role of expert within the health care encounter. In the case of type 1 diabetes mellitus (see Ch. 5, part 2), this occurred despite clear evidence of established patient sophistication in self-care decision-making'. Why may members of the health care team retain the expert role when working with people with chronic illness?

Chronic diseases are multiple diseases

The systematic and degenerative effects of many chronic diseases are such that the failure of one organ or physiological system leads eventually to the involvement of others. In addition, long-term disability related to an existing chronic condition is likely to generate further disease. This can be illustrated with reference to complications associated with diabetes mellitus. These include vascular damage, which may result in renal and visual dysfunction, and an increased risk of myocardial infarction. Impaired circulation to the lower limbs also predisposes to the development of gangrene, the onset of which is, in turn, influenced by degeneration of the nervous system and greater susceptibility to infection (Crumbie 2002a). Amputation of an affected limb results in further alteration of physical, psychological and social functioning. Clearly, the disabling effects of chronic conditions are not merely confined to features of the disease process, but are compounded by the consequences of treatment used.

Efforts to adjust to the reduction in activity, imposed by chronic disease, are complicated by the multiplication of symptoms and the increasing disability that results (Strauss et al 1984). For example, chronic pain not only inhibits movement but also correlates with atrophy in the brain's prefrontal cortex and impairs decision making (Melton 2004). To be confronted with the inevitability of deterioration is a substantial psychological challenge to individuals and their carers, acting as an additional source of stress. Individuals fearing the prospect of total disability might regard any development of their disease with anxiety and anger, directing these emotions towards close associates and health workers. Carers are confronted with difficulties in dealing with this, at the same time as they face increased demands placed on them to compensate for the individual's failing abilities. These demands may include seeking information about services, learning new skills and accommodating more physical activity when managing care. This has a considerable impact because care giving is carried out in the context of other competing demands, such as employment, marriage and child rearing (Bull & Jervis 1997).

Health care professionals can be perceived by individuals as being incapable of resolving certain problems or, in the case of problems resulting from treatment, actually being responsible for them. This has obvious implications for the quality of nurse–patient relationships, which in order to be genuinely therapeutic must be characterised by mutual trust and cooperation.

Chronic diseases are disproportionately intrusive

A significant aspect of living with a chronic illness is the 'daily grind' of monitoring and managing its features (Locker 2003). Such work is unrewarding, unrelenting and

inescapable. As one person with chronic fatigue syndrome (CFS) explained: 'For one wonderful moment when you wake up you forget. But there it is, again. It's the hardest work I've ever done and there's no time off'. This prompts a fundamental shift from the self and life that 'used to be' towards recognition and acceptance of a 'new normal' (Harpam 1997, Fennell 2003). Adaptation is central to wellness but is far from straightforward, particularly because 'good adaptation' is judged by others (Radley 1994). The emotional burden involved can be added to by shame and guilt at failing to recover or adjust as quickly as expected. Individuals can feel responsible for not doing better, in the light of images of chronically ill people as 'brave', with an innate capacity to tolerate adversity, or assumptions that they must simply adjust to the obvious (LeMaistre 1996). Pressure can be added where media portrayals of triumph over tragedy create models of behaviour which individuals feel they must live up to. For example, a man with lymphatic cancer recalled: 'Everything tells you to think positively. So, when the tumour came back I thought it was my fault. I hadn't thought positively enough'.

In episodes of acute illness it is both feasible and acceptable to gain temporary exemption from normal social obligations. This is not always possible, however, for those with chronic illness who must restructure daily life such that persistent features of their condition and periods of crisis can be accommodated. It may be difficult for these people and their families to enjoy a sense of continuity, as their capacity to pursue various activities will vary unpredictably over time. It is unsurprising that individuals become sick and tired of feeling sick and tired (Donaghue & Siegel 2000). Parson's (1951) conceptualisation of the sick role makes sense of illness as a social state, but its applicability is questionable in long-term illness, since an obligation to recover is implied. The sick role does, however, facilitate access to helpful resources and chronically sick people are expected to adhere to medical advice in the same way as those who are acutely ill (Field & Kelly 2003).

Chronic illness often imposes changes to normal domestic routines to allow for physical limitations and requirements of treatment regimens. Structural alteration of accommodation may also be required to install equipment and reassign room space to allow access to household facilities. These adaptations, together with alterations in appearance and behaviour associated with the long-term disease, will impact on other members of the household and affect familial relationships.

Chronic illness will also have economic implications. Even if not totally disabled, continued employment might be impossible because of the demands which the condition and its treatment make upon time, strength and stamina. Difficulty in adhering to work schedules and periods of absence during relapses can give the impression that chronically ill people are unreliable. Individuals may be assigned to less demanding positions and be overlooked for promotion because they are perceived to have a poor prognosis and are thus not deserving of the investment of training for more advanced work (Taylor 1995). Gaining employment may be problematic in itself; the prospect of incapacity and variable function may be seen by the employer to represent risk and hidden costs, including lost production and redeployment of other workers. Despite there being advantages in disclosing health status to an employer, it is understandable that people with chronic illness are often reluctant to do so because it affects their workplace identity. For example, a woman with multiple sclerosis maintained her silence for 8 years to avoid being 'stuck with the MS label, to become Sukie with MS as opposed to just Sukie' (Freeman 2002). Disclosure can also lead to an individual's competence being doubted. This diminishes self-esteem, giving rise to guilt and fear of letting others down and can result in chronically ill people sensing that they have to work harder than others to prove their worth.

Chronic illness affects the individual's ability to participate in social activities. The degree to which these are impeded will depend to some extent on whether the individual has learned to deal with the features of the disease process. For example, fear of frequent episodes of loose stools and odour are major social concerns for people with ulcerative colitis (Robinson 2004). The management of these features is particularly difficult in settings where toilet facilities are not readily available. Individuals may respond either by withdrawing from interaction or by planning outings carefully, using known routes and venues with accessible lavatories. Anxiety regarding the accidental emission of diarrhoea during sexual encounters can be met by avoiding intimate relationships, instituting strategies such as keeping an unobtrusive towel at the bedside or having spontaneous sexual encounters to avoid anticipatory preoccupation with the disorder.

The nature of chronic disease is such that it impinges on domestic, work-related and recreational activities. This is liable to result in involuntary social isolation affecting individuals and their close associates (Biordi 1998). People who are chronically ill require sustained support to manage their conditions and treatment regimens. Their families' daily activities are often centred around meeting these needs, and it may no longer be possible for them to pursue interests which they once enjoyed together. Providing long-term care changes relationships and compels those who have acquired reluctantly an unexpected caring role to make fundamental changes to their entire way of life.

Chronic diseases require a wide variety of ancillary services

There is an abundance of statutory and voluntary agencies in the UK concerned with the care and support of people with long-term illness. Statutory support is provided in the main by the National Health Service, the Department of Work and Pensions and the local authority social services. Care within institutional and domestic settings requires the close collaboration of a wide range of representatives of these agencies, such as nurses, therapists, doctors, social workers, civil service employees and home care workers. This collaboration can be difficult to achieve, given the number and variety of staff necessary to meet an individual's needs, and problems are sometimes compounded by poor interagency coordination and frequent transfers between care settings (Howkins 1995).

The definitions adopted by formal agencies to categorise individuals and allocate resources are not generally compatible with the experience of chronically ill people. For

example, assessment to determine eligibility for benefits and support services may fail to acknowledge variation in function during episodes of crisis; if the assessment is performed during a period of relative wellness, the type and level of support required at other times may not be apparent to the assessor.

Some people do not obtain support because they perceive the organisation of services to be complex or somewhat arbitrary. Ineffective communication presents an obstacle when individuals who are entitled to benefits lack information or have difficulty interpreting the information they are given. In addition, some families may be reluctant to seek or accept help because to do so would be at variance with their cultural values regarding responsibility and self-sufficiency.

Systems for the organisation and provision of care are complex, with variation between UK constituent countries. Cross-party commitment to the concept of community care since the 1960s has been formalised in legislation, such as the National Health Service and Community Care Act 1990 (DH 1990) and Community Care (Direct Payments) Act 1996 (HMSO 1997), and is a feature of the government's modernisation agenda. The latter also aims to improve interagency working so that integrated health and social care is user focused (DH 1997b, 1998a,b, 2001c). This reflects trends towards casting the service user as consumer (Alabaster et al 2000). Key reforms implemented from the 1990s include splitting the commissioning and provision of care and dominance of the market by the private and voluntary sectors. Related initiatives, including the introduction of unified health and social assessments, have enabled the development of creative and flexible care packages. The responses of many agencies remain ineffective, however, due to differences in priorities and practices, as exemplified in the differential provision of 'free' nursing and personal care in care home and domestic settings in the UK constituent countries. Funding of health and social care are devolved functions but varying degrees of devolution have resulted in diverse governmental responses (Scottish Executive 2001a, Northern Ireland Assembly 2002, Age Concern England 2003, Long-term Care Commission 2003, Welsh Assembly Government 2003).

Differing priorities and practices have significant implications for quality of life. For example, giving priority to people who have complex needs and are at risk of admission to residential care means withdrawing low-level support from others who, in turn, become more dependent on their informal carers. An emphasis on personal or physical care also results in classifying social needs as lesser wants (Means et al 2003). Carers are entitled to a separate assessment of their needs but this may not occur, as many partners and family members take caring as the natural order of things and it is expected that they have assumed the role willingly (DH 1997a). People with long-term illness and their families may not, therefore, receive the kind of help which they believe would be of greatest benefit to them (Pitkeathley 1991, Finkelstein & Stuart 1996).

Chronic illness is expensive

The direct and indirect costs of chronic illness are high. While expensive technological intervention is not always required, support is ongoing and increases in intensity as the individual's condition progresses. Chronically ill people make repeated contact with health agencies to monitor the effectiveness of treatment and rehabilitation programmes. This involves regular encounters with members of primary and secondary health care teams. Individuals are likely to experience multiple pathology as a result of systemic and degenerative disease and, since contemporary medical services are organised by area of specialisation, they need to attend a variety of clinics. Someone with diabetes mellitus, for example, may require referral to a physician in renal medicine, an ophthalmologist and a vascular surgeon.

The long-term prescription of medication to control or palliate features of chronic conditions has significant financial and ethical implications. Rationing of health care has become more explicit in the face of growing demand and the increased availability of treatment options, coupled with pressure to reduce expenditure (British Medical Association 2002, Ham & Robert 2003). Limited resources mean that decisions regarding treatment options are concerned with identifying the potential benefit to the individual and justifying whether such expenditure on a single patient is warranted. For example, lipid-lowering drugs used to reduce the risk of dying from coronary artery disease in men with hypercholesterolaemia at the beginning of the 21st century cost £162 500 per life saved (Ferner & Mann 2001).

Treatment intended to inhibit the development of underlying disease, but which does not necessarily cure or save lives, can also be costly. For example, individuals with ambulatory relapse-remitting multiple sclerosis, i.e. a pattern of disease characterised by at least two attacks of neurological dysfunction over the preceding 2-year period, followed by complete or incomplete recovery, can be prescribed interferon beta-1a or b, to be administered by injection (Kita & Goodkin 2000, Sweetman 2002). This may decrease the frequency of relapses and prevent the accumulation of neurological damage, although evidence that it improves clinical disability is equivocal (Weiner et al 1997, Rice et al 2003). Treatment in the UK is prescribed to between 2 and 5% of suitable patients (Coles 2001) at a net annual cost at the time of writing of £7260–£12 068 per person (Joint Formulary Committee 2003). Clinical governance should aid people with chronic illness by eradicating inequalities in care and raising standards, though frameworks and working practices differ among UK countries (Ward 2002). The Healthcare Commission carries out clinical governance reviews in England and Wales which consider the implementation of NSFs and guidance from the National Institute for Clinical Excellence (NICE). Such guidance is provided in Scotland by NHS Quality Improvement Scotland and the Scottish Intercollegiate Guidelines Network, while the Northern Irish approach is under development. NICE recommendations are intended to inform professionals' decisions without overriding patients' individual circumstances and the Institute states that people should not be denied access to treatments while these are undergoing appraisal (NICE 2003). The extended time taken to appraise beta-interferon use in multiple sclerosis and provisional opinion that prescription should not be offered to new patients has, however, been criticised. Delays in implementing a UK-wide risk-sharing

scheme, whereby a cohort of patients is monitored and manufacturers paid less should the drugs fail to meet expectations, resulted in prolonging the 'postcode lottery' and in frustrating individuals who feared that progression of their symptoms in the meantime would disqualify them from receiving treatment (MS Society 2003). Balancing the interests of stakeholders, including doctors, the pharmaceutical industry and self-help groups lobbying for access to treatment is a complex process.

Additional medications may need to be introduced to the regimen as illnesses evolve and to compensate for side-effects of treatment or medication already prescribed. Changes in the treatment programme may be initiated by episodes of crisis. This, and the increased use of support services during such times, is a source of considerable expense.

Repeated periods of admission for acute hospital care may be necessary to achieve management of crises. Interdisciplinary involvement is essential in view of the effect that chronic illness has on all aspects of the individual's life. Cost containment in health care has led to a reduction in the length of stay in acute care hospitals; however, the presence of acute illness superimposed on a chronic condition inevitably results in a longer stay (Daly 1993).

The cost of chronic illness in comparison with that of acute illness is very high in respect of lost employment, reliance on state benefits and social exclusion.

32.7 Where resources are limited, it could be argued that efforts should be directed towards patients for whom improvement can be assured rather than those who are chronically ill or disabled (Hinsliff 2004). Why should patients with a chronic illness be given equal consideration?

For further exploration of related ethical issues, see Thompson et al (2000).

A FRAMEWORK FOR UNDERSTANDING THE EXPERIENCE OF CHRONIC ILLNESS

The features of chronic illness detailed above are reflected in the framework presented by Strauss et al (1984) for understanding the experience of ongoing ill health. This framework is built around the five components outlined in the following.

Key problems

Any disease has the potential to create multiple problems for individuals and these are liable not only to disrupt routine activities but also to lead to social isolation and attendant psychological and familial difficulties. For example, people with multiple sclerosis and their associates may have difficulty adjusting to the effects of variation in ability and fatigue experienced. It can be difficult for them to make firm arrangements to attend social gatherings, and friends may eventually hesitate to extend invitations when the affected individual withdraws repeatedly from events due to fatigue. Family members may begin to experience regret and resentment as outings and social activities are curtailed.

Basic strategies

Patients and their associates need to develop a repertoire of methods or techniques for overcoming key problems. For instance, individuals with diabetes mellitus can learn to adjust their behaviour and treatment regimen when attending social occasions where food and drink are offered. Their selection of type and quantity of food may be guided by their treatment regimen, rather than purely by desire. If they do not wish to bring their condition to the attention of others at this time, they might avoid alcoholic drinks on the pretext of wanting to 'keep a clear head'. Conversely, they may choose to amend the timing and dosage of insulin injections to allow for indulgence in the food and drink which they actually prefer. Creative non-adherence (Taylor 1995) to treatment schedules or 'intelligent cheating' (Pressly 1995) is common in chronic illness and can result in errors; however, such mindful adaptation reflects individuals' assertion of control and successful renegotiation of life situations in their own context.

Agents

Employing basic strategies can require the assistance of family members, friends, acquaintances or strangers. These 'agents' may function in various ways, for example by assisting in the maintenance of a treatment regimen or protecting the individual from harmful effects of the disorder. Someone who has epilepsy may need help from colleagues such that, should an unexpected seizure occur in the workplace, the individual is eased to the ground and away from dangerous machinery (see Ch. 9).

Organisational or family arrangements

The strategies adopted to address key problems require the coordinated effort of the individual and the agents involved. The establishment and maintenance of arrangements rely on trust, skilled interaction, sufficient resources and realistic negotiation of the roles, responsibilities and expectations of all concerned. Someone who is housebound due to long-standing arthritis may be able to enlist family members and neighbours to do shopping, pick up drug prescriptions and collect benefit monies. The continued success of such arrangements will depend on each person involved having a clear appreciation of what actually is required, as well as an understanding of their own contribution to the well-being of the individual, in the context of the help given by others.

Consequences

The strategies and arrangements adopted by chronically ill people and their associates may be successful in resolving key problems but can have implications for the agents taking part, thus creating further problems. For example, the paced schedule of activities that enables individuals with chronic obstructive pulmonary disease (COPD) to accommodate oxygen deprivation and recovery times between tasks may present little opportunity for flexibility. Events such as a visit to the hairdresser's can disrupt well-established routines, with implications for both the individual and carer alike. Both parties are also faced with developing a lifestyle structured by the demands of the presenting condition, within which spontaneity has no place (see Research Abstract 32.1). Adopting the roles of carer and cared for also have an inevitable impact on relationships, changing established patterns of engagement. Marriott's (2003) insight into the all-consuming consequences of caring

RESEARCH ABSTRACT 32.1

Carers of the chronically ill

The Office for National Statistics (2002) used data obtained from the General Household Survey (GHS) to explore trends in caring and revealed the following:

- 21% of households contained a carer
- Women were more likely to be carers than men — 18% compared with 14%
- 8% of 16–29 year olds have caring responsibilities, compared with 24% of 45–64 year olds and 16% of those aged 65 years and above
- Almost a third of married or co-habiting women aged 45–64 were carers
- A third of carers were the only support for the main person cared for
- 21% had been caring for someone for at least 10 years
- 28% of carers spent at least 20 hours a week on their caring responsibilities and 1% 50 hours or more
- Half of those spending 20 hours or more a week on caring were looking after someone needing constant attention and who could not be left for a few hours
- 35% of those devoting at least 20 hours per week to caring reported a limiting long-standing illness, rising to 47% among older carers
- 39% reported that their physical or mental health had been affected as a result of caring
- 41% of people being cared for received visits from health, social and voluntary services; those living with their carers were less likely to receive services than those living in different households.

for a spouse with Huntington's disease and the 'emotional whirlpool' entered into, is helpful in coming to understand the stresses imposed; for example, the conflict experienced when carers sense that their lives are no longer their own but feel that it is selfish to resent this.

The elements in Research Abstract 32.1 provide a means of thinking about the experience of chronic illness from the perspective of the people concerned. Living with chronic illness is influenced by a range of interacting physical, psychosocial and spiritual elements. It is only through exploring these that the meaning for each individual can be truly appreciated.

For more information about the social psychology of chronic illness, see Livneh & Antonrak (1997).

32.8 'Chronic illness is a lonely experience. It makes for a sense of uniqueness that often leads to a feeling of separateness and alienation. It tends to foster a perception that you are in a world of your own and cannot join the ranks of mainstream culture' (Klein & Landau 1992). Refer to this, or any self-help guide or website for people with a chronic illness. Has this helped you to understand the experience of living with a chronic condition? If so, in what way? Why is the use of self-help groups of particular value to people with chronic illness?

NURSING INTERVENTION

Developments in the location and organisation of care

Nurses encounter adults with chronic illness in a range of community and institutional settings including the person's own home, care homes and hospitals providing acute, intermediate or continuing care. Statutory and other agencies have responded to the shift in provision to community care by attempting to meet rising demand and provide user-focused services, while accounting for the shortcomings of long-term institutionalisation (Benjamin 1997). Ironically, the payment of care home fees through social security benefits favoured institutional care (Leathard 2000). Domiciliary care is viewed as resource effective, while also being preferable for and preferred by individuals.

People with chronic illness have diverse needs which sometimes cross, or fall between, traditional service boundaries, resulting in inappropriate and fragmented provision. Moving into long-term care is generally seen as the last resort for people with chronic illness but can come as a relief where, for example, an inflexible care package has been in place. Nurses have an important role in supporting individuals and their carers in considering care options, adjusting to new environments, grieving for their past life and constructing a future (Jarrett 2003). The quality of daily life while in long-term care will depend upon the extent to which staff recognise residents' adult status, enable them to exercise choice in their activities, avoid socialised dependency and help them to preserve links with the wider social world. All of this should be aided by the introduction of standards for care homes (DH 2001d, Scottish Executive 2001b, Welsh Assembly Government 2004) which are, arguably, more stringent than those applied to statutory agencies. Regional anomalies regarding the nature of nursing care and 'postcode funding' have led to delayed admissions, care home fees rising to compensate for shortfalls and the closure of some establishments.

Trends in service provision mean that nurses are more likely to encounter chronically ill people who are living in their own homes. Community nursing is an essential component of home care and visits can continue over a period of years in this context. Carers' needs have not always been a focus of nursing intervention; however, developments favouring partnership may change this and result in nurses acting as co-experts with the carers. In addition, NHS reforms are diverting resources towards primary care and nurses' involvement in primary care groups/trusts (PCGs/ PCTs), or community health partnerships (CHPs) in Scotland, provides a platform for their promotion of the worth of working with family units in this setting (McClure 2001).

Acute hospital care occurs in relation to the establishment of diagnoses, periods of crisis during which features of the illness are exacerbated and when the disease process necessitates stabilisation or palliation. Such contact is therefore intermittent and recurrent. It should also be borne in mind that hospitalisation may result from the development of unrelated health problems. Disease management in the form of integrated care pathways has particular relevance in chronic illness because it presents a structured

means of planning and delivering coordinated, patient-oriented care as part of a sequential journey, instead of as a series of separate episodes. There is, however, a danger that rigid adherence to protocols may actually prevent individuals having a say in their treatment (Hunter 2000).

The foundation for the nursing role

While the contribution of health professionals is crucial during diagnosis, in relapses and in the establishment of treatment regimens, individuals and their associates are primarily responsible for handling the condition on a daily basis.

A significant minority of chronically ill people are unable to function independently and responsibility for their support frequently rests with family members. The nursing role is therefore far from restricted to the delivery of direct care. For example, the cognitive and physical capacities of individuals and their carers to develop required practices must first be assessed. It is also vital to ensure that the information that they need to implement care regimens at home has been successfully communicated (see Case History 32.4). In pursuing the goal of optimum self-management, the nurse must also be prepared to adopt a flexible approach to care. During some phases of long-term illness it may be necessary to act for patients and carers, while on other occasions support will be focused on monitoring the performance of self-care activities, imparting knowledge, teaching practical skills or giving emotional support to facilitate coping behaviour. This means that nurses need to be committed to forming and maintaining collaborative, empowering relationships (McWilliam et al 1997, Crumbie 2002b).

The notion of empowerment has particular value for people living with chronic illness; however, they are likely to have lost power, control and confidence in their own abilities, through the psychological effects of the illness or institutionalisation. Empowerment is an enabling process that enhances personal control and facilitates the process of recreating self. This strategy will, however, present difficulties for those nurses who feel that sharing information and skill constitutes a threat to their control of the caring situation or somehow undermines their professional role.

32.9 After reading Case History 32.4, how do you think communication could have been enhanced to prevent the problems which occurred when Mr P was learning about his diabetes? The community nurse recognised the need to respond to Mr P's difficulties with language by involving a link worker. A number of different people could have been asked to perform this role in the hospital setting:

(a) a young female family member
(b) any member of the local South Asian community
(c) a member of the hospital catering staff who speaks the same language as Mr P
(d) a community link worker employed for this purpose on a sessional basis.

What are the advantages and disadvantages of using each of the above as an interpreter? You may like to think about issues relating to culture, age, gender, varieties of Asian language, availability and confidentiality.

CASE HISTORY 32.4

Mr P

Mr P is 62 years old and lives with his wife and their son V in a suburban area of a large city. The family own and manage a successful video rental business and are active within the local South Asian community.

Mr P usually enjoys good health but had been feeling unwell during recent months, experiencing frequency of micturition and an increased thirst. He was eventually persuaded to visit his general practitioner and was admitted to hospital on the GP's advice. A diagnosis of diabetes mellitus was made and medical staff decided that control could be achieved through a combination of prescribed oral hypoglycaemic agents and dietary management (see Ch. 5, part 2). In the days which followed, stabilisation of blood glucose levels was achieved. Nursing staff and the ward dietitian spent time with Mr P explaining the nature of his condition and his future role in its management. He seemed to listen carefully to what was said but did not ask questions of the staff. It was believed that this was an expression of his quiet and reserved nature which had been in evidence since admission. The dietitian was anxious to speak to Mrs P about her husband's dietary requirements, but the latter was not able to visit the hospital during office hours. Mr P said that he had discussed his condition with his wife and was confident that he would be able to cope after discharge. He was very much looking forward to returning home.

The responsibility for Mr P's nursing care was transferred to staff outside the hospital by way of the community liaison nurse. When the community nurse, N, visited to assess the level of support which would be needed, she was greeted by V. He told her that both he and his mother were concerned about Mr P, who now appeared to be little better than he had been before admission to hospital. N checked Mr P's blood glucose level and found it to be higher than expected. In an attempt to discover the likely cause of this problem she asked Mr and Mrs P what they knew of the condition and to describe the treatment regimen.

It soon became clear that Mr P had misunderstood the information given to him in the hospital. He felt that the staff had been kind and concerned for his welfare, but he had observed them to be busy and did not wish to detain them unnecessarily by asking what he feared were trivial questions. He also confided that he was a little deaf and could not always hear what was said to him. The nurses had spoken quietly and quickly but Mr P had been too embarrassed to ask them to repeat all the information given. Although his working knowledge of English is good, Mr P uses this as his second language in daily life. Unfamiliar vocabulary presented during his admission had not enhanced communication with hospital staff. N discovered that Mr P believed he should reduce only the amount of sugar in his diet. Apart from this his food intake was unaltered, being predominantly foods high in fat and with a high glycaemic index. N recognised that the specific support she could give was limited and decided to offer the family contact with a community link worker and Diabetes Specialist Nurse.

The complexity of long-term illness and its impact on individual lifestyle and functioning have already been emphasised. It is all too easy for nurses to make assumptions about the problems experienced by individuals on the basis of medical diagnosis alone. There are additional implications arising from classifying people as 'chronically ill'. The overuse of this label can give the impression of a homogeneous group for whom care can be planned unilaterally.

Using frameworks and models to guide practice

The case has already been made that, although a variety of characteristics are shared by people with chronic illness, there is considerable diversity in the way ongoing ill-health affects individuals. It is therefore advantageous to adopt an approach to nursing which explicitly recognises the uniqueness of each individual and enables the totality of their situation to be understood. The use of a formalised framework to guide practice is also valuable in that it presents a systematic prescription for action and encompasses a sound theoretical base.

A variety of models has been constructed to articulate beliefs about the essential components of nursing practice and the underpinning concepts and theories. These conceptual models are intended to provide a descriptive representation of the reality of practice and consideration of the concepts of person, environment, health and nursing is generally regarded as central to them (Fawcett 2000). The selection of a particular model largely depends on the extent to which it reflects the nursing team's own personal values and what they perceive their work goals to be. Several possible advantages can be gained when a team agrees as to their model of choice; not least among these are consistency and continuity of nursing action.

While a number of models have relevance for nursing adults with chronic illness, the three models discussed below may be of particular interest to nurses entering this field of care.

Orem's self-care model

It is likely that the self-care deficit nursing theory (SCDNT) put forward by Orem (2001) would be favoured by nurses who consider its emphasis on client autonomy and motivation to be consistent with the aim of helping individuals to accept responsibility for themselves. This might seem appropriate, given the role chronically ill people play in managing their condition. Its concern with independent action is, however, more complex than face value suggests. The concept of self-care must be seen in the context of the model's other components, in order for the underlying theory to be understood and the whole operationalised.

Self-care is the contribution people make to their own continued existence and involves practising activities to maintain health and well-being (Gast 1996). Nurses assist patients and their associates to achieve self-care, taking individual ability and need into account. Following negotiation with all parties concerned, care is organised in terms of one of three nursing systems. These are wholly compensatory, i.e. the nurse may perform activities for the individual; partly compensatory, i.e. the nurse may assist the individual in carrying out shared activities; or supportive–educative, i.e. the nurse may help the individual to develop the ability to act on their own behalf. The decision to use a nursing system or a combination of systems is not static but changes in response to patient need over time.

Orem's model therefore presents some advantages for the care of chronically ill people in a variety of settings. The importance of partnership with both patient and carers is acknowledged and their involvement in planning nursing interventions considered essential. Attention is given to the notion that they are active in learning to live with the effects of the condition and it is assumed that they are motivated to do so. The variation in nursing activity necessary to address the range of problems likely to be experienced during the course of long-term illness is also accounted for.

Roy's adaptation model

Another model, which may be applied when nursing chronically ill individuals, is that devised by Roy (Roy & Andrews 1999). This takes the view that human behaviour is influenced by an interrelated set of biological, psychological and social systems. Each of these systems is directed towards achieving a state of relative balance which will, as far as possible, promote regularity of function and the ability of each person to adapt positively to environmental stimuli. Roy identifies three types of stimuli to which individuals are exposed: focal, contextual and residual. A focal stimulus is something which has an immediate effect on the person; a contextual stimulus is a contributory circumstance; and a residual stimulus arises from beliefs or attitudes relating to past experiences. Maladaption occurs where the effect of any stimulus exceeds someone's capacity to make a positive response. This results in a threat to continued health and well-being. Roy's model accepts that individuals possess a unique capacity to deal with stimuli, such that people react differently when faced with the same events. The ability to adapt thus varies from person to person.

Nursing intervention is needed when an individual's usual methods of coping with stressors prove ineffective. The nursing role centres on promoting adaptation, both in maintaining health and during periods of illness, and is concerned with the manipulation of stimuli so that patients are able to respond in a positive way. This model also has value for care in long-term illness in a variety of settings. Its focus is congruent with the belief that it is desirable for people to develop the ability to live with the effects of their condition and that they should collaborate in their care. Nurses are encouraged to consider factors which influence the individual's total situation, not merely the immediate problems confronting the person. In this way it is possible for nurses to appreciate the effects of the disorder on the patient's personal functioning over time and how the person feels about this. The model assists nurses in identifying successful coping mechanisms which have been used in the past and elements likely to impede future adaptation, so that intervention may be planned with realisable goals. Care can therefore be tailored in relation to individual resources.

The Roper–Logan–Tierney (RLT) model

A more detailed examination will be made here of the model for nursing put forward by Roper et al (2000). This model has been widely adopted in the UK and is thus one with which many nurses are familiar. In addition, it is based on ideas drawn directly from practice and articulated in terms which are readily understood. This representation of the reality of practice is such that the model can be identified as being 'for real nurses, nursing real people' (Newton 1991). Examples of how it may be applied have already been given in earlier chapters.

The authors based their model for nursing on a model for living, demonstrating that health status and lifestyle are closely related. An awareness of this relationship helps nurses to perceive that their role is broadly concerned with health maintenance as well as being disease orientated. Roper et al's portrayal of an uncomplicated view of nursing is a deliberate attempt to provide a flexible framework which can be applied across settings. The stated purpose of this model is to equip practitioners with a means to plan and deliver individualised care. This refers mainly to nurse-initiated activity, but acknowledges the contribution of other members of the health care team. The model also offers a method of thinking about the beliefs, aims and practice of nursing in general terms.

The RLT model for nursing comprises the following five components:

- the activities of living (ALs)
- life span
- the dependence/independence continuum
- factors influencing the ALs
- individualising nursing.

These will now be considered in turn with reference to the care of adults with chronic illness.

Activities of living Roper et al (2000) identified 12 activities of living as follows:

- maintaining a safe environment
- communicating
- breathing
- eating and drinking
- eliminating
- personal cleansing and dressing
- controlling body temperature
- mobilising
- working and playing
- expressing sexuality
- sleeping
- dying.

Living can be described as a fusion of the ALs, and which individuals experience and carry out differently (Holland et al 2003). Although the ALs present a framework for assessment when applying the model to practice, there is a danger that some nurses may use it simply as a 12-point checklist to guide this and subsequent aspects of care. The model's other dimensions may be overlooked as a result (Price 1991) and this would both restrict its usefulness and yield a limited understanding of the needs of patients and their families.

The focus of nursing intervention in this model is on assisting individuals in the prevention, resolution and management of problems identified in relation to the ALs. Problems are defined as actual or potential, as nurses are concerned not only with problems which actually exist but also with preventing the development of others.

The performance of any of the ALs requires the co-ordination of a complex pattern of behaviour. The ability to communicate, for example, relies on a number of skills, including the reception and interpretation of information and the formulation and transmission of appropriate verbal and non-verbal responses. This is influenced by many variables, such as the efficiency of physiological and psychological functions. There is thus considerable scope for errors to occur and it is likely that people with chronic illness will experience a wide range of associated problems. For instance, some individuals may not understand or express ideas verbally following a stroke, while others find no difficulty in this area but are unable to articulate words clearly (see Ch. 9). In either case, individuals will be limited in their ability to make their thoughts and feelings known and this will cause frustration for all concerned.

Speech deterioration also takes place in, for example, Parkinson's disease (see Ch. 9). In this condition, communication may be further inhibited by memory impairment and loss of facial expression. The latter provides the listener with poor feedback and results in the absence of important non-verbal cues. Alteration in physical appearance can also present a barrier to communication. People may be embarrassed when they encounter disfigurement and avoid casual social contact with someone whose appearance disturbs them. In addition, they may make unfair assumptions about the individual's mental state. Wheelchair users often comment that people tend to speak over their heads to anyone who happens to be accompanying them, even when it would be more appropriate for them to be addressed directly.

It is common for people with chronic illness to find that disruption in the performance of one AL leads to difficulty in the performance of others. For instance, someone who has COPD and experiences shortness of breath may discover that their capacity to walk, eat and drink, communicate and attend to personal hygiene is also compromised. The restriction in mobility associated with arthritis can also interfere with the performance of workplace, domestic and recreational activities. For example, the purchase of food can prove problematic due to an inability to carry shopping, and the preparation of meals may be made difficult by reduced physical dexterity.

Life span This component of the model represents the passage through life from conception to death. The progression along the life span is marked by continual change as the individual moves through a series of developmental stages, each of which is associated with the expression of different levels of physical, cognitive and social function. As mentioned previously, adulthood is a period generally characterised by self-reliance which centres around occupational and family interests. There is, of course, great diversity in the lifestyle and behaviour exhibited by individuals during this life stage. Chronological age does not give the nurse sufficient information to appreciate the likely impact of chronic illness. Rather, the nurse will need to gain an understanding of the developmental tasks which the individual has already achieved, those aspired to and the value placed on them by the individual and by those close to them.

Obtaining this kind of information would reveal the existence of actual or potential problems requiring nursing intervention. For example, a woman who has multiple sclerosis (MS) and wishes to become pregnant, may have to confront issues such as sexual dysfunction, the impact of discontinuing disease-modifying or other medication due to her pregnancy, and whether her functional impairment

would present difficulties in meeting the needs of an infant. Once the nurse recognises this as a source of emotional distress it can be accounted for in the care planning process; for example, the woman's need for accurate, evidence-based information may be met by referral to an MS specialist nurse (Watkiss & Ward 2002).

The dependence/independence continuum This component acts as a reminder that individuals are not always able to perform each of the ALs independently (Holland et al 2003). Some people have yet to acquire the necessary skills or do not have the means to develop them, whilst others lose abilities which they once had, possibly as a result of illness or trauma.

No single measure reflects the capacity for independent function in all ALs, since it can be argued that few, if any, people are truly self-sufficient. In addition, the concepts of dependence and independence have meaning only when considered in relation to each other. For these reasons, any form of assessment will have a subjective bias which is determined by the nurse's interpretation of each individual's abilities in comparison with clinical, developmental and social norms (Newton 1991). For example, assumptions about the inevitability of universal deterioration with age and chronic illness need to be questioned. Health professionals must not fall into the trap of labelling or stereotyping older people. Take, for example, the case of a practice nurse performing an 'over 75 years' assessment of a frail woman who has chronic arthritis. Prior to the patient's arrival, the nurse assumed the encounter would focus on support and services for health needs. To her astonishment she found herself discussing the Open University's services for disabled students; her client was planning to gain a degree!

The interactive nature of the ALs was mentioned earlier with reference to the way difficulty in carrying out one activity can affect adversely the performance of others. This has implications for the maintenance of independent action in chronic illness. In recognition of this, it is essential that attention is paid to each of the ALs when assessing a patient's dependence/independence status.

Factors influencing the activities of living Individual differences can be identified in the way in which the ALs are performed, regardless of the point reached in the life span or the level of dependence held. Knowledge of five influential factors assists nurses in taking an holistic view of a patient's situation:

- biological
- psychological — incorporating intellectual and emotional factors
- sociocultural — incorporating spiritual, religious and ethical factors
- environmental
- politico-economic — incorporating legal factors.

These factors, acting singly or in combination, influence each of the ALs to some degree. It is not always easy to distinguish the influence of one group of factors from that of another since they are interrelated and share several areas of concern.

Consideration of these factors during assessment provides the basis for a deeper understanding of the cause of difficulties experienced by individuals as well as indicating likely outcomes. This has particular relevance for people with chronic illnesses given the timescales involved, the multiple effects of these disorders and the cycle of deterioration associated with them. For example, knowledge of normal anatomical structure and physiological function enables the nurse to appreciate the effects of disease processes. This is useful both in guiding immediate action to alleviate existing problems and in devising care to prevent the onset of anticipated complications. An exploration of psychological status will reveal what the individual comprehends about the condition. The capacity and motivation to acquire further information and develop the skills necessary for self-management can also be identified.

The behaviour exhibited in everyday life in relation to the promotion of health and the management of chronic illness has strong social and cultural determinants. The nurse should attempt to understand how the condition has affected the individual's accustomed roles and in what respect this has influenced relationships with others. A male manual worker who has disabling back pain, for instance, may perceive that his role as head of the family group is threatened when he is no longer able to continue employment and requires help from his partner to perform basic living activities.

Environmental factors such as noise, climate and atmospheric pollution can affect the performance of each of the ALs in protracted illness. People with COPD experience worsening of their symptoms during periods of poor air quality and find it difficult to obtain adequate sleep if their home is located in a noisy neighbourhood. The structure and layout of buildings in which activities are performed are also of relevance here. Someone who suffers from arthritis and lives in a top-floor flat without a lift may not be able to negotiate the stairs easily in order to leave the building. This would further reduce their mobility, limiting opportunities for social interaction and activities such as shopping for clothes and food. Access to health centres can be made difficult if they are sited at some distance from available public transport or situated on a steep incline. This may deter individuals from attending appointments and result in inadequate monitoring of treatment regimens and a lack of attention to some features of their illness. Admission to hospital is a source of anxiety to people for whom the environment is unfamiliar. The distance between facilities and the need to share bathing and sleeping accommodation may interfere with the individual's routine performance of a number of ALs.

The organisation of all public services is subject to political and economic influences. These factors therefore have a significant effect on the manner in which people conduct their daily lives. Despite the high direct and indirect costs of chronic illness (see p. 1081), it is not always given priority in resource allocation. This has implications for staffing levels and the provision of equipment, and hence for the level of support patients are offered as they strive to attain optimum functioning and independence. Poor resourcing has additional implications for individual lifestyles. If a chair of a suitable height cannot be obtained for someone who has arthritis, resulting in an inability to rise to a standing position, it will not be possible for the individual to exercise or get to the toilet independently.

Individualising nursing As noted previously, the way each person carries out the ALs is unique. Such individuality arises from the complex interaction between the components described above and is apparent in the frequency, location and timing of activities, rationale for the use of particular practices, and the knowledge, beliefs and attitudes of the person concerned. An appreciation of this provides the foundation for individualised nursing. The process of nursing is used as a vehicle to translate Roper et al's theory into practice and to systematise the delivery of care (Holland et al 2003).

APPLYING THE ROPER–LOGAN–TIERNEY MODEL USING THE NURSING PROCESS

Assessment

This stage of the nursing process is a dynamic and ongoing activity, rather than a single event associated with the first encounter between nurse and patient. In protracted illness, an initial assessment is important because it presents a structured method of data collection which will create a total picture of the individual and thus provide a baseline against which change can be measured (see Case History 32.5). It must be acknowledged, however, that in ongoing illness circumstances are seldom static and therefore continued assessment is essential.

Collection of data pertaining to biography, health and the ALs is needed to ensure nursing needs are assessed effectively. It is likely that these elements will be closely related in chronic illness; for example, the perception of the individual's health status which the individual and the carers have can shape the performance of some ALs. Efforts should therefore be made to obtain a comprehensive assessment at any stage of the nurse–patient relationship.

A number of issues warrant attention during the assessment of chronically ill people, regardless of the setting concerned. Some are related directly to the disease process and include the type and duration of the presenting condition, methods already used for managing symptoms and the extent to which strategies have been developed to cope with the uncertainty generated. Details of the treatment regimen should also be collected to help the nurse ascertain how the individual deals with incorporating this into daily life.

Review of biographical data provides an opportunity for nurses to explore the individual's previous lifestyle and to appreciate the changes imposed by long-term illness in this context. The impact of these changes should be reviewed with reference to the ALs while the other components of the model are borne in mind. It is suggested that all the activities should be considered so that for each individual their specific relevance can be established and relationships between them identified. For example, some people may be concerned that their condition hastens the prospect of dying, while others may instead express profound grief at the loss of social function which has resulted from the gradual relinquishment of personal and occupational roles.

The Roper, Logan and Tierney model (2000) prompts nurses to pay attention to the individual's abilities as well as disabilities in carrying out the ALs through reference to the dependence/independence continuum. Any equipment used to assist independence can be identified and the involvement of support services and carers can be explored. This part of the assessment may well help to determine whether the individual has a realistic idea of personal abilities.

Although much of the data required for assessment may be obtained from the patient, other sources of information must not be ignored. The views of both formal and informal carers should be elicited to build up a more detailed impression of behaviour and events. For example, when a man with motor neurone disease (MND) is admitted to hospital for respite care, a community nurse might communicate an observation that during recent months there has been a marked deterioration in the relationship between

CASE HISTORY 32.5

H

H is a 19-year-old nursing student who was diagnosed in early adolescence as having epilepsy. Since leaving home to take up his studies, H has become more acutely aware that he is in some way 'different' from other people. Although realising the importance of informing teaching and placement staff of his condition, should any seizures occur whilst he is working with equipment or patients, H feels as if he is introducing himself as an epileptic first and an individual second. He believes that people are more likely to remember him by his diagnosis rather than his personal qualities.

H's epilepsy had been well controlled by prescribed medication but recently he has become tired, vague and forgetful. He has experienced seizures in the student residences and in the hospital canteen and feels angry that he seems to be losing control of himself.

Although H's medication was changed following a visit to the outpatient department, the seizures have continued. Their onset is unpredictable and H finds that he is increasingly anxious about the uncertainty of his situation. He spends much of his time wondering when the next seizure will occur. He has not taken sick leave because he fears that this would detract from his image, which he considers to be already tarnished by his condition.

H has stopped riding his bicycle and limits his excursions to journeys within a small radius of the hospital campus. His friends do not seem to understand this change in behaviour. H had always been the first to suggest visits to the pubs and clubs in the city centre. They respond by going out without him and suggest that he is taking himself too seriously. H feels isolated and is annoyed by having to think before doing anything.

When he next visits the outpatient department H's unstable condition results in admission to hospital for monitoring of his seizures. U, H's allocated nurse, finds him to be aggressive during her initial assessment. As they talk, H tells her that he has always made every effort to take his medication at prescribed intervals and yet his difficulties persist. He thought that he had recognised the problems his current situation presents for his safety and had adjusted his activities accordingly. He now feels as though he were somehow being punished for this. H considers that he has done everything in his power to help himself and he expresses resentment towards hospital staff because he believes that they have failed him. H is also concerned that he will not be able to continue to cope with the demands of his studies. His sole ambition is to become a nurse. From what he says, U becomes aware that H has lost confidence and lacks self-esteem. Her assessment reveals that H's condition has more implications for his care than had at first been obvious.

the patient and his partner, although the couple strenuously deny that this has taken place. This could then be interpreted with reference to the features of MND and the key problems associated with this, and accounted for in the plan for care.

Planning

Care is planned to address the actual and potential problems identified in the course of assessment. The priority accorded to each problem depends upon the situation in which the individual is placed, though life-threatening problems assume precedence over those with a less immediate impact. Aside from this, priority setting in chronic illness should always be negotiated by the nurse, patient and main carer. An open discussion is useful in clarifying the meaning of each problem to the individual, determining how problems are related to each other and creating a shared awareness of difficulties. This helps to foster collaborative relationships and enhances the motivation of all concerned.

32.10 Sometimes a care plan has been well established prior to any nursing involvement at home or in hospital. In Case History 32.5, H had established his, with the previous help of his family. What might the implications of this be for H and his carers when the nurse as a professional carer becomes involved?

The aim of the care plan is to assist the patient in preventing, solving, alleviating or managing problems as far as is possible by using best practice. Goals are set for each actual and potential problem and appropriate activities devised to attain them. In chronic illness it is particularly important that goal-setting is realistic in terms of the individual's capacity to achieve such goals and is consistent with personal values and priorities. Both short- and long-term goals can be specified. However, given the instability of chronic illness, the selection of broad objectives for eventual achievement, such as acceptance of the condition and total self-management, might be inappropriate. It is preferable to simplify these by dividing them into a series of short-term goals so that progress can be achieved. This provides patients with a stimulus and sense of purpose (Holland et al 2003). Goals must also be expressed in measurable terms so that their attainment is obvious to patient and carer.

Care plans should describe prescribed nursing interventions and patient participation in detail. This offers a means of ensuring continuity of care and is of particular value in chronic illness; for example, it can help to prevent confusion when an individual is learning to develop a routine for renal dialysis in a domestic setting. It also articulates nursing's contribution to interdisciplinary planning, for instance with reference to integrated care pathways.

Implementation

The actions proposed in the care plan are realised in this phase of the nursing process. It is tempting to believe that the majority of nurses will experience little difficulty in this area because they are familiar with the idea of carrying out practical activities. While there may be some truth in this assumption, there is a tendency for ease of performance to conceal the depth of knowledge and the complex array of skills needed to meet the needs of chronically ill people effectively.

The delivery of care in relation to the ALs should be consistent with the way in which individuals usually behave, whether or not they normally require assistance. As in Orem's (2001) model, this may require the nurse to act for the patient, to supplement and develop the person's self-care capability or to help in the development of an understanding of the promotion of health. In order to determine the emphasis to be placed on each of these activities in a given situation, nurses must be sensitive to the individual's experience of chronic illness in the light of the factors considered in the first part of this chapter, while being aware of the possibilities of their nursing role.

The development of a therapeutic relationship with patients and their carers is a sound basis from which to work. It is important for nurses to gain their patients' trust and to recognise that, under normal circumstances, they have the responsibility for managing their daily lives and features of the disease process. In both hospital and domestic settings, nurses must be mindful of their role in enabling these individuals to retain control of their situation rather than expecting them to conform to alien norms and expectations.

In chronic illness, nursing intervention is far from restricted to the delivery of physical care, although the value of this should not be underestimated. Assisting another person in carrying out any activity, such as washing and dressing, requires more than the ability to reproduce simple practical actions. Nurses need to be prepared to help patients to express their needs and, if necessary, to adopt the role of advocate in liaising with formal and informal carers. The promotion of health and self-care capability requires an understanding of an individual's developmental level as well as of effective teaching techniques. This involves the use of refined communication skills, as does the role of counsellor and supporter to both the patient and the family.

When helping an individual to adapt to the presence of a protracted degenerative disease and the difficulties which this can cause, the nurse should present explanations honestly, yet positively, to foster realistic hope for the future. Non-verbal communication, principally that of touch, can be a helpful way to strengthen a caring relationship, providing this is culturally appropriate. Extending traditional nursing skills in relation to touch has significant benefits for people with chronic illness. The provision of massage, for example, can be of value in assisting them in dealing with stress, enhancing self-worth, achieving palliation and facilitating sympathetic reconnection with a body that has 'let them down' (Vickers 1996).

Evaluation

The effectiveness of nursing interventions can be judged by evaluating whether or not goals have been achieved. This phase of the nursing process lends meaning to those which precede it. The extent to which goals have been achieved should be measured objectively where possible. For example, successful self-management of insulin-dependent diabetes can be demonstrated by HbA1c measurement

and a pattern of stability in blood glucose readings (Coates & Boore 1995). It is also possible to identify movement on the dependence/independence continuum in response to teaching programmes or how patients cope with symptoms.

The evaluation of some aspects of care is, however, largely dependent on subjective data. For instance, it is difficult to measure to what extent a patient has adapted to the idea of having a chronic disease. Evaluation in this area could be guided instead by discussion with the individual and interpreting responses in terms of known elements, such as interest in the management of the condition or avoidance of discussion of the illness and its related problems.

The achievement of any goal for care relies on a variety of situational variables. It is therefore sometimes difficult to identify whether or not nursing strategies have been successful. The contribution of staff and material resources, efforts made by carers and the emotional status of the patient can all influence outcome. Nurses should be prepared to recognise that not all interventions they initiate will be effective for each individual, even if they have been used with success on previous occasions. This acts as a stimulus for reassessment, from which revised problem statements and new goals for care can be generated.

The importance of the nurse's own self-evaluation must not be forgotten. Caring for chronically ill people engenders considerable emotional labour for a number of reasons. Nurses sometimes find it difficult to work within the boundaries of their occupational role where over time relationships develop with individuals and their families. They can find it difficult to accept the inevitability of the patient's decline and to have a meaningful role where medicine deems that nothing more can be done (Alabaster 2003). It is also possible that they will identify with the patient, particularly if they occupy the same stage of the life span. Some nurses will be unable to form close protracted relationships with particular patients due to differences in personality, culture and attitude. Individual nurses must recognise that they cannot be all things to all people. Exposure to another's traumatic experience is a source of vicarious stress and the cumulative impact of working with chronic illness adds dimensions to this. Nurses should be supported in developing strategies to manage their own experience of sharing difficult journeys in often restrictive service environments and be offered genuine opportunities for clinical supervision and reflection (Rolfe et al 2001).

CONCLUSION

Nurses encounter people with chronic illnesses in a variety of settings. Effective care requires not only a full understanding of the patient's particular condition, but also a grounding in human and physical sciences so that the experiences of the individual and the family can be interpreted accurately. The nursing role is collaborative in nature and involves the expression of technological, clinical and interpersonal skills. In the long term, emphasis is placed on caring, a concept fundamental to nursing but which has often been overshadowed by other considerations. Working with individuals with chronic illnesses presents nurses with the opportunity to reaffirm their unique contribution to health care.

Finally, it is suggested that a good foundation for the development of an effective nursing role is for the nurse, and indeed the interdisciplinary health care team, to avoid thinking about the individual in need of intervention as a chronically ill person but, rather, as a person who happens to have a chronic illness.

INTRODUCTION

Palliative care is the term given to the approach adopted when cure is unlikely and it is expected that the patient will die in the foreseeable future. People of all ages die, in a range of settings — at home, in hospitals, in nursing homes and in hospices. They die of many different diseases. Some die suddenly and some die slowly. Palliative care has been developed to help those who are dying slowly or, as is often said, living with dying. Led by the hospice pioneers, this approach to care has a recent and inspiring history (Gamlin 2001, Davies & Seymour 2002, Doyle et al 2004).

Many reasons have been given as to why this specialty developed quickly and comprehensively in the UK in the late 20th century. Among the most notable are:

- the improvements in medical care, which have lengthened the time from diagnosis to death
- the promotion of honesty and openness between doctor, patient and family regarding a life-threatening diagnosis and prognosis
- the intolerance of the physical and mental suffering witnessed by those caring for patients with cancer.

The World Health Organization (WHO) provides a useful definition of palliative care (Sepulveda et al 2002):

> *Palliative care is an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychological and spiritual.*

The need to apply evidence-based knowledge to the care of people dying from diseases other than cancer has long been recognised. This important area of development in palliative care is detailed in a number of publications (Addington-Hall & Higginson 2001, Hockley & Clark 2002, Doyle et al 2004).

At its best, palliative care is teamwork where the patient and family are part of the interdisciplinary team. The care is individual, sensitive, non-judgemental, detailed and time-consuming. Patients and their families are met where they are, i.e. the health professional should have no preconceived ideas about them; there is no such being as a typical dying patient. It is a style of care in which the successful outcome has been redefined to mean a good death — a death that meets the expectations of the patient first and foremost, but also those of the family, close friends and the health professionals.

Delivering good palliative nursing care requires knowledge and a wide range of skills and it draws on life experience, self-awareness and motivation. It requires the nurse to understand and respect the roles of all the interdisciplinary team members and to work together with them to achieve a comprehensive and consistent approach to care. It is a daily challenge, which can be harrowing and stressful; however, the ultimate reward of facilitating a good death is very satisfying and worth striving for.

In the UK and many other countries, specialist palliative care nurses, sometimes known as Macmillan nurses, and specialist palliative care teams are well established in the community, in some hospitals and in the hospices. These

specialists provide expertise for patients and families with problems that are difficult to manage. They frequently advise colleagues from other areas of health care. The palliative approach to care, however, is the right of all patients, no matter what their diagnosis, lifestyle or age. It is essential, therefore, that all nurses develop knowledge and skills to offer this style of care.

In this chapter, a model for palliative care is presented. The model is flexible in that it can be adapted to suit each individual and their circumstances, and therefore can guide the nurse to provide person-centred and family-centred care. The style of record keeping used within a health care setting is often very personal to the interdisciplinary team; it may have been designed or adapted to their satisfaction. Therefore, the suggested model does not have a set written format; it may be used along with the established documentation.

The text has been structured by applying the model to the case studies of three patients. The first patient's care is used to outline the application of the model without exploring the necessary detailed knowledge required to implement the care. In contrast, the care of the second and third patients is given in more detail. Issues of communication, psychological theory, pathophysiology and symptom control are discussed, illustrating the application of theory to practice. A nurse's formal reflection, using the reflective cycle described by Gibbs (1988), is presented in relation to Case Study 2 (see Box 33.3, p. 1109).

A MODEL FOR PALLIATIVE CARE

In the busy world of health care, the sheer volume of information available to the nurse in relation to palliative care could be overwhelming. This is not a narrow specialty where the range of in-depth knowledge and specific skills is limited to a particular organ and its pathology. The knowledge base for palliative nursing care is necessarily broad and derived from many disciplines. The very diversity of the population who may benefit from palliative care demands a structured model which, although fixed in its parts, is totally flexible in its content.

The model in Figure 33.1 is presented as a guide for the clinical nurse in the early 21st century. This nurse, in the climate of continuous lifelong learning, is envisaged as a critical thinker, i.e. one who challenges assumptions and looks for creative and workable solutions to problems, who critically reads literature and appraises research and, in partnership with the interdisciplinary team, implements reflective, evidence-based practice.

The three salient features of the model are presented. The order of their application should be interchangeable depending on individual circumstances. They are:

- *Building a relationship* with the patient and family to explore their experience with the life-threatening illness and to become informed as to their functioning, i.e. their roles, bonds and coping strategies, as well as to ascertain their needs, priorities and wishes
- *Anticipating the symptoms* that may occur by using knowledge of pathophysiology and disease management
- *Applying the principles* of palliative care:
  — employing good control of symptoms
  — facilitating adjustment to losses and changes in lifestyle, for both patient and family
  — providing support to carry out pursuits that give pleasure for as long as possible.

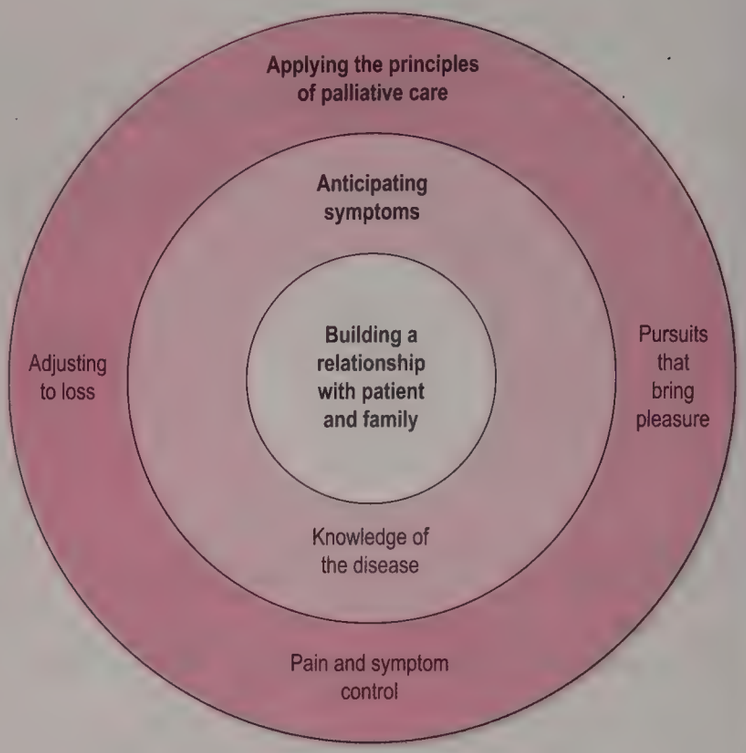

Fig. 33.1 A model for palliative care.

Central to the model is the quality of life of the patient and family. When a patient requires palliative care, immediate problems are often overwhelming physical suffering, such as pain or nausea and vomiting. It is essential that these problems are tackled and the symptoms reduced before exploring the patient's psychosocial concerns.

Before embarking on the case studies, each aspect of the model will be considered in more detail.

Building a relationship and developing a profile

Communication is an essential feature of palliative care. This includes verbal, non-verbal and written communication with the patient and family and within the interdisciplinary team. Particular emphasis is therefore placed on this aspect of the model at the outset.

When it is recognised that the intention of a patient's care has become palliative, this often means subjecting the person to information-seeking interviews. However, one of the most commonly reported problems in the last few months of life is fatigue (Sweeney et al 2004), and patients often complain that too many people ask them the same questions (Faulkner 1998). Therefore, effective communication within the team must be developed to protect these tired, frail patients, without compromising opportunities for them to share their fears, problems and concerns (Kinghorn 2001).

Combined interdisciplinary written documentation in the form of patients' notes is being adopted by many teams.

In addition, interdisciplinary team meetings are being held regularly at which the many different facets of patient and family problems may be discussed and shared goals set.

Patients and families need to feel secure that confidentiality will be maintained concerning matters revealed to the health care team. It is often believed that patients realise that they are being cared for by a team of staff and that they therefore implicitly agree that information given to one may be shared within the team. This should not be assumed. It is useful at times to remind patients and families that information is shared within the team and to emphasise that they do not have to talk about areas they prefer to keep private.

The ethics of confidentiality are beyond the scope of this text; readers wishing to explore this important area in more detail may refer to Randall & Downie (1999).

To implement the model, a great deal of information needs to be gathered in relation to the patient and the family. This section gives an example of a named nurse building a relationship and developing a profile.

Before embarking on an interview with the patient, the named nurse should ascertain what information is required, recognising that the patient profile will very likely be added to throughout the illness. The patient's notes should be read, as they may contain a great deal of the required information regarding diagnosis, treatment and other problems. However, it is wise to remember that the problems as perceived by the referring doctor or nurse, or the team currently caring for the patient, may be different from those causing the greatest concern to the patient (Heaven 1995, Davy & Ellis 2000). Communication with other members of the team may reveal that another interview is planned on the same day, and the team members may agree to sit down with the patient together. If not, one of the interviews should be postponed until the following day to prevent overtiring the patient.

An ideal situation for an assessment interview will be one in which privacy is provided without interruption. The nurse will give good eye contact, display warmth and respect, and the patient's physical comfort will be attended to. Skilful questioning will be utilised and blocking behaviour curbed. Many authors discuss sound communication and counselling skills (Faulkner 1998, Davy & Ellis 2000, Stein-Parbury 2000, Kinghorn 2001).

The patient should be engaged in a conversational interview (Brown 1995) by being encouraged to talk about their main current problems. It is then useful to enquire about how each problem affects the patient's life and about their expectations of getting help with these problems, i.e. what are the patient's goals? Should the patient concentrate on physical concerns, it is useful to indicate that feelings are also important. From this conversation, the named nurse should be able to appraise the patient's understanding of their illness (Heaven 1995, Kinghorn 2001). The patient may become tired or distressed during the interview, in which case the nurse must enquire if the patient wishes to stop. The distressed patient should not be abandoned. A cup of tea might be appreciated and the mood lightened by moving the conversation away from the difficult topic.

The framework in Box 33.1 is suggested as a means of helping the patient to communicate fully about specific physical or emotional problems (Heaven 1995).

Box 33.1

Assessing a specific problem

To assess a problem fully, be it physical or emotional, it is useful to structure your questions using the following framework:

- Nature — what is it like?
- Location (for a physical problem) — Show me where you get it
- Severity — what is it like at its worst?
- Frequency — how often do you get this?
- Duration — how long does it last?
- Triggers — what starts it up? what makes it worse?
- Alleviating factors — what helps?
- Impact on life — how does this affect your day-to-day life?
- Impact on feelings — how does this affect how you are feeling in yourself?

Adapted from Heaven (1995).

Having given the patient the opportunity to discuss their concerns, it is useful to move on to include the family. A family tree or genogram is a good method for gathering information in a form that is easily shared within the team (see Fig. 33.2). Compiling the genogram may encourage the

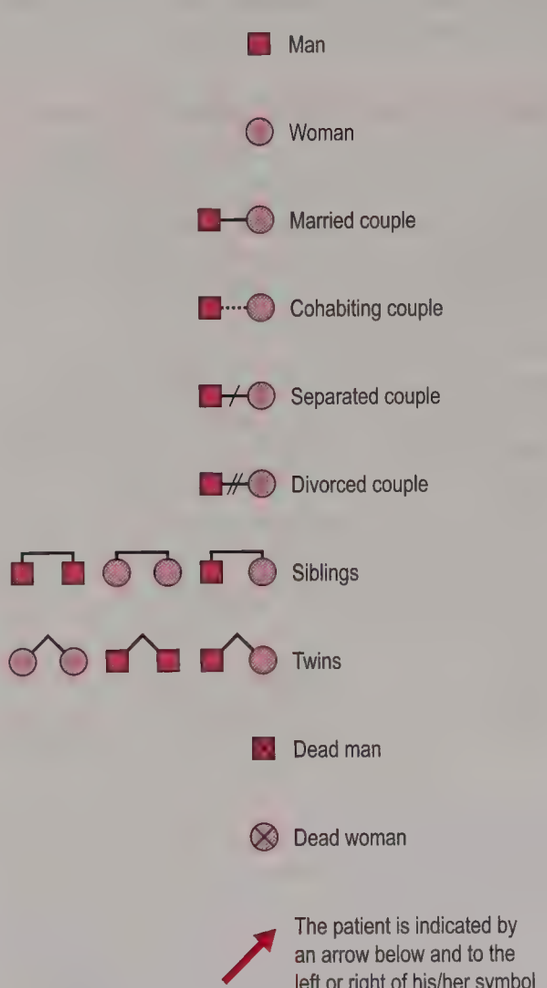

Fig. 33.2 A genogram is a code for recording a family, using the symbols shown. (Adapted from McGoldrick & Gerson 1985.)

patient to talk about roles, relationships and personalities and to identify issues of concern. In addition, it demonstrates an interest in the patient's family, thus reinforcing the principle that family support is an integral part of palliative care (Murray Parkes et al 1996, Davy & Ellis 2000).

Following the interview, the named nurse will clearly and succinctly document the information and communicate any immediate issues to the appropriate team member.

Anticipating symptoms

Consideration now needs to be given to the nature of the life-threatening illness and any other existing medical problems from which the patient may suffer. For example, if caring for a person with cancer, the named nurse needs to know how that disease may spread (see Ch. 31). If the person has AIDS, it will be important to have an understanding of opportunistic infections or HIV-related malignancies that may occur (see Ch. 37). Complications of advanced disease can often be anticipated and, in some cases, effective management instigated. This can result in an improved quality of life for the patient and is therefore an important aspect of good palliative care. The named nurse may wish to update knowledge of the specific disease process; the chapters in the first section of this book are a rich source of relevant information.

The named nurse is now in a position to prepare a summary of the patient's main problems, expectations and priorities and of the patient's understanding of the illness and the problems that may occur.

Applying the principles of palliative care

Once the named nurse has developed a profile and identified the actual and potential problems that the patient may have, a plan of care can be devised. This will be done with the patient, the family and the interdisciplinary team. In the plan, the principles of palliative care will be applied.

Pain and symptom control

The key components of good symptom control in palliative care are well described (Twycross & Wilcock 2001, Faull & Woof 2002, Regnard & Hockley 2004). In summary, the interdisciplinary team must work with the patient to:

- make a thorough assessment of each symptom
- discuss causes and treatment options
- plan symptom management in the light of the patient's expectations and priorities.

Attention to detail is also important, as is continuous review of the situation, because of the progressive nature of disease. All of this must be underpinned by an understanding of the pathophysiology of the symptom.

Facilitating adjustment

Making the adjustment from thinking of oneself as a relatively healthy person who will die someday in the future, to thinking of oneself as an ill person who is dying right now, is a very big step. Theorists have described the potential emotions and behaviours of people in this situation (Barraclough 1999, Houldin 2000). Many variables influence the responses of the dying patient and the family, the most notable being personal characteristics, level of social support, past experience of illness and death, age, culture, religious belief and the characteristics specific to the illness.

Loss is an abiding feature in the life of a person who is dying — loss of future, loss of role, loss of independence. This period in the palliative care patient's life has been compared to bereavement. Many of these patients perceive that those who are dying are shunned by health professionals because they cannot be cured. The nurse caring for the dying person needs to be acutely aware of this and must demonstrate the importance of the individual by displaying interest and respect, e.g. by consulting the patient about needs, wants and priorities and thereby helping to maintain self-esteem.

It has been suggested that a useful starting point for understanding an individual's response to a life-threatening illness is to consider the question: 'What does this illness mean to this person?' (Barraclough 1999).

Supporting pursuits that give pleasure

Supporting the patient in carrying out pursuits that bring pleasure plays a vital part in maintaining hope and improving quality of life (Houldin 2000, Chaplin & McIntyre 2001). This might be anything, from moving a patient's bed out into the hospice garden to enjoy the summer sunshine, to enabling a very frail patient to attend the performance of a much loved play. The named nurse in palliative care needs actively to seek these opportunities.

Case Study 1 will briefly illustrate the model.

CASE STUDY 1 — MRS A

Building a relationship, developing a profile and anticipating symptoms

Mrs A was admitted to the community hospital the previous day. She was admitted by her general practitioner (GP) because of pain and rectal bleeding. The named nurse spends time building a relationship and developing a profile of the patient and her family:

- *Main problems* — the patient identifies these as a foul rectal discharge with some bleeding, pain at times in her perineal area and a sensation of wanting to empty her bowels continuously (tenesmus). In addition, her husband, who has suffered a stroke, is already in the same hospital.
- *Expectations* — Mrs A is pleased to be in the hospital — 'my husband is so well looked after, and I am so tired and weary'. She does not expect that the smell will go away but she is sure the staff will not let her suffer.
- *Priorities* — the things that are most important to her are seeing her family, her faith, playing the piano, and having her clothes on during the day.
- *Understanding of illness* — Mrs A speaks openly about her cancer. She admits that she put off going to the doctor because of caring for her husband. When she was told her diagnosis, it was a relief to have it out in the open. It was a shock for the family and she is still trying to help them to come to terms with it, especially her eldest daughter.
- *Anticipated symptoms* — because of her diagnosis of advanced rectal cancer, her main anticipated problems

are pain, difficulty with defaecation, possible development of fistulae between the bowel, bladder and the vagina and a small risk of catastrophic rectal haemorrhage.

Having obtained this information, the named nurse will liaise with the other members of the interdisciplinary team, in particular the family doctor, who will have completed a medical examination. A care plan will then be written. Towards the end of life, a patient's condition may change rapidly, and therefore the care plan should be reviewed daily and updated promptly.

Applying the principles of palliative care

The care plan for Mrs A, structured by the three principles of palliative care, will include the following.

Pain and symptom management

- Stop the prescribed co-codamol 30/500 and commence 4-hourly oral morphine (normal release formulation) to enable titration of the optimum daily dose of morphine required to control perineal pain, plus commence paracetamol 6-hourly. Also, begin amitriptyline as an adjuvant analgesic for the tenesmus. For a detailed discussion of pain management, see pages 1103–1105.
- Continue the prescribed combined softening and stimulant oral laxative, co-danthramer.
- Ensure that emergency drugs have been prescribed, to be given in case of a catastrophic haemorrhage.
- Offer a daily bath to soothe the perineal area.
- Install air freshening unit in her room.

Adjustment to loss and change

- Ensure that openings are given to Mrs A to talk about her feelings should she so wish. Mrs A has requested some time with her priest and this has been organised for today. A family meeting has been arranged for Friday at 15.00 h.
- Make it possible for the family to spend time together in privacy.

Pursuits that give pleasure

- Put arrangements in place for Mrs A to play the piano in the sitting room in the late afternoon; she may wish her visitors to accompany her.
- Ensure that the timing of help with personal hygiene does not prevent Mrs A going to the Sunday service in the chapel.

To demonstrate its flexibility, the model will now be applied more fully to two further case studies. The detailed content will include evidence-based theory and practice, providing a transferable body of knowledge as a basis for palliative nursing care practice in hospital, hospice, home or nursing home.

CASE STUDY 2 — MS M

Day 1 Ms M is a 39-year-old mother and company director who is separated from her husband. She has advanced breast cancer with metastases to bone, liver and brain. Ms M has been admitted to the hospice at her own request, having had a short admission 6 months previously for pain management. The referral from the GP requested admission for escalating pain, nausea and vomiting, and general deterioration in her condition.

On admission, Ms M is very pale and quiet. She is accompanied by her mother who looks distressed. Neither of them appears to recognise S, the named nurse who cared for them on the previous admission. Quietly and without speaking much, S, displaying warmth and concern in her non-verbal communication, settles the new patient into her bright comfortable single room. Together, she and one of the medical staff talk with Ms M about her immediate physical problems. The doctor carries out a brief examination. Having administered a s.c. injection of the analgesic diamorphine and an i.m. injection of the antiemetic cyclizine (local practice may be to give cyclizine s.c.), S leaves Ms M to rest. The doctor will return later to take a medical history and carry out a full physical examination. Some time is spent with the patient's mother listening to her concerns and reassuring her before arranging for a friend to take her home.

Using the model, S has started to build a relationship with the patient and her family. It is not appropriate at this stage to tire the patient with a psychosocial interview. Pain and symptom control must take priority. The provision of good palliative nursing care requires knowledge of the patient's disease, including the anticipated problems, as well as knowledge of pain management.

The anticipated symptoms of advanced breast cancer

In common with many patients suffering from advanced disease, patients with breast cancer may complain of insomnia, fatigue, anorexia, constipation or sore mouth. They may be at risk from pressure ulcers and infections. The causes of these problems are many and varied; observant and vigilant nursing care may alleviate or prevent these conditions. There are, however, symptoms associated specifically with advanced breast cancer and its spread. Fortunately, many of these can be anticipated and some can be managed to prevent unnecessary suffering.

Bone is generally considered the most common site for disseminated breast disease (Hoskin & Makin 2003, McIllmurray 2004), followed by metastases to lung, liver and brain. It is important to remember that this is metastatic spread of the original disease. For example, when a patient with adenocarcinoma of the breast is diagnosed as having metastases in the femur, she has breast cancer in the bone, not a primary bone cancer.

Bone metastases

The bones most commonly affected by metastases are the ribs, vertebrae and pelvis, followed by the long bones, in particular the humerus and the femur. Patients often have metastases in more than one site.

The problems that may arise as a result are localised or neuropathic pain (see Ch. 19), pathological fracture, spinal cord or nerve root compression and bone marrow infiltration. In the past, hypercalcaemia would have been included

in this list. Although this serious paraneoplastic disorder is associated with bone metastases, it is not now thought to be due directly to bone destruction. It will therefore be discussed separately.

The clinical diagnosis of bone metastases may be confirmed radiologically. It is not unknown, however, for the X-ray to appear relatively normal, contradicting the clinical examination, and therefore a bone scan may be required to confirm the diagnosis. Radiotherapy, orthopaedic surgery, chemotherapy and hormone therapy are all used to manage this complication of cancer. Until these therapies can be organised, analgesics may give some relief.

A single dose of radiation is usually effective in relieving localised bone pain, although around 15–20% of patients will fail to respond to radiotherapy (Hoskin & Makin 2003). Patients should be warned that it can take 2–4 weeks for a response to be noticed. Side-effects from the treatment are usually minor. Hemibody radiotherapy is a useful treatment for scattered bone pain, but because of the associated potential toxicity, it has to be considered on a holistic basis for a patient with far-advanced disease.

Radiotherapy is generally an effective method of relieving bone pain and facilitating healing of a pathological fracture. It may be used as the sole treatment or in conjunction with surgery. Orthopaedic surgery in the form of surgical internal fixation of a long bone is an effective method of either preventing a pathological fracture or quickly relieving the severe pain when a fracture has occurred.

Chemotherapy may be a useful treatment for bone metastases, when the primary tumour is chemosensitive, and may be given in conjunction with local radiotherapy. Hormone therapy is often beneficial to relieve the pain of bone metastases in patients with hormone-sensitive cancer of the breast.

Spinal cord compression is a very serious complication of bone metastases in the vertebrae. Bone metastases will be the cause in approximately 85% of patients with this condition (Twycross & Wilcock 2001). The tumour may encroach on the spinal cord, causing paralysis. This serious condition most commonly affects the thoracic vertebrae. However, for a significant minority, the site will be the lumbar region, and a smaller group will be at risk from quadriplegia because of tumour in the cervical vertebrae. Disease in more than one site is common. Spinal cord compression can be prevented, and therefore anticipation of this condition is of major importance.

Patients who are at risk of this complication, including patients with a diagnosis of breast cancer, must be warned to seek help immediately if they become aware of any of the following symptoms:

- a history of increasing back pain, which may radiate and be worse on movement and lying down
- sciatic-type pain in the lower back
- muscle weakness, which may make climbing stairs difficult and tripping-up common
- the sensation of weakness, or a loss of feeling, in the lower limbs or buttocks
- urinary hesitancy or retention, sphincter disturbance with incontinence of urine or faeces, or constipation (Twycross & Wilcock 2001).

In addition, neck pain, pain radiating to the shoulders and arms, or general weakness in the upper body should not be overlooked as this may be indicative of a cervical cord lesion.

Diagnosis is made on clinical examination and confirmed by an urgent magnetic resonance imaging (MRI) scan. Management must be considered immediately, as the progression to paralysis can be very rapid with significant implications for deterioration in the quality of life. Oral or i.v. corticosteroids would be commenced to reduce any peritumour inflammation (Twycross & Wilcock 2001). Analgesics such as oral morphine may also be required to provide some comfort for the patient.

Local radiotherapy is very effective and is usually the treatment of choice. However, some patients may benefit from surgery to stabilise the spine.

Lung metastases

The most common radiological abnormalities of lung metastases are multiple opacities in the lower lobes of the lungs. Lymphangitis carcinomatosis, the infiltration of the pulmonary lymphatics by tumour, may also be a problem. The severity of symptoms will depend on the number, site and size of the metastases. Dyspnoea may be caused by invasion of lung tissue, lymphangitis, pleural effusion or infection. Pain may also be caused by the pleural involvement. Haemoptysis and cough may be due to lobular collapse (Hoskin & Makin 2003).

Patients with breast cancer who have dyspnoea due to bronchial obstruction may respond to chemotherapy, radiotherapy or hormone therapy if these treatment options have not already been exhausted.

Respiratory symptoms are common in patients with advanced illness, with and without cancer (see Ch. 3). The management of acute breathlessness in chronic obstructive pulmonary disease is discussed in Case Study 3.

Liver metastases

Liver metastases indicate widespread dissemination of the disease and are therefore a poor prognostic sign. They may present as stretched capsule pain due to liver enlargement or be noticed on clinical examination of the abdomen. The diagnosis can be confirmed by ultrasound examination. As in the previous sites of secondary tumour discussed above, chemotherapy may be an option for the patient with breast cancer.

The enlarged liver may be the cause of a 'squashed stomach syndrome' with resultant nausea, vomiting, reduced gastric emptying and oesophageal reflux. The patient might also complain of dyspnoea, peripheral oedema and ascites. Liver function may be adequate until far on in the illness when jaundice and pruritus may occur (see Ch. 4).

Corticosteroids are very useful in relieving the pain of a liver enlarged with advanced cancer. Cancerous cells are frequently surrounded by inflamed oedematous tissue; a corticosteroid such as dexamethasone will reduce this swelling and therefore the overall dimensions of the tumour. The result is some relief of the pain (Regnard & Hockley 2004).

Brain metastases

On occasion, secondary cancer in the brain is the presenting sign of a patient's cancer. It is, however, more commonly

a sign of widespread disseminated disease with a poor prognosis. The main symptom of a severe headache is the result of local pressure produced by the tumour, associated haemorrhage or oedema of the surrounding brain tissues. The headache is often described as being like a tight band around the head, which is sometimes worse in the morning. It may be associated with visual disturbances, nausea and vomiting, confusion and altered consciousness.

Other signs and symptoms will depend on which area of the brain is affected, with many patients having tumours in multiple sites. Suspicion should be raised when the patient appears to have cognitive impairment, i.e. confusion, memory loss or personality change, or if suffering from seizures, motor or sensory loss, or difficulty with balance.

The diagnosis may be confirmed by a brain scan. However, if the patient is very frail, a corticosteroid such as dexamethasone for a few days may help to confirm the diagnosis by relieving the symptoms. Radiotherapy to the whole brain is the usual method of treating cerebral metastases for patients who are strong enough and have a prognosis of longer than a few weeks. Corticosteroids will be given to the patient to relieve the symptoms until the radiotherapy has an effect and to treat the potential increase in cerebral oedema, which may be a temporary result of the therapy. The patient must be gently warned of the likely hair loss.

Paraneoplastic disorders

These are generally thought to be due to substances produced by the tumour or by other cells in the body in response to the tumour. Some paraneoplastic disorders are life threatening and many have a detrimental effect on the patient's quality of life. Therefore, when implementing this model of palliative care for a patient with a specific cancer, reference must be made to an oncology text (Hoskin & Makin 2003). The paraneoplastic disorder most commonly associated with breast cancer is the metabolic disorder of hypercalcaemia.

Hypercalcaemia is an easily managed disorder and therefore knowledge of its symptoms is important in anticipating this life-threatening condition (Twycross & Wilcock 2001, Hoskin & Makin 2003). Untreated hypercalcaemia can have a miserable effect on the patient's quality of life.

There was a time when it was believed that the high calcium in the blood was due to the mere presence of bone metastases. This theory has been superseded; it is now recognised that many patients with bone metastases do not develop hypercalcaemia and that some patients without bone metastases do. A simple outline of the present understanding will be given, as will the symptoms and management of the condition.

It would seem that various substances released from tumour cells cause tumour-induced hypercalcaemia. The most common of these is the parathyroid-related protein (PTHrP — not to be confused with the parathyroid hormone). PTHrP causes the reabsorption of calcium from bone and renal tubular reabsorption of calcium.

A high serum calcium will cause an osmotic diuresis, leading to polyuria, dehydration and thirst. The action on smooth muscle and the central nervous system may cause constipation, confusion and nausea. As this is a biochemical imbalance, it can stimulate the chemoreceptor trigger zone (CTZ) in the brain to cause vomiting.

The symptoms associated with rising calcium levels may therefore include the following: fatigue, lethargy, weakness, anorexia, thirst, nausea, vomiting, constipation, polyuria, delirium, drowsiness or coma. Death may be preceded by renal failure and/or cardiac arrhythmia in severe untreated hypercalcaemia.

Immediately a clinical diagnosis is made, treatment will begin by rehydration with i.v. normal saline. The drug treatment of choice is a bisphosphonate such as i.v. pamidronate, which should normalise the serum calcium concentration within a week. This drug inhibits osteoclast activity and therefore inhibits bone reabsorption. It does not block PTHrP-mediated renal tubular reabsorption of calcium (Twycross & Wilcock 2001).

The effect on the patient is often dramatic. However, the condition will recur and the treatment will need to be repeated regularly for the remainder of the patient's life. This management alone may relieve the many symptoms associated with the condition, but until this reversal comes about, vigorous pain and symptom management will be necessary.

Building a relationship and developing a profile

Day 2 Ms M has had a settled night requiring further s.c. diamorphine at 04.00 h with good effect. Today her pains will be assessed and titration of analgesics will be commenced. Simultaneously, other physical problems will be addressed, but attention is first given to total pain and suffering (see p. 1102). It is known that pain and other symptoms are often difficult to manage because of psychological and emotional concerns. Therefore S, the named nurse, has determined to carry out an initial interview with Ms M today, and later will arrange to spend time with Ms M's mother.

S refreshes her memory by reading the patient's notes. Ms M's genogram constructed on the previous admission is useful (see Fig. 33.3). She is also aware of the detailed clinical examination carried out by the consultant physician earlier this morning. To enable her to implement the model, S will need to collect information from the patient, so that an up-to-the-minute patient-centred care plan can be written. Ensuring the patient's comfort and that they will

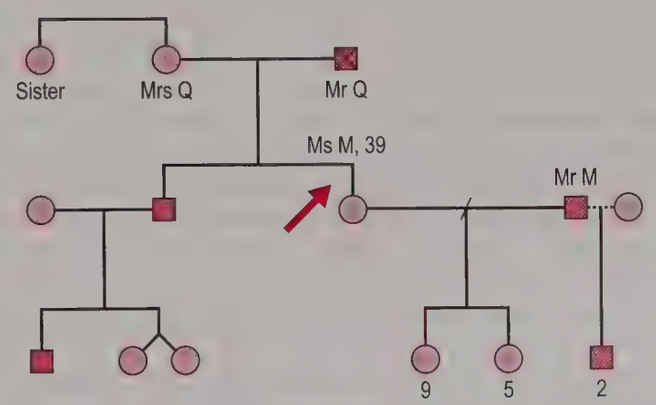

Fig. 33.3 Genogram for Ms M.

not be interrupted, S gently encourages Ms M to talk about her situation and her feelings.

Gradually responding to S's warm approach, Ms M confides that she has underestimated the emotional pain of leaving her children and that she is very worried about her mother. Ms M goes on to explain that her daughters, aged 5 and 9, have moved in on a permanent basis with their father, his new partner and their 2-year-old son. This seemed to be the most practical solution as he is a good dad and really loves them. It was, however, a terrible wrench: 'I cried and cried and really upset Mum. My mother is used to me being strong; all this is difficult for her'.

Ms M continues by repeating that she knew that this was the best for her children, and that their father's new partner is a real 'earth mother' type. She jokes about this having its good and bad points; that she as a career woman would have brought them up to be strong, independent women like herself. 'However, they know I am dying, we have talked and cried about it and read the right books. I have tried my best to prepare them.'

Note that S asks Ms M what her main problems, expectations and priorities are. She does not ask her directly about her understanding of the disease or the anticipated problems, as that would have been insensitive. S is able to document the information from the conversation; other members of the team will be consulted to add to this section of the assessment:

- *Main problems* — the patient initially identifies these as uncontrolled pain, nausea and vomiting, and sheer exhaustion. Following the above conversation, she admits to emotional pain, but wishes it to be recorded that she would only talk to S about it.
- *Expectations* — having had her pain alleviated on a previous admission, she hopes that the doctor will be able to help her again. She trusts him and is comforted by his determination; she knows he will not give up on her. She also expects to go home again.
- *Priorities* — Ms M identifies that she needs to rest. She requests not to be disturbed in the mornings until at least 10 o'clock. Getting her assets put in trust for her daughters has been a lengthy procedure. Fortunately, her lawyer and business partner will come to the hospice for final signatures sometime in the week, and then she will be able to relax. It is very important for Ms M to see her daughters; she has, however, instructed her husband that the girls are only to visit at the weekend, as she does not want to prejudice their schooling. Her mother and her aunt will be in every day. They are her main carers and have a need to visit. Other people have been asked by Ms M not to come.
- *Understanding of illness* — having read widely in relation to her disease, including searching the internet, Ms M has been involved in the decisions at every stage of her illness. She assures S that it has been a conscious decision to come to the hospice, as she liked what she had read about palliative care units. She is also aware of the complications that might come about because of her disease.
- *Anticipated symptoms* — because of her diagnosis of advanced metastatic breast cancer, Ms M's main anticipated problems are pain at multiple sites, hypercalcaemia, anaemia and spinal cord compression. Because she is receiving morphine, constipation must be prevented.

Having obtained this information, S ensures that Ms M is not upset and is comfortable before writing up the assessment and the care plan. Ms M thanks S for listening to her, saying with a wry smile: 'It has helped to talk, but I will not be making a habit of it'.

Later in the day, S spends some time talking with Mrs Q, the patient's mother. From this conversation, she is made aware that the patient and her mother had a strained relationship before the daughter's illness. Mrs Q had at times found her daughter's forceful personality difficult, although she is very proud of her. She was very upset when the marriage broke down and continues to admire her son-in-law for his gentle, loving nature and his good parenting skills.

She cries when she tells S of how the last few weeks have been so much better. It has been like 'having her little girl again', as she has helped her to shower and dress, and she talked about the past. Now she feels so useless and is dreading the next few weeks.

S gently asks who Mrs Q has to talk to, having noticed on the genogram that she has a sister. She is very relieved when Mrs Q speaks warmly of the support her sister is providing and the importance of her friends in the church.

S reminds Mrs Q that the hospice staff are available to help families as well as patients. She also decides to ask Ms M how she would feel about her mother coming in some days to help with her physical care.

Before moving on to care planning, the reader will realise that knowledge of suffering, pain assessment and management, as well as managing nausea and vomiting, are necessary to implement this patient's care.

Suffering

Pain and suffering are terms that are sometimes used as if they had the same meaning; this demonstrates a deep misunderstanding of human suffering. Physical pain can usually be controlled or reduced, whereas suffering is a much more complex phenomenon, encompassing emotions and psychosocial concerns that may elude control (Roy 1998, Houldin 2000).

Patients and families may suffer because of unresolved issues from the past. There may be guilt, remorse, loss of hope and fear of the future. People who are dying have lost control over their future, have suffered multiple losses in relation to their previous lifestyle and are often witnessing their decline into total dependence on others. In addition, they may be suffering through observing the effect their imminent demise is having on their family, and may be worried about how their survivors will cope. The family members are suffering by watching their loved one's decline, feeling useless and unable to help. Previous bad experiences of poor symptom control in the dying may be the cause of considerable anxiety.

Coping styles have attracted much interest in the literature. There is no doubt that some people cope much more effectively than others in stressful situations. Some individuals are flexible in being able to change their lifestyle to their new circumstances, to seek information, to be involved

in the decision making, to maintain hope and to preserve their self-worth. Others become helpless and hopeless and go into a steep decline (Barraclough 1999, Chochinov & Breitbart 2000, Folkman & Greer 2000).

Many factors are involved. These are as diverse as personality, the manner in which the bad news was broken, and the social support available. A previous coping style is not always useful in relation to facing a life-threatening illness. This can be very distressing for patients and families as they struggle to cope with the fearful situation. Changing coping styles is not generally an option. What is recommended is to provide extra coping strategies to enable the individuals to achieve some relief from the suffering.

Realising the enormity of suffering, by both patient and family, can be daunting in palliative care. However, some help can be offered. By building up a relationship with the patient and the family, the nurse may gain some insight into what would be useful.

Daily communication with the family is a good method of giving support. The family members should never feel they have to search for someone to talk to, or that the nurse or doctor is too busy. A conscious effort must be made to give the family members respect by memorising their names and displaying warm body language towards them. Listening to their concerns is often useful, as is exploring who they have outwith the family to give support. Practical solutions may help, such as providing privacy for the patient and family to talk and for Ms M's mother to be involved in her daughter's physical care.

Mind and body are inextricably linked. The stresses caused by suffering may evoke physiological effects on the body. Complementary therapies may therefore be of great benefit to patients. Relaxation, massage, music therapy and other distractions may help to relieve the stresses of dying and should be available alongside mainstream medicine (Cassileth & Schulman 2004).

Whenever the patient seems to be very anxious or down, or when the usual pain management does not appear to be having the desired effect, the nurse caring for the dying must consider whether all avenues have been explored to assist the patient with the suffering. This may mean referring the patient to a social worker, counsellor, chaplain or a clinical psychologist.

The health care team may also suffer. Realising that clinical skills and knowledge are insufficient to relieve the patient's suffering may cause considerable distress (Bernard & Creux 2003). A culture of support must be developed by those caring for the dying, to enable them to realise, through maturity and experience, that there are limits to what can be achieved in relieving the suffering of some individuals.

Roy (1998) supports this, urging the health care team to 'realise your limits, there are some kinds of suffering that are so bound up in another person's uniqueness that they cannot be spoken away by other human beings, no matter how compassionate their words might be'.

Anxiolytic medications such as the benzodiazepines, e.g. temazepam, lorazepam and midazolam, are frequently prescribed in palliative care. They can help the patient sleep at night and get some relief from inner torment (Twycross & Wilcock 2001).

In getting to know Ms M, S recognises that the patient has trust in her hospice doctor because of her previous good experience of being helped with her pain. She also recognises that this is a woman who has what the psychologists call a 'high internal locus of control' (Murray Parkes et al 1996), i.e. she has a need to continue to have some control over her circumstances. S will therefore ensure that Ms M is consulted and informed as to any decisions being made about her care. S is also realistic in knowing that she cannot take away the profound sadness that her patient feels at the loss of her future as a mother. She can empathise with her and provide her with openings to talk about it and pleasurable distractions, but she cannot remove that suffering.

One area of suffering that can generally be helped is the management of physical pain. When physical pain is relieved or reduced to a level acceptable to the patient, other areas of suffering can be explored. Before moving on to this section of the chapter, the reader is advised to read Chapter 19.

Pain assessment

Despite the complexity of pain, a vast amount of knowledge is available to manage pain effectively. However, pain that is not identified will not be treated, and pain will not be treated vigorously enough if its severity is underestimated (Vallerand 1997, Farrer 2001).

It has now been well accepted that the patient's self-report is the most reliable indicator of pain (McCaffery & Pasero 1999). Self-report of pain, however, is rarely an option in the confused or non-verbal older patient. Behaviour becomes the main method of assessing pain in these individuals (Lefebvre-Chapiro 2001). In addition, of course, there are many personality, attitudinal and cultural reasons why people do not reveal their pains. These range from being loath to admit to an increase in pain, as this may signify progression of their disease, to being unwilling to admit that the doctor's best efforts have been to no avail.

Patients who are dying have more than one pain, and therefore the nurse committed to helping the patient must systematically and regularly assess and document information about these pains.

The following information should be documented in relation to each pain:

- location
- severity
- radiation
- type (dull/acute)
- when started
- aggravating factors
- alleviating factors.

The nurse, having assessed the patient's pain, should then discuss this with the medical staff. It is essential this be done in an informed manner by giving a detailed description of the pain as outlined above. It is poor practice when requesting medical attendance to give the blank statement that the patient is in pain.

Pain management

An accurate diagnosis of new pains derived from observation, discussion and physical examination must be undertaken by a physician. This is essential, as the new pains may

Box 33.2

Analgesic medications commonly used for cancer pain

Step 1 — Non-opioids for mild pain
Paracetamol or non-steroidal anti-inflammatories (NSAIDs)

Step 2 — Opioids for mild to moderate pain
Codeine often combined with paracetamol, e.g. co-codamol 30/500

Step 3 — Opioids for moderate to severe pain
Normal release — Oramorph or Sevredol
Controlled release — MST Continus or MXL
Diamorphine by subcutaneous injection

require laboratory or radiological investigations and other treatments as well as analgesics.

Analgesic medications, given regularly to prevent the recurrence of pain, are central to effective pain management. It is essential that an adequate, regular dose is calculated and administered, enabling the patient to be as comfortable as possible without being drowsy. A list of those commonly used for cancer pain is given in Box 33.2.

Adjuvant medications are frequently given along with analgesics in the effective management of pain (see Ch. 19). Some pains do not respond well to the analgesics codeine, morphine and the other medications that are known collectively as opioids. Bone pain and neuropathic pain commonly require adjuvant therapy. A list of adjuvant analgesics is in Table 33.1.

Principles have been established by the World Health Organization (WHO 1986, 1996) to guide medical staff in the management of chronic pain. In addition, the Scottish Intercollegiate Guidelines Network (2000) publication on *Control of Pain in Patients with Cancer* is readily available online. Registered nurses must have a sound knowledge of these principles and guidelines to promote good interdisciplinary understanding and patient confidence.

Table 33.1 Adjuvant analgesics commonly used for cancer pain

Medication	Example	Indications
Non-steroidal anti-inflammatory	Diclofenac	Bone pain, soft tissue infiltration
Corticosteroids	Dexamethasone	Raised intracranial pressure Nerve compression Soft tissue infiltration Hepatomegaly
Tricyclic antidepressants	Amitriptyline	Nerve compression or infiltration, paraneoplastic neuropathies
Anticonvulsants	Gabapentin	
Bisphosphonates	Pamidronate	Bone pain

An adjuvant may be given in conjunction with an analgesic from any step on the ladder.

The WHO analgesic ladder

The key principles of the WHO approach are that analgesics be given by the mouth, by the clock and by the ladder.

By the mouth This convenient and easy route of administration should be the method of choice for as long as possible. When the patient can no longer tolerate oral medicines, the s.c. route is frequently used by setting up a syringe driver.

By the clock Morphine solution is effective for 4 h. Therefore, it *must* be administered regularly every 4 h. The exceptions to this are the controlled-release preparations, such as MST Continus.

Persistent pain must be prevented; it is inhumane to allow pain to return before administering the next dose. In an inpatient setting, care must be taken, therefore, that the patient does not have to wait on a routine drug round for this analgesic. A more accurate timing of drug administration may be achieved if it is given directly by the patient's named nurse or deputy, or by self-medication.

By the ladder Having taken a careful history and carried out a physical examination, the doctor will now be in a position to prescribe medication for the patient's pains. This may be a combination of analgesics and adjuvant therapies.

If the patient's management starts on step 1 of the ladder (mild pain), paracetamol may be given until the ceiling of 4 g in 24 h has been reached, i.e. the upper dose limit of this drug. If it does not control the pain then a drug on step 2 (mild to moderate pain) will be prescribed. Co-codamol 30/500, a combination of the step 2 opioid codeine and paracetamol, is commonly used. It is referred to as co-codamol 30/500 as each tablet contains codeine 30 mg and paracetamol 500 mg. It will be given up to the ceiling of two tablets 6-hourly. When that ceases to control the patient's pain, the step 2 opioid is stopped and a drug on step 3 (moderate to severe pain) will be prescribed. It is essential to note that paracetamol may be continued simultaneously with a step 3 opioid. The decision to use a step 3 opioid should be based on patient need, not the prognosis. The outdated practice of saving morphine for the last few weeks of life is misinformed.

A normal-release oral preparation of morphine, such as Oramorph or Sevredol tablets, will be prescribed, with the intention of establishing a regime that will relieve the pain without causing oversedation. This is known as titration. A common starting dose of normal-release morphine is 5–10 mg, except in the older person or the cachectic patient when 2.5 mg might be the starting dose. It will be prescribed to be taken 4-hourly round the clock, i.e. at 06.00, 10.00, 14.00, 18.00, 22.00 and, if awake, at 02.00 h.

Should the patient be in pain between doses, a breakthrough dose equivalent to the standard 4-hourly dose will be given. If a breakthrough dose is given, the timing of the next regular dose must not be altered. For example, if a patient has Oramorph at 06.00 h and requires a breakthrough dose at 09.00 h, the dose due at 10.00 h will still be given on time. An adjuvant medication may be given in conjunction with an analgesic from any step on the ladder.

Some common side-effects might be expected when a patient commences on step 3 opioids. Transitory effects

may be sleepiness and nausea; these usually pass in a few days. More troublesome are constipation and a dry mouth. Constipation must be treated prophylactically; a laxative such as co-danthramer must be prescribed at the same time as the opioid.

Occasionally intolerable side-effects such as opioid toxicity, intractable constipation or a poor response to morphine might cause the physician to prescribe an alternative opioid, such as oxycodone or fentanyl. This is referred to as opioid switching or rotation (Farrer 2001, Twycross & Wilcock 2001).

When the dose of morphine has been stable for 24–48 h, the patient may be prescribed the daily dose of morphine in a controlled-release preparation. For example, on her first admission, Ms M was stabilised on 10 mg of morphine 4-hourly, i.e. 60 mg daily. She was therefore discharged home on 30 mg of MST Continus 12-hourly. She was also instructed to take a sixth of her daily dose, i.e. 10 mg of normal-release morphine mixture for breakthrough pain if required.

Around 80–90% of pain due to cancer can be relieved with oral analgesics and adjuvant medications following the WHO guidelines. The remaining percentage of pain can be difficult to manage (Portenoy et al 2004).

For detailed information on difficult pain problems, see Scottish Intercollegiate Guidelines Network (2000) and Twycross & Wilcock (2001).

Fear of addiction

One barrier to effective pain control in palliative care is the fear that patients, families and some health care professionals have of addiction to opioids. This fear is unfounded when the patient has physical pain. The confusion frequently arises when the patient on opioids requires increasing doses to relieve the physical pain.

An understanding of the terms 'addiction', 'tolerance' and 'dependence' is useful to reassure the patient and family. Addiction, i.e. psychological dependence, is usually seen in individuals who are taking morphine in the absence of physical pain. In contrast, tolerance is an involuntary physiological response to opioids when, having taken the opioids for some time, the patient requires larger doses to benefit from the same analgesic effect. Physical dependence is another physiological response, which these patients may show when an opioid is suddenly stopped (Twycross & Wilcock 2001).

Tolerance and physical dependence are not the same as addiction. Less than 1% of patients receiving opioids for physical pain over many months will develop addiction. However, 75–100% of patients receiving opioids for some months will develop tolerance and physical dependence (American Pain Society 1992). Other authors consider that the requirement for increasing doses is due to disease progression and not pharmacological tolerance (O'Neill & Fallon 1998).

Assessing and managing Ms M's pain

Until recently, Ms M completed a pain diary on a daily basis.

She found it a useful method of monitoring her pain management and of communicating with her doctors. In the last week, however, she has been too exhausted to continue this activity. She is therefore pleased that both the hospice physician and S are systematically assessing her pains.

The doctor, using a body chart and writing directly into the patient's notes, has thoroughly documented the patient's description of her pains along with the findings of the physical examination.

S has learned from past experience that very ill patients sometimes overlook communicating a feature of their pain when faced with a formal enquiry. She has therefore decided to carry out a pain assessment while bedbathing Ms M. Carefully observing the patient's non-verbal communication, S asks Ms M to talk about her pains as she helps her to wash. She also encourages Ms M to use her hands to identify where she is sore.

Ms M identifies three pains. First, she rubs the upper right quadrant of her abdomen and states that a feeling of extreme pressure builds up from deep inside her body. It has been getting steadily worse over the last few weeks, especially if she tries to lie on her right side. S recognises this as visceral pain because of a liver enlarged with metastases and a stretched liver capsule. Ms M has been prescribed the opioid analgesic diamorphine by s.c. injection and the adjuvant medication dexamethasone (a corticosteroid) for this pain. Before admission, Ms M was trying to take MST Continus 60 mg 12-hourly for this pain; however, nausea and vomiting affected concordance.

For guidance on transferring patients from oral morphine to subcutaneous diamorphine, see Scottish Intercollegiate Guidelines Network (2000) and the Lothian Palliative Care Guidelines (Lothian NHS Board 2004).

Second, Ms M places her hands around her head and describes the tight band of headache that is frequently worse on waking in the morning. The dose of dexamethasone already prescribed for her liver pain has been increased to reduce the cerebral oedema caused by cerebral metastases. In addition, paracetamol 4 g in 24 h will now be prescribed to help relieve this headache. The doctor has discussed with Ms M the role of palliative radiotherapy in treating this problem, if she can bear losing her hair again.

Third, Ms M grimaces as the skin over her right femur is washed. When encouraged, she points with her finger to a specific area of pain in the bone that is causing discomfort. Extensive bone metastases were a considerable problem almost 1 year previously when they were successfully managed with hemibody radiotherapy. Ms M is upset as she recognises that this may be a recurrence of bone metastases. S listens and gently reassures her that the paracetamol being commenced for her headaches may also relieve bone pain. In addition, there is a group of analgesics known as non-steroidal anti-inflammatory drugs (NSAIDs), which can bring considerable relief. Having left her patient refreshed and comfortable, S carefully documents a detailed pain assessment in the patient's notes. She then seeks out the doctor to discuss the pain in Ms M's right femur.

Managing nausea and vomiting

Nausea and vomiting are common, very distressing symptoms in palliative care. The pathophysiology of nausea and vomiting is complex and incompletely understood. There is no WHO antiemetic ladder to guide the interdisciplinary

team, but efforts have been made to identify a logical approach to these symptoms (Twycross & Back 1998, Mannix 2004). This involves:

- understanding the pathophysiology
- assessment
- explanation
- individualising the plan of care
- attention to detail.

An understanding of the pathophysiology of nausea and vomiting (Campbell & Hately 2000, Twycross & Wilcock 2001, Mannix 2004) is important to allow the named nurse to actively participate in planning care and to explain care to patients and their families.

In order for vomiting to occur, the body needs to have detectors to identify the need to vomit, a coordinating centre and effectors which make the vomiting take place. The main detectors of the need to vomit are in:

- the gastrointestinal tract
- the chemoreceptor trigger zone (CTZ), a specialised area of the brain on the floor of the fourth ventricle
- the inner/middle ear
- the higher brain centres.

Messages from each of these detectors are transmitted to the vomiting centre in the medulla, which coordinates vomiting. Transmission from the gastrointestinal tract to the vomiting centre is via the vagus nerve. As this nerve innervates other tissues, vomiting may be stimulated by disease or trauma to other organs, e.g. the pharynx, liver or bladder. Direct stimulation of the vomiting centre by pressure, trauma or disease may also cause vomiting.

In advanced cancer, therefore, the vomiting centre can be activated in a number of ways:

- Vagal stimulation caused, for example, by gastric or bowel distension, liver capsule stretch, mediastinal disease or genitourinary problems
- Stimulation from the CTZ caused by chemical abnormalities in the blood, e.g. uraemia, hypercalcaemia, drugs or bacterial toxins
- Stimulation from the inner/middle ear due to infection, movement or local tumour
- Stimulation from higher central nervous system centres by anxiety, fear or revulsion
- Direct stimulation from raised intracranial pressure (Regnard & Comiskey 1995, Mannix 2004).

Many neurotransmitter receptors have been identified as playing a part in these vomiting pathways (Mannix 2004) and understanding of this is developing. What is important in terms of patient care is to appreciate that particular antiemetics are thought to block messages about the need to vomit at specific points along the vomiting pathways. It is this action which produces improvement or control of nausea and vomiting. Some of the commonly used antiemetics in palliative care act centrally at the vomiting centre, vestibular centre and/or the CTZ. Some act peripherally in the gastrointestinal tract and some act at both levels (Twycross 1999). Specific antiemetics may therefore be selected for specific causes of nausea and vomiting.

- *Cyclizine* acts centrally at the vomiting centre and in the inner or middle ear, and is therefore useful in managing the vomiting associated with raised intracranial pressure or motion.
- *Haloperidol* acts centrally at the CTZ and is an effective antiemetic for chemical causes of nausea and vomiting, such as hypercalcaemia or opioid-induced vomiting.
- *Metoclopramide* has its principal site of action peripherally in the gastrointestinal tract, where it acts by improving gastrointestinal motility. It may therefore be used to treat motility problems such as gastric stasis or 'squashed stomach syndrome'.
- *Levomepromazine* is a broad-spectrum antiemetic that has activity at the vomiting centre, vestibular centre and CTZ. It is useful in vomiting of uncertain or mixed origin and when other antiemetics have failed. In situations where an antiemetic is required and a degree of sedation is appropriate, levomepromazine may be prescribed.
- *Ondansetron* and *granisetron*, although very effective in the vomiting associated with cancer chemotherapy, have yet to find a place in the management of nausea and vomiting from other causes in palliative care (Mannix 2004).

Careful assessment of nausea and vomiting is crucial. Working with the patient, the team puts together a detailed picture of these symptoms. Recent guidelines emphasise the importance of the clinical picture in assessing and managing nausea and vomiting (Bentley & Boyd 2001, Lothian NHS Board 2004). Information about the onset, nature, pattern and severity of the nausea and vomiting is required. The doctor's comprehensive physical examination of the patient is another important source of information. Blood tests may be organised to check serum urea, calcium and electrolyte levels. In the process of care, the named nurse may acquire an understanding of the meaning of this symptom to the patient.

Management of nausea and vomiting involves identifying the cause(s) of the symptoms and discussion with the patient. Only in this way can care be truly individualised. The named nurse is central to this process. Reversible causes, such as pain, oral infection or raised intracranial pressure, should be treated.

The interdisciplinary team may consider non-pharmacological measures as part of the plan. The potential benefits of non-pharmacological approaches such as transcutaneous electrical nerve stimulation (TENS), acupuncture and guided mental imagery are acknowledged in the literature (Mannix 2004), but more research is required. An appropriate antiemetic should be selected, either while reversible causes are treated or in the longer term. Because of the progressive nature of advanced disease, regular review of symptom control must be planned.

The challenge for the interdisciplinary team in caring for Ms M is to use these principles to tailor symptom management to Ms M's problems, expectations, priorities and wishes. A detailed history and physical examination are undertaken by the palliative care consultant. Blood tests are organised to measure urea, electrolytes and serum calcium levels. S, the named nurse, learns from Ms M that during the week prior to admission, Ms M felt pressured by her mother to eat at mealtimes: 'It seemed so important to her that I should eat. Like a mother coaxing a child to clear her plate. She means it for the best …'.

Identifying the cause(s) is vital to managing nausea and vomiting. In advanced disease, there may be more than one cause. For Ms M some likely causes might be:

- raised intracranial pressure due to cerebral metastases
- 'squashed stomach syndrome' because of an enlarged liver
- hypercalcaemia
- anxiety about pleasing her mother by eating at mealtimes.

The blood tests are satisfactory and the serum calcium is normal. The interdisciplinary team decide that Ms M's vomiting is most likely to be associated with her cerebral metastases. Cyclizine, an antiemetic directed principally at the vomiting centre, is selected. Cyclizine 50 mg i.m. (local practice may be to administer this drug s.c.) is given to Ms M shortly after admission, as the oral route is best avoided until vomiting settles. The corticosteroid dexamethasone is increased to treat the raised intracranial pressure. It is acknowledged by Ms M and the team that not feeling pressured to eat may in itself improve the symptoms. The importance of Ms M deciding when and what she wants to eat is documented in the care plan.

On review next day, Ms M has not felt sick or been sick since admission. When this symptom is discussed with Ms M, she makes it clear to S and the doctor that she does not want to start taking an antiemetic regularly if it is not required. It is agreed with Ms M that cyclizine be prescribed on an 8-hourly as-required basis in the meantime. S or her deputy is to discuss this with Ms M on each shift and it is to be reviewed with the doctor each day.

Attention to detail is the key in assessing Ms M's nausea and vomiting, in planning its management with her and in reviewing its effectiveness.

The assessment and management of nausea and vomiting in palliative care are addressed in more detail in Mannix (2004) and Regnard & Hockley (2004). In particular, discussion of the complex issues of managing nausea and vomiting in intestinal obstruction, not addressed here, can be found in Regnard & Hockley (2004) and Ripamonti & Mercadente (2004).

Applying the principles of palliative care (a care plan for Ms M)

It is useful to be aware that every day in this hospice ward, the named nurse or her deputy ensures that the patient's activities of living are met and reviewed and that care is tailored to the individual patient's capability on that day. A pressure area assessment, mouth assessment, manual handling assessment and a record of the care given are documented daily for the purposes of good team communication and to facilitate audit. In addition, however, the care plan for Ms M is structured by the three principles of palliative care. This part of her care plan, for the third day of her present admission, is given below.

Pain and symptom management

- Set up a syringe driver at 11.00 h loaded with diamorphine 40 mg and dexamethasone sodium phosphate 10 mg, scheduled to be delivered in 24 h; see prescription sheet. (It is good practice to check local drug information sources for compatibility of drugs used as a subcutaneous infusion.)
- Check accuracy of delivery every 4 h by measuring the length of the solution remaining and checking that the indicator light is flashing.
- Check site of the 25G 'butterfly' cannula inserted subcutaneously in the left upper arm 4-hourly.

These medications are being given to relieve deep pain in the right upper quadrant of the abdomen (from the liver) and a tight band of headache. Constant attention should therefore be given to assessing these pains to ensure medication efficacy. When able to tolerate oral medications, the NSAID diclofenac may be prescribed for bone pain. If that is the decision, a gastroprotective medication such as omeprazole will also be prescribed.

- Administer one bisacodyl and one glycerine suppository as prescribed, as she is unable to tolerate co-danthramer at present and is complaining of rectal discomfort.
- Do not disturb until 10.00 h, as she is very tired.
- Encourage Ms M to decide when and what to eat. A supply of her favourite foods is kept in the patients' fridge in the kitchen. Topping up of this supply will be organised by Ms M. The antiemetic cyclizine 50 mg is prescribed, orally, i.m. or s.c. on an 8-hourly as-required basis. This is to be reviewed each shift.
- Support the patient to perform her own mouth care with toothbrush and toothpaste.

Adjustment to loss and change

- Ms M is a highly organised person who has coped with her illness and impending death in a practical fashion, by being informed and involved. She has made careful arrangements for those who will survive her. She is very private regarding her feelings. However, she has spoken to S about her profound sadness. It is important to her that she is seen to be coping bravely. S will provide her with opportunities to talk should she wish to. Ms M's estranged husband and her daughters are being helped by counselling arranged by their family doctor.
- Ms M is expecting her lawyer at 14.00 h today. This is an important meeting for which she requires to conserve energy. She would very much like to be helped to sit out in a chair and to be wearing a smart outfit.

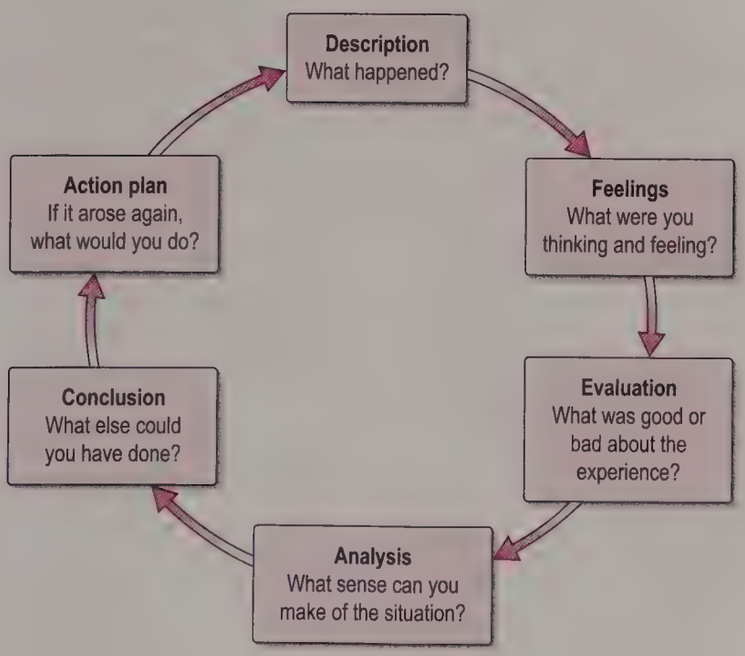
Facilitating pursuits that give pleasure

- Ms M likes to have her radio tuned to Classic FM and does not watch television. She enjoys picking up and sending her own e-mail. She can do this in the day hospice if taken by wheelchair.
- It is very important for Ms M to get her *Financial Times* every day. As she is very tired, encourage one of the volunteers to ask her if she would like it read to her.
- Ms M's daughters are in a school concert this week. She is determined to go to the school and give the girls a surprise on Thursday afternoon. Having been seen at sports day last month in a wheelchair, she is sure she will not embarrass her daughters. A nursing auxiliary has agreed to go with Ms M. They will be taken in the

hospice people carrier, which will wait for them, enabling them to return at any time.

This care plan is constantly being updated as the patient's circumstances change. Good written documentation is essential for good communication within the team and with the patient and family. It is an important element in high-quality care.

S's reflection



Good staff support systems must be in place to enable nurses like S to cope with caring for dying patients and their families. In the hospice ward in which she works there is a good culture of support. The senior staff make it explicit that they value their staff by involving them in important decisions, providing a pleasant working environment and granting generous study leave. The nurses and other members of the interdisciplinary team are quick to recognise when difficult situations are being encountered by their colleagues. They help each other by being flexible and by being available to listen to worrying concerns.

In addition to this, a system of formal clinical supervision is in place. S uses a reflective diary to prepare herself for her monthly supervision. She also uses a formal model to help her learn from experience when an incident from work is very troubling. One such incident happened during this week in relation to caring for Ms M. S broke down and cried when handing over to the patient's named nurse on night duty. Naturally, her colleague was very sympathetic; recognising that S was very tired she listened to her and then encouraged her to go home to her family.

S was concerned at her behaviour and decided to try to make some sense of it by analysing the incident using Gibbs' (1988) reflective cycle (see Fig. 33.4). This reflection (see Box 33.3) is written in the first person.

S wrote this reflection on her day off. She found it a very cathartic experience. However, she felt relieved following the exercise and decided that she must care for herself more vigilantly. She therefore immediately arranged to go swimming and out for lunch with a friend.

S will take this reflection to clinical supervision next week, as the wise counsel of the very experienced home care sister who is her supervisor is a major part of her professional support system.

1108 Fig. 33.4 The reflective cycle. (Adapted from Gibbs 1988.)

CASE STUDY 3 — MR Z

Mr Z is being cared for at home by his wife, daughter-in-law and the primary care team. At the age of 75, this retired gardener wants to die in his own home surrounded by his family. He is very fortunate that his GP and the district nurses in the practice have extensive experience in palliative care. They occasionally seek help from the local hospice but that has been less necessary in recent years.

Mr Z knows and is known to his doctor well, as his chronic obstructive pulmonary disease (COPD) has caused a gradual deterioration in his health for 6 years. Recently M, the district nurse, has been visiting the house regularly to dress Mrs Z's varicose leg ulcer. She has discussed Mr Z's steady deterioration with Dr J and, along with the patient and family, has made plans for the patient's end-of-life care at home. M is concerned, however, that this will not be possible as Mrs Z, who is a few years older than her husband, is also in poor health.

Working closely with the social services, equipment has been installed to ensure patient comfort and carer safety. This comprises a hospital bed, hoist, a wheelchair and sliding sheets. Oxygen equipment, including a regular supply of cylinders, has been in place for a year. Fortunately, the house is all on the ground level, a walk-in shower was installed to replace the bath some years ago, and Mr Z has an upright adjustable armchair.

Although M knows this patient and family well, she recognises the importance of going back to the model of palliative care (see Fig. 33.1) to ascertain that all aspects of care are being addressed.

Building a relationship and developing a profile

In reconsidering the relationship the primary care team have built up with the family, M studies the genogram that Dr J has drawn of Mr Z in the patient's notes (see Fig. 33.5).

Mr and Mrs Z have two sons and a daughter, having lost a third son in childhood. Their sons are both married and their daughter is divorced. All three have had two children of their own, so the Zs have six grandchildren. The oldest grandchild, whose wedding 3 years ago was the last social event Mr Z enjoyed, has recently had her first child.

The sons and their respective wives all live in the same neighbourhood as Mr and Mrs Z. They are all patients of the same health centre and are regarded as a very close supportive family. Their sister lives in Minnesota; she has not been home since the wedding.

This family is pulling together in stressful circumstances. They have open clear communication, flexible boundaries and roles, and yet they all have clearly designated responsibilities. Mr Z is always consulted on family matters. Although frail and the centre of care and attention, he is

Box 33.3

S's reflective account

Description — what happened?
On Thursday evening, when handing over to the night staff, I managed to get to my last patient, Ms M, when I could not continue as I started to cry. This had never happened before. I do occasionally cry at work, but it is normally done discreetly. It had been a very busy day, part of a difficult week. Two of my patients had died, one of whom I had known for many months. His family were extremely distressed at the end, especially his mother — after all he was only 35. I was glad I was on duty at the time as I had come to know them well.

After that family had gone home in the early afternoon, I had been auditing part of our admission standard. This involved accessing patients' notes from 6 months ago. The colleague who was supposed to help me with the audit was off sick. I went ahead without her because the secretary had looked out the notes, a considerable amount of work. Many of the patients whose notes had to be read have died since then; it was therefore a sad task.

Later in the evening one of my patients, Ms M, was talking about her daughters' excitement at performing in the school concert. It reminded me of when my daughters were young and I showed her a picture of my older daughter's graduation last month. Afterwards I wished I had not, as I saw the sadness come over her. I quickly changed the subject and some minutes later left the room.

I was tired when the night staff came on duty; however, that is a common experience. What was uncommon was for me to break down and cry.

Feelings — what were you thinking and feeling?
I was very embarrassed. My immediate thought was that my colleagues would think I was not coping. It was a distressing experience, especially as I cried all the way home and into the night. I felt better the next morning and was very grateful I was again on the late duty, as it gave me time to recover.

I know I am good at my job, and feel valued for my maturity and experience. I felt that I handled the young man's death well and really helped his family cope. Doing the audit was awful; I should have realised how it was affecting me and stopped. I have done a similar exercise before but always with a colleague.

I felt rotten at my lack of self-awareness in relation to Ms M. I know that her greatest source of emotional pain is in not being part of her daughters' future. Their graduation is potentially part of that. I like and admire Ms M and I do think she trusts me to do my best for her. I would be very upset to lose that trust. I also feel very guilty that I may have hurt her.

Evaluation — what was good and bad about the experience?
The good was that M, the night nurse I was handing over to, is a particularly valued colleague. She is wise and always helpful. On this occasion, she said, 'It is surprising we don't all break down more often, especially at the end of a harrowing day when we are exhausted like you are'. I felt supported and relieved to be going home.

The bad was my momentary lack of self-awareness, which meant that I might have reminded a patient of her emotional pain; also, that I left her room without giving her the opportunity to talk about it. Although in retrospect that was probably wise — because of my tiredness, talking at a deep emotional level with a patient would have been ill advised.

Analysis — what sense can you make of the situation?
That I have very high expectations of myself and therefore get very upset if I do not always get things right. That I need to continue to develop my self-awareness, particularly in recognising and taking appropriate action when I am stressed, such as in doing the audit unsupported. Also, that I need to be more vigilant with my communication, especially when tired.

That helping Ms M means a lot to me, I respect and admire her. I would be very upset if I lost her trust. I also feel I have a good understanding of her profound sadness, as I have had the joy of seeing my own two daughters into adulthood. Perhaps that was why I let her see the photograph.

Conclusion — what else could you have done?
I could have been open with Ms M and apologised for being insensitive. However, would that have benefited the patient or me? Ms M has acknowledged her emotional pain and indicated that she does not generally find it useful to talk about it. Perhaps I am being overly sensitive, as on the following day she asked me about my girls and asked me to bring in more pictures. She also indicated that she had asked her mother to bring in the photograph albums of her daughters so we could share them.

In relation to the audit, when I found it distressing I should have stopped and consulted the audit coordinator.

Action plan — if it arose again, what would you do?
I would indicate to the night staff that I had had a very emotional day and would be grateful if they would not be 'nice' to me as I might break down! I would give a brief report without any deep discussion and then I would go home. I would, of course, reassure them that a detailed report on each patient had been documented. In future, if an audit partner is off sick I will cancel the audit.

still the head of the family. The younger son is beginning to take on his father's role, as he is looked on as the family representative when decisions have to be made. The older son, a quiet man, occupies himself by ensuring that heavy physical tasks are attended to. Mrs Z is the coordinator and the communicator, although recently she has been very forgetful. The relationships within the family are warm and affectionate; they are tolerant of each other's idiosyncrasies.

M recognises these traits as being those of a well-functioning family (Bloch et al 1994, Davies et al 1994). She is aware, however, that the stress of nursing a dying relative at home has the potential to destabilise any family. Therefore, the primary care team must provide constant support, education and reassurance to enable this family to complete its task.

A district nurse is required to have a wide knowledge base in many areas of health care. This depth of knowledge cannot always be easily remembered. M acknowledges this and has therefore developed her information-seeking skills, frequently using the local nursing library and accessing the internet. In relation to this family, she recognises the need to revise her knowledge of the disease process of COPD to enable her to anticipate the symptoms Mr Z may suffer from at the end of life.

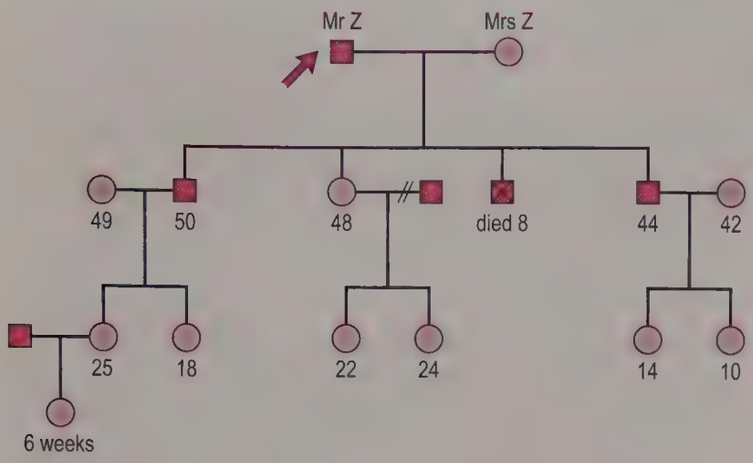


Fig. 33.5 Mr Z's genogram.

The anticipated symptoms of advanced COPD

Although there are many types of advanced pulmonary disease, of which Mr Z's diagnosis of COPD is one, the final problems are very similar (see Ch. 3). These are respiratory failure, cardiac failure and infection (Herbst 1996, Shee 2001). COPD is a broad classification for a number of conditions in which there is a chronic obstruction to airflow entering and leaving the lungs. Usually these conditions are bronchitis, an excessive secretion of mucus within the airways, and emphysema, an increase in the size of the air sacs distal to the terminal bronchioles with a loss of alveolar walls and elastic recoil of the lungs.

Advanced COPD often progresses to produce hypertrophy and failure of the right ventricle (right-sided heart failure). This is the result of the lungs being deprived of oxygen, which causes hypoxaemia, decreased arterial saturation, and hypercapnia, increased carbon dioxide in the blood, resulting in ventilatory insufficiency. This in turn leads to increased resistance in the pulmonary circulation with subsequent pulmonary hypertension. It is the pulmonary hypertension that leads to the right-sided heart failure (Smeltzer & Bare 2003).

The anticipated symptoms of advanced COPD are extreme breathlessness and a productive cough. An increase in the decline of the patient's forced expiratory volume (FEV) has been shown to be a useful indicator of the terminal phase of the patient's illness (Leach 2004). In addition, a drop in body weight due to increased metabolism from the effort of breathing and difficulty in maintaining an adequate nutritional intake indicates a poor prognosis (Herbst 1996). Other symptoms that should be anticipated include generalised muscle weakness and osteoporosis due to prolonged steroid therapy, pain from the osteoporosis, and chest pain due to ischaemic heart disease. Pulmonary embolism is also a risk due to immobility.

As the right ventricle fails, it should be anticipated that venous congestion and impaired sodium excretion might cause oedema in the peripheral tissues. Venous congestion of the abdominal organs may cause anorexia and nausea, and hepatic congestion may cause abdominal pain from an enlarged liver. In addition, there may be distended neck veins, ascites or a pleural effusion. Headache, confusion and stupor may come about because of carbon dioxide retention.

The medical management of COPD includes the use of long-term oxygen. Studies done in the 1980s in both the UK and the USA (Shee 1995) demonstrated that the use of long-term oxygen and cessation of smoking were the only actions that prolonged life in these chronically ill patients. However, physiotherapy, including a gentle exercise programme and breathing exercises, is thought to improve the patient's quality of life.

Exacerbations of chest infections are usually treated with antibiotics. Inhaled medications, such as the bronchodilators salbutamol and terbutaline, as well as the anticholinergic drug ipratropium bromide, are useful in relieving breathlessness, if they are administered correctly. The nurse must educate the patient and family in how to do this; an explanation of this method of delivering medication is given in Chapter 3.

Inhaled or oral corticosteroids may be prescribed for their anti-inflammatory effect. Oral corticosteroids may be prescribed to promote a feeling of well-being and increase the appetite (Shee 2001).

Severe breathlessness frequently responds to normal-release oral morphine. It should be started at a low dose (Leach 2004). There is a slight risk that some patients may develop carbon dioxide retention, respiratory acidosis. Therefore, a patient with advanced COPD who is commenced on morphine should be observed for headache and disorientation. It is useful to remember that a laxative must be prescribed when opioids are commenced.

A low dose of an anxiolytic such as lorazepam may partially relieve breathlessness by helping the patient to relax. Diuretics and a reduction of oral fluids to 1500 mL a day can help to relieve oedema (Leach 2004).

Monday In preparation for a team meeting on Tuesday at which the Z family will be discussed, M revised the pathophysiology of COPD in her local nursing library. She now feels prepared to seek information from Mr Z on which to plan care, i.e. based on his needs and priorities. She finds Mrs Z preoccupied making a fancy dress costume with her granddaughter, and takes the opportunity to speak to Mr Z on his own. M has structured her information-seeking guided by the headings suggested earlier in this chapter. In a short period, M skilfully gathers wide information to develop a profile and care plan. One potential problem she is aware of is constipation.

Constipation is a very common problem for patients in the palliative phase of illness. It can cause abdominal pain and embarrassment. It may lead on to other serious problems such as faecal impaction, overflow diarrhoea, urinary dysfunction, nausea, vomiting and even confusion (Atkinson & Virdee 2001). Careful assessment, management and documentation of this symptom may make the difference between the patient staying at home and hospital admission. The nurse's role in this is crucial.

In patients with advanced disease, many factors may work together to cause constipation. Sometimes constipation is disease related. For example, in the patient with cancer, the site of the tumour or the presence of hypercalcaemia may be a cause. Eating very small helpings of food with little roughage, drinking considerably less than

before and restricted mobility may all contribute to the development of constipation. When opioids are added to this scenario, constipation becomes a certainty. Opioids have a number of effects on the bowel. They reduce peristalsis, inhibit fluid secretion (Regnard & Hockley 2004), increase sphincter tone and diminish sensitivity to rectal distension (Sykes 2004). In this way, the patient can quickly become constipated, struggling to expel small, dry, hard stools.

Anticipation and assessment of this symptom form the basis for effective management. In other words, the district nurse does not wait until the patient complains of constipation, but is constantly alert to this possibility, reviewing the situation at each visit. As part of holistic assessment of the patient, the nurse needs to take a careful and sensitive history. This will include enquiry about:

- previous bowel habit
- the most recent stool (when it was passed, what it was like, any problems experienced)
- intake of diet and fluid
- concordance with laxative regimen
- other medications taken
- accessibility and acceptability of toilet arrangements.

Most important of all, the nurse needs to explore sensitively the patient's perception of the problem, i.e. his priorities and expectations. Where constipation is suspected, abdominal and digital rectal examinations are indicated (Sykes 2004). Depending on local policy and practising within the *Code of Professional Conduct* (Nursing and Midwifery Council 2004), a nurse may perform a digital examination of the rectum. A plain X-ray of the abdomen may be useful in assessing constipation (Sykes 2004).

The management of constipation is about more than prescribing and administering laxatives (Atkinson & Virdee 2001). It involves attention to the relief of pain and other symptoms, to fluids and diet and to adapting toilet facilities. Especially in the community, education of the patient and family may allow the patient to remain in control of this very personal and private aspect of care. Most patients in palliative care will, however, require a laxative. An understanding of laxatives is vital, especially for the district nurse who may also be a nurse prescriber (Campbell et al 2001).

Oral and rectal laxatives may be classified as predominantly peristalsis-stimulating or predominantly stool-softening agents. Danthron and senna are predominantly stimulants. An example of an oral stool softener is docusate. Bulking agents are rarely used in palliative care because they are unpalatable, require to be taken with a large volume of fluid and may complete an incipient intestinal obstruction. There is evidence to suggest that the combination of a stimulant and stool softener (e.g. co-danthrusate or co-danthramer) gives the most favourable results, at an acceptable dose, with a minimum of unwanted side-effects (Sykes 2004). The dose should be titrated against patient response.

As the majority of patients prefer oral to rectal measures (Sykes 1997, cited in Atkinson & Virdee 2001), the nurse should endeavour to keep the use of enemas and suppositories to a minimum. All rectal measures act, to a greater or lesser extent, by stimulating the anocolonic reflex. Enemas and suppositories, however, can also be classified as stimulants or softeners. For example, the stimulant bisacodyl suppository is useful for evacuating soft stool from the rectum. A microenema or phosphate enema may be effective in softening and evacuating more solid stool. Arachis oil enema or glycerine suppository may be used to soften hard stool, where this needs to occur before further treatment to evacuate the bowel will be possible. When rectal treatment is given, the doctor should review the oral laxative prescription and increase the dose if appropriate. Many teams will have devised a multidisciplinary protocol for the use of oral and rectal laxatives.

The management of constipation in palliative care patients is addressed in more detail in Regnard & Hockley (2004) and Sykes (2004).

Mr Z has never in his life had problems with constipation. When Dr J prescribed an opioid for Mr Z's increasing breathlessness, he simultaneously prescribed the laxative co-danthramer suspension 5 mL at night (a combined softener and stimulant). M emphasised to Mr Z and his wife the importance of taking this regularly (as prescribed), rather than waiting to see if constipation developed. Mr Z indicated that he could not bear the taste of the laxative, so M arranged for the doctor to change the prescription to co-danthramer one capsule at night. She also warned Mr Z that his urine may turn pink as result of taking co-danthramer, as this is a recognised side-effect of the laxative (Regnard & Hockley 2004).

While gathering information for the profile, M asks Mr Z about his bowels. He says that although he has been taking the 'medicine', his bowels have not moved for 3 days. Until now, his bowels have moved daily. At first he was glad, because 'it's such an effort with this breathlessness' and he rationalised that as he was 'not really eating' it did not matter. However, people eating very little can still become constipated, because desquamation, gut secretions and bacteria mean that waste is still produced in the bowel (White 1995). M explains this to Mr Z. On further sensitive questioning, M learns that the last stool passed was small, as he 'hadn't the puff to push more out'. Mr Z is now beginning to experience rectal discomfort.

Together they discuss some options. M explains that a rectal examination would allow her to give appropriate treatment. Rectal examination is within the scope of M's professional practice and there is a local multidisciplinary protocol on the use of rectal laxatives in the community. As rectal examination is an invasive procedure, M carefully and thoughtfully discusses and negotiates the need for this with Mr Z. Because he is tired from his conversation with M, they agree that she will come and help with his care first thing tomorrow. If it is still required, she can treat his constipation then.

Tuesday morning Before attending the multidisciplinary meeting, M goes to Mr Z's house. While assisting his daughter-in-law to wash Mr Z in bed, she notices that his abdomen is quite soft. There is no reason to suspect an intestinal obstruction. Gentle rectal examination reveals that his rectum is loaded with fairly hard faeces. A microenema is given as indicated on the protocol. M documents this in his notes, and shortly afterwards she helps Mr Z to the toilet and his bowels move well. It is clearly an enormous effort for Mr Z to get to the toilet. He acknowledges that

a commode may be useful, but 'not yet'. M decides to place an order for a commode to be ready if required. She also makes a note to discuss Mr Z's laxative prescription with Dr J at the meeting later. A small increase in oral laxative may be worth considering. Such discussion between the nurse and doctor is crucial in caring for the palliative care patient with constipation in the community (Doyle & Jeffrey 2000).

Before the extended multidisciplinary meeting, M writes the following summary into the patient's notes in preparation for updating the interdisciplinary care plan.

Main problems Extreme breathlessness is Mr Z's main problem. It has been getting steadily worse for years. He now requires help with washing, dressing and going to the toilet. He uses continuous oxygen administered with nasal cannulae, which he describes as 'his lifeline'.

Eating is a problem, as he does not have the energy to lift the food to his mouth and his dentures are loose. He finds it embarrassing but his wife is now feeding him her good home-made soups and his favourite puddings. He is, however, still losing weight and that is upsetting as he already thinks he looks like 'a bag of bones'.

Breathlessness is also making it difficult to empty his bowels. It is very exhausting and therefore he has been pleased that recently bowel movements are infrequent. He has rationalised that this is because he is not eating. He has in fact become constipated and the reasons for this have been explained to him.

Expectations Mr Z expects that soon he will not be able to get out of bed except when the nurses come and use the hoist. This is causing him some concern as the bedroom window looks out onto a brick wall whereas the sitting room has large windows onto the garden.

Doctor J has promised him he will die at home. That is all he is hoping for now. He is sure that everyone will rally round and he will try not to be too much bother to anyone: 'One day soon I will just stop breathing. I wouldn't say this to the family but it will be a relief, I am worn out with all of this being ill'.

Priorities Mr Z has a beautiful garden, which he laid out over 30 years ago. It is maintained by his older son, who lives with his wife and grown-up family in the next street. Mr Z tells M that watching the garden throughout the seasons is still his greatest pleasure. He impresses on her his need for the garden, although now he is just a spectator, not the worker he used to be. He jokes about how he used to rush back to it from the family holidays. Mr Z chuckles as he reminisces about this and then becomes serious again, anxious that M understands why he must die at home.

He insists that his only other pleasure is being with the family when they all gather round in the evening. This is why he wants to be able to continue to sit in his chair in his own sitting room.

Understanding of illness Mr Z demonstrates a full understanding of his illness. He has shared with M how he expects to die. The actual process of dying does not appear to be worrying him; what he is concerned about is where the last days of his life will be spent.

Anticipated symptoms Because of Mr Z's diagnosis of COPD and his long-term incapacity, he has many actual and potential problems. His skin is very friable due to long-term use of steroids, and recently he has lost 2 stones in weight. Nocturnal dyspnoea affects his sleep. His main anticipated physical symptoms are increasing oedema of the lower limbs, pressure ulcers, sore mouth, constipation, pain in the chest and/or the right upper quadrant of the abdomen. Disease progression may lead to chest infection, pulmonary embolism and respiratory and/or cardiac failure.

Mr Z may also become very anxious and frightened and may have a respiratory panic attack. He has previously attended a nurse-led clinic to promote self-management of these problems (Syrett & Taylor 2003).

Applying the principles of palliative care

Pain and symptom management

- *Support the family in helping Mr Z to take his medication regularly.* He is continuing to take the bronchodilators salbutamol and ipratropium by nebuliser, oral prednisolone 10 mg daily and furosemide 80 mg daily for ankle oedema. Mr Z has continuous oxygen by nasal cannulae at 2 L/min via an oxygen concentrator. For 2 weeks he has been taking oral morphine 2.5 mg 4-hourly to ease his severe breathlessness. This has been a useful addition to his pharmacological management, easing the dyspnoea, especially at night.
- *Monitor Mr Z's pain control.* Mr Z insists that he has no pain. However, he did admit that his chest felt more relaxed since commencing on the morphine and he is not breathing so rapidly.
- *Monitor Mr Z's bowel function.* The laxative co-danthramer suspension 5 mL has been changed to co-danthramer one capsule at night, as Mr Z hates the sickly taste of the liquid preparation. Rectal treatment by means of a microenema was given for constipation. The need to increase the oral laxative will be discussed with Dr J at the meeting. A commode has been ordered, so that it is ready when Mr Z wants it.

Adjustment to loss and change

- *Support Mr Z and his family in their ongoing adjustment to loss and change.* Mr Z has suffered many losses throughout his long illness. He appears to have adjusted to his increasing incapacity in a positive fashion, although when he could no longer work in his garden he was angry with the doctors and could not believe there was not a cure for his illness.

  Mr Z states that he is not a religious man but a man of the soil, observant of the life cycle as well as of the seasons. He is sorry he will not see the snowdrops again but he recognises that his life span is ending. He has had a good life and has few regrets although he is worried about how his wife will cope with his death. She has suffered from depression regularly throughout her life and was in hospital on two occasions, once after they lost a son. The other occasion was when her elderly mother died.

Pursuits that give pleasure

- *Encourage and support Mr Z to live at home with his family during this final illness.* Mr Z has impressed on all of the health care team that being in his own home

surrounded by his family looking out on his beautiful garden gives him the greatest pleasure. He cannot concentrate on television and is too weary to read.

Obtaining a wheelchair 3 months ago from the social services has been a great success, as Mr Z can again be out in the garden, with the help of his family.

Tuesday (cont'd) Mr Z is the subject of a case conference at which the extended primary care team are present; Mr Z's younger son is also in attendance. Dr J leads the meeting, ensuring that all present have the opportunity to contribute. Two main issues arise which require discussion with the patient.

M tentatively raises the issue of moving Mr Z's hospital bed from the master bedroom into the sitting room. This is accepted as sensible by the son, but he is not sure what his father's reaction will be to the suggestion. Mr Z has slept in the same room as his wife for over 50 years. The son agrees to discuss the move with Mr Z.

The son informs the team that his father has been incontinent of urine regularly in the mid-morning for a few weeks, but he will not tell the nurses. Dr J suggests that he would talk with Mr Z about this 'man to man' and suggest a urinary catheter.

M suggests that it is time for the care assistants to assist the family with the patient's personal care on a daily basis.

When the son leaves the meeting to go back to work, Dr J takes the opportunity to introduce to the team the concept of an 'integrated care pathway for the dying patient', being piloted by the neighbouring health centre. He indicates that Mr Z would be a suitable patient for this multiprofessional document which replaces existing documentation with a template based on evidence-based guidelines relating to the care of the dying (Ellershaw & Wilkinson 2003).

Wednesday Dr J visits Mr Z in the late morning, a time when patients' respiratory problems are often at their least troublesome. He finds Mr Z in his bed in the sitting room; the family made the move with their parents' consent on the Tuesday evening. After a short useful discussion, Mr Z thanks the doctor for his help and readily agrees to have a urinary catheter inserted. Dr J is very concerned that Mrs Z is looking very tired and frail. He records her blood pressure, which is slightly raised, and takes some blood for a full blood count.

M calls in the early evening on her way home to teach the sons catheter care, including emptying the closed system bag.

Friday The older son pays an early morning call to his father, sharing a cup of tea before his mother rises. This is a routine for father and son, especially in summer time. Before leaving to go to work, the son becomes aware that his mother is not around, and on going to waken her he finds that she has died in the night. Shocked and unsure what to do, he is relieved when he sees M's car drawing up at the gate.

M immediately arranges for Dr J to come to the house. When he has certified Mrs Z as dead, the doctor, district nurse and the son sit down together to make plans for sharing the bad news. The son and Dr J will speak to the immediate family. M will tell Mr Z.

M is very aware of the need for this communication to be sensitive and structures her approach following the framework advised by Buckman (1992). She starts by 'firing the warning shot': 'You know how your wife has been looking so tired and frail lately. Well, Dr J had noticed and did some tests on her. I am afraid I have a shock for you'. At this point M hesitates to ensure that Mr Z had heard and understood her communication. The patient nods his head. M continues, gently telling him in 'bite-sized pieces' what happened that morning. Mr Z reaches out towards her, holds her hands but says nothing. They sit for a few minutes. M then asks, 'What can I do for you?'. After a long silence, Mr Z says: 'It is for the best. She has gone before me'. After another long silence and a few tears, he asks to see his son, and M leaves them together.

Monday, week 2 It has been a busy weekend for the Z family as they try to come to terms with Mrs Z's sudden death. There is a sense of unreality about what has happened as they arrange for the funeral, care for Mr Z and support each other. Many emotions and feelings are being experienced in this initial period of grief, as the impact of the event becomes a reality (Murray Parkes et al 1996, Worden 2003).

Wednesday, week 2 The Z's daughter arrived from the USA on Tuesday. She is causing some anxiety in the household, as she is very critical of her father's care, indicating that such an ill man should be in hospital. At the sons' request, Dr J and M have an appointment to see her in the health centre this morning. The health care team will have to employ patience and understanding towards a family member who may be very insulting in her attitude about their care. This reaction has been described by Jenkins and Bruera (1998) as the 'daughter-from-California syndrome'. It refers to the reactions and behaviour of an absentee member of the family who returns during a serious illness.

Four characteristics are described:

- shock at the extent of the patient's deterioration
- unrealistic expectations regarding treatment options, because of lack of involvement in treatment decisions
- guilt about being absent at such an important time
- reassertion of role through conflict.

Friday, week 2 M has timed her visit to Mr Z to coincide with the time of his wife's funeral, knowing that it will be an emotional time, a time in which she can demonstrate her support by being there. Most of the family have gone to the crematorium. M enters by the garden, as she has many times before. Standing in the door, she witnesses an intimate family picture. The eldest granddaughter is sitting by the bed breast feeding her baby, and her husband is at the other side of Mr Z's bed reading from the Psalms.

On approaching the bed, M realises that Mr Z is dying. His peripheral circulation is failing, he is covered in a drenching sweat, his skin feels cold and clammy and his extremities are blue. There is a Cheyne–Stokes pattern of breathing and he appears to be unconscious. M speaks to him but there is no response. She then concentrates on explaining to the young couple that their grandfather is dying. By the time the family return from the funeral, Mr Z has died — as he had wished, in his own home.

Wednesday, week 3 On the day following Mr Z's funeral, M and Dr J have arranged to meet the family to offer their condolences, answer any questions regarding their parents' deaths and offer bereavement support.

Bereavement Talking with the health professionals who have become known and trusted by the family during the final illness may help the family in this early phase of grief to accept the reality of the loss. Discussing the death and answering questions can help to dispel anger and prevent needless guilt arising. It can give the family the opportunity to criticise the care provided. Relatives rarely feel able to do this when the patient is alive. It can also give the family the opportunity to thank the health professionals and therefore finish the experience of living with the terminal illness and move into the adjustment period of the bereavement (Murray Parkes et al 1996).

Case review

Part of the primary care team's support system is to hold a debriefing meeting following difficult situations. M and Dr J are pleased to hold such a meeting following the deaths of Mr and Mrs Z.

The interdisciplinary team members discuss the patients' illnesses and the care and management provided. The postmortem carried out on Mrs Z concluded that she had suffered a stroke.

A lively discussion is held postulating the possible outcome had intervention been offered before the event. The successful conclusion to Mr Z's final illness allows the team to feel satisfied. M and Dr J are supported by their colleagues' praise for the organisation and hard work, which enabled Mr Z to die at home in very difficult circumstances.

Bereavement assessment is discussed. A leaflet containing information about the help available both in the health centre and from Cruse bereavement care has been left with the family. M is going on holiday for 2 weeks and has arranged to meet the family for a bereavement visit on her return.

CONCLUSION

Working in a hospice, one is often asked: 'What is so special about palliative care?'. This chapter has endeavoured to answer that question by demonstrating how this approach to care can be utilised in a hospital ward, in a hospice and in the home. It is never appropriate to say that 'there is nothing more that can be done'; what can be done is to implement a palliative care model, the focus being on the quality of life of the patient and the family in the time that they have left together.

INTRODUCTION

This chapter will address the rehabilitation requirements of two categories of patient: those in whom some recovery is expected, the aim being to achieve optimal improvement in function by applying specific therapeutic techniques, and those with progressive and chronic conditions where more emphasis is placed on social, psychological and environmental factors than on specific interventions (Nolan et al 1997).

Rehabilitation is an issue of considerable political and health care team interest, both nationally and internationally (DH 2001a, WHO 2001). The National Service Framework for Older People (DH 2001a) requires effective rehabilitation services, with nurses playing a pivotal role within the inter-professional team and it has been argued (Edwards 2002) that the scope for the nursing contribution to rehabilitation has widened considerably. Although Henderson's (1966) assertion that nurses are 'rehabilitators par excellence' has often been quoted to support the view that nurses have a unique role in rehabilitation care, Nolan et al (1997) consider that nursing has not yet fulfilled its potential in the field of rehabilitation. Pre- and post-registration nurse education should enable nurses to develop the competencies that will enable them to reach their potential within the rehabilitation setting (Low 2003). This chapter aims to address competency in rehabilitation nursing by presenting general principles that nurses can apply to a range of practice situations.

Evidence-based practice

Evidence-based knowledge about illness and disability is necessary to enable patients to take an active part in their care and to enable health care professionals to develop appropriate care interventions (DH 1996). It is both ethically and professionally desirable that nursing care is based on current, research-based and accessible information. The Nursing and Midwifery Council's *Code of Professional Conduct* (2004, para. 6.5) states: 'You have a responsibility to deliver care based on current evidence, best practice and, where applicable, validated research when it is available'. Therefore nurses are required to be research-minded to enable them to evaluate current health care research and implement the findings in their practice.

What is rehabilitation?

There are many definitions of rehabilitation, but little agreement on any one definitive definition. Rehabilitation has been defined as being concerned with the restoration of an individual's social, physical and emotional functions and abilities to their prior level (Gibbon 1992). Other definitions view rehabilitation as enabling an individual to reach the optimal level of functioning they are able or motivated to achieve (Davis & O'Connor 1999, Edwards 2002). Chamberlain (1997) has suggested that whereas disability limits choice, rehabilitation can restore choice to a disabled person. However, it has to be recognised that not all patients can achieve full recovery as many have complex health problems which will prevent this from happening. Wade (2002) points out that rehabilitation is a way of thinking rather than a way of doing. Barnes and Ward (2000) suggest that rehabilitation is an individual, active and dynamic process, the basic nature of which is to work with a disabled person and the family in a partnership. O'Kelly (1997), who suffered a stroke at a relatively early age, and while fully involved in his professional career, states:

> *Rehabilitation is an active process in which disabled people work together with professional staff, relatives and members of the wider community, to achieve their optimum physical, psychological, social and vocational well-being.*

CASE HISTORY 34.1

Mrs J

Mrs J is a 35-year-old woman who has been newly diagnosed with multiple sclerosis. She has two children at junior school. Her husband is a lorry driver. She works as a waitress in a café. Her most prominent problem is fatigue and muscle weakness that gets worse as the day progresses, but is relieved by rest. She is keen to return to work as soon as possible.

Rehabilitation should therefore focus on helping patients achieve their own goals (see Case History 34.1). Smith (1999a) suggests that the aims and characteristics of rehabilitation are as follows:

- Reduction of disability and handicap
- Independence
- Empowerment
- Problem solving
- Client centredness
- 'Holistic' approach
- Educational process.

The approach to a patient with an acute illness differs from the approach to the care of a patient with a chronic illness. This is because a chronic illness places new demands on patients, which may limit their self-care abilities (Neal 2001) (see also Ch. 32). However, the individual who survives an acute illness may experience disability and chronic ill health. For example, a person who has a stroke may experience three different care environments — emergency, acute and rehabilitation — each with a different intervention focus (Burton 2000a). In an acute care setting, a major focus of the nurse's role is the physical care of the patient. As rehabilitation progresses, nurses steadily and intentionally reduce the physical care provided. However, they simultaneously increase the team's emotional and psychological support as the patient copes with the process of rehabilitation (Sheppard 1994).

In recent years, there has been a shift towards a more patient-centred approach to rehabilitation. This philosophy advocates patient autonomy and independence with patients empowered to be actively involved in their care (Preston 1994, Wilson 2000). In this patient-centred philosophy the individual becomes the expert in taking control of and managing their own care. Goal planning has been seen as a way of increasing patients' involvement in rehabilitation (Duff et al 1999, Playford et al 2000). It is a part of the care process that involves both the interprofessional team and the patient in identifying the patient's needs. Both parties negotiate and establish goals based on individual need (Kennedy et al 1996).

34.1 Review Case History 34.1 and reflect on what the nurse's role would be in supporting this patient in her desire to return to work. Discuss this with your mentor on your community placement.

Who needs rehabilitation?

Rehabilitation skills are inherent in evidence-based nursing practice and have been described for specific conditions elsewhere in this book. The purpose of this chapter is to focus on those patients whose health condition causes continuing disability and consequent activity limitations.

World Health Organization international classification of functioning, disability and health (ICF)

In May 2001, the World Health Assembly approved a new international classification of functioning, disability and health (ICF) (WHO 2001). In contrast to the previous WHO international classification of impairments, disabilities and handicaps (WHO 1980), which focused narrowly on the impact and consequences of disease and, according to Gray (2001), suggested a linear causal relationship among these three consequences, the ICF takes a multiperspective approach and provides 'a classification of people's health characteristics, within the context of their individual life situations and environmental impacts' (WHO 2001). The ICF has two parts, each with two components (see Fig. 34.1):

- Part One deals with functioning and disability. The term 'functioning' encompasses all body functions and structures, activities and participation, whereas the term 'disability' encompasses impairments of body functions and structures, activity limitations and participation restrictions. The ICF points out that the term 'impairment' does not necessarily mean a disease is present. It is a broader and more inclusive term, e.g. the loss of a limb is an impairment of body structure but is not a disease.
- Part Two deals with environmental factors, e.g. the physical, social and attitudinal environment for each individual, and with personal factors, e.g. gender, race, culture, age and lifestyle. These factors combine to

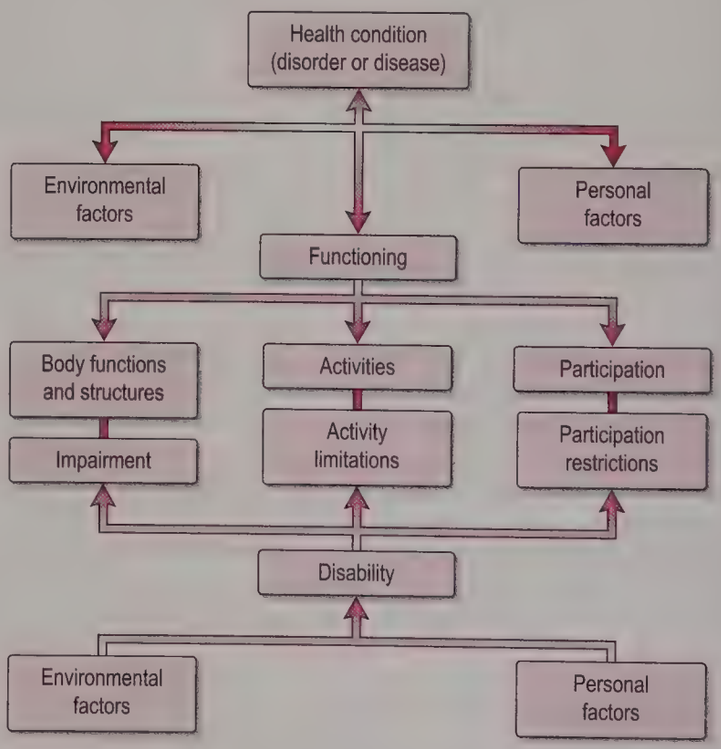

Fig. 34.1 Interactions between the components of the international classification of functioning, disability and health. (Adapted from WHO 2001, with permission.)

constitute the all-important context in which individuals live with their health condition, and which impacts on all aspects of their functioning and disability.

The ICF (WHO 2001) was designed in an attempt to find a common language with which to code and classify functioning, disability and health, and thus permit international comparisons. More than 50 countries took part in its compilation, including people with disabilities and related organisations, leading to a feeling of 'ownership' by all its users. Through its use, the World Health Organization hopes that disability advocacy will be fostered and more interventions will be identified which can improve levels of participation. It is acknowledged (WHO 2001) that more research is needed to evaluate the application of the ICF to practice, and Grimby and Smedby (2001) suggest various ways in which this could be fruitfully explored.

For more detail on the ICF, and examples of the application of ICF concepts to individuals (Annex 4), see WHO (2001).

THE PSYCHOLOGY OF DISABILITY

The effects of illness and disability on the psychological status of a patient may be intense. As nurses are with the patient 24 h per day, they are in a unique position to observe and assess a patient's behaviour and to provide first line psychological support (Thomas 1999, Pellatt 2003) (see Research Abstract 34.1). To enable nurses to carry out this important role, an understanding of the psychology of disability will provide the basis for the sustained therapeutic relationship which is crucial in the rehabilitation process. By being aware of the psychological responses of individuals to trauma and disability, nurses can differentiate between what is an expected or normal response and that which requires referral to a professional with different, more developed skills (Tripp 1999).

RESEARCH ABSTRACT 34.1

Perceptions of the nursing role in spinal cord injury rehabilitation

One section within a large ethnographic study (Pellatt 2003) aimed to identify how nurses and patients perceived the nursing role in spinal cord injury rehabilitation. Semi-structured interviews were carried out with 14 spinal cord injured patients and 14 registered nurses from a large spinal cord injury unit. Patients had a range of levels of injuries and were either in the rehabilitation stages of being a new injury or had been injured for some years. The nurses had been qualified for at least a year, had undertaken a post-registration course in the specialty and had a role in decision-making processes as named nurses and/or key workers.

The findings suggest that patients value the nursing contribution as a means of emotional and physical support, but that they do not necessarily see nursing input as rehabilitation. Nurses see their role as multifaceted, but identify difficulties in crossing over from an acute care philosophy to a rehabilitation philosophy.

The implications for practice are that the roles and responsibilities of nurses should be more clearly defined for patients. Nurses need to develop self-awareness and explore ways of working that empower patients to make decisions about their care.

Pellatt G 2003 Perceptions of the nursing role in spinal cord injury rehabilitation. British Journal of Nursing 12(5): 292–299

Stigma

The concept of stigma is an important factor in the consideration of the social situation of people with disabilities. An appreciation of the dynamics of a stigmatised illness can help nurses understand the social and psychological aspects of their patients' lives. Originally, the term stigma referred to physical blemishes, which were perceived by the ancient Greeks to signify something unusual or bad about the moral status of an individual (Sim 1990). Goffman's seminal work (1968) describes stigma with reference to an individual deemed to be socially unacceptable due to a failing or handicap, which marks them out as a tainted person. There are two types of stigmata — those that are immediately apparent to others, such as the use of a wheelchair or obvious scarring, and those that are not immediately visible or apparent to others, such as epilepsy. The stigmatised person is perceived to deviate from what society regards as normal (Faugier & Sargeant 1997). People without stigma may generalise from a particular disability to an assortment of disabilities or imperfections. This may lead to people speaking to a person in a wheelchair as if that person does not understand, to shout at someone who is blind or to speak to the companion of a person with a disability rather than to the person with the disability (Joachim & Acorn 2000). In many countries and cultures, physical appearance affects how people feel about themselves and also how others perceive them. People with chronic illness or disability may have conditions that alter their appearance, e.g. a person who has suffered a hemiplegic stroke. Others may have a change in appearance that, although not immediately visual to others, is felt by them to be stigmatising, such as a colostomy.

Stigma has also been viewed in terms of dependency. Illness may mean that an individual is in the dependent position of receiving care without being able to contribute in return (Sim 1990).

Some people with a disability have argued that their contact with nurses and other health care professionals tends to be disabling. French (1994) pointed out that research findings on whether the attitudes of health professionals towards stigmatised individuals are more or less positive than those of the general public tend to conflict. However, the weight of evidence suggests that the attitudes of health care professionals are not very different from those of the general public and may become more negative as professional education proceeds. Scullion (1999), in a study of student nurses, found that disability was conceptualised as a form of deviation, a condition of dependency or a concept that was difficult to define.

It is important that nurses realise that patients' self-concept reflects the reactions of others to them. Negative attitudes held by nurses towards stigmatised groups can

adversely affect their care. Contact with chronically ill or disabled patients may give rise to a variety of emotions but how these emotions are displayed will impact on the patient's care. Expression of distaste will be hurtful, and pity may be perceived as patronising and reinforce the person's sense of inferiority. Professional detachment may lessen rapport and accentuate the social distance experienced by the stigmatised person (Sim 1990). To avoid this, Lucke (1999) has identified that nurses and other health care professionals need to be committed to forming caring relationships with patients. A caring relationship is one in which professionals share their knowledge and experience with patients, thus communicating respect and value for the patient.

Grief

The impact of sudden disability has been described as similar to that of bereavement. In her seminal text, Kubler-Ross (1969) described a model of grief that encompassed five interdependent emotional stages:

- Denial
- Anger
- Bargaining
- Depression
- Acceptance.

This model has also been adopted for describing the stages that individuals undergo when they experience a severe illness or disability (Wilson & Fletcher 2002). However, it is important to recognise that the five stages may occur simultaneously, may overlap, or may not occur at all. It is also important to be aware that an individual's cultural background and religious beliefs will influence reactions to loss and grief (Holland & Hogg 2001).

Morse (1997) has developed a five stage model, *Responding to Threats to Integrity of Self*, which describes a person's responses to illness or injury. The theory is one of recovery and rehabilitation. The stages are as follows:

- *Vigilance* — where the individual suspects that something is wrong: a feeling of dis-ease or illness or the checking for the extent of injury after an accident
- *Disruption* — where the individual attempts to hold on to life, i.e. enduring to survive
- *Enduring to live* — where the individual develops strategies to help bear the pain, maintain control and gradually consider the implications of the injury or illness, i.e. striving to regain self
- *Suffering* — where the individual begins to struggle with grief, what has been lost and the altered future, i.e. striving to restore self
- *Learning to live with the altered self* — where the individual learns to live with the changes that have occurred, such as paralysis, an amputation or fatigue.

Nurses have an important role to play in helping patients as they go through the stages of grief and adapt to change. It is vital that nurses facilitate both the setting and achievement of goals by the patient. Rehabilitation should focus on what the patients can achieve, not on what they cannot do, but at the same time should recognise each patient's own limits. Nurses can empower patients by enabling them to recognise new possibilities (Wade G 1998). For example, patients in Lucke's (1999) study identified that caring nurses and therapists created an atmosphere in which they were able to identify that they were still able to have meaningful relationships with their partners and children despite having a disability. A Swedish study of people with muscular dystrophy identified that participants trusted rehabilitation staff whom they perceived to be supportive, committed and knowledgeable. This enabled them to develop problem-solving skills and to capitalise on the things that they were able to do (Natterlund & Ahlstrom 1999).

Stress and coping

Stress is discussed in depth in Chapter 17.

People use different strategies to cope with stress. According to Engel (1964) stress caused by illness and injury may be due to:

- loss or threat of loss of anything that is of great importance to an individual
- real or threatened injury to the body
- frustration of drives.

How an individual copes with the demands of illness or injury depends on the method used to cope with stress (Groomes & Leahey 2002). The most common ways of coping are:

- *problem focused*, where people with disabilities collect information about treatments or take action such as modifying the house to enable wheelchair access
- *emotion focused*, where people with disabilities aim to reduce the impact of the stress response by controlling their emotions or conversely venting frustration, anger or despair; the individual may exhibit resigned acceptance or coming to terms with the disability
- *avoidance*, where people with disabilities focus on small, manageable components of a situation or focus on the perception that there are others worse off than them.

Research has suggested that an individual's ability to set flexible but durable goals will influence their psychological adjustment to physical disability (Brillhart & Johnson 1997, Elliott et al 2000). However, the loss of control experienced by people with chronic illness and disability may cause anxiety and depression (Kennedy et al 2003). This may in turn lead to helplessness and dependency (Mahat 1997) (see Case History 34.2), which may be factors in the motivation of patients to participate in their rehabilitation (Maclean & Pound 2000).

CASE HISTORY 34.2

Mr S

Mr S is 75 years old and has suffered a stroke that has left him with a left-sided weakness. He has been admitted to a rehabilitation unit from an acute ward and has expressed surprise that he is expected to participate in his own care as the nurses in the other ward did everything for him.

34.2 Review Case History 34.2. Consider the role of the nurse in enabling Mr S to understand the rehabilitation process and to participate as a partner with the nursing staff.

The rehabilitation team has an important role to play in supporting patients as they work through the psychological processes associated with disability and chronic illness. They need to be positive, encouraging and willing to empower patients to become actively involved in their rehabilitation. Nurses need to be aware that they may inadvertently encourage patients to adopt a passive role by doing things for them in order to complete their care more quickly (Maclean et al 2000). For the person with disability, social support supplied by family and friends acts as a buffer against the stressors caused by the disability (Davidhizar 1997). The supportive role of the patient's family and friends, and the support that they need to undertake that role, should be recognised and facilitated by the rehabilitation staff.

RESEARCH ABSTRACT 34.2

The nursing role in stroke rehabilitation

A study undertaken by Burton (2002b) describes the nursing role in stroke rehabilitation and three factors which shape that role. The method used was reflective enquiry to collect data that were grounded in the realities of clinical practice. The study took place in a 24-bedded rehabilitation unit, and 13 qualified nursing staff participated by completing reflective accounts of clinical incidents that had been important to them. A total of 35 incidents were collected for analysis.

Three role categories were identified: the nurse as care giver; the nurse as facilitator of personal recovery, which involved helping, comforting, teaching and working with the patient and family; and the nurse as manager of multidisciplinary provision.

The findings suggest that nurses have a key role in stroke rehabilitation but need to build on and develop new partnerships with patients and carers.

Burton C 2000b A description of the nursing role in stroke rehabilitation. Journal of Advanced Nursing 32(1): 174–181

THE PROCESS OF REHABILITATION

The interprofessional team

It has been recognised that an interprofessional team approach to rehabilitation is more effective than when individuals work in isolation or as a unidisciplinary group (Seaman 1999). Evans et al (1995) argue that patients who receive an interprofessional rehabilitation service are more likely to survive, have greater functional ability and have a better chance of returning home than those who do not. An interprofessional team brings together separate but interlinked professional skills. Team members share a common goal and common objectives and work together to achieve that goal (Engel 1994). The membership of the interprofessional team may vary considerably; however, a successful team is thought to have five important attributes (Miller et al 1999):

- A central purpose that transcends disciplinary boundaries
- All members understand each other's roles and recognise where roles overlap
- Members appreciate other disciplines' knowledge — how it is gained and used
- Members value different perspectives, can accept changes in authority and status and are willing to accept challenges
- Members are able to resolve conflict by understanding the difference between accountability and responsibility of different team members and knowing what is expected of them.

The skills required by a rehabilitation team will vary depending on the needs of the person with a disability. However, the core skills required by all teams will include assessment and management of impaired physical mobility, dexterity, communication, eating and swallowing, cognition, continence, tissue viability and emotional well-being, as well as counselling skills. Medical knowledge of diagnosis, prognosis, drug treatment and its complications must be readily accessible. In addition, team members need team-related skills such as communication, good information recording, public relations, teaching, evaluation and monitoring of outcomes, and research and development (Harvey 1997) (see Research Abstract 34.2).

It has been suggested that rehabilitation programmes aim to change an individual's behaviour in ways that support improved physical, social and psychological functioning (Kennedy & Hamilton 1999). It could be argued that the identification and setting of appropriate goals is one of the skills that characterises rehabilitation professionals (Wade D 1998). Goal planning involves all members of the interprofessional team. In the first stage of the process the patient and the named nurse together complete a needs assessment checklist. This checklist is composed of benchmarks for quality of care and expectations of independence. Categories of assessed need include activities of daily living, bladder, bowel and skin management as well as social and psychological issues (Duff et al 1999). By using a needs assessment and goal planning approach to rehabilitation, patients are able to think about their personal needs and therefore increase their involvement in and control over the rehabilitation process. It also enables staff to recognise what the key issues are for a particular patient. It is important, when assessing the category of independence, that no distinction is made between verbal and physical independence, so as to enable all patients to have the potential to achieve 100% independence. Even if unable to achieve a task physically, if patients are able to instruct others how to do it for them, they are considered verbally independent.

When using a needs assessment and goal planning programme, the patient is allocated a key worker who can come from any professional discipline in the team. The key worker coordinates the goal planning meetings and works with the patient and the interprofessional team to establish and identify needs, clarify goals and set targets. Goal planning meetings normally take place every 2–3 weeks, with the goals being reviewed and additional goals set. As confidence in the process is gained, the patient is able to

take over from the key worker and coordinate the process for themselves (Foley 1998).

In the community, the concept of 'need' was central to the implementation of the NHS and Community Care Act (DH 1990). Professional groups were required to develop systems for needs assessment that promoted the views of the client. This has meant, for example, that community nursing services are responsible for the development of appropriate methods of identifying clients at risk or in need of intervention (Carney et al 1996). However, whichever tools are used to assess need, it is vital that assessment is not seen as a single event (Cowley et al 1996) and that the views of clients and their carers are taken into account (Tranter & Sullivan 1996).

Outcome of the rehabilitation process

There has been considerable emphasis by professionals on the attainment of the physical goals of rehabilitation. Where they are appropriate, physical goals are important and there are several quantitative tests available to measure functional outcomes. It has been suggested that the financial climate of health care requires both efficient and effective rehabilitation that has measurable outcomes. Functional gain is an easily observable indicator of successful rehabilitation (Nolan & Nolan 1998). However, these functional measurements have been criticised as being generically applied to all patients, without taking account of the context in which the patient's rehabilitation is taking place. The implication of this is that they can be used across many settings with no consideration being given to the meaning in context of the functional outcomes for the individual patient (Williams 1996). For example, although a patient may be able to get dressed in the morning in the hospital setting, it may take them so long to dress unaided once they are at home that they are unable to get to their place of work on time. This will prevent the individual from earning a living and force them to rely on benefits.

In addition, reliance on functional outcomes which do not address the value of qualitative aspects of people's lives, such as satisfying and meaningful relationships, suggests that people with severe disability have less potential than those with less disability.

Rehabilitation is therefore concerned with both qualitative and quantitative aspects of life. It involves not only preventing complications, but also providing therapy and, for example, the fitting of adaptive equipment, and psychological assessment and counselling (Glass 1999, Thomas 1999).

ROLES

The role of the patient

Patients should be regarded as co-workers in the rehabilitation process and their contribution should be regarded as equally important as that of health care professionals (McLeod 1995, DH 2001b). One of the patient-focused outcomes in the government's document *Essence of Care* (DH 2001c) is that patients have control over their own health care. This document provides benchmarks for best practice, one of which states that 'patients/clients and practitioners are working in partnership to establish their responsibilities in meeting self-care needs'.

The notion of patients having expertise in the management of their conditions has been encouraged by the government in its document *The Expert Patient: A New Approach for Chronic Disease Management for the 21st Century* (DH 2001b). The aim is to enable individuals with chronic illness to self-manage their illness, based on empowerment and assertiveness. However, there is conflicting evidence about patients' expectations of their role in the rehabilitation process. In some studies, patients did not expect to be involved actively in the planning and implementation of rehabilitation (Sheppard 1994, Abbott 1999). Other studies suggest that patients do recognise the importance of their own role in rehabilitation (David 1995, Brillhart & Johnson 1997). Proot et al (2002) suggest that patients use the strategies of 'taking responsibility' and 'initiative' to facilitate their autonomy in the rehabilitation process, encompassing:

- cooperation
- anticipating
- problem solving
- taking stock of the situation
- investing own effort
- refusing, i.e. deciding to decline.

Lucke (1999) cites patients with spinal cord injury who see being able to take charge of rehabilitation as an outcome of good relationships between themselves and rehabilitation team members.

It is important that health care professionals recognise the fact that rehabilitation may be hard work for patients. Patients have described rehabilitation as a mental and physical struggle (Sheppard 1994, Maclean et al 2000). In a Canadian study of spinal cord injured patients, the rehabilitation phase was described by patients as doing 'hard labour in jail' (Carpenter 1994) (see Box 34.1). However, there are strategies that health care professionals can use to enhance the rehabilitation experience for patients by enabling them to take control of the process, such as:

- providing information
- supporting patients in activities of living (ALs), e.g. dressing
- promoting mobility
- communicating with patients
- guarding against a paternalistic approach
- enhancing patient choice
- working in partnership with patients and their families.

By adopting these strategies the rehabilitation team can challenge patients to solve their own problems and act in a more consultative role (Proot et al 2002) (see Case History 34.3).

The role of the nurse

The role of the nurse in rehabilitation has suffered from a lack of clarity. However, the role is multifaceted and Long et al (2001) (see Research Abstract 34.3) have identified six core elements:

- Assessment
- Coordination and communication

Box 34.1

An experience of rehabilitation

It was a lovely hot sunny day. The sea looked so inviting. I was 16 and on holiday with my Mum, Dad and younger brother. There was a causeway jutting out into the sea and my brother and I had been jumping into the water from it all day. However, this time I must have jumped differently, as I went into the sea head-first. I felt my head hit the sand and felt a crack in my neck. I couldn't move, I couldn't feel anything, I thought I was going to drown. Luckily my brother realised something was wrong and screamed to my Mum and Dad who were nearby. They and some other people dragged me out of the water and called an ambulance. I was taken to the local hospital where they diagnosed a fracture/dislocation of my sixth and seventh cervical vertebrae. This left me with limited use in my arms and no sensation or movement in my trunk and legs. They applied skull traction to my head to keep the spine still. At that time I don't think I really realised what had happened to me; I remember Mum being in tears and that I had tubes and things in me but that's about all.

Soon afterwards I was transferred to a spinal cord injury centre. It was here that the impact of what had happened hit me. The staff were very honest with us about the fact that I was unlikely to recover any more movement or sensation. They were very supportive and explained everything that they did to me in those early stages. I was shattered. I couldn't see any future for me. All around me were people in wheelchairs so it soon dawned on me that this was how things would be. However, I found it very comforting to have people in a similar situation beside me — they were experiencing similar feelings and could tell me what it was like to go through the different stages of rehabilitation.

I was kept on bed rest for 10 weeks, during which time I had physiotherapy and the occupational therapist made splints for my hands to prevent them contracting up. Then a collar was made for me and I was ready to get up in a wheelchair for the first time. I was so excited as I had seen other patients whizzing about in their wheelchairs. The nurses got me up in the wheelchair and stayed with me, but I was so disappointed. I felt terrible, so weak and dizzy. I was put back into bed after 20 min. However, gradually I got up for longer periods of time. I went to physiotherapy and occupational therapy. I had hydrotherapy, which was really scary at first as I kept remembering being in the water, unable to move or breathe. It was incredibly hard work and sometimes I felt so tired, but I was determined to work as hard as possible so that I could get home. I practised what I had learnt in the departments and with the nurses on the ward. I gradually got stronger and stronger until I was able to wash and dress. I had a suprapubic catheter to prevent urinary incontinence and I learned to manage my bowels. All the staff pushed and encouraged me, and made sure I and my family learned as much about my condition as possible so that we could teach others when I went home.

In the meantime some alterations had been carried out on our house, which luckily was a bungalow, so that when I was discharged home I was able to get into my bedroom and the bathroom. When I went home I was able to manage most things for myself, but I had a district nurse who looked after my catheter and was there if we needed anything, from equipment to advice. I knew I could always contact the spinal unit and attended outpatients for check-ups. I went back to school and got my 'A' levels and I then went to university and got my degree. I also learned to drive, so I drive an adapted car with hand controls.

I now work as a journalist on a local newspaper. I have moved into my own adapted flat. In my spare time I play wheelchair rugby, although I don't think I'll make the Olympic team! I have a great circle of friends that I go out with to pubs and clubs. I have been very lucky in having a supportive family who have let me do things at my own pace and did not try and cushion me from the realities of living in the world with a disability. They have always been there for me.

CASE HISTORY 34.3

S

S is 18 years old and has sustained a fracture of her 7th cervical vertebra resulting in limited arm function and no sensation or movement in her legs. She has been learning how to transfer from her wheelchair on to the toilet using a lateral transfer board (sliding board) with a physiotherapist. It is the weekend and she wishes to practise the technique before her next physiotherapy session on Monday.

34.3 Review Case History 34.3 and consider the role of the nurse in helping S to practise what she has been taught in her therapy sessions.

- Technical and physical care
- Therapy integration and therapy 'carry-on', i.e. enabling patients to practise what they have learnt to do with therapists and giving them support and encouragement to undertake these tasks at weekends and evenings
- Emotional support
- Involving the family.

It should be noted that some nurses will undertake aspects of all these roles at any one time, whereas others may be involved in only one or two areas.

Assessment

Nurses will carry out an initial assessment from which the nursing care plan is developed. A range of models and frameworks is available to enable nurses to structure a holistic assessment of the patient's rehabilitation needs and goals, and to plan appropriate interventions to meet those needs and goals (Johnston 1996). However, the choice of model will be defined by the setting within which the rehabilitation nursing takes place. The most important aspect of whichever model is used is that of patient-centred care, partnership between patients and nurses being central to the delivery of effective rehabilitation. For example, Orem's (2001) model is widely used in rehabilitation settings to determine self-care activities and to assess activities that require nursing input that is wholly compensatory, partially compensatory or supportive of educational needs.

RESEARCH ABSTRACT 34.3

The role of the nurse in the rehabilitation team

This research aimed to explore how nurses identified the physical, social and emotional needs of patients and carers, and the nurse's desired and actual role in contributing to meeting those needs, from the perspective of the nurse, other professionals, patients and carers (Long et al 2001). The research also investigated pre- and post-registration education and development in preparing nurses for this role and keeping up to date in rehabilitation. Data were collected using a two-phase design:

1. an ethnographic study of three contrasting case study areas: fractured neck of femur, rheumatoid arthritis and stroke, to which 49 participants were recruited
2. national expert workshops with four groups: users, carers and carer organisations; nurses; interprofessional team members; and educationalists.

A comparative analysis of the nurse's role across the three case study areas suggested that the nurse's role in rehabilitation is dependent on the needs with which patients present. The nurse is often seen as someone who 'does for' a patient; however, nurses aimed to get patients to do things for themselves. Nurses sometimes felt that patients equated rehabilitation with therapy. Six core nursing roles were identified:

- *Assessment* — nurses performed an initial assessment from which the nursing care plan was devised and referrals to other team members made
- *Coordination and communication* — included gathering, synthesising and disseminating information, liaison, negotiation and discharge planning
- *Technical and physical care* — perceived as 'routine' roles by nurses and other team members
- *Therapy integration and therapy 'carry-on'* — involved creating an environment that was therapeutic and facilitated rehabilitation through addressing emotional, social and physical barriers to rehabilitation; it also involved the nurse building on the work of therapists
- *Emotional support* — where nurses assist patients to come to terms with, and understand the ramifications of, their condition
- *Involving the family* — nurses were often seen as the first port of call when seeking advice or information.

The authors found that nurses in rehabilitation settings felt undervalued and under-recognised as a specialty by their own profession. Their colleagues from other professions perceived nurses as being task orientated and disempowering in their approach to patient care. Nurses were often not able to attend team meetings and this affected team communication.

Pre-registration education was not considered as providing adequate preparation for a rehabilitation role and nurses felt that there was a need for better access to specific post-registration education to enable them to participate in the rehabilitation process.

The authors identified that nurses need to have a full understanding of the philosophy, models and principles that underpin rehabilitation. Rehabilitation therefore should be integrated into nursing education so that, on completion of their pre-registration education, nurses can work effectively in rehabilitation settings. They can subsequently develop specialist rehabilitation skills at post-registration level. Generic themes such as communication, coordinating care and problem solving could be taught interprofessionally. Work-based learning would enable the development of skills and knowledge pertinent to the local setting.

The authors conclude that to enable nurses to play their full role in rehabilitation, client expectations need to be modified by education, explanation and information from 'doing for' to 'helping you do it yourself'. They suggest that higher education institutions and service providers need to work in partnership to produce nurses who can provide a quality service and that there should be an interprofessional approach to rehabilitation education.

Long A, Kneafsey R, Ryan J et al 2001 Teamworking in rehabilitation: exploring the role of the nurse. The English National Board for Nursing, Midwifery and Health Visiting, London

If Orem's model of nursing is adopted, the assessment will include the patient's self-care requisites and 'basic conditioning factors'. Basic conditioning factors are both external and internal to the individual, such as age, developmental state, pattern of living and the availability and adequacy of resources. Because injury or chronic illness places many new and different demands on the patient, there may be a wide range of self-care limitations. The assessment should cover a wide range of areas and be undertaken in partnership with the patient (Burks 1999, Orem 2001).

Coordination and communication

Nurses are present with patients 24 hours a day, 7 days a week, and therefore there is considerable scope for nurses to coordinate the functions of the multidisciplinary team (Aylett & Fawcett 2003). The involvement of multiple personnel and departments means that that there is a need to prevent fragmentation so that the care the patient receives is as integrated as possible (Johnson 1995). Nurses are able to provide information relating to a patient's progress, coping and emotional health (Burton 2000b) (see Research Abstract 34.3). Nurses can clarify goals and promote decision making as part of their coordinating role. However, this role requires a detailed knowledge of interprofessional working. It also requires a high level of communication skills, diplomacy and assertiveness. Rehabilitation nurses also need to have knowledge of service delivery systems to enable them to carry out this role (Nolan & Nolan 1998).

The need to cover a 24-h service means that nurses have to work shifts and this can impede communication, as team meetings to discuss a patient's progress are often arranged for the Monday–Friday, 9am–5pm work pattern (Pellatt

2003). Low (2003) points out that if the team agrees that nurses are coordinators of patients' care, then nurses must be empowered to fulfil that role effectively (see Research Abstract 34.3).

Technical and physical care

Within this role, nurses are described by Kirkevold (1997) as conserving function. This entails maintaining normal functions, preventing complications and trauma, and meeting the patient's basic needs such as personal hygiene and elimination.

Nolan and Nolan (1998) have identified the knowledge that nurses need in order to deliver skilled physical care as:

- detailed knowledge of physiology, related anatomy and pathology of relevant conditions, e.g. stroke and multiple sclerosis
- knowledge of normal anatomy and physiology
- knowledge of a range of therapeutic interventions
- knowledge of a range of measurement indices and their operational bases.

Technical skills required by nurses in rehabilitation settings, in both hospital and the community, cover a wide range, including all the activities of daily living. For example, a patient may require urinary catheterisation, administration of medication, wound dressing and management of nasogastric and percutaneous endoscopic gastrostomy (PEG) tubes to meet nutritional needs (Kneafsey et al 2003).

Key areas of concern in maintaining the physical and mental well-being of patients include those discussed below (Baillie 2001, Long et al 2001). Some require primarily the demonstration of practical skills by the nurse, whereas others require psychosocial skills or, more frequently, a blend of both.

Care of the skin A variety of pressure ulcer risk assessment scales is available (see Ch. 23). A benchmark of best practice, as outlined in the *Essence of Care* (DH 2001c), is that all patients identified as being at risk should undergo a screening process that progresses to further assessment. The patient in need of rehabilitation may have mobility problems and any neurological impairment will increase the risk of skin damage and pressure ulcer formation, particularly if sensation is poor or absent. There may also be psychological factors that will increase the risk of pressure ulcer development, e.g. the patient's coping strategy and the stage reached in adapting to the disability or illness (Graham 1997). The rehabilitation programme therefore needs to be tailored to the individual rather than the individual having to adjust to the rehabilitation programme. Pressure ulcers can have serious consequences and greatly impede the rehabilitation process, so effective preventive measures are essential. These measures include provision of a suitable support surface that does not impede mobility, use of correct moving and handling techniques, adequate nutrition, education, pain management and skin care (Pellatt 2001). The National Institute for Clinical Excellence (NICE) has published guidance on preventing pressure ulcers and the use of pressure-relieving devices (NICE 2003).

Continence There is a high incidence of continence problems in patients undergoing rehabilitation (Pellatt 2001). Assessment of mobility problems and the level of manual dexterity are important. Nurses should have knowledge about specialist services, such as those provided by a continence advisor and by support organisations, so that they can advise and refer patients as appropriate. Continence management requires careful assessment of each individual and knowledge of appropriate strategies and products. Continence care for the rehabilitation patient should be based on the best evidence available (Baillie & Arrowsmith 2001). A detailed discussion of continence can be found in Chapter 24.

Nutritional care A detailed discussion of nutrition can be found in Chapter 21. Rehabilitation patients may have a number of problems with eating, drinking and feeding themselves, due for example to paralysis, poor coordination or tremor. Patients may have an altered level of consciousness or may be suffering from severe fatigue. Conditions such as stroke may affect a patient's ability to swallow — dysphagia (Child & Higham 2001). Some patients may be unable to speak — aphasia — and therefore be unable to articulate their food preferences and/or cultural dietary requirements (Bowie 1999).

Hygiene Helping patients to wash and dress has been recognised as a fundamental function of the rehabilitation nurse (Pellatt 2003). Problems of paralysis, altered sensation and cognitive changes may affect the patient's ability to carry out this very personal aspect of care. The patient should be assisted to maintain their personal hygiene including oral hygiene and shaving. If the patient usually uses deodorants, aftershave or make-up, then helping to continue this routine will add to the patient's feeling of well-being and self-esteem (Major 2001).

Sexual health Sexuality encompasses a whole range of aspects of a person's life. It includes not just the sexual act but how a person dresses, behaves and interacts with others. An injury or chronic illness may impact on a person's sexual health, due to both physical and psychosocial limitations and barriers, but this does not mean, as is sometimes thought, that they are asexual beings (Smith 1999b). In the rehabilitation patient, alterations in sexual function may be due to any of the following:

- Impaired physical mobility — which may limit transfers on to a bed, cause difficulties in dressing or undressing, or in attending to personal hygiene
- Increased or decreased sensation — when sensation is altered, the pleasure derived from stimulation may not be perceived in some of the body's erogenous zones (Smith 1999b)
- Pain — which may limit positioning of the body and may cause depression
- Bowel and bladder incontinence — which causes embarrassment and worry
- Fatigue — one of the side-effects of brain injury, stroke, rheumatic disease and multiple sclerosis which may lead to lack of energy and enthusiasm for sex
- Changes in libido — some stroke patients, for example, experience decreased sexual interest

- Genital sexual dysfunction — patients with diabetes mellitus, spinal cord injury and multiple sclerosis may have erectile dysfunction or impotence (Astbury-Ward 2000)
- Decrease in fertility — men may suffer from decreased fertility due to a reduced sperm count after spinal cord injury and some brain injuries. Semen quality and motility are reduced secondary to recurrent urinary tract infections, elevated deep scrotal temperature (caused by the position of the legs when seated in a wheelchair), medication, prostatic fluid stasis, spermatozoan contact with urine due to retrograde ejaculation, testicular denervation and changes in seminal fluid due to endocrine abnormalities (Sipski & Alexander 1992, McDonald & Sadowsky 2002, Naderi & Safarinejad 2003)
- Medication — analgesics, used for treating pain, that depress the central nervous system, antispasmodics, antihypertensives and some tranquillisers can cause a range of sexual problems (Greco 1996)
- For some patients, notions of self-worth and sense of identity focus on the dysfunctional or disfigured part of the body (Price 1996) to the detriment of their sexual health.

The rehabilitation nurse must be prepared to address sexuality and sexual health with patients on an individual basis. To do so effectively, knowledge and skills in counselling and intervention techniques are essential. Nurses require sensitivity to support patients as they work through their grief and anxieties and help them to find ways of focusing on other qualities, skills and personal appearance (Nolan & Nolan 1998).

Although it could be said that nurses, because of their 24-h care of the patient, are ideally placed to discuss sexual health with patients, Smith (1999b) argues that they are not fully addressing the rehabilitation patient's sexual health needs. However, nurses should be able to recognise where there is a need for a patient to receive specialist sexual health advice and discuss this with the patient and the rehabilitation team, prior to referral.

Therapy integration and therapy 'carry-on'

Nurses play an important role in reinforcing the input of therapists in rehabilitation by assisting the patient to incorporate the skills learned in episodic therapy sessions into the rest of their day. In so doing, nurses are able to assess progress on a 24-h basis and feed back information to the rehabilitation team. For example, a physiotherapist may teach a patient how to transfer from a wheelchair on to the toilet, using a lateral transfer board (sometimes called a sliding board). The rehabilitation nurse will then support and encourage the patient to practise this manoeuvre on a daily basis early in the morning, late at night and at weekends so that the patient is confident and competent by the time of discharge home. Nurses have been described as 'closing the circle', ensuring that rehabilitation is a continuous process (Johnson 1995), but this role can cause tensions, if some nurses perceive themselves as 'jacks of all trades' (Hill & Johnson 1999), expected to take on roles when other professionals are not available. However, the continuation and integration of therapy has an important therapeutic value for patients, as it enables them to translate the development of physical skills into activities of daily living (Burton 2000a).

Emotional support

The 24-h contact that nurses have with patients can be an important source of emotional support (Pellatt 2003). An empathetic approach allows nurses to understand patients' underlying needs and emotions in order effectively to support them when undergoing rehabilitation. Empathy is the ability to see the world from another person's point of view and involves being non-judgemental and non-evaluative. To achieve this, nurses need to imagine how it feels to be that person. Shaw (1996) has likened the nurse–patient relationship to the rapport that two people develop when they share a journey and go their separate ways at the end.

During the rehabilitation process emotional support is necessary to help patients develop strategies to work through the grieving process. Unless they have gone through this process it may be difficult for them to accept any rehabilitation intervention. However, grieving takes time and patients' physical recovery cannot wait for this to be experienced. For successful physical recovery, rehabilitation must start immediately and sensitive support is important if, at this point, a patient is not emotionally ready for it (Hill & Johnson 1999).

Patients have identified that nurses provide emotional support when they convey a sense of commitment and are ready to take the time to listen to what they have to say. Nurses who are sensitive to patients' wishes and enable them to speak about their situation in peace and quiet are a source of support (Natterlund & Ahlstrom 1999). A basic responsibility for the nurse is to establish a trusting relationship with the patient. This will enable the nurse to facilitate a normal grieving process, to promote hope and to prevent depression as patients come to terms with the extent of their disability or the implications of their illness (Kirkevold 1997). A caring relationship between nurse and patient will contribute to patients' feelings of well-being and this contributes to mood, motivation and self-esteem, which in turn can empower patients to move forward in their rehabilitation (Lucke 1999).

Providing a caring, supportive relationship requires emotional work on the part of the nurse (James 1992). Emotional work is the mental work required to manage one's feelings: the aim is to reflect positive feelings both in one's behaviour and in encouraging a patient's feelings of self-worth and security. The nurse in a rehabilitation setting must develop social skills such as listening, acknowledging the other's perspective, identifying and acting on behavioural cues, and speaking clearly. These are activities that can be enhanced by self-awareness and educational programmes (McQueen 2000).

Involving the family

Stressor change affecting one family member also affects the other family members and lack of family involvement in the patient's rehabilitation process can lead to failure to achieve rehabilitation goals (Dean-Baar 1996). Involvement of family members is therefore vital, both for the patient and the family, who need to be included and informed about

CASE HISTORY 34.4

Mrs D

Mrs D is 64 years old. She is married and has two daughters, both of whom live nearby but have their own families. She has rheumatoid arthritis, which causes her pain and considerable limitation of mobility. She is concerned that she is becoming more dependent on her family and the condition is affecting her social activities and her family relationships.

what is happening. Support from the family enables the patient to make choices and to carry out a range of activities. However, Holland and Hogg (2001) point out that roles and responsibilities in families will vary in different circumstances and cultures. The patient may, for example, be part of a close and extended family, while others may be from a single parent family. The way in which members give, or are able to give support, can impact on the patient's autonomy, positively or negatively. While families can be an important source of information about a patient, with regard to their previous life and customs, some families are overprotective and therefore constrain the patient's autonomy and progress to maximal independence. Nurses therefore need to work in partnership with families as well as the patient and educate them together in identifying goals and objectives, assisting the patient appropriately and being involved in the discharge planning process (Proot et al 2002) (see Case History 34.4).

34.4 Review Case History 34.4 and identify what support may be available for Mrs D and her family.

THE WAY AHEAD

As the 21st century progresses, there will be a considerable increase in the number of people, particularly older people, with chronic illness and disability (DH 2001a). There has been a move away from long-term care, with a drive towards earlier hospital discharge (Kneafsey et al 2003), and this is likely to continue. A report by the Audit Commission (1997) concluded that there was too little investment in preventive and rehabilitative services, which led to unplanned admissions of older people which, in turn, caused premature admission to long-term residential care. The report recommended investment in prevention and rehabilitation, the aim being to enable more people with chronic illness and disability to live at home. The National Service Framework for Older People Standard 3: Intermediate care (DH 2001a) states:

> *Older people will have access to a new range of intermediate care services at home or in designated care settings, to promote their independence by providing enhanced services from the NHS and councils to prevent unnecessary hospital admission and effective rehabilitation services to enable early discharge from hospital and to prevent premature or unnecessary admission to long-term residential care.*

The community nurse therefore has an important role in the provision of community rehabilitation and in particular may be the main contact for older people and their carers in the community (Kneafsey et al 2003).

Inadequacies in service provision in the community have been highlighted by both nurses and patients (Long et al 2001), and it is felt that there may be a lack of specialist interprofessional care. When they are discharged home, patients may need services such as physiotherapy, occupational therapy, podiatry, social work and specialist nursing. They may require aids such as wheelchairs and house adaptations, and their carers may require physical help and support.

There is considerable scope for community nurses to act as care coordinators (Aylett & Fawcett 2003) or as care managers to provide support that will help maintain the patient's dignity and prolong independence, thus preventing hospital admission and readmission.

The community nurse's role is to:

- monitor the patient's well-being
- support both patient and family
- initiate intervention as required
- liaise with colleagues in social services and in the other health care professions.

To fulfil these roles effectively, the nurse must have detailed information about the patient's continuing rehabilitation programme (Casley 1997).

Long-term health maintenance

The issue of where rehabilitation ends, if it does end, and where long-term health maintenance begins is viewed differently by professionals and users of rehabilitation services. Davidhizar and Shearer (1997) prefer the term 'high level wellness' that includes psychosocial functioning. However, as individuals with a disability or chronic illness grow older it is important that long-term health maintenance is considered. Studies carried out in the UK and USA over the last 50 years with people with a spinal cord injury suggest that as they age, they are likely to develop complications such as respiratory problems and urinary tract infections (Frankel et al 1998, Lammertse 2001). Equally, wheelchair users are at risk of developing musculoskeletal problems and degenerative changes in their shoulders as they age (Crewe 1991, Waters & Sie 2001) (see Case History 34.5).

CASE HISTORY 34.5

N

N is 20 years old and has a paraplegia injury, which means he has no sensation or movement from the waist down since a car accident a few months ago. He is keen to learn everything he possibly can about his condition so that he can prevent any complications occurring when he goes home.

The concept of a 'disability career' was identified by Safilios-Rothschild (1970). The career spans the first instant that symptoms or an accident are experienced, to the final stage when no further effort is made to change the extent of the residual disability. Disabled people follow different pathways as they pass through a series of definable stages during this disability 'career'. The Disability Movement has, however, questioned whether disabled people need the services of professionals at each of these stages (Craddock

1996, Oliver 1996). Problems arise when disabled people are defined as 'ill'. This can mean that disabled people's lifestyles are broken down into segments when their care needs are being assessed. The reality is that, for some disabled people, their problems are associated with illness, but many disabled people are fit and healthy (Finkelstein & French 1993). If an independent living approach is adopted, the focus of support will move away from an emphasis on impairment and treatment to the importance of removing external barriers and encouraging self-direction.

Kneafsey et al (2003) suggest that three concepts should inform the community nurse's practice:

- The restoration and achievement of an optimal level of functioning in roles which the patient and carer value
- The goal of independent living
- User and carer autonomy.

34.5 Review Case History 34.5. What sort of information and health promotion advice will N need from the rehabilitation nurse to enable him to prevent possible complications at home?

CONCLUSION

This chapter has shown that the nurse's role in rehabilitation is diverse. Nurses are in a position to have a considerable impact on the rehabilitation process. However, rehabilitation is in itself a multidimensional concept that is difficult to define. What is clear is that rehabilitation must be a partnership between the patient and health care staff and include the family where appropriate. Nurses have a key role to play in facilitating autonomy and participation of patients in the setting of rehabilitation goals that are meaningful and of importance to the patient.

34.6 (a) Investigate rehabilitation provision in your locality. Visit a disabled living centre or an employment retraining centre.

(b) Study the role of a specialist rehabilitation nurse, e.g.:
- stoma nurse
- stroke coordinator
- multiple sclerosis specialist nurse
- breast care nurse
- spinal injury liaison nurse
- neurorehabilitation nurse.

(c) Study disability experientially, e.g.:
- wear special lenses that simulate a visual impairment
- go shopping in a wheelchair
- eat, using only one hand — your left, if you are right-handed; your right, if you are left-handed
- try washing and dressing using only one hand.

(d) Assess the ease of access to public buildings, transport and shops in your locality by accompanying a wheelchair user.

(e) Attend a multidisciplinary team meeting.

(f) Attend a case conference.

INTRODUCTION

Old age has always been a possibility but it is now an increasing probability — at least in the developed world (Kirkwood 1999). Medical, social and economic advances of the last century have largely eradicated a range of 'killer' diseases which robbed people of life in their childhood or early adult years. Infectious diseases, for example, and the widespread use of antibiotics — one of the major medical 'spin-offs' of the Second World War — have accounted for a dramatically decreased mortality from infections which would previously have proved fatal (Christiansen & Grzybowski 1993). Concomitantly, nutrition has improved, people generally live in better housing and health and safety has become more important in the workplace. Some of the more dangerous occupations such as coal mining have been made safer or have largely disappeared due to changing economic circumstances.

The outcome of the above changes is that more people are living longer: Figure 35.1 shows a striking difference in the age profile between the 1990s and approximately 100 years ago; Figure 35.2 shows that life expectancy at birth in Europe and North America has increased over the second half of the last century and that this is expected to continue; Figure 35.3 shows how this has had an impact on the number of people aged over 65 years, mainly in the developed world. This has social and economic consequences (Masson 1990) which impinge upon the health services and upon nursing.

Consequences of an ageing population

More people are living longer. As explained above, this has been due in part to the eradication of many diseases and improvements in the treatment of other diseases. However, there has been a resultant increase in the prevalence of diseases that are, largely, associated with old age (Armour & Cairns 2002). These include cancer, heart disease and dementia.

Socially and economically, the changing demographic profile of the population, with an increasing proportion of older people, is challenging for society. The likely impact on health and nursing services — and how this should be addressed — was recognised in the UK when the Royal Commission on Long Term Care (1999) reported to the UK government at the end of the last century. The increasing, but not inevitable, likelihood of developing particular diseases with age demands health service resources at the primary and secondary levels. The economic consequences are obvious, as a sector of the population which is not, generally, economically active and which in fact may be economically demanding due to retirement and pension payments, requires an increasingly larger slice of the economic cake (Masson 1990, Heller 1998). This is compounded by the fact that towards the end of the last century there has been a trend of earlier retirement (Posner 1995) as shown in Figure 35.4. These are facts which must be faced and not avoided by governments, planners and health services. They are not meant to cast a shadow over the fact

	1880s	1990s
Born alive	1,000,000	1,000,000
Alive at 5 years	736,818	991,350
Alive at 25 years	684,054	984,230
Alive at 35 years	568,993	977,500
Alive at 45 years	502,915	963,960
Alive at 65 years	309,020	830,990
Alive at 75 years	161,164	612,740
Alive at 85 years	38,575	286,950
Alive at 95 years	2,153	45,450
Alive at 100 years	223	8,710

that more people are living longer; the 'burden' of an ageing population is often referred to in the literature (Warnes 1993) but this longevity is an indicator of success in health and social terms, even if governments and planners in the developed world have been taken by surprise (Olshansky et al 1993).

35.1 Older people have been referred to as 'our neglected assets' (Help the Aged 2004). What positive contributions socially and economically do older people make in society? As you meet older people with health care problems and deficits, are you aware of the positive contributions that may be part of their life experience?

It is the job of governments to introduce policies to cope with the changing demographic profile and it is the job, increasingly, of nurses, to work with individual older people who have health needs. Clearly, nurses are not the only people to work with older people and the role of other members of the multidisciplinary team will be referred to throughout the chapter. The other members of the multidisciplinary team include doctors, social workers and therapists but, however large the team of people working with an older person, it should be the older person who is the focus of the team and not any particular discipline.

WORKING WITH OLDER PEOPLE

Nurses increasingly work with older people whether or not they specialise in this area (SNMAC 2001). Some nurses choose to work exclusively with older people in hospitals

and the community (Watson 1993a). However, with the increasing proportion of older people in our society, unless the choice is made to specialise in working with children or in maternity care, nurses will increasingly meet older people in general medical and surgical wards, in the community and in many specialist areas. For example, in hospitals, two-thirds of beds are now occupied by people aged over 65 years and there has been an increase in emergency admissions of people aged over 75 years, over half of whom suffer from ill-defined conditions (SNMAC 2001). Therefore, the vast majority of nurses will work with older people and most other nurses should understand the implications of ageing and develop the skills which are necessary to work with older people. The possible causes and the implications of ageing will be considered later in the chapter but, in this section, the skills that nurses need to work with older people are explored.

In one sense, older people are no different from other people nurses come into contact with in the course of their work, despite the negative images that are often used to portray older people in our society (Carrigan & Szmigin 2000). Like any patient, the older person requires sensitivity, tact and professionalism. In relation to the media and advertising, one could be mistaken for assuming that the best things in life are only available for younger people (Loretto et al 2000). Advertising of clothes, cars and cosmetics, albeit that many of these are designed to hide the signs of ageing, are conveyed as purely of interest to younger people. If the subject of an advertisement is not about pensions and retirement issues, the target audience is almost exclusively younger people (Carrigan & Szmigin 2000). Television and films focus on younger people, often presenting them in a positive light, while older people are often portrayed more negatively. Nurses are part of society and it is understandable that they too may have negative images of older people. Such images will not be dispelled by propaganda on behalf of older people but by evidence and an understanding of the ageing process and the facts about ageing. Nurses should avoid, in particular, holding and conveying stereotypes. One popular stereotype, for instance, is that older people are either no longer interested in sex or are incapable of sexual relations. Thankfully, there is plenty of evidence to the contrary (Kaye 1993, Araujo et al 2004), but the stereotype persists.

35.2 Identify current media descriptions and media images of older people. Are these negative or positive? How do nurses and other professional colleagues refer to older people in day-to-day work conversations? Is ageism an issue in health care?

In 1998, with specific reference to the care of older people in acute wards in general hospitals, the Health Advisory Service 2000 produced a pivotal report entitled *Not Because They Are Old* (HAS 2000 1998). The HAS report can be described as 'pivotal' because it gave rise to two further influential reports which will be discussed in this chapter. One of these, on the nursing contribution to the care of older people (SNMAC 2001) will be described here and the other, the *National Service Framework for Older People* (DH 2001a), which outlines UK government policy with regard to the care of older people, will be discussed later. *Not Because They Are Old* catalogued the lamentable level of care which many older people experience in hospital and some of these areas of concern are shown in Box 35.1.

Box 35.1

Areas of concern identified by HAS 2000 (1998) in relation to the care of older people

- Poor satisfaction with care
- Delays in admission
- Poor physical environments in wards
- Shortages of equipment and supplies
- Staff shortages
- Poor quality food and drink
- Lack of help with feeding and nutrition
- Lack of privacy and dignity
- Negative interactions between staff and patients
- Communication problems with patients and staff

Amongst other things, the HAS 2000 report recommended that older people themselves and their relatives must be more involved in the care of older people in hospital, there must be more clarity about who is responsible for the nutrition of older people in hospital and that better education is needed for staff, including nurses, about the specific needs of older people in hospital.

As a response to the need for better education of nurses highlighted by HAS 2000, in 2001 the Standing Nursing and Midwifery Advisory Committee (SNMAC) commissioned research into the care of older people, as it related to nurse education, and produced a report *Caring for Older People: A Nursing Priority — Integrating Knowledge, Practice and Values* (SNMAC 2001). This report highlighted deficiencies in the care of older people and in the education of nurses about the care of older people. Amongst other things, SNMAC noted the points listed in Box 35.2.

Box 35.2

Issues in the care of older people identified by the Standing Nursing and Midwifery Advisory Committee (2001)

- Older patients and their carers are the least satisfied of all groups with the care that they receive from the NHS when they are acutely ill.
- Older people now comprise two-thirds of all patients in acute settings.
- The nursing care of older people is highly skilled and physically and emotionally taxing.
- The care of older people is mainly deficient in fundamental aspects of nursing, failing far too often to meet their basic needs for food, fluid, rest, activity and elimination.
- Course curricula must be revised to ensure that much more attention is given to caring for older people, for example, to disability, rehabilitation, palliation, and the treatment of chronic illnesses, as well as the fundamental skills of nursing. Media portrayals of the profession, particularly in recruitment campaigns, need to reflect that the majority of patients requiring acute care are older people.

SNMAC identified that one of the core skills lacking in the nursing care of older people was communication. They also identified that the 'fundamental skills' required in the care of older people such as bathing, help with using the toilet and assistance with feeding were tasks often delegated to unqualified staff. To provide good nursing care for older people, nurses need to have skills which include an understanding of the ageing process and of the multiple pathologies and diseases of old age. Nursing assessment, care planning and care pathways for older people should include physical and psychological needs, mental health needs and prioritisation of complex needs. Nutrition and medication management, including self-medication, were also identified as necessary skills. Nurses also need to understand the role of the multidisciplinary team including physiotherapy, occupational therapy and dietetics and the part these other professions play in the care of older people.

In terms of nurse education, the adult branch of nursing, to which this chapter is relevant, should be 'reoriented' (SNMAC 2001) to highlight the needs of older people. Specifically, recruitment campaigns need to reflect the care of older people and 'challenge the stereotype of nursing older people as unskilled and unrewarding'. This can be achieved by emphasising such things as the independence of older people, the success of rehabilitation and that palliative care, when no further curative treatment is available, can improve quality of life for older people. The SNMAC report is the platform for the philosophy and detail of the present chapter. In addition, other bodies such as Help the Aged (1999) have addressed the issue of the dignity and privacy of older people who are in acute hospitals and the United Kingdom Central Council for Nursing, Midwifery and Health Visiting (1994) addressed similar issues in the care of older people living in nursing homes.

In summary, one of the fundamental attributes required by the nurse working with older people is to treat them as individuals and not as a homogeneous group (Watson 2003). Each older person has a unique history and a unique perspective on life; older people are not less intelligent than their younger counterparts and they do not appreciate being treated as such. The older person must be at the centre of the nursing care of older people. The next section will examine the ageing process and the evidence for changes associated with it, and will evaluate the extent to which older people require specialised care.

THE PROCESS OF AGEING

That ageing takes place is beyond dispute (BSRA 2004), despite the efforts of people to deny this or to hide the effects of the ageing process. Most of what is considered ageing is quite superficial. Aspects of the ageing body, such as the loss of elasticity in the skin leading to wrinkling and the loss of hair colour and thinning of the hair — all the aspects which obsess us most and which, as a result of that obsession, ensure large profits for the cosmetics industry — have little or no clinical significance (BSRA 2004). They are external indicators that ageing is taking place but, without the application of cosmetics, people age very differently. Some people retain their hair into old age, others become grey haired prematurely and others seem not to suffer from wrinkling of the skin to the same extent. Of course, environmental factors may play a part in the appearance of ageing. For example, sun-bathing, a popular pursuit of the young to make their bodies more acceptable to others, often the opposite sex, is almost guaranteed to lead to premature ageing of the skin (Rutishauser 1994).

There are other features of ageing which are less superficial, such as increasing kyphosis of the spine leading to a more stooped posture and a decline in height (Christiansen & Grzybowski 1993), partially associated with the loss of skeletal tissue (bone and cartilage) which results from ageing (see p. 1136). There are, however, myths about ageing, for example, that older people are less intelligent or lose their memories. These myths need to be exposed, as they will below.

Why do we age?

Before looking at the ageing process in some detail it is worth pondering, briefly, what the purpose of ageing is, if indeed it has a purpose. Why do we age? Why do we not remain as youthful looking as we were at maturity, say in our early 20s, for the whole life span? This question is hard to answer biologically. Most nursing students, when asked why we age, will answer that it is necessary to age and die to make way for future generations. This is possibly true but it does not answer why we age. Ageing alone does not necessarily cause death, as the extreme longevity of some individuals demonstrates. Certainly, ageing may lead to death but there are many alternative ways to die which would be sufficient to make way for the next generation. It is thought that ageing may confer some biological advantages for our species in the sense that, biologically, we invest more energy in maintaining vitality during the years that we are reproductive and, as we grow older and our reproductive potential declines, less energy is invested in maintaining vitality, which leads to ageing (Kirkwood 2001). This kind of thinking has led to the development of one of the most credible theories of ageing: the 'disposable soma theory' which, essentially, postulates that the somatic cells (body cells) are disposable from the perspective of maintaining the species and exist to ensure that our gametes (sperm and egg cells) can be brought together at fertilisation to produce new members of our species (Kirkwood 2001). However, we can merely speculate about why we age; it is more relevant to consider how we age and what this leads to in terms of the effects of ageing on the human body.

How do we age?

The question of how we age refers to the underlying biological mechanisms that lead to the outward signs of ageing and other physiological changes that take place in the body. The precise mechanisms of ageing are not known and theories abound. However, some of the theories refer to outcomes of ageing rather than mechanisms. As we age, the body does, to some extent, wear out and this is encapsulated in the 'wear and tear' theory of ageing (Kirkwood 1999). There are clear aspects of 'wear and tear' in the body as we age: in the weight-bearing joints of the body, the knees and hips, it is almost inevitable that osteoarthritic changes will take place but these will not necessarily be debilitating, unless the process is very advanced

or is exacerbated by the older person being very overweight, for example. This constitutes 'wear' but there are also people who accumulate sports injuries in their younger and more active years, especially of the joints, which may stay with them into old age and this constitutes 'tear'. The ligaments and tendons of the body, which are composed of collagen, become less flexible as we age, and this is also responsible for the wrinkling of the skin of which collagen is a major component. The stiffening of collagen is due to chemical processes which increase the amount of chemical cross-linking between the collagen strands (Christiansen & Grzybowski 1993) and this stiffening of ligaments and tendons compounds the weakening of the muscular system and the thinning of bones.

Almost all of the systems of the body become less efficient with age and the unifying physiological process of homeostasis becomes less able to correct physiological deficits and restore the former balance in the systems of the body; this is described in the 'homeostatic imbalance theory' (Herbert 1992). However, these theories are based on observations and are just as likely to be the result of the process of ageing rather than underlying mechanisms in themselves. Other theories of ageing, such as those based on the reduction in somatic cell doubling with age (Christiansen & Grzybowski 1993) and those related to the harmful and cumulative effects of oxygen, are also likely to be based on outcomes rather than mechanisms.

Another observation about ageing is that the immune system becomes less efficient. It protects us less well and even loses its ability to distinguish self from non-self, leading it to attack somatic cells. This has led to a theory of ageing based on autoimmunity (Christiansen & Grzybowski 1993). However, while there are some age-associated diseases which are autoimmune, for example, type 2 diabetes and rheumatoid arthritis, this, again, may be an outcome of ageing rather than an underlying mechanism.

The 'state of the art' in research into ageing points to mechanisms operating at the genetic level (Kirkwood 2002). As our somatic cells divide and duplicate during mitosis, part of this process is the replication of DNA and this process is always accompanied by some errors in replication called mutations. Enzymes exist in cell nuclei that can detect and repair most mutations; however, this process is not perfect and some mutations will always appear in the DNA of newly divided cells. It is reckoned, despite the highly conservative nature of DNA replication, that no two somatic cells are identical. DNA is the template, through the process of transcription, for RNA which in turn is used in the process of translation to order the sequence of amino acids during protein synthesis and proteins are involved in every aspect of the functioning of the human body: structural, metabolic and regulatory (Watson 2005). In this way, with the accumulation of errors in DNA as we age, it is logical that there will be an accumulation of errors in protein molecules and that this will lead to inefficiency in every aspect of the function of the human body. Ageing, therefore, is viewed as an accumulation of errors in the protein of the body and this, eventually, leads to increasing inefficiency and all of the obvious, and less obvious, signs of ageing (Kirkwood 2002). It is also observed that, as cells age, a region at the end of the DNA molecule called the telomere becomes shorter (Ahmed & Tollefsbol 2001). Telomeres may have some protective role towards DNA in chromosomes and shortened telomeres have been found in people with progeric syndromes which lead to premature ageing (Dyer & Sinclair 1998).

Ageing is considered to be about 25% heritable (Kirkwood 2002). In other words, the rate at which we age and, indeed, our longevity is related to genetic factors transmitted from our parents. On the other hand, it is hard to extricate the inherited from the environmental and there are other factors which may accelerate the ageing process. One of the biochemical mechanisms thought to be related to ageing is that of the toxic effects of oxygen and free radicals, the highly reactive molecules in the body (Goyns 2002). The fact that these molecules are damaging is possibly related to ageing, as there are mechanisms that protect us from the harmful effects of these molecules. However, free radicals in the body are increased, for example, by smoking (Christiansen & Grzybowski 1993) and our ability to deal with free radicals may be dependent upon some dietary factors such as eating sufficient fresh fruit and vegetables. Despite this speculation about the causes of ageing and related factors, it should be noted that there is no 'cure' for the ageing process. The pharmaceutical industry sells many products on the basis that they can reverse or arrest the effects of ageing. However, apart from a few topical applications that can reduce wrinkling of the skin, there is nothing that can arrest or reverse the underlying causes; these are simply not well enough understood and are, possibly, not amenable to 'treatment'. Ageing is not, in itself, a disease (BSRA 2004).

What happens to us as we age?

Some of the superficial aspects of ageing have already been mentioned, but these have little or no clinical significance. In fact, it should be understood that ageing, as well as being an inevitable process, is also quite natural and that ageing in itself is not pathological or an indicator that someone is or will become ill (BSRA 2004). On the other hand, there are some age-associated diseases and it is relevant to see how these are related to the underlying process of ageing.

As we age we generally have less ability, as previously mentioned, to maintain homeostasis. This is not a problem under circumstances where, from the physiological perspective, the body is not unduly stressed. However, in conditions of extreme temperature or dehydration, for example, an older person will usually be less able to adapt than a younger person (Watson & Fawcett 2003) and this will be particularly important when an older person has an infection.

Cardiovascular and respiratory systems

Most systems of the body show signs of ageing. The cardiovascular system ages in terms of cardiac output (Horan 1992) and elsewhere in the cardiovascular system there is increased deposition of atheromatous plaques in the blood vessels (Christiansen & Grzybowski 1993), leading to less adaptability and a tendency to increased blood pressure (see Ch. 2). The heart and blood vessels become less responsive to adrenaline and noradrenaline ('down-regulation') which means that the homeostatic mechanisms for maintaining blood pressure become less efficient (Collins 1998).

One tangible outcome of this is a tendency towards postural hypotension (Watson & Fawcett 2003) whereby a sudden change in position from sitting to standing is less well tolerated and blood pressure remains low, leading to dizziness or even fainting due to cerebral insufficiency.

In tandem with these changes in the cardiovascular system there are changes in the respiratory system such that it becomes less efficient at extracting oxygen from the blood (Horan 1992). This is not usually a problem but it does lead to exercise intolerance. The older person may well be able to go about their normal level of activity as these systems have considerable reserve capacity but will, for instance, be less able to run to catch a bus than they were when they were younger. Clearly, these changes will be compounded by changes in the musculoskeletal system (see Ch. 10).

Another consequence of changes in the cardiovascular system, through a combination of arterial disease and raised blood pressure, is a greater tendency in older people to suffer from cerebrovascular accidents, more commonly known as stroke (DH 2001a). Stroke essentially leads to the deprivation of a blood supply and, thereby, of oxygen to a region of the brain. The effect of a stroke can range from being fatal, through severe and permanent disability to full recovery. Deterioration in the blood supply to the brain can also lead to more chronic cerebrovascular disease which may lead to ischaemic dementia (McKeith & Fairbairn 2001), transient ischaemic attacks (Slack 1999) or to a fully evolved stroke.

Musculoskeletal system

With age our muscles atrophy, tendons and ligaments become less flexible and the skeleton becomes weaker due to the fact that less bone material is laid down in the skeleton (Christiansen & Grzybowski 1993). This is particularly marked in postmenopausal women but also in some men who may suffer from osteoporosis (NIH Consensus Development Panel 2001). The combined effects of osteoporosis and thinning of the cartilaginous discs between the vertebrae lead to a more stooped posture and this, in conjunction with the atrophy of skeletal muscle, of which the diaphragm is one, contributes to the reduced efficiency of the respiratory system (Christiansen & Grzybowski 1993).

Digestive system

The digestive system, because it is largely composed of smooth muscle which atrophies with age, shows some decline in motility with age and also some decline in its absorptive capacity (Christiansen & Grzybowski 1993) (see Ch. 4). However, these changes are minimal and they should not lead to any significant changes with ageing. Many older people complain of constipation and older people use greater amounts of laxatives than younger people (Harari et al 1993). However, this may not necessarily be associated with the ageing process. It is quite common for older people to be edentulous (Clay 1999) but this situation is likely to decline as dental care and diets improve. Dentists are now more likely to adopt a conservative and restorative approach than to remove teeth at the first signs of decay.

Renal system

The renal system is one which shows significant changes with ageing (Christiansen & Grzybowski 1993). However, the kidneys, in common with all the other systems of the body, have considerable reserve capacity and a decline in filtration rate is unimportant except in illness and in the administration of medication. This will be considered in more detail later in the chapter.

Endocrine system

With age, there are changes in the endocrine system which, along with the nervous system, is one of the main homeostatic regulators of the body (Watson & Fawcett 2003) (see Ch. 5). While the absolute levels of hormones in the body are relatively unaffected, the changes lead to decreased responsiveness of the endocrine system, both through the 'axes' between effector organs and their endocrine glands and in the responsiveness of tissues, due to the 'down-regulation' of hormone receptors in the tissues. This can be seen in the phenomenon of postural hypotension, referred to earlier, and also in the fact that older people take longer to acclimatise when they move between climates of extreme temperature (Schofield 2000). This latter phenomenon is due to the fact that acclimatisation is achieved by changes in the levels of circulating thyroxine: levels of thyroxine increase in cold climates and decrease in warmer climates. With age, the pituitary–thyroid axis is less sensitive to these changes, leading to slower acclimatisation in older people (Schofield 2000).

Immune system

The changes in the immune system that occur with age are complex. The overall levels of immunoglobulins remain relatively stable with ageing but the composition of these immunoglobulins changes and more immature T cells are produced (Christiansen & Grzybowski 1993). This may lead to decreased defences against infections and also to the phenomenon in some older people whereby they do not necessarily exhibit pyrexia when they have a bacterial or viral infection (Horan 1992). Instead, the presence of an infection may only be noticed when it is quite advanced, when confusion and drowsiness may occur.

As mentioned above, in old age, the immune system may become less able to distinguish 'self' from 'non-self', leading to autoimmunity whereby the immune system begins to attack its own tissues. Type 2 diabetes is, for example, a disease with autoimmune components and is definitely associated with ageing. The immune system also plays a key role in keeping cancer cells under check via immune surveillance which becomes less effective with age (Redmond & Aapro 1997) (see also Chs 16 and 31).

Nervous system

Despite misconceptions, the nervous system remains relatively unchanged with ageing (Christiansen & Grzybowski 1993). There are very few changes of any note in the central nervous system and some changes in the peripheral nervous system. The psychological aspects of ageing will be considered separately.

With age, the speed of nervous conduction slows and reaction times, measured in milliseconds, decline (Deary 2001). However, these are merely observations and have little, if any, impact on the life of an older person and have no clinical relevance. Except in degenerative neurological conditions, such as Alzheimer's disease, there is no widespread loss of nervous tissue with age.

In the peripheral nervous system there are changes but not all of these are associated with nervous tissue. For example, there is an inevitable decline in vision as we age and this is due to changes in the eye, rather than in the neural conduction system from the eye to the brain. With age it is common for the lens to become more opaque (Wolf 2004) and some older people suffer from cataracts which, if untreated, severely limit their vision. In the ear, the bones which transmit sound waves from the outer to the inner ear — the malleus, incus and stapes — tend to become fused together, thereby reducing their ability to transmit sound, leading to reduced hearing (Christiansen & Grzybowski 1993). This does not mean that all older people are blind and deaf but this reduction in hearing and vision has to be taken into account when considering their care and support.

Other aspects of the peripheral nervous system which change with age are taste and pain perception (Christiansen & Grzybowski 1993). It is not uncommon to hear older people complain that they do not enjoy their food as much as they used to and to see them enhance their food with copious amounts of salt, for example. This can have consequences for nutrition as will be discussed below. That older people suffer from pain must be made clear, but Seers (1999) argues that they have a reduced acuity to pain sensation. This means that, while they feel pain, they sometimes have difficulty in locating it and describing it and, as a result, many older people suffer from vague aches and pains. It appears, therefore, that the senses decline somewhat with age and this can lead to a decline in the ability to sense extremes of heat and cold. This can be potentially dangerous, leaving older people more vulnerable, for example, to hypothermia (Watson 1993b) (see Ch. 22).

Psychological aspects of ageing

Contrary to popular myth, there are very few psychological changes with ageing. Older people are no less intelligent, are no less able to remember and recall and are no more stubborn than their younger counterparts. The facts are plain; other than in neurodegenerative conditions such as dementia, memory and intelligence remain relatively intact with age and the personality we are born with is usually the one we take into old age. There is some loss of short-term memory with ageing (Ponto 1999) but this does not usually interfere with leading a normal life. Some older people do suffer from age-associated memory impairment (Deary 1995); however, it is unclear as whether or not this is a precursor to dementia. Intelligence, measured using standard IQ tests, does not decline with age. There is some change in intelligence, with a decline in fluid intelligence (e.g. problem solving) and an increase in crystallised intelligence (the application of learning to new problems), but these changes do not have a significant impact on daily living (Ponto 1999).

There is an abundance of theories related to psychological ageing and this abundance demonstrates that, in fact, very little is known about the psychological changes, if any, that accompany ageing. One of the most popular theories, based on the seven stages of ageing, was proposed by Erikson (Ponto 1999). According to this theory and others that are closely related to it (Ponto 1999), there are identifiable stages in the psychology of ageing during which the ageing person either manages or fails to come to terms with their life before moving on to the next stage, with the ultimate stage of ageing leading to the older person either being at peace with life and reconciled to what they have, or have not, done and experienced. The problem with such theories, while they make interesting frameworks for literature about ageing, is that they lack any empirical evidence. Clearly, people age and gain experience and, sometimes, wisdom regarding the life course and their own part in it, but it is not uncommon to hear older people, and people at almost any stage in their life, say that they feel no different as they age. Apart from the obvious physical signs of ageing, they think, react and often act in old age as they did when they were younger (Thomson 1993). Such testimony does not support theories which depend on stages of ageing.

Two juxtaposed, but popular, theories have dominated the psychosocial theories of ageing in recent years and these are, respectively, the activity theory of ageing (Ponto 1999) and the disengagement theory of ageing (Ponto 1999). Both theories acknowledge changes with ageing; the former that as people age they give up certain activities and take up others and the latter, that as people age they give up activities and gradually withdraw from life and from society. While there is evidence to support both theories, it is unlikely that these are really psychosocial ageing theories but rather explanations for observations of ageing as experienced by different people. Withdrawing from life and society is almost inevitable as people age; they leave work, family and friends move away and die and they become physically less able to participate in certain activities. However, such a view of ageing is derived from economically developed societies where retirement is the norm. In some parts of the world older people do not or cannot retire. They remain economically active into advanced years and never have the opportunity to withdraw or to take up other activities in old age, hobbies and travel being prime examples in developed countries (International Labour Organisation 1990).

DISEASES AND OLD AGE

Old age and disease are not synonymous but, as alluded to above, some diseases are more common in old age. The British Society for Research on Ageing has addressed the issue of biological ageing directly (BSRA 2004), defining ageing as 'a normal biological process that increases the frailty of otherwise healthy organisms'. The effect of ageing is to 'compromise(s) a creature's ability to cope with physiological stress producing an increased likelihood of long-term sickness and death'. The BSRA document dispels the myth that there is no identifiable 'ageing process', a view adhered to until recently by many in the medical community. Ageing, therefore, is not in itself an illness nor 'the sum of symptoms of the diseases from which the older person suffered'. Rather, there is an underlying biological process, which is entirely normal, and the study of this process is worthy in itself and not just in relation to those degenerative diseases that are associated with old age. Ageing, however, 'is thus an independent but potent risk factor for the development of many diseases and imposes serious quality of life issues in its own right.

Table 35.1 Breast cancer incidence by age

Age	Incidence
Up to 25	One in 15 000
Up to 30	One in 1900
Up to 40	One in 200
Up to 50	One in 50
Up to 60	One in 23
Up to 70	One in 15
Up to 80	One in 11
Up to 85+	One in 10
Lifetime risk	One in 9

The relationship of the ageing process to disease is akin to that between a worn part and a broken part'.

One of the diseases, while not exclusively associated with ageing, but which increases markedly in prevalence with age is cancer (Redmond & Aapro 1997) as shown in Table 35.1. Cancer is, essentially, a genetic disease in the sense that it originates in mutations in DNA which lead to uncontrolled growth of affected tissues, with disastrous consequences for the organs that are affected. With age, the likelihood of genetic mutations increases and the mechanisms, including surveillance by the immune system, that keep mutated cells in check become less effective with age. Some cancers of old age are sex-specific, namely prostate cancer in males and breast cancer, albeit not absolutely specific to women, in females (Redmond & Aapro 1997).

Cardiovascular disease increases with age and this is due for the most part to the deposition of fatty plaques in the arteries. This leads to an increase in heart disease with age, expressed as angina and heart failure, and also to cerebrovascular disease and arterial disease elsewhere in the body. The phenomenon of autoimmunity has already been referred to and this is implicated in the age-associated disease, type 2 diabetes.

Dementia, caused mainly by Alzheimer's disease and cerebrovascular changes, is definitely associated with age (Harvey 2001). While dementia, leading to profound memory loss and decline in cognitive function, is not inevitable with age, by the age of 90, one in two people will suffer from some degree of dementia (www.alzheimers.org.uk).

The impact of dementia goes beyond the individual older person with dementia; it takes a considerable toll on those who live with the person, usually family members. The government has pursued policies of care in the community since the late 1980s and this, combined with the changing age profile of society, has led to more older people with dementia being cared for at home, in the community (Nolan et al 2002). This has meant that carers 'have moved from the margins of social policy' (Nolan et al 2002), and they now occupy a more central role. There is now a much greater emphasis on the involvement of carers of people with dementia and, indeed, of people with dementia themselves in participation in service delivery and development (Killeen 2001).

Frailty and multipathology

The discussion of ageing so far has presented what is known about the biological and psychological aspects of growing old. Some diseases which are more common with age have also been described. However, this is quite a superficial explanation of why older people need nursing care; in fact, the reasons for this are quite complex and are often unrelated to a single medical diagnosis and more related to the poorly defined concept of frailty (Markle-Reid & Browne 2003) which results from the common occurrence of multipathology in older people. It is very uncommon for older people not to have some manifestation of pathology and it is common that older people suffer from a range of disorders (Ruzicka 1997). None of these disorders is, in itself, life threatening but the total effect of several of these disorders may cause a significant strain on a person who is already compromised by the process of ageing, such that they lose their independence. This, rather than a single diagnosis, is what prompts the need for nursing care. For example, an older person may suffer from mild heart failure, rheumatoid arthritis or osteoarthritis, type 2 diabetes and some degree of memory loss. Each of these is not serious enough to require help with activities of daily living and even the combination can be coped with, but a serious incident, such as a fall or a chest infection, may tip the balance towards loss of independence and, thereby, dependence on nursing care.

The reasons why older people require help with their activities of daily living was conceptualised by Isaacs (1981) in the four giants of geriatric medicine, also known as the four I's shown in Box 35.3. These four factors concisely describe the manifestations of multipathology and, furthermore, they describe a vicious circle of circumstances that compound each other. The four I's also have in common the fact that none is easily treatable and all require human helpers to enable the older person to cope. This serves to emphasise the role of the nurse in working with older people.

The four I's are interrelated: if an older person falls, they may become immobile either as a result of injury related to the fall, e.g. fractured neck of femur, or due to fear of a subsequent fall; immobility may lead to incontinence and also to sensory deprivation and confusion. Certainly, immobility will lead to muscle atrophy and this may prevent the older person from becoming fully mobile again. Incontinence will be considered again below.

Box 35.3

The four 'giants' of geriatric medicine identified by Isaacs (1981)

- Immobility
- Instability
- Incontinence
- Mental impairment

35.3 In relation to older people who have difficulty with mobility, explore with them the effect of this on their lives.

It can be seen, therefore, that an older person who presents to the doctor with one of the four I's represents a very complex case. To treat the presenting cause is difficult, if not impossible. Treating the many underlying causes may require the prescription of a range of medications and this leads to another common phenomenon in older people — polypharmacy.

Polypharmacy

Polypharmacy is the prescription of more than four medications at the same time (DH 2001b). For the older person, the prescription of any medication has to be considered carefully. Due to the decline in glomerular filtration, older people require lower doses of most medications to achieve the desired effect (McGavock 2003). The therapeutic range of most medications is reduced such that lower doses are required to have the desired effect but also to avoid unwanted side-effects. The situation is compounded when more than one medication is prescribed, as older people are also more prone to adverse medication interactions whereby the administration of one medication either reduces the effect of another or enhances its effect and side-effects. While the prescription of medications remains largely a medical responsibility, monitoring the effects and side-effects of medications is a major nursing responsibility.

35.4 Identify a number of older people living at home who have been prescribed several medications. Analyse the particular risks to these older people from polypharmacy.

Medications and older people

The problems which older people may have with medications arise as a result of the normal ageing process, the multipathology from which many older people suffer and difficulties in adhering to medication prescriptions. Of course, the problem often arises with prescribers who may not understand these difficulties sufficiently and who do not take enough care in their prescribing practices.

The main problem associated with ageing, already referred to, is the decreased filtration capacity of the kidneys. The effect of this is to alter the distribution of medications in the body — the pharmacokinetics (McGavock 2003) — such that for any given dose there is usually a higher level in the blood of an older person than in a younger person.

The down-regulation of cell receptors for hormones referred to earlier also affects medication receptors and this means that some tissues become less sensitive to certain medications, referred to as pharmacodynamics (McGavock 2003). For example, the tissues of the cardiovascular system, the blood vessels and the heart muscle, become less sensitive to adrenaline and noradrenaline (Collins 1998). However, older people are more sensitive to some other medications; for example, the cardiovascular system becomes less sensitive to adrenergic medications and the central nervous system becomes more sensitive to phenothiazines.

There is no general rule, but it can be seen that medication prescribing for older people requires considerable skill. For example, there will always be a tendency to lower medication dosages — that is a general rule — but where these medications are less effective there may be a tendency to increase the dose. The combined effect of pharmacokinetics and pharmacodynamic changes in older people will generally narrow the therapeutic index of the medication: there will be a narrow range within which the medication will work without leading to side-effects. The *British National Formulary* gives specific guidance in relation to prescribing medication to older people and this is summarised in Box 35.4.

Some of the other normal effects of ageing may become more significant for older people who are prescribed medications. The older person, who is likely to be taking more than one medication, may suffer from reduced hearing and poorer memory which may lead to difficulty in understanding a complicated medication regimen (Watson 2002). Poor vision may compound this due to difficulty in reading

Box 35.4

Guidelines for the administration of medications to older people

- First always question whether a drug is indicated at all.
- LIMIT RANGE. It is a sensible policy to prescribe from a limited range of drugs and to be thoroughly familiar with their effects in the elderly.
- REDUCE DOSE. Dosage should generally be substantially lower than for younger patients and it is common to start with about 50% of the adult dose. Some drugs (e.g. long-acting antidiabetic drugs such as glibenclamide and chlorpropamide) should be avoided altogether.
- REVIEW REGULARLY. Review repeat prescriptions regularly. In many patients it may be possible to stop some drugs, provided that clinical progress is monitored. It may be necessary to reduce the dose of some drugs as renal function declines.
- SIMPLE REGIMENS. Elderly patients benefit from simple treatment regimens. Only drugs with a clear indication should be prescribed and whenever possible given once or twice daily. In particular, regimens which call for a confusing array of dosage intervals should be avoided.
- EXPLAIN CLEARLY. Write full instructions on every prescription (*including* repeat prescriptions) so that containers can be properly labelled with full directions. Avoid imprecisions like 'as directed'. Child-resistant containers may be unsuitable.
- REPEATS AND DISPOSAL. Instruct patients what to do when drugs run out, and also how to dispose of any that are no longer necessary. Try to prescibe matching quantities.

If these guidelines are followed most elderly people will cope adequately with their own medicines. If not, then it is essential to enrol the help of a third party, usually a relative or a friend.

NB: For the latest guidelines, refer to the current edition of the *British National Formulary*; the BNF is updated twice yearly.

labels and instructions and this, combined with reduced manual dexterity, either due to muscle atrophy or arthritis, may lead to problems opening medication packages (Watson 2002). Clearly, a great deal can be done to alleviate medication-related problems for older people and, in the UK, a National Service Framework, published as part of the *National Service Framework for Older People*, deals specifically with medicines and older people (DH 2001b).

- At the point of prescribing, clear, concise instructions should be given regarding medication prescription and this should be enhanced with written instructions — in clear large type — which the older person can take home.
- Pharmacists can provide packages with labels which have large writing and medicines in packages which are easily opened.
- Childproof containers are particularly problematic for some older people but, of course, additional precautions are required by older people who may be living with young children; packages that are not childproof must be kept out of their reach.

A range of professions is involved in ensuring that older people derive the most benefit from their prescribed medications and nurses have a key role to play with older people at home and in hospital. A detailed consideration of medications and older people and the strategies to help them is beyond the scope of this chapter but one major initiative is helping older people to learn about their medications while in hospital and to learn to self-administer these. This involves being able to allow older people to keep their medications while in hospital (Heath & Webster 1999). Secure storage is essential and accurate recording is required but this should ensure that older people can return home and be more independent with their medications.

Medication interactions and side-effects

Medication interactions are, of course, not unique to older people; when more than one medication is administered to anyone then there is the possibility of a medication interaction. As older people tend to take more medications, their chance of having a medication interaction is increased.

Some of the problems older people suffer from, including the 4 I's, may be caused by adverse medication reactions. Such reactions are more likely in older people due to the narrowed therapeutic index of medications and some classic adverse reactions include confusion, depression, falls, postural hypotension, constipation, urinary incontinence and Parkinsonism. The medications responsible are shown in Table 35.2 (Offerhaus 1997).

Table 35.2 Medications causing adverse reactions in some common disorders of older people

Confusional states	Depression	Falls	Postural hypotension	Constipation	Urinary incontinence	Parkinsonism
Hypnotics	Methyldopa	Hypnotics	All antihypertensives	Codeine	Loop diuretics	Antipsychotics
Tranquillisers		Tranquillisers	Diuretics	Dextro-propoxyphene	Hypnotics	Medication for vertigo
Antidepressants	Beta-blockers	Antidepressants	Antianginal medication	Narcotic analgesics	Tranquillisers	Methyldopa
Antipsychotics	Tranquillisers	Antipsychotics	Beta-blockers	Diuretics	Antipsychotics	
Anticholinergics (centrally acting)	Levodopa	Antihistamines	Hypnotics	Anticholinergics	Prazosin	Metoclopramide
Non-steroidal anti-inflammatory drugs	Corticosteroids	Carbamazepine	Tranquillisers	Disopyramide	Labetalol	
Levodopa		Phenytonin	Antidepressants	Verapamil		
Bromocriptine		Glyceryl trinitrate	Antipsychotics	Nifedipine	Beta-blockers	
Antidiabetics (hypoglycaemia)		All medication liable to produce postural hypotension	Antihistamines	Antipsychotics	Lithium*	
Corticosteroids			Levodopa	Antidepressants	All medication liable to produce faecal impaction	
Digitalis glycosides		—			—	
Anticonvulsants						
Cimetidine						

*Because of polyuria.

Box 35.5

Medicines and older people: issues identified by the Department of Health (2001b)

- Many adverse reactions can be prevented
- Some medicines which could benefit older people are under-used
- Medicines are not taken because older people and their carers have not been involved in making decisions about their treatment
- Medicines are wasted due to some repeat prescription practices
- GPs change medication after older patients are discharged from hospital
- Primary and secondary care communication is poor
- Labels on some medications are inadequate
- Getting to the surgery or the pharmacy can be a problem for some older people
- The contribution that carers could make in helping older people with their medication is often not addressed
- Medication review could reduce costs
- Some long-term medications could be withdrawn without adverse effects

Box 35.6

Questions the older person could be asked during a medication review

- How long have you been taking/using this medicine?
- Is the medicine in its original container?
- What is the purpose of this medicine?
- Do you know how to take the medicine, when and how often?
- Do you have a daily routine for taking this medicine?
- Do you have any side-effects from this medicine?
- Do you have any medicine allergies?
- Do you buy (or has anyone else bought for you) any non-prescription medicines from the chemist or any other shop such as a supermarket?
- Has anyone (such as a friend or neighbour) given or 'lent' you any medicines, vitamins, herbal or homeopathic products to use?
- Do you use/take any other form of medication or home remedies or products prescribed by any other source of advice?
- Any other similar questions that may be important in individual cases

Reproduced with permission from the Department of Health (2001a).

The *National Service Framework: Medicines and Older People* (DH 2001b) was produced for some of the reasons summarised in Box 35.5. One of the main recommendations from the NSF was for medications review for older people and a framework for this, including the questions that should be asked of older people, was outlined. Questions, which are very relevant to nursing practice, are shown in Box 35.6.

THE NATIONAL SERVICE FRAMEWORK FOR OLDER PEOPLE

The care of older people is currently guided by the *National Service Framework for Older People* produced by the UK Department of Health in 2001 (DH 2001a). The NSF provides an overarching framework which deals with attitudes to the care of older people, primary and secondary care and, as described earlier, with specific aspects of the care of older people such as medicines. The NSF is presented as eight standards shown in Box 35.7.

Box 35.7

National Service Framework standards

- Standard one: rooting out age discrimination
- Standard two: person-centred care
- Standard three: intermediate care
- Standard four: general hospital care
- Standard five: stroke
- Standard six: falls
- Standard seven: mental health in older people
- Standard eight: the promotion of health and active life in older age

Reproduced with permission from the Department of Health (2001a).

Standard one

The first standard: rooting out age discrimination, sets the tone for the NSF and also hopes to set the tone for the care of older people in the UK. Essentially, with regard to NHS services, these should be provided 'regardless of age' with clinical decisions being made on the basis of the health of an older person and not on the basis of their age. The concept, once familiar in the care of older people, that any older person has had 'a good innings' and does not deserve further treatment is no longer acceptable (Watson & Buswell 2001) — if indeed, it ever was.

Standard two

Person-centred care, which is the focus of the second NSF standard, is a key concept in the care of older people and has long been championed by nurses working and researching in this area. The NSF promotes this by saying that older people must be treated as individuals and that they should be able to make choices about their care. Standard two also promotes the idea of a single assessment procedure which crosses the primary–secondary care interface and also spans health and social care. The objective here is to provide less fragmented pathways of care to older people by providing and sharing information across different settings.

Standard three

One of the objectives in caring for older people is to promote their independence and to provide care as close to home as possible. This has been seen over the last 20 years with the advent of care in the community initiatives (Henwood 1992); there is often a gap in care between hospital and home which is evident when an older person is able to leave

hospital but not quite ready to manage on their own at home and this should be addressed through intermediate care, the focus of standard three of the NSF.

Intermediate care is a controversial subject and the concept itself almost defies definition (Andrews et al 2004). Across the UK there are as many different models of intermediate care as there are services delivering it and it has become the focus of research in recent years. Intermediate care may be anything from district nursing care, meals delivery or having a carpenter visit to make alterations such as adding handrails, which will help the older person to be independent (Andrews at al 2004). The point behind intermediate care is that it should be person-centred and based on the needs of the older person; it should also be time limited, perhaps to a number of days or weeks after which, if the older person continues to require such care, it is no longer intermediate and other care services, social and health, are required.

Standard four

It is recognised that the care of older people in general hospitals can be poor and this was reported in some detail in the landmark report entitled *Not Because They Are Old* (HAS 2000 1998). Older people are often, frankly, neglected in general hospitals in emergency departments, outpatient departments and in wards. This has been alluded to earlier in the chapter but the report by HAS 2000 highlighted prolonged waits in inappropriate surroundings leading to disorientation and development of pressure ulcers, and inadequate care on general wards with poor attention to nutrition, all of which may result in older people leaving hospital with more problems than those with which they entered. Standard four of the NSF addresses this issue directly and specifies that there should be specialist teams to provide advice on the care of older people in hospital and that a consultant in geriatric medicine should be available. Also, nurses should have appropriate education for the care of older people and attention should be given to the maintenance and improvement of the older person's health while in hospital, making use of a wide range of services.

Standard five

Stroke is a particular problem in older people due to changes in the vascular system of the brain and the NSF provides a separate standard (standard five) for this. Standard five includes, for example, stroke prevention and delivery of services by specialist stroke teams, including rehabilitation and long-term support.

Standard six

Another problem that is more common in older people is falls and this is related to one of the four 'giants of geriatric medicine' (Isaacs 1981), namely, instability. Falls lead to injury and are usually indicative of some underlying problem. Falls which result in injury may lead to immobility and the NSF standard six recommends the development of programmes to prevent falls in older people, improvements in the care of older people who have fallen and the prevention and treatment of osteoporosis. The National Institute for Clinical Excellence (2004) has published a clinical guideline related to falls in older people.

Standard seven

The mental health of older people includes the full range of mental health problems suffered by younger people, but depression and dementia are particularly common. Services across the UK vary widely for older people with mental health problems and the NSF specifies key interventions in standard seven for the promotion of good mental health, early recognition and management of mental health problems and the availability of specialist services for older people. In relation to this standard, it is recognised that those caring for older people with mental health problems at home require information, advice and support.

Standard eight

The NSF concludes with standard eight which relates to the much neglected area of health promotion and active living for older people. Pointing out that dependency and disability are not inevitable aspects of growing old, the NSF cites evidence that risk factors in later life can be modified and that there is no reason to withhold health promotion from older people. Specific interventions relate to heart disease, mental health and cancer and the NSF recognises that such programmes must be tailored for older people, taking into account cultural and ethnic diversity (RCN 1998). Interventions should be aimed at diet and nutrition, physical activity and immunisation, for example, annual winter protection from 'flu.

35.5 Community nurses such as health visitors, district nurses and general practice nurses meet older people at home, in health centres and other community settings. Compare the contribution of these nurses to health promotion and care of older people.

SPECIFIC ISSUES IN THE CARE OF OLDER PEOPLE

It has been emphasised throughout this chapter that old age is not, in itself, a pathology and that old age is not inevitably associated with physical and mental problems. Nevertheless, it has also been demonstrated that there is some association between old age and some physical and mental problems and the nurse working with older people needs to understand these. The range of potential problems that could be covered is large but this section will focus on two specific areas: nutrition and incontinence.

Nutrition and older people

Older people generally suffer from more problems with nutrition than younger people (Copeman 1999) and it is especially the case that older people in hospital suffer greatly from nutritional problems (Tierney 1996). Mainly, although not exclusively, older people suffer from under-nutrition which leads to weight loss and vulnerability to secondary problems of infection, skin breakdown, poor recovery from illness and from surgical procedures (Watson 2003). The reasons why older people suffer from poor nutrition are varied and encompass not only some of the biological problems which may be associated with age, such as lack of teeth and a reduced sense of smell and taste, but also such things as being immobile or less mobile due to a fall (Copeman 1999). This may prevent the older person from being able to prepare food or from being able to

shop for appropriate food. However, there are also social and economic reasons why older people may become poorly nourished. Generally speaking, older people in retirement have reduced incomes compared to their working years and this may lead them to reduce their food intake or to eat foods that are less nutritious than they require (Copeman 1999). Older people with cognitive impairment related, for example, to dementia are particularly at risk of undernutrition (Watson 1997), especially in the terminal stages, but weight changes can become apparent very early, for example, in Alzheimer's disease (Barrett-Connor et al 1996).

The most important requirement for nurses caring for older people, with regard to nutrition, is to understand that problems can arise (see Ch. 21). Nurses have a considerable responsibility in hospital and at home to detect if an older person is suffering from undernutrition and towards this end they should be able to assist in the assessment of the nutritional status of older people. Usually, it is sufficient for the nurse to be able to screen for nutritional problems and then to pass this information to the doctor or the dietitian. However, the nurse, especially in hospital, has a major responsibility for helping older patients to eat and drink; whatever dietary supplements are prescribed by the doctor or dietitian, they will be completely ineffective if the older person with malnutrition cannot eat, drink or swallow. It is beyond the scope of this chapter to provide comprehensive guidance on the nutritional care of older people but excellent guidance, along with recommended dietary intakes and strategies to help older people to eat, has been published by Age Concern (see Box 35.8) (Copeman 1999). Other authors have outlined assessment strategies for dietary intake (Green & McDougall 2001) and fluid requirements (Woodrow 2002) in older people.

Box 35.8

Recommendations for food consumption by older people

- Dietary energy intakes of older people should tend to the generous, except for those who are obese
- Older people should derive their dietary intakes from a diet containing a variety of nutrient-dense food
- An active lifestyle, with prompt resumption after episodes of intercurrent illness, is recommended as contributing in several ways to good health
- Steps should be taken to increase the awareness by health professionals of the importance of both overweight and underweight in older people
- Intakes of fibre comparable to those of the general population are advised for most older people
- The statutory fortification of yellow fats other than butter with vitamins A and D should continue
- Older people should be encouraged to increase their dietary intakes of vitamin C
- Older people, in common with those of all ages, should be advised to eat more fresh vegetables, fruit and wholegrain cereals
- Older people should be encouraged to adopt diets which moderate their plasma cholesterol levels
- Older people should be encouraged to consume oily fish and to maintain physical activity to reduce the risk of thrombosis
- A daily intake of 6 g of salt is advised
- The calcium intakes of older people in the UK should be monitored
- Doorstep deliveries of milk for older people should be maintained
- All older people should be encouraged to expose some skin to sunlight regularly during summer; if not possible, vitamin D supplements should be given
- Health professionals should be aware of the often inadequate food intake of older people in institutions
- Assessment of nutritional status should be a routine aspect of history taking and clinical examination when an older person is admitted to hospital

Reproduced with permission from Copeman (1999).

Continence and older people

First of all, the myth must be dispelled that older people commonly suffer from incontinence. People can suffer from incontinence at any age but, as with many physical problems, there is an association between incontinence and ageing (Norton 1999). When referring to incontinence, it is usually urinary incontinence that is being implied; faecal incontinence is relatively rare. Urinary incontinence is more prevalent in women than in men but the frequency of incontinence rises in both men and women with age (Heath & Watson 2003). Urinary incontinence can lead to multiple problems that span the psychological, the social and the physical. People find urinary incontinence profoundly embarrassing and can become socially isolated as a result, with the condition completely dominating their lives (White & Getliffe 2003).

Urinary incontinence (see Ch. 24) can arise for several reasons but can usually be classified (Williams et al 1995) as follows:

- detrusor dysfunction arises from an inability to suppress spontaneous contractions of the bladder leading to voiding of urine
- stress incontinence arises through incompetence of the pelvic floor muscles and, while this is common in women following childbirth, it can arise in men following pelvic surgery
- outflow obstruction arises when there is something blocking outflow of urine from the bladder, for example, it may arise in constipation, prostate hyperplasia or as a result of a tumour, and this leads to urine overflowing periodically under the pressure in the bladder
- neurogenic bladder arises when the peripheral nervous supply to the bladder has been damaged; a common cause of this is dementia.

Urinary incontinence in older people is difficult to resolve unless the cause is obvious and easily obviated, such as an obstruction to outflow which can be removed or a urinary tract infection which can be treated. Nurses should understand the possible associations between ageing and urinary incontinence. In the absence of effective treatments, nurses should approach older people suffering from urinary incontinence with sensitivity, tact and the hope — in the absence of a cure — that life with urinary incontinence can be made more bearable (see Ch. 8).

Once again, it is beyond the scope of this chapter to provide detailed guidance regarding the management of urinary incontinence but it should be noted that a variety of appliances, some specific to men and some to women, are available and that technology in this area has vastly improved in recent years with the introduction of highly absorbent gels which help to keep the person with incontinence dry and free from odour.

PROMOTING THE DIGNITY AND INDEPENDENCE OF THE OLDER PERSON

It is hoped that the need to respect the dignity and independence of older people has been promoted thus far in this chapter. However, it is important finally to specify some areas of care where this can be promoted. There is no point in pretending that old age is a positive experience for everyone. Nevertheless, is behoves the nurse to have as positive an attitude towards ageing as possible and this will not, necessarily, be engendered only by working with older people. Reading around the subject of old age is very important and Hepworth (2000) in *Stories of Ageing*, for example, has studied how old age is portrayed in literature: often it is sad, sometimes amusing but always interesting to see how others view this, almost inevitable, stage of life. It is also important to realise that health promotion applies in old age as much as it applies in younger years (Bernard 2000) and, through empowerment and action, many older people have been able to take control of their lives in adverse circumstances and make a valuable contribution to health and social policy.

Consent

Often, however, nurses work with older people who are vulnerable; they may be in poor physical health and confused. This does not mean that their rights can be overridden, even in the apparent pursuit of the best interests of the older person; action taken must not lead to an affront to dignity. Wherever possible, the consent of an older person to treatment or even a seemingly innocuous nursing intervention is required (DH 2001c); specifically, treatment, including life-saving treatment, cannot be forced on an older person without consent. In particular, restraint should not be applied unnecessarily to an older person who is confused and who may be wandering or aggressive due to confusion. Clearly, patient and staff safety are paramount considerations but restraint has such harmful consequences (Strumpf et al 1998) that it should only be applied under very controlled conditions for which the Royal College of Nursing (1999) has produced relevant guidelines.

Related to restraint is the issue of elder abuse. This has been known about for many years but is becoming more widely acknowledged (CDNA 2003, British Geriatrics Society 2005). Nurses should be able to recognise signs of abuse and know what action to take.

CONCLUSION

This chapter has explored some aspects of the care of older people. More comprehensive texts should be consulted, many of which are referred to in this chapter (Matteson et al 1997, Heath & Schofield 1999, Redfern & Ross 1999). Likewise, there are specific areas of the care of older people which can be studied in greater depth such as nutrition (Copeman 1999), incontinence (Getliffe & Dolman 2003), intermediate care (Wade 2004) and dementia (Cantley 2001). As a nurse working with adults you will inevitably encounter older people in the course of your practice. You will have much to offer each older person you meet and, in turn, they will have much to offer you.

INTRODUCTION

36.1 In preparation for reading this chapter, carry out the following exercise:

(a) List as many legal and illegal substances you can think of. Beside each, briefly write your feelings, positive or negative, relating to these substances. For example, are they acceptable/attractive/frightening?

(b) Write a brief description of your feelings in relation to:
- illegal substance use and substance users
- alcohol use and problem drinkers
- tobacco use and smokers
- legal substances (e.g. prescribed medication, tea, coffee) and their users.

This chapter provides an introduction to substance use and outlines the important contribution that nurses can make to the care of people with substance use problems. The term 'substance use' refers to legal substances, i.e. alcohol, tea, coffee, tobacco and prescribed medications, and currently illegal substances, i.e. cannabis, cocaine, opiates and opioids. Whatever the nature of substance use, it must be considered in the context of the individual's personal history and circumstances; stereotypes of the substance user must be abandoned in favour of a more individualised and holistic understanding of the person. Not all substance use is problematic. As in all areas of nursing, interventions on behalf of the individual with substance use problems must be based on thorough assessment and should involve the individual and the family, as partners in care.

Because substance use may have physical, mental, emotional, social and economic implications for the individual, multiagency collaboration and approach to treatment is essential to ensure all dimensions of the person's situation are considered, as adjustments necessary to resolve a substance use problem are made (DH 2002a). Prochaska and DiClemente's (1986) seminal integrative model of change and Miller and Rollnick's (2002) motivational interviewing are outlined as approaches that will be relevant to nurses.

The importance of early identification cannot be overemphasised. To assist nurses in all fields in recognising the signs, and understanding the long-term effects of excessive or inappropriate substance use, the second half of the chapter outlines the physical, social, spiritual and psychological effects of using a range of legal and illegal substances. Alcohol use is discussed at some length, given the high prevalence of alcohol-related problems in the UK; emphasis on alcohol use and associated problems is reflected in the Scottish Alcohol Plan (Scottish Advisory Committee on Alcohol Misuse 2002) and the Alcohol Harm Reduction Strategy for England (Prime Minister's Strategy Unit 2004). However, Saunders and Marsh (1999) suggest that it is misleading to consider alcohol and drug use as separate entities, given the many similarities between their social, psychological and medical implications.

In view of the wide range of psychoactive substances that can be obtained by legal or illegal means, and the wide range of therapies that are available to individuals who seek help, this chapter cannot hope to be comprehensive. Readers are directed to the 'Further reading' list (p. 1167)

when pursuing any topics of special relevance to their area of practice.

'Understanding drug use' is an interactive CD-ROM that provides an excellent overview of substance use problems and helps to put problematic substance use in perspective. Contact: The Drug and Alcohol Coordinator, Southern Public Health Unit, Bunbury, Western Australia (tel: +61 (08) 9792 2500; e-mail: raquel.willis@health.wa.gov.au).

For an overview of alcohol use, see Cooper (2000).

Definitions

Dependency

Drug dependency is described by the World Health Organization (WHO 2004a) as 'a cluster of cognitive, behavioural and physiological symptoms indicating that the individual continues the use of the substance despite significant substance-related problems'.

Dependency may be psychological or physical, or both, and is clinically defined by at least three of the following:

- A strong desire or sense of compulsion to take the substance
- Difficulties in controlling substance-taking behaviour in terms of its onset, termination or levels of use
- A physiological state of withdrawal
- Evidence of tolerance
- Progressive neglect of alternative pleasures or interests
- Persistent use despite clear evidence of overtly harmful consequences (WHO 2004a).

Thus, dependency may develop when an individual becomes physically, socially or psychologically reliant on a substance, such that life without it becomes intolerable. Dependency is not automatic. Saunders and Marsh (1999) argue that any substance can be used without the user becoming dependent on it.

During the 1960s, many experts attempted to clarify the distinction between addiction and habituation. These two terms were subsequently abandoned in favour of dependence. It is therefore safe to assume that 'dependence' and 'addiction' refer to the same thing. However, an increasing number of professionals working within the substance use field believe that such labels as dependence and addiction are, at best, unhelpful in the treatment setting.

Other terms

Drug The WHO Expert Committee on Drug Dependence describes the word 'drug' as 'a term of varied usage'. As a medicinal product, 'drug' can refer to 'any substance in a pharmaceutical product that is used to modify or explore physiological systems or pathological states for the benefit of the recipient' (WHO 1985). In addition, the term is used to refer to non-prescribed and illicit substances that include alcohol, tobacco and caffeine.

Tolerance and cross-tolerance are generally understood in pharmacology, the former as 'a decrease in response to a drug dose that occurs with continued use', and the latter as 'the development of tolerance to another substance, to which the individual has not previously been exposed, occurring as a result of acute or chronic intake of a substance'.

Substance misuse This is 'the result of a psychoactive substance, drug or alcohol, being consumed for a purpose other than that for which it was intended, and that causes physical, social and psychological harm' (Rassool 1998). However, it could be argued that many people consume substances, e.g. alcohol, intentionally for social reasons and that such intentional use can result in physical, social or psychological harm. Many illicit substances, e.g. ecstasy, are manufactured specifically to help individuals enjoy a social occasion. Therefore the user is consuming the substance for the purpose for which it was intended. The smoker with a diagnosis of lung cancer will have experienced physical harm as a result of using tobacco for the purpose intended. These individuals have not 'misused' but 'used' substances in a manner that could be harmful or hazardous. The term ***substance use*** may therefore be a more appropriate term to apply to individuals who use drugs or alcohol and it is the term that will be used throughout this chapter. Substance use could be described as a continuum ranging from low risk use, through harmful and hazardous use to dependence. Not all individuals will remain static on the continuum nor will all progress to dependence. Individuals may move back and forth along the continuum during their substance-using career in response to personal and/or social circumstances.

Detoxification is a process of removing from the body the substance on which the individual is physiologically dependent. During this process, medication may be prescribed and the individual is assisted in making lifestyle adjustments such that the substance is no longer needed. Detoxification is increasingly undertaken in the home environment. Only severe cases, in which complications have been identified, require hospitalisation (Cooper 1994).

Withdrawal symptoms These are best described as psychological and/or physiological reactions to the reduction or complete withdrawal of the substance of use. How long withdrawal lasts depends on the previous use of the substance and on the nature and extent of both physiological and psychological dependence (Cooper 1994).

A MODEL FOR CHANGING ADDICTIVE BEHAVIOURS

In 1984, a seminal conference held in Scotland aimed to 'develop a more comprehensive model of change for the treatment of addictive behaviours' (Prochaska & DiClemente 1986). It was agreed that any model developed should be applicable to the many different ways in which people change, ranging from those requiring maximum intervention (hospitalisation) to those needing minimal intervention, e.g. self-help manuals (Prochaska & DiClemente 1986). This model had to be applicable to the variety of dependency behaviours that individuals wish to change and, at the same time, to advance the understanding of how people change their behaviours, from the stage at which a problem is recognised to the point at which it is resolved.

Prochaska and DiClemente (1986) proposed a model of change, which is now widely accepted. This model provides a framework that assists professionals in organising their

knowledge and in making case management decisions. Prochaska and DiClemente felt that this model should take account of the person who self-changes as well as the individual progressing through therapy and that it should be applicable to the wide range of dependency problems that exist. In addition, it should help the therapist to synthesise the various treatment methods presently available.

The Prochaska and DiClemente (1986) model is 'three-dimensional', integrating changes, together with processes and levels of change. The model comprises four stages — pre-contemplation, contemplation, action and maintenance — which may be conceived of as cyclical, thus allowing the individual to join or leave the process of change at any given stage (see Fig. 36.1). This model is also referred to as 'the integrative model of change' or 'the motivation to change model'. Its stages are described as follows:

- *Pre-contemplation stage* — at this stage the individual is not aware of dependency. This could be because of ambivalence, denial or selective exposure to information. As the individual becomes aware of the problem, progression to the next phase is made possible.
- *Contemplation stage* — at this point the individual admits that something is wrong and begins to think seriously about behaviour change. This stage may last for a few weeks to many years, and some individuals never progress beyond this point.
- *Action stage* — here, the individual makes a commitment to alter the problematic behaviour. This is a brief stage; when the decision has been made the individual progresses to the next stage.
- *Maintenance stage* — at this point, new behaviour is strengthened and develops into self-efficacy; the individual's feeling of being in control is maximised. This stage affords the exit point to termination.

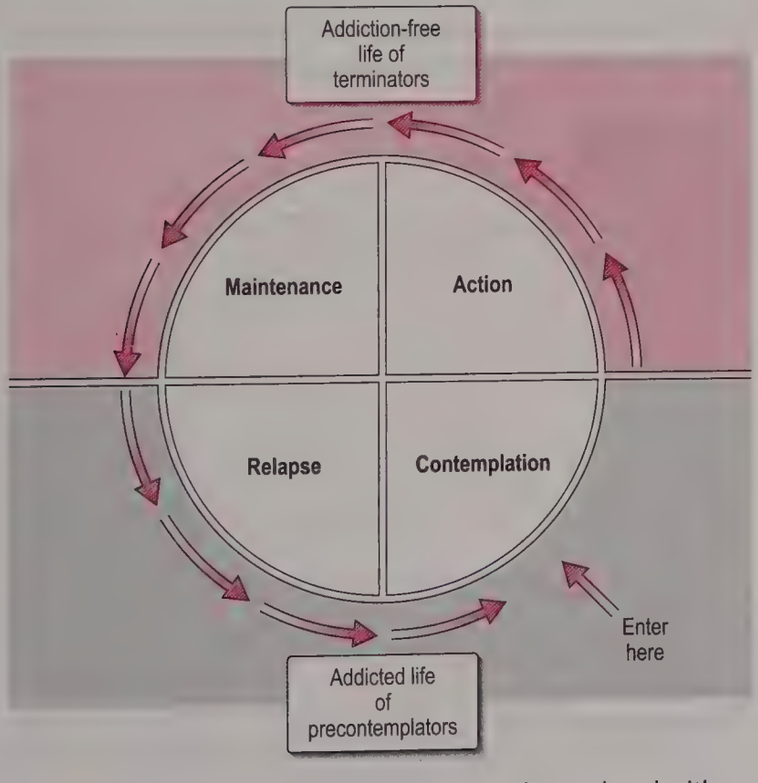

Fig. 36.1 The integrative model of change. (Reproduced with permission from Prochaska & DiClemente 1986.)

At the maintenance stage, the individual may temporarily lapse as a result of the extreme effort required to maintain the change in behaviour. Occasionally this extends to relapse, in which case the individual often goes back to the pre-contemplation stage before rejoining the cycle. Prochaska and DiClemente (1986) suggest that 84% of 'relapsers' progress back into the contemplation stage. In addition, it has been indicated that the typical self-changer makes three revolutions of the change cycle before exiting into a relatively dependency-free life (Schacter 1982, Prochaska & DiClemente 1983). However, some individuals do become arrested at one particular stage.

It is essential that the individual and the professional are in agreement as to which stage of change is relevant at a given time. Any resistance to therapeutic interventions often comes as a direct result of the therapist and client working at different stages of the change process. Prochaska and DiClemente (1986) explain the importance of this as follows:

> *The more directive, action-orientated therapist would find a client who is at the contemplation stage to be highly resistant to therapy. From the client's perspective, however, the therapist may be seen as wanting to move too quickly … A therapist who specialises in contemplating and understanding the causes of problems will tend to see the client who is ready for action as resistive to the insight aspect of therapy. The client would be warned against acting impulsively. From the client's perspective … the therapist might be warned against moving too slowly.*

In applying the Prochaska–DiClemente integrative model of change in their interventions with substance-using individuals, nurses should never hesitate to seek help and advice from more experienced or knowledgeable practitioners. Nurses should strive to be well informed about all aspects of substance use. Nurses of all levels and specialties have contact with individuals with substance use problems and therefore need to be aware of the physical, social, psychological and legal consequences of dependency and the implications of these for the individual, the family and the nurse (Prime Minister's Strategy Unit 2004).

THE ROLE OF THE NURSE

Although our understanding of substance use has improved in recent years, there remains a tendency for nurses and other professionals to fail to identify substance-using individuals. The Scottish Advisory Committee on Alcohol Misuse (2002) and the Prime Minister's Strategy Unit (2004) suggest a multidisciplinary approach is essential and expound the need for shared care as an effective intervention for those with substance use problems.

Inadequate preparation in pre/post-registration nursing education is a barrier to providing effective management and interventions for these individuals. However, the Alcohol Harm Reduction Strategy for England (Prime Minister's Strategy Unit 2004) makes specific recommendations regarding the need for pre/post-registration education and training for all health professionals in the early identification of alcohol problems. Nurses may feel unable or reluctant to engage with substance-using individuals for a number of reasons:

- *Role legitimacy* – nurses are uncertain as to whether, or how far, harmful substance use falls within their remit

- *Role adequacy* – nurses perceive a lack of knowledge and skill in identifying and responding to substance-using clients
- *Role support* – nurses feel that they would have insufficient access to or support from specialist services should they identify a harmful substance user (Cooper 1994).

For some professionals, increased knowledge and understanding of substance use may challenge their own values, attitudes and beliefs. Their own use of alcohol or drugs may be questioned, giving rise to negative attitudes towards substance use. Such attitudes may impact on the quality of care provided. The individual who uses substances is often viewed as not motivated to change, manipulative and self-destructive (Banerjee et al 2002). Professionals may find it difficult to work with someone who is perceived as a demanding individual. Nurses must be aware of their own attitudes towards substance use and of how this impacts on standards of care.

In their interactions with individuals with a substance use problem, it is important for nurses to recognise that the substance used is but one part of the problem. Each person presents with unique concerns that may cause, contribute to or interact with the development of the presenting state. Individuals experiencing substance use problems often change their behaviour as a direct result of crisis, such as a change in an important relationship, an accident or illness, redundancy, a birth or a death. Such events can curtail, neutralise or enhance the nurse's endeavours with an individual (Davidson 1991) and must be taken into account in the formulation of treatment and intervention. During interactions with the person, the nurse should be prepared to:

- identify the individual with a substance use problem
- recognise the types of problems experienced by the individual
- assist the individual in the process of acknowledging, exploring and understanding substance use
- appreciate the individual's own perception of substance use
- consider with the individual the treatment and intervention options
- facilitate achievement of the person's chosen goal(s)
- acquaint the individual with available services and facilities
- act in a non-judgemental way
- provide nursing interventions in withdrawal
- provide understanding and support should relapse occur.

36.2 The following exercise may help the reader to imagine themselves in the problem substance user's place. For 1 week, stop using your favourite substance, e.g. tea, coffee, alcohol, chocolate, tobacco. At the end of the week, make a few notes on the following:

(a) How easy did you find it to live without the substance?
(b) Was your mood affected? If so, in what way? Did you experience cravings?
(c) What strategies did you use to avoid temptation?

Identifying substance use

The early identification of substance use is important in providing appropriate intervention or accessing relevant support. Box 36.1 lists various signs and symptoms that can indicate the existence of a substance use. However, there is a danger that some of these may be dismissed as being attributed to the primary illness. For instance, an individual in an acute mental health unit may exhibit increasing symptoms of psychosis, restlessness and anxiety in the hours following admission. This may be misdiagnosed and treated according to a primary diagnosis of acute psychotic disorder. Alternatively, an individual who arrives in a surgical ward in the morning, in preparation for an operation, may become overanxious and agitated by the evening, which may be interpreted as preoperative apprehension. It is possible that both individuals may have alcohol-related problems. Therefore, during assessment, nurses should be aware that not every feature listed necessarily applies to a given individual, nor does the existence of any one feature demonstrate or exclude conclusively a substance use problem.

Whilst the use of alcohol and drugs has increased over the past few decades, not all individuals who use substances will develop related problems. Many individuals limit their use to weekends. During the week, nurses, for example, hold positions of responsibility and trust and their weekend substance use does not appear to impact on their ability to complete daily tasks. The majority of individuals use substances responsibly and are aware of the effects and consequences of such use.

Substance use is often time limited. When responsibilities change at home (relationships/children) and at work (promotion), most individuals adjust their substance use. Although there are health risks associated with this type of use, the damage is less severe and disabling than through prolonged, repeated use. For a small minority, however, their substance use will continue and dependence may occur. They may use substances as a means of release or a way

Box 36.1

Signs that may alert the professional to the existence of a substance-using client

- Physical health problem, e.g. vitamin deficiency, gastritis, infections, ulcers
- Mental health problem, e.g. anxiety, depression, suicide attempts
- Symptoms of substance use, e.g. tremor, shakes, sweating
- Problem at work, e.g. lateness, absenteeism, accidents
- Criminal offences
- Family problems, e.g. neglect, child disturbance, marital disharmony
- Requests for help, e.g. from the client, family or other professional
- Evidence of substance use, e.g. smell, used equipment
- Known history of substance use
- Family history of substance use
- Other, e.g. complaints of fatigue, lethargy, insomnia, restlessness

of coping with memories of traumatic childhood events, difficult family or marital relationships or work-related stress. For these individuals the accurate early identification of problems and the provision of timely interventions are essential.

Approaching a substance use problem

If assessment identifies a substance use problem, further exploration of the substance use should be raised in a non-threatening manner. While the individual may initially be evasive or defensive, at least there has been a demonstration of concern and a first approach. The subject should not be laboured but the nurse should be tactful and sensitively try to make progress at each contact. The nurse is not a judge, but a facilitator, educator and carer.

Bedside conversations in large wards do not facilitate confidentiality. Curtains round a bed do not block out sound. Nurses should consider where and how they would want to be approached if they were in the same situation and apply the standards of confidentiality that would be expected for themselves in their interactions with others.

If nurses are unsure about how to proceed, they should seek advice and support. Local agencies may be helpful, as may colleagues who have similar individuals on their caseloads. Mutual support is essential in all areas of nursing.

Assessment

Intervention should only be undertaken following a full and systematic assessment of the individual's and the family's needs. If treatment is to be effective and therapeutic, a complete picture of the person's substance use must be obtained. Moreover, a clear understanding of the person's chosen treatment goals is essential. Is the aim to reduce use, to change to a less harmful substance, to control use, withdrawal or total abstinence?

Many individuals with substance use problems 'sound out' a service before committing to care. Therefore, any information given on treatment options should be clear and to the point, and communicated both verbally and in written form. Assessment should include details of past and present substance use. In preparation, the individual could be asked to complete a diary similar to that shown in Figure 36.2. The following factors should always be considered in any assessment:

- psychological state
- work, social and cultural factors
- problematic effects of use
- motivation for treatment
- family psychodynamics
- relevant personal factors
- physical state and complications.

Brief intervention

Brief intervention is an approach less intensive than that of traditional methods. It can range from 5–10 min of information-giving, to three to five individuals, or group, sessions involving motivational interviewing techniques. Brief intervention is usually opportunistic, i.e. the primary reason for contact with the nurse is not related to substance use. Brief intervention is aimed at non-dependent substance users whose consumption is harmful but who are not experiencing consequential major health problems. However, it can be offered to those expressing concern or seeking advice about use. Brief intervention is motivational and should encourage the individual to conclude that a reduction in use, or less harmful use, is beneficial. It should aid individuals in identifying their own goals in order to reduce or modify substance use. Information, written and verbal, should be provided regarding the health risks associated with the particular substance use and any advice given should be tailored to individual needs.

Bien et al (1993) identified six elements shown to be effective in brief intervention, described as the FRAMES model:

- **F**eedback — assessment and evaluation of the problem
- **R**esponsibility — emphasising personal choice
- **A**dvice — explicit advice on changing behaviour
- **M**enu — aiding the development of alternative goals and strategies
- **E**mpathic interviewing — a non-confrontational reflective approach
- **S**elf-efficacy — instilling optimism that chosen goals can be achieved.

All nurses, whether working in hospital or community, should be capable of offering this intervention. The World Health Organization (2001) offers an excellent manual on brief intervention in primary care that includes guidance for clinicians, an education brochure and self-help book (see Box 36.2 for information offered in brief intervention).

Prevention

Whether or not an individual develops a substance use problem depends on the social resources available. It is vital that the problems and experiences that can set the stage for substance use problems are recognised by health and social care professionals and that relevant agencies persevere in improving and developing preventive strategies at both local and national levels.

In recent years, campaigns such as 'No Smoking Day' and 'Drinkwise Day' have had some effect. Most health authorities now have a drug and alcohol advisory service, as well as a health promotion officer dealing with HIV/AIDS-related issues (see Ch. 37). Initiatives such as outreach programmes and needle exchange schemes have proved valuable in the early identification of substance users (see p. 1175).

Nurses and substance use

It is important that nurses are aware of the high levels of stress that they may experience in their professional lives, which can make them vulnerable to substance use problems (Coombs 1996). It is very hard for a nurse to broach this subject with a colleague suspected of substance use. It is equally as difficult for the nurse with a substance use problem, as it is for any other person, to admit to this and ask for help because of the negative attitudes and stigma still

Box 36.2

Brief intervention

Information offered in brief intervention to a problem drinker in a primary care or acute ward setting:
The nurse has identified an individual at possible risk of harmful alcohol use. This may be through conversation during routine procedures or as a direct/indirect result of the person's attendance/admission to the clinical area.

Accurate assessment

The Fast Alcohol Screening Test (FAST) enables the nurse to assess the need and level of intervention required if alcohol use is hazardous. FAST consists of four questions and is completed in 1 min. A score of 3 or more indicates a risk of alcohol-related harm. To obtain a clearer picture of the extent of a person's alcohol use, a drinking diary could be completed (see Fig. 36.2). A drinking diary highlights the frequency, levels, patterns and triggers to an individual's alcohol consumption on a 'typical' week that can subsequently be explored. From the drinking diary the individual can be taught how to calculate the weekly alcohol consumption in units (also referred to as 'standard drinks'). The risk levels and appropriate interventions required are as follows:

- *Low risk*: men <21 and women <14 units/week — general preventive strategies; it is important to note that the recommendations suggest low risk and ***not*** no risk
- *Moderate risk*: men 21–50 and women 14–35 units/week — brief intervention strategies
- *High risk*: men >50 and women >35 units per week — specialist agency referral
- *Binge drinking*: men >8 units and women >6 units/drinking session — information specific to binge drinking and intervention as above depending on level of consumption.

Providing information

During brief intervention, the nurse offers practical advice and information, tailored to meet the needs of the individual. Information on weekly and daily drinking is provided, in addition to how to calculate units. Offering information on the consequences of harmful alcohol use should be considered, paying attention to the harm associated with intoxication, binge drinking and excessive use (see Box 36.4). The individual is aided to consider the positive and negative consequences of alcohol consumption in relation to social, physical, psychological and spiritual needs. Practical advice can be given on how to reduce alcohol consumption. Examples include changing strength of drinks from a higher to a lower alcohol content, drinking more slowly, alternating alcoholic and non-alcoholic drinks, eating food (e.g. crisps), engaging in other activities whilst drinking to slow consumption (e.g. playing pool, darts or cards), or setting limits on consumption. It is useful to consider alternative activities to drinking that the individual may find enjoyable.

Written material to complement and build on, if necessary, the information provided during an intervention should be offered. Appropriate contact details of local alcohol services should be provided where necessary. If referral to a specialist agency is required and the individual agrees, the nurse may make contact to arrange a full assessment or provide written details.

associated with substance use in today's society. The nurse with a substance use problem may ask the following questions (Cooper & Faugier 1993):

- Will my colleagues find out details of my problem and treatment?
- If I cannot look after myself, how can others be entrusted to my care?
- Will treatment for a substance use problem be noted on my record and limit my professional development?
- How will I relate to the nurses who are caring for me?
- Will I be suspended, disciplined or asked to leave?
- Will I be considered responsible enough to continue in my profession if I accept help?
- How will I convince others that I can be trusted to hold drug cupboard keys?
- How can I impress on senior managers and nursing colleagues that any future time off from work is not due to the substance use?
- How will I arrange regular time off to keep my counselling appointments?

How nurses can get help

The nurse who has acknowledged a substance use problem should check to see whether the employer has an alcohol and drug workplace policy. If a nurse feels that substance use problems, of any kind, are affecting working life, then seeking help before formal measures by the employer become necessary is imperative. It is possible to approach the Occupational Health Service or an outside agency in confidence. If the problem has been brought into the open by a warning from an employer, then the workplace policy will be invoked and the nurse referred to Occupational Health for further support and treatment. The nurse should make sure that the policy is duly followed. Although probably under a contract, by which improvement in work performance is required, the policy is usually in the nurse's favour, protecting job security whilst undertaking agreed therapy, and providing adequate time off to attend counselling and treatment sessions.

DUAL DIAGNOSIS

The term dual diagnosis is applied to individuals who experience a coexisting mental health and substance use problem (drugs or alcohol). This term is not a diagnostic label but rather it signifies an individual with a coexisting mental health and substance use disorder who has complex needs rather than two distinct problems (Banerjee et al 2002). Dual diagnosis encompasses a diverse group of individuals with differing types of mental disorder, with varying degrees of severity, who may be using one or more psychoactive substances in varying frequencies and in varying amounts (Ryrie & McGowan 1998).

The Department of Health (2002b) identify four possible mechanisms that may lead to a dual diagnosis:

- A primary psychiatric illness precipitating or leading to substance misuse
- Substance misuse worsening or altering the course of a psychiatric illness
- Intoxication and/or substance dependence leading to psychological symptoms
- Substance misuse and/or withdrawal leading to psychiatric symptoms or illness.

It is estimated that approximately one-third of the UK mental health population has a substance use problem and that 50% of individuals seen by drug and alcohol services have some form of mental health problem (Banerjee et al 2002). Individuals with a severe mental illness are more than twice as likely as the general population to have an alcohol disorder and those who have an alcohol problem at some point during their lifetime more than double their likelihood of experiencing mental health problems (Regier et al 1990).

Clenaghan (2000) considers there are a number of theories as to why people with a mental health problem use substances. Such theories include:

- for the same reasons as others in the community use alcohol or drugs
- as an attempt to alleviate the symptoms of mental illness
- to reduce the side-effects of medication.

Concern for this group of individuals has increased in recent years and current service provision appears unable to address their needs adequately. Individuals with a dual diagnosis, when compared to those with a mental health problem alone, are more likely to have:

- increased risk of suicide
- more severe mental health problems
- homelessness and unstable housing
- increased risk of being violent
- increased risk of victimisation
- more contact with the criminal justice system
- family problems
- history of childhood abuse (sexual/physical).

They are also:

- more likely to slip through the net
- less likely to be compliant (Banerjee et al 2002).

The Department of Health (2002a) offers a treatment model within which different approaches may be required at differing stages. The model aims to aid clinicians in acknowledging the long-term nature of interventions with dual diagnosis individuals and in identifying and offering appropriate and timely interventions. The model consists of four stages:

- *Engagement* — the development and maintenance of a therapeutic clinician–client relationship that is empathic, non-judgemental and non-confrontational
- *Persuasion* — draws on the principles of motivational interviewing, exploring ambivalence and motivation to change
- *Active treatment* — can only take place if goals are realistic and set by the client
- *Relapse prevention* — educating clients about their early warning signs; anxiety management and coping skills training.

Readers with a special interest in the area of prevention are referred to Keene (1997) and Watson (2000).

SUBSTANCE USE: SOME FACTS

LEGAL SUBSTANCES

Caffeine

> *The sufferer is tremulous and loses his self-command; is subject to fits of agitation and depression. He loses colour and has a haggard appearance. As with other agents, a renewed dose of the poison gives temporary relief, but at the cost of future misery.*
>
> *(Cited in Pickles 1991)*

Coffee, tea, colas, 'energy' drinks and some analgesics contain caffeine, a substance that has a stimulating effect upon the central nervous system. The existence of a caffeine withdrawal syndrome is now accepted. Silverman et al (1992) stated that 'caffeine withdrawal can produce severe symptoms, and health care professionals should be aware of the problem'. Participants in their double-blind study underwent physical and psychological tests during a period of normal diet followed by a period of caffeine-free diet. Half the group, who received a caffeine supplement during the second period, reported no significant change. The other half, given placebo drugs, recorded more headaches, increased use of analgesics and greater fatigue. Depression and anxiety scores were also abnormally high in this group. Drinking more than eight cups of coffee per day is likely to induce symptoms of withdrawal. Caffeine intake above 300 mg/day has been associated with low birth weight and miscarriage. This increased risk is possibly due to the extended half-life of caffeine in pregnant women from 4–6 h to 18 h and the cumulative effect of this (COT 2001). The equivalent of 300 mg of caffeine is three average mugs of coffee, six average cups of tea, eight regular colas and eight standard 50 g chocolate bars.

Tobacco

Nicotine is the drug in tobacco that causes addiction (USDHHS 1989). The World Health Organization (2003) refers to tobacco consumption as the 'global tobacco epidemic'. There were about 5 million tobacco-related deaths worldwide in 2003, an increase of over one million from 1990. Smoking tobacco is globally and regionally recognised as one of the top 10 risks in terms of the burden of disease it causes (WHO 2002) and is the world's leading preventable cause of death (WHO 2003).

It takes between 10 and 19 s for the chemicals contained in tobacco smoke to produce an effect within the brain (Royal College of Physicians 2000). The primary effect of nicotine is that it appears to stimulate the release of dopamine in the brain (Taylor Hays 2000), a chemical similar to adrenaline, which is responsible for emotional response and pleasure. Nicotine's positive effects include reduced stress and anxiety, relaxation, the enhancement of cognitive function, weight control (USDHHS 1989) and mood modulation (Nissell et al 1995). The rapid decline of these effects, however, encourages further use, and dependence develops quickly. If tobacco use is stopped abruptly, restlessness, irritability, anxiety, nervousness, impaired cognitive function and concentration, and craving may be experienced.

Tobacco use is on the rise and every second a smoker will die of tobacco-caused disease (WHO 2003). Around 120 000 people die each year from smoking-related causes in England alone (Royal College of Physicians 2002). In 1998, Raw et al estimated the health cost of tobacco-related illnesses as up to £1.7 billion a year. In 2002, 10% of 11–15 year olds were regular smokers (DH 2003).

Consequences for health

The high cost of tobacco use to the nation's health is clearly demonstrated in Table 36.1. Tobacco use is also thought to be a contributing factor in the development of pancreatic cancer, peripheral vascular disease, respiratory infections, cancer of the lungs, mouth and throat, coronary heart disease, and increased severity of asthma (WHO 2004b).

Women and smoking A total of 30% of women smoke during pregnancy, a figure that has remained consistent for at least a decade (Owens & Penn 1999). Women from lower socioeconomic backgrounds are at increased risk from tobacco use with 43% of women in social groups C2DE smoking during pregnancy, compared to 15% from groups ABC1 (Owens & Penn 1999). It has been suggested that pregnant women who smoke run the risk of spontaneous abortion, low birth weight and infant death (Bloch 2000). Reports have suggested a close link between smoking and sudden infant death syndrome (SIDS) (Mitchell et al 1992, 1993).

The incidence of cancer of the cervix is high among women who smoke heavily (Health Education Authority 1996) and, as in the general population, women who smoke increase their risk of coronary heart disease, stroke, blood clots, pulmonary embolism, circulatory disease, and raised blood pressure and cholesterol levels (Health Education Authority 1996).

Smoking has also been associated with reduced fertility in both men and women (British Medical Association 2004).

Passive smoking

Children and adolescents exposed to passive smoking have been quoted as being at risk of the adverse effects of smoking. Impaired respiration, chest infections and asthma in children are more often associated with parental smoking

Table 36.1 Estimated incidence of tobacco-related death in the UK in 1997

Disease	Number
Lung cancer	29 200
Ischaemic heart disease	24 300
Chronic obstructive pulmonary disease (COPD)	23 700
Other cancers: buccal cavity, oesophagus, larynx, bladder, kidneys and cervix	15 900
Aortic aneurysm and atherosclerotic peripheral disease	5800
Peptic ulcers	2000

Adapted from Royal College of Physicians (2000).

than with any other causative factor (Pagliaro & Pagliaro 1996).

People who are subjected to the smoke of others in the home have a 24% increased risk of developing lung cancer (Hackshaw et al 1997) and a 23% increased risk of developing heart disease (Law et al 1997). The effects of tobacco smoke on non-smokers can include nose, throat and chest irritations, breathing difficulties, coughing, red and runny eyes, headaches, dizziness, nausea, lack of concentration and decrease in lung function. Those with long-term health problems such as asthma, chronic bronchitis, allergies and heart problems are especially at risk.

Cessation aids

It has been suggested that 68% of male and 65% of female smokers would like to stop (Office for National Statistics 2002). However, pharmacological and psychological dependence often prevents them from doing so. The NHS Cancer Plan (DH 2000) identified that a third of all cancers were related to smoking and set a target to reduce smoking among manual groups from the 1998 figure of 32% to 26% by 2010 and outlined a plan of how this would be achieved (see Box 36.3).

A combination of pharmacological therapy and behavioural intervention is the most effective treatment for nicotine dependence (Taylor Hays 2000). Pharmacological interventions include nicotine replacement therapies such as transdermal patches, gum, lozenge, nasal spray, inhaler and sublingual tablet in addition to bupropion (Zyban), a non-nicotine medication. Behavioural interventions include specialist interventions in the form of smoking cessation clinics, counselling and group work, and opportunistic brief interventions by non-specialist practitioners. Information provided in a successful brief intervention should include the setting of a definite stop date, problem-solving skills training and relapse prevention training (Taylor Hays 2000).

Changing to a low tar brand of cigarette has not been shown to reduce the risk of developing tobacco-related harm. This is due to the smoker consuming the tobacco more vigorously than the machine used in the laboratory for testing tar levels and adapting their smoking behaviour, consciously or otherwise, so as to increase nicotine intake. Nicotine intake per cigarette has been shown to be up to eight times greater than the machine-smoked yields (Jarvis et al 2001).

The Health Education Authority produces booklets that the nurse may find useful.

- Action on Smoking and Health (ASH) produce a set of information sheets (see 'Useful websites and addresses', p. 1167).

Box 36.3

Tobacco control strategy

- Commitment to ban tobacco advertising
- New specialist NHS smoking cessation services
- Nicotine replacement therapy is available on prescription from GPs (DH 2001)
- Nicotine replacement therapy to be made available on general sale rather than only through pharmacies or on prescription — available since May 2001 (DH 2001)
- Bupropion (Zyban) available on prescription from primary care
- Updated guidance on smoking for health care professionals and commissioners from the Health Development Agency
- A best practice code to enforce the law against cigarette sales to children under 16
- A new media campaign and an NHS smokers' help line

From Department of Health 2000, 2001.

Alcohol

36.3 For a 1-week period, keep a daily diary of your alcohol consumption, using the format given in Figure 36.2. When you have read the following section, refer to your diary as you discuss with your colleagues your reactions to and reflections on your own alcohol use.

Alcohol is the most popular psychoactive substance in society, consumed by approximately 90% of the UK adult population. One of the first recorded uses of alcohol was in 3500 BC by the Egyptians and alcohol's effects on man are recorded in the Bible. Plato is reported to have written:

> *When a man drinks wine he begins to be better pleased with himself and the more he drinks the more he is filled full of brave hopes, and conceit of his powers, and at least the string of his tongue is loosened, and fancying himself wise, he is brimming over with lawlessness and has no more fear or respect and is ready to do or say anything.*

When used in moderation, alcohol is a social 'lubricant', lowering inhibitions and facilitating social interaction. However, binge drinking, excessive, heavy and prolonged use, has serious consequences for health.

Over the past 70 years, alcohol consumption has more than doubled in the UK (Royal College of Physicians 2001) and continues to increase. It is estimated that one in three men and one in five women drink above the weekly recommended limits (Prime Minister's Strategy Unit 2003). The economic cost in industry is estimated to be up to £6.4 billion/year from absenteeism and loss of productivity (Prime Minister's Strategy Unit 2003). The cost to the NHS per year from alcohol-related injury and illness is estimated to be approximately £3 billion, up to 12% of its total spending (Royal College of Physicians 2001). The total cost of alcohol-related harm in England is up to £20 billion per year and includes harm to health, crime and antisocial behaviour, loss of productivity and social harm such as family breakdown (Prime Minister's Strategy Unit 2004). The highest risk groups are those aged between 16 and 35 and young women aged 16–24, whose average weekly consumption has increased by 93% since 1992 (Office for National Statistics 2004). Drinking culture in the UK promotes occasional but heavy drinking sessions. 'Binge drinking' is the term applied to describe this pattern of consumption and is of increasing concern. Binge drinking accounts for 40% of male and 22% of female drinking occasions (Prime Minister's Strategy Unit 2003).

Alcoholic drinks mainly comprise water and ethanol (alcohol) and are produced by the fermentation of fruits, vegetables or grain. Congeners are added to give the drink its distinctive flavour, taste and smell.

Units of alcohol

One unit (or 'standard drink') of alcohol contains approximately 8 g of absolute alcohol. This is based on a standard measure of an average-strength drink, i.e. half a pint of beer, lager or cider, a single measure of spirits, e.g. whisky, gin, vodka, a standard glass of wine, a small glass of sherry or a measure of vermouth (or aperitif). Therefore, if a total of 2 pints of average-strength lager and a small sherry were consumed, the total number of units consumed would be 5. However, since many varieties of alcoholic drinks of varying strengths are available, it is difficult to estimate how much alcohol an individual has consumed. Table 36.2 gives an approximate guide to the calculation of unit consumption for drinks of various strengths.

What is less harmful?

It has been suggested that the following units represent maximum levels for 'less harmful' weekly consumption. Consumption above these levels can be expected to lead to increased health problems:

- For men: up to 21 units; not exceeding 4 units/day
- For women: up to 14 units; not exceeding 3 units/day.

Alcohol absorption and elimination

Alcohol is one of the quickest-acting orally administered substances. It is also a toxic substance. The only organ capable of eliminating alcohol from the body is the liver. Alcohol passes chemically unchanged from the stomach into the blood supply within 5 min. Adding carbonated drinks, alternating alcohol with carbonated drinks, drinking on an empty stomach and drinking quickly may speed up absorption.

It takes approximately 30 min for alcohol levels to peak in the blood and 1 h for the liver to eliminate 1 unit. Any other alcohol taken during this time will accumulate in the blood, awaiting processing. Therefore, if 8 units are consumed (e.g. 4 pints of lager or 4 double spirits) the liver will take approximately 8–9 h to eliminate all the alcohol.

Table 36.2 Calculation of unit consumption for alcoholic drinks of various strengths

Type of drink	Measure	Number of units
Export beer	1 pint	2.5
	1 can*	2
Strong beer or lager	1 pint	4
	1 can*	3
Extra strong beer or lager	1 pint	5
	1 can*	4
Strong cider	1 pint	4
Spirits	1 bottle	30
Table wine	1 bottle	7
	1 L bottle	10
Sherry	1 bottle	13
Low-alcohol beers and lager	1 pint	0.66
Low-alcohol cider	1 pint	0.5

*1 can = ¾ pint.

Health consequences of excessive alcohol use

Binge drinking, excessive, chronic or inappropriate alcohol use can lead to a wide range of health problems affecting virtually all parts of the body (see Fig. 36.3). In addition to the possible consequences of intoxication, binge drinking, excessive regular use and dependence (see Box 36.4), alcohol consumption, even at moderate levels, can interfere with the effects of many prescribed drugs such as oral contraceptives, antibiotics, anti-inflammatory agents, tranquillisers, antidepressants and diuretics. The habitual overuse of alcohol is associated with a number of psychosocial problems.

Long-term use and withdrawal

Tolerance develops quickly with regular use. Physical as well as psychological dependence can occur. Sudden withdrawal can be accompanied by unpleasant symptoms such as sweating, increased anxiety, tremor, headache, thirst, nausea and occasional vomiting. Delirium tremens and convulsions may also be experienced, but are rare.

Those who have suffered severe withdrawal symptoms in the past or who, following assessment, appear to be at risk, will need a supervised withdrawal (Cooper 1994). Contrary to popular belief, it is possible for someone with an alcohol problem to return to 'normal' social drinking or controlled drinking.

Box 36.4

Alcohol use: associated harm

Consequences of intoxication
- Accidents
- Acute poisoning
- Acute gastritis
- Drug overdose
- Epileptic-type seizures
- Head injury
- Suicidal behaviour

Consequences of excessive regular use
- Anxiety
- Cancer of the mouth/throat
- Depression
- Fatty liver
- Liver cancer
- Liver cirrhosis
- Pancreatitis
- Peripheral neuritis
- Phobic illness
- Sexual impotence
- Stomach haemorrhage

Consequences of dependence
- Alcoholic psychosis
- Anxiety
- Delirium tremens
- Depression
- Hallucination
- Paranoid states
- Polydrug abuse
- Withdrawal: epileptic seizures

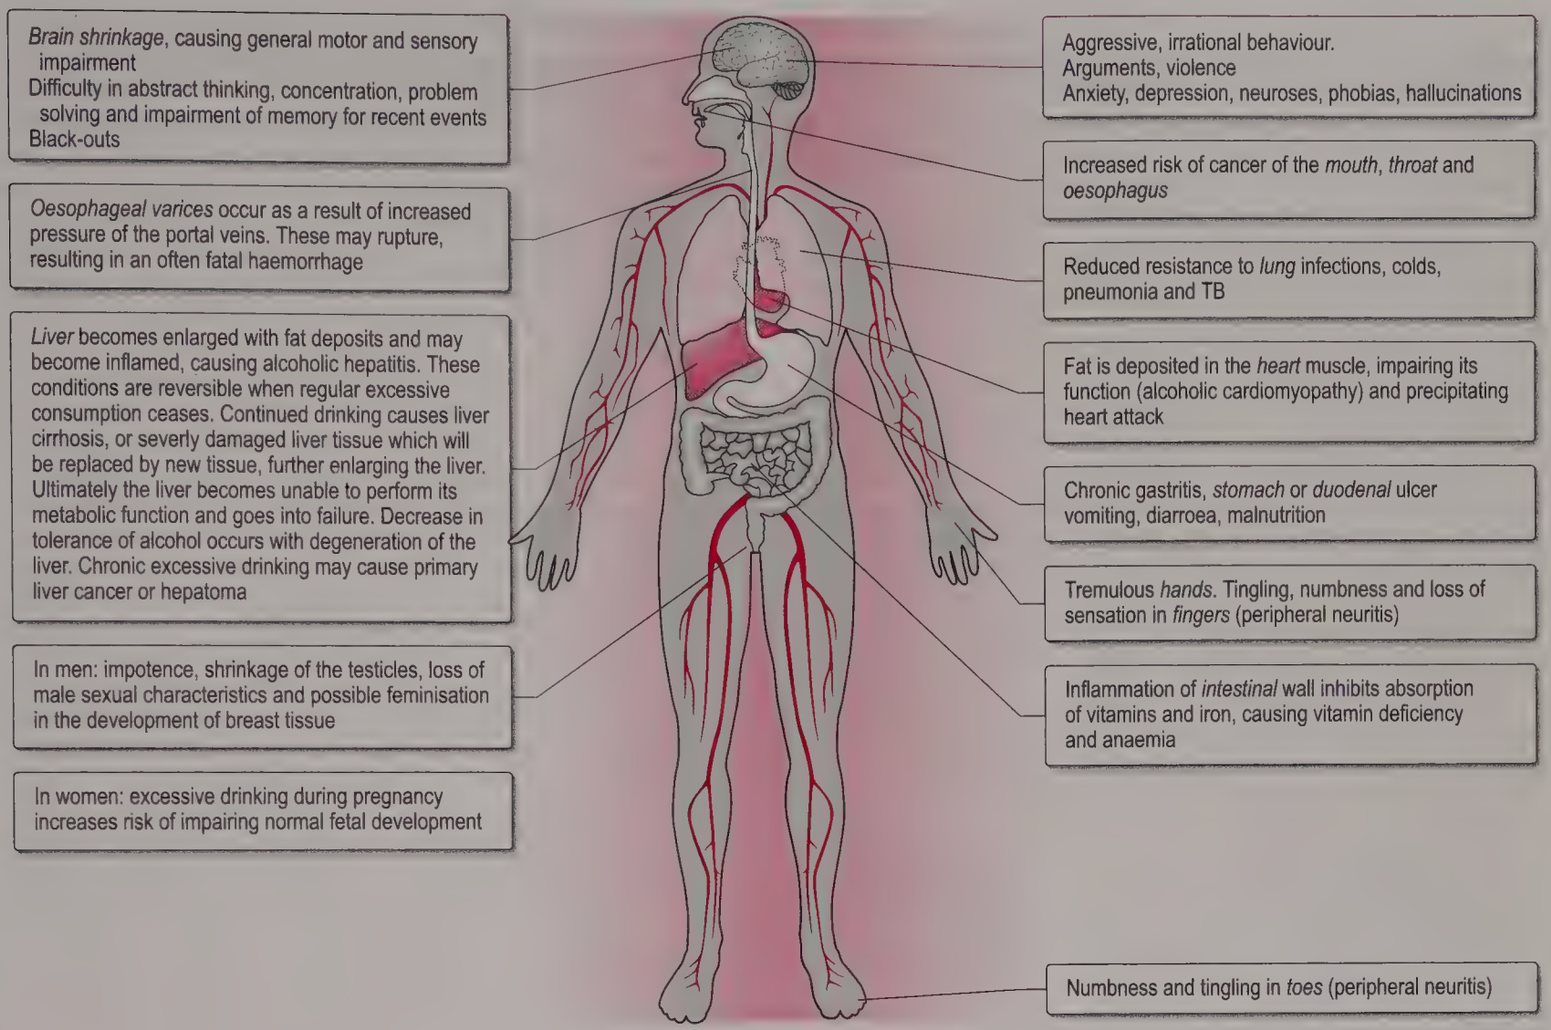

Fig. 36.3 Consequences of excessive consumption of alcohol.

Teenage drinking

The issue of teenage drinking in the UK has given rise to a certain degree of public alarm. Newspaper articles condemn the behaviour of the young drinker and demand that underage drinking be stopped. However, there is little available evidence to suggest that the majority of teenagers do anything other than drink sensibly, or, indeed, that heavy consumption at an early age leads to excessive or chronic alcohol use in later life (Alcohol Concern 2004).

Children in our society encounter alcohol at an early age. However, Coggans and McKellar (1995) suggest that 'despite the apparent high levels of alcohol-related disorders involving young people in recent years there is nothing new about the phenomenon'. The authors continue by suggesting that alcohol-related hooliganism has been with us for centuries!

Young people tend to be introduced to alcohol by their parents. Most, from an early age, accept alcohol as part of everyday life. While excessive alcohol use is a real problem for some teenagers, what is needed is not a demand for total abstinence among young people, which would be unenforceable in practice, but increased education on the risks of binge drinking, inappropriate or excessive alcohol use — including the links with HIV/AIDS, promiscuous behaviour and teenage pregnancy — and other substance use (Cooper 2000). Teenagers should be allowed to develop their own concepts about the appropriate use of alcohol in a straightforward and, most importantly, informed manner. A failure to be open in our approach to the subject of alcohol use may only serve to entice young adults to explore this 'forbidden' territory in a spirit of rebellion.

36.4 Do you think that there is a widespread teenage drinking problem in the UK? If so, how could you as a nurse help to prevent drinking problems among young people?

Women and alcohol use

It is generally acknowledged that alcohol-related problems amongst women are increasing (Plant 1997). Compared with men, women's health is more likely to be affected at lower levels of alcohol intake. This occurs mainly because women have less body water than men, and therefore alcohol is less diluted within the body (Morgan 1992). There are key physical differences in the way a woman's body copes with alcohol. Factors concerning the female reproductive system can influence metabolism and play an integral part in alcohol-related harm (Plant 1997).

Women present to caring agencies with the same alcohol-related problems as men, e.g. gastritis, duodenal ulcers, peripheral neuritis, cancer of the mouth, throat or oesophagus, amnesic episodes and suicidal behaviour. However, women who drink excessively have a greater risk of acute inflammation of the liver than men. Moreover, any damage

to the liver in child-bearing years may increase in severity even after cessation of alcohol intake (Plant 1997).

Women present to helping agencies with their own specific set of problems, which include guilt, low self-esteem and depression. This requires sensitive nursing skills. The individual needs to feel sufficiently at ease with a professional to disclose substance use problems. In order to gain the woman's confidence, the nurse must be non-judgemental, supportive and well informed about appropriate sources of help.

Alcohol in pregnancy There is a recognised syndrome in babies of women who regularly consume large amounts of alcohol in pregnancy. Jones and Smith (1973) called this 'fetal alcohol syndrome'. They recorded several features commonly found in babies of alcohol-dependent women, including growth deficiencies, delayed development, joint and heart abnormalities, microcephaly and fine motor dysfunction. Facial features included asymmetrical ears, receding chin, receding forehead, upturned nose and short palpebral fissure length.

Plant (1997) suggests that there are several social factors that may influence birth defects, including tobacco and alcohol consumption and general socioeconomic environment. Investigating specific levels of alcohol consumption during pregnancy, Plant found that 'women who consumed 10 units of alcohol on a single occasion during pregnancy were more likely than other women to have damaged offspring'. However, levels of alcohol consumption within the accepted limits are not associated with birth defects.

36.5 Test your factual knowledge by answering the following questions.

(a) On average, how much (i) wine, (ii) spirits, (iii) beer, (iv) lager would you need to drink to be over the legal limit for driving?
(b) Which parts of the body are affected by alcohol, and what are the effects?
(c) What organ in the body breaks down alcohol?
(d) After drinking 1 pint of ordinary beer, how long will it take before the alcohol in it is completely burned up by the body?
(e) Which of these is an effective way of sobering up?
- Drinking a cup of strong black coffee
- Taking fresh air
- Taking physical exercise
- Taking a cold shower
- Making yourself sick.

(f) What level of daily consumption is considered to lead to the possibility of alcohol dependence?
(i) 4 pints of beer
(ii) 8 glasses of wine
(iii) 2 single measures of whisky
(iv) 2 double measures of rum
(v) 6 glasses of fortified wine
(vi) 3 pints of lager.
(g) Is the recommended safe limit of drinking for women lower or higher than that for men?
(h) Equal amounts of alcohol have a greater effect on a young person than on the average adult male.
Why is this?
(i) What can speed up the effect of alcohol?

Alcohol and the older person

As the body ages, its ability to tolerate alcohol diminishes. The liver and kidneys become less efficient, and the elimination of alcohol from the body becomes slower. The effect of alcohol on reflexes, balance, self-control and judgement may compound existing health problems, increasing the risk of falls and other accidents. Equally, many older people take medication such as hypnotics, analgesics and anti-inflammatory drugs which, when mixed with alcohol, increase the risk of health problems.

Age can bring with it many difficulties such as financial hardship, loneliness, isolation, insomnia, pain and susceptibility to cold. (Note that a 'hot toddy' will not warm a person up. Alcohol dilates the blood vessels, allowing heat to escape and increasing the risk of hypothermia.) Many older people eat unbalanced diets and have a poor appetite; some may sacrifice food for alcohol.

Some older people may use alcohol to block out feelings of loneliness. Many of these individuals will find it hard to come forward for help, and it can sometimes be difficult for professionals to recognise alcohol and/or other substance use problems among this client group (Graham et al 1998, McKee 2000). The relatives of an older person may dismiss such drinking as a minor foible or take the view that alcohol helps them to cope. Nurses working in this field may hear relatives and carers expressing sentiments such as 'It will do her no harm' or 'What else has she got to live for?'. Even GPs have been known to suggest alcohol as a remedy for insomnia in older people. This can be unwise, as the physical, social and psychological effects of alcohol are often felt among this client group at a relatively low level of consumption.

Treatment Older people who have come forward for help, or who have been identified as having an alcohol-related problem, often feel guilt and shame. In many cases, information on the sensible use of alcohol is all that is required to relieve anxiety and enable the person to adopt healthier drinking habits. It is important to remember, however, that age does not make someone less able to make decisions about their own life. If the individual does not wish to reduce or modify consumption, that is a personal choice. Professionals have a responsibility, nonetheless, to ensure that the individual has adequate information on which to base informed decisions.

The Alcohol Harm Reduction Strategy

(Prime Minister's Strategy Unit 2004)

This highlights the increasing concerns of drinking behaviour among young people aged 16–35 and especially of women aged 16–24 years. The strategy aims to reduce consumption among these groups by implementing national guidelines on improving education and training for all professionals in the identification and management of individuals with alcohol-related problems. The report emphasises the need for increased service provision, improved access to services, the implementation of clear integrated care pathways and multiagency collaboration. It further highlights the importance of improving education programmes to increase young people's knowledge of alcohol, its use and effects, the associated harms and to promote sensible drinking.

CASE HISTORY 36.1

A personal account

My drinking took off in my early twenties. I saw myself as a failure in love, a failure in my career and I blamed my father for everything. With so much hate in my head, I had to have something to ease the pain and so I used alcohol … as the anger inside increased.

After a while … I couldn't feel comfortable without the aid of a drink. It began to take over my life and the terrible craving began. As the anger inside got worse, so did my need for alcohol. Current resentments were coloured and magnified by the anger from the past and all I could do was escape from my misery ... I was cruel to my family and a 'mouse' to the outside world … I hated myself for being such a fraud.

I was breathalysed and banned twice for drink driving. I lived in a state of perpetual fear, unable to function without a drink, vowing to stop drinking and then drinking again. Totally out of control. I was a mess with no peace of mind and no self-esteem at all.

Sometimes I think of [my] addiction as a train that will not stop. The train seemed so comfortable when you first got on. Soft velvet seats, plenty of room to spread your legs and the fare was reasonable too. It started slowly, increasing in speed as the weeks and months rolled by. For some strange reason the train wouldn't stop, it just kept on going, faster and faster … The plush seats were threadbare after a while. The ticket collector wore a frown and the weather was dark clouds and rain the whole time. For some strange reason I wanted to stop, yet I wanted to keep on going. The train was my life and I was not to blame. I longed to see my family again without the noise of the train. I had to shout at them all of the time because of the noise … I tried to explain that I *need* the train more than anything else in the world, then said I'd get off as soon as I could …

Any obsession is hard to break … People have to be desperate before they go on their hands and knees for help. For many years I denied my drinking was out of control … I would swear off the stuff every morning yet pick up a drink the same afternoon and carry on drinking for the rest of the day. It was a terrible treadmill. I couldn't escape, yet I kept kidding myself that somehow, someday, my problem would just go away … I used to sit in a room on a Sunday afternoon, away from my wife and sons, feeling alone and apart, just waiting for the pubs to open. Always there was a desperate need to drink and once I had one I could never drink enough …

I variously blamed my wife, my mother-in-law, my boss and my ill fortune in life for my drinking ... but I was the problem and my drinking had nothing to do with anyone else. For years I was blind to my own shortcoming and forever bemoaning the faults of others. I could see nothing wrong with the way I behaved. I desperately struggled to keep my family in order who seemed to be falling apart. The truth is I was the one who was falling apart and I just couldn't see it …

I was lucky. One day I answered the door to a health visitor who, I assumed, had come to see my hopeless, incompetent wife. Straightaway the woman confronted me and asked if I would go for help with my drinking. I had never seen the woman before in my life but the shock was so great that I agreed there and then to seek help for my problem. Had I known my interfering mother-in-law had arranged it all and that it was her intervention that saved my life there would have been hell to pay. Thankfully the truth was kept from me until I was able to take it with equanimity! The fact is she was a lovely caring woman but I just couldn't see it at all …

(Neville D. Lewis 2002, with permission)

Comment

Neville commenced a sustained period of abstinence and attended local groups for support and treatment. Through counselling he addressed issues surrounding his anger and the feelings toward his father and experienced 'spiritual enlightenment' that he found helpful. Neville is now able to drink alcohol socially, drinking in a way he finds relaxing, with his friends, and not as a means of managing his anger. For the past 13 years Neville has avoided intoxication by remaining within the recommended daily and weekly drinking limits.

For a personal account of alcohol addiction, see Case History 36.1.

Safe drinking recommendations

(DH 1995, WHO 1996)

- As a rule do not consume more than two standard drinks per day.
- Have *at least* two alcohol-free days per week.
- Consistent drinking of 4 standard drinks per day for men and 3 per day for women is *not* advised as a sensible drinking level because of the progressive health risks.
- Sensible limits should not be saved up for one drinking session.
- Avoid drinking to intoxication.
- Some individuals, because of lower body weight, composition, metabolism or during pregnancy and whilst breast feeding, should consume lower levels of alcohol.
- The intake of up to 2 units per day can have a moderate protective effect against heart disease for men over 40 and postmenopausal women. However:
  - — non-drinkers should not be advised to start drinking for their health, and
  - — those individuals who consume up to the 2 standard drinks per day should not be encouraged to increase their consumption to reduce the risk of heart disease.

36.6 On the basis of the information given in this section, how would you define 'the sensible use of alcohol'? Can alcohol in any way be beneficial?

Anxiolytics and hypnotics

In 2001, approximately 25 million prescriptions for anxiolytics and hypnotics were prescribed in the UK (Prescription Prescribing Agency 2001). Among consumers of these drugs, women form the larger group, although there is a steady increase in prescriptions for men, which appears to be associated with unemployment and poor employment prospects. The most common group of prescribed anxiolytics and hypnotics are the benzodiazepines: diazepam, lorazepam and temazepam. It is estimated that 174 000 adults aged 16–59 years used benzodiazepines in England in 2002/2003 (Condon & Smith 2003).

Seivewright (1998) has noted that tranquilliser (anxiolytics and hypnotics) withdrawal carries with it serious physical and psychological risks. Once dependent, abrupt cessation is dangerous. Therefore, it is essential that any withdrawal is gradual, perhaps over years. Because the

symptoms of withdrawal often mirror the symptoms of the original complaint, dependence often goes unidentified until the substance is reduced or stopped or until tolerance develops. Withdrawal symptoms are similar to phobic anxiety states and may include fear, agoraphobia, suicidal feelings and panic attacks.

The Royal College of Psychiatrists' (1997) report on benzodiazepines recommends their primary use in the short-term treatment of severe anxiety and related symptoms, where the individual is experiencing significant distress or problems in social functioning. The report states that to reduce the risk of dependence, benzodiazepines should not be prescribed regularly for more than 1 month; the report advocates their use on an 'as required' basis every few days. For insomnia, the report recommends limiting use to 2–4 weeks at the lowest dose.

Effects

The effects of hypnotics and anxiolytics commence within 1 h of administration and last up to 12 h. They include:

- relief from tension
- a sense of calm and relaxation
- decreased self-control, alertness, power of observation and level of dexterity
- control of anxiety
- short-term memory loss
- lowered inhibitions
- release of aggression
- the onset of sleep.

With intoxication, the individual may experience dysarthria, ataxia, nystagmus and emotional lability.

It is not clear how long it will take an individual to become dependent, although an increase in anxiety has been noted after 4 weeks' use. By 6 months, the risk of dependency is greatly increased. Psychological dependence is common.

Tolerance can develop with both therapeutic and non-therapeutic use and withdrawal symptoms may occur even with therapeutic doses (see Box 36.5). Whilst these are not potentially fatal, they can be very unpleasant and have been described by some as worse than those experienced in heroin withdrawal.

Support during withdrawal

As withdrawal symptoms commence even after a small reduction in dosage, the withdrawal process needs to be undertaken gradually. It may take several months or years for the person to be able to live comfortably without the substance.

Support, whether given individually or in a group, is essential. Nurses should be aware of the unpleasantness associated with withdrawal and the fear and emotional stress this process is likely to cause the individual and the family.

For useful information on the process of tranquilliser withdrawal, see Seivewright (1998).

Box 36.5

Common tranquilliser withdrawal symptoms

- Convulsions
- Dry retching
- Hand tremor
- Headaches
- Increased tension/anxiety
- Irritability
- Loss of feeling/emotion
- Mental confusion
- Muscle pain/stiffness
- Nausea
- Nightmares
- Palpitations
- Panic attacks
- Personality change
- Profuse sweating
- Rebound insomnia
- Weight loss

Volatile substances

Many solvents, glues, gases and volatile substances are readily available in homes, shops, offices and factories. Under normal use, they are reasonably safe. However, they are sometimes inhaled specifically for their depressant effect on the central nervous system. The Scottish Executive (2003) describe three kinds of volatile substance use among young people:

- experimental — by those who want to know what it is like
- recreational — by those who use volatile substances more frequently, usually in a group
- problematic — regular, long-term use.

An average of 73 premature deaths per annum is associated with volatile substance use (Field-Smith et al 2004), with 14% of 11–15 year olds claiming to have tried a volatile substance (Boreham & McManus 2003). Substances of use are adhesives, cleaning fluids, aerosols and fuels, with the primary substance of use being butane lighter fuel which accounted for 59% of solvent-related deaths in 2001 (Field-Smith et al 2004). In addition to being relatively easy to obtain, these solvents offer a cheap alternative to alcohol and other drugs.

Effects of solvent inhalation

Effects commence within 7 s of inhalation and last for approximately 30 min. Continual sniffing maintains the effect, with most users reporting elevation of mood and hallucinations (WHO 2004a). As the level of intoxication is reduced, the user experiences nausea and headache. With the repetition and deep inhalation, overdose may result, causing loss of control, disorientation and unconsciousness. On cessation, recovery usually follows quickly. Concentration of the substance and intensification of effects can be achieved by placing a plastic bag over the head. This method brings with it the danger of asphyxiation.

It is not easy to identify use, as the presenting problems may appear to be similar to behaviour associated with 'normal' adolescent development, e.g. moodiness, aggression, loss of appetite, disinterest and aloofness. With regular use, tolerance may develop. Whilst physical dependence does not appear to occur, evidence suggests there is an increased risk of psychological dependence for some users (WHO 2004a).

Dangers of excessive and frequent use

It is important for the substance user to avoid exertion, as this may affect the function of the heart and increase sensitivity. Any exercise may lead to collapse and death.

Other dangers include damage to the liver, lungs, kidneys, heart and central nervous system, as well as death by suffocation, accidents, direct toxic effect on the heart and inhalation of vomit. Gas squirted directly into the mouth can cause suffocation.

Britton and Noor (2003) identify a range of approaches to prevention and intervention that are adopted in relation to solvent and other drug use:

- maintaining the user's confidentiality
- collecting information
- accurate assessment and identification of needs
- providing information and education appropriate to needs
- offering activity substitution: individual or group
- providing individual counselling or therapy
- encouraging parental/carer education and involvement in treatment
- offering family counselling or therapy
- organising self-help groups
- organising community action
- educating professionals.

36.7 As a nurse who may at some stage come into contact with solvent users, consider which method or combination of methods listed above would be most effective, and why? What other measures can you think of? How would you introduce them?

ILLEGAL SUBSTANCES

Illicit drug use in the UK has steadily increased since the 1950s (Handford & Colenso 1998). This is reflected in the number of persons found guilty, cautioned, given a fiscal fine or dealt with by compounding (an administrative sanction used by Customs involving a financial penalty) for drug offences, which rose from 13 400 in 1978 (Home Office Statistical Bulletin 1979) to 113 050 in 2002 (Ahmad & Mwende 2004). Thirty-six per cent of adults aged 16–59 admit to having used an illicit drug (Condon & Smith 2003), an increase of 8% since 1994. The high risk groups are those aged 16–29 with 50% reporting illicit drug use, an increase of 7% since 1994. Young males aged 20–29 are 1.4 times more likely than females to use illicit drugs, with 63% and 60% of males aged 20–24 and 25–29 respectively reporting substance use (Ramsey et al 2001). Since 1998, cocaine, crack, ecstasy and Class A drug use has significantly increased (Aust et al 2002). Cannabis, reclassified to Class 'C', is the most commonly used prohibited substance, with 44% of 16–29 year olds having imbibed (Ramsey et al 2001). More than 5 million British people regularly use cannabis, 2.4 million ecstasy, and 2 million amfetamines and cocaine (The Observer 2002). There may be some evidence to suggest that drug use is associated with frequency of drunkenness, with 59% of binge drinkers (18–24 years old) reporting drug use in the past year compared to 33% of non-binge drinkers (Richardson & Budd 2003).

Opiates and opioids

Opiates are derived from the sap of the opium poppy (*Papaver somniferum*). They are narcotic analgesics. Their synthetic equivalents are collectively known as opioids.

Heroin

Heroin ('H', 'smack') is a narcotic made from morphine, injected ('shooting' or 'mainlining') or smoked over tinfoil through a small tube ('chasing the dragon'). The purity of the drug is often unknown, and consequently accidental overdose can easily occur and may be lethal. Heroin users who share needles and syringes ('works') are at risk of septicaemia, hepatitis and HIV/AIDS (see Ch. 37).

The effects of heroin include euphoria, drowsiness and a sense of well-being and raised self-esteem. Tolerance develops quickly, demanding increased intake to achieve the desired effect. Physical and psychological dependence may follow. Contamination of the substance often leads to severe allergic reactions, which may be exacerbated by poor diet and self-neglect. This degenerative process may lead to death if medical care is not available. Withdrawal is unpleasant and is often described as being 'like a severe dose of flu'. Other problems include constipation and vomiting. Complaints of diarrhoea, abdominal cramps and muscle spasm are common. Although it has been suggested that withdrawal from heroin is easier to achieve than withdrawal from nicotine, alcohol or methadone, it should be attempted gradually, using reducing doses of methadone as a heroin substitute.

Stimulants

Amfetamines (Amphetamines)

Amfetamine ('speed', 'billy') is usually found in powder form that can be 'snorted' (sniffed), 'bombed' (swallowed), smoked (through a pipe) or injected. The effects, intensity and duration depend on the route of administration and dosage but usually last around 3–6 h.

Amfetamine is a stimulant that activates or excites the central nervous system and is similar in function to the body's own natural stimulants, adrenaline and noradrenaline. Amfetamine increases energy levels, but as the body replaces the energy used, the user feels tired, depressed and hungry, i.e. the opposite of how the amfetamine makes them feel.

Medically, amfetamines are used in the treatment of depression, obesity and attention deficiency disorders. Amfetamine is more physically toxic than cocaine. The liver can struggle to break down amfetamines in large doses, which can result in liver damage and failure. The combined use of amfetamine and alcohol is therefore not advised, due to the increased risk of liver damage. In low doses, amfetamines increase heart rate, blood pressure, respirations and body temperature. The user will experience alertness, wakefulness, improved confidence and elevation of mood. At higher doses, amfetamine can induce dizziness, nausea/vomiting, cardiac arrhythmia, paranoia, confusion and insomnia/sleep disturbance.

Cocaine

Cocaine ('coke', 'charlie') is an alkaloid derived from the coca plant, a shrub native to South America. This white crystal-like powder is a powerful but short-acting central nervous system stimulant. Cocaine stimulates the release of dopamine in the brain, a chemical that is thought to be involved in emotional responses and pleasure. Dopamine is also thought to be involved in the gross, automatic movements of skeletal muscles. Cocaine can be sniffed

('snorted'), injected or smoked (in the form of 'crack'). When cocaine is treated with baking powder and water, it forms into tiny chalk-like lumps or 'rocks' and is referred to as 'crack'.

The effects of cocaine peak within 15–30 min and then gradually decrease. The user experiences an elevation in mood, increased alertness, concentration and energy. This physiological arousal and euphoria lead to an indifference to pain and fatigue. Normal requirements for food are decreased. Large doses may lead to agitation, anxiety, hallucinations and erratic behaviour.

Dependence is usually psychological. The individual may complain of depression, fatigue and inability to cope. Chronic use may cause restlessness, nausea, sleeplessness, paranoia, hyperexcitability and depression. Repeated sniffing also leads to erosion of the nasal membrane and respiratory problems.

Hallucinogens

Hallucinogens (psychedelics, psychotomimetics or psychotogens) include lysergic acid diethylamide (LSD), hallucinogenic mushrooms and cannabis. The prime effect of these substances is the alteration of perceptual functions of the brain.

Cannabis

It is generally believed that, when used occasionally, cannabis has no long-lasting effects and is safer than alcohol. Cannabis, a preparation of the hemp plant, is available in three forms:

- 'grass', a dried leaf (marijuana)
- resin, a compact block ('hash')
- oil, the most highly concentrated form.

Cannabis is essentially a depressant with hallucinogenic properties. Cannabis contains around 60 chemicals known as cannabinoids, which stimulate naturally occurring cannabinoid receptors found in the brain and parts of the body. These receptors are thought to have a role in pain perception/management, motor coordination, cognition, memory and reward, amongst others. The main psychoactive chemical in cannabis is known as tetrahydrocannabinol (THC).

Cannabis is usually mixed with tobacco and smoked (as a 'joint') and this is the most popular method of administration. The effects commence after 2–3 min and can last up to 4–6 h, depending on strength and dose. Smoking cannabis is the most physically damaging method of use and carries the highest progressive health risks. The main health hazards appear to derive from those associated with tobacco use, although damage may occur to the airway and respiratory system when cannabis is used without tobacco, due to the smoke and high level of heat required to burn cannabis. The advantage of smoking cannabis is the user's control over the dosage, being able to discontinue use when the desired effect is achieved. Cannabis may also be ingested in cakes, meals and hot drinks. The effects when eaten are more powerful and intense than when smoked and the user has little control over the effects once ingested. The immediate effect is one of relaxation, talkativeness and hilarity. Intensification of sound and colour may also be experienced. There is a reduction in short-term memory function and in motor skill. Concentration is poor. High doses of cannabis can lead to confusion, anxiety/panic, paranoia and depersonalisation.

Learning to use cannabis is an acquired skill. The inexperienced user may experience nausea, dizziness, impaired vision and disorientation (a 'whitie' or 'colonel whitie') due to being unable to identify correctly the adequate dosage. However, the user soon learns, through repeated use and discussion with peers, how to regulate the dosage to achieve and maximise the desired effect.

In recent years, the medicinal use of cannabis has increasingly been researched.

For current knowledge and research into the medicinal use of cannabis, see Mathre et al (2001–2003), Cannabis – the whole story, parts 1–7.

The therapeutic use of cannabis is now strongly associated with pain management for individuals with cancer, AIDS, arthritis, spinal cord injury, peripheral neuropathy, migraine, central post-stroke pain and multiple sclerosis, in movement disorders such as Parkinson's and Huntington's disease and in insomnia. At present, such use is illegal according to UK law. However, the debate rightly continues around legalisation for specific medical use. One would eventually hope that common sense will prevail and legalisation will follow. Until the law is changed, significant numbers of these groups are denied effective legal clinical intervention.

Lysergic acid diethylamide (LSD)

LSD ('trips', 'acid') is a derivative of ergot, a fungus commonly found on rye and other grasses. An exceedingly potent substance, only minute doses of LSD are required to achieve a hallucinogenic effect.

The short-term user experiences a 'trip', in which hilarity, elation, heightened self-awareness, hallucinations (visual, auditory, olfactory and tactile), disturbance of perception, increase/decrease of passage of time, disorientation, disassociation from the body, anxiety and paranoia may occur. Physiological effects include increases in heart rate, body temperature and blood pressure. At low doses, LSD increases respirations; however, at higher doses it will depress the respiratory system. These experiences commence within 1 h following ingestion and peak 2–6 h later, gradually fading after 8–12 h depending on dosage.

Excessive and long-term use can cause prolonged psychological reactions and re-experiencing of past 'trips' ('flashbacks'). However, LSD is not known to cause physical dependence.

'Magic' mushrooms

There are approximately 12 varieties of mushroom that contain hallucinogenic chemicals. The most common of these mushrooms is *Psilocybe semilanceata* ('liberty cap').

'Magic' mushrooms contain two active ingredients, psilocybin and psilocin. The mushrooms may be crushed, eaten fresh, brewed in a tea or cooked in soup. The user experiences effects similar to those of LSD. Commencing within 30 min, the effects peak at approximately 3 h and last 4–10 h.

Dependence, withdrawal and overdose are unlikely, the primary danger to health lying in the possibility that the individual may pick and consume a poisonous mushroom by mistake. Symptoms of poisoning include vomiting, diarrhoea, stomach cramps, watery eyes and mouth, twitching or 'fits' and respiratory problems.

Methylenedioxymethamfetamine (MDMA, Ecstasy, E)

MDMA is a stimulant drug with hallucinogenic properties. It stimulates the production of serotonin, a naturally released chemical in the brain that affects mood. This increase in serotonin leads to an increase in an individual's mood (euphoria). Once the MDMA is eliminated from the system, the body has difficulty in replacing lost serotonin quickly. Less serotonin is released with each electrical impulse and fewer serotonin receptors are activated. This produces feelings of depression, restlessness, irritability, sleep disturbance and anxiety. It is thought that prolonged repeated use of Ecstasy may cause permanent reductions in serotonin production leading to lasting alterations in mood (mood swings, dysthymia and depression). Other possible effects of long-term or excessive use can include anxiety, insomnia, lasting memory impairment, suppression of the immune system and liver damage.

MDMA usually comes in tablet form, occasionally powder form that is 'snorted', and the effects usually begin after 20–60 min and last between 3 and 6 h. The effects and duration depend on dosage and purity of the drug. The effects at low doses include increased heart rate, blood pressure and energy, dilated pupils, loss of appetite, blurred vision and tightening of jaws. The user may experience feelings of warmth and empathy, enhanced sense of communication and increases in perception and sensual experience. Higher doses can lead to hyperthermia, hypertension, hyponatraemia (abnormally low blood sodium levels due to dehydration), cardiac arrhythmia, anxiety, confusion/disorientation, hallucinations and paranoia.

36.8 Take 30 min to write down your feelings, attitudes and experiences relating to cannabis. Once you have completed this task, read the articles by Mathre and colleagues (2001–2003) on Cannabis – the whole story, parts 1–7. These articles attempt to put the use of cannabis into perspective. Once you have completed your reading, spend 30 min repeating the above writing exercise/task and see how and/or if your opinions have changed and why you think this is.

36.9 Consider the evidence for and against the main aspects of substance legislation. Discuss the following quotations. How convincing are the arguments? Should all substances be legalised? Explain your reasoning.

(a) 'Prohibition, which worked in the 50's ... simply cannot work now as it goes against the grain of social change ... Since present policies have failed, and in my view have no chance of succeeding, it is surely time to devise some new approach that would take drug supply out of criminal hands and bring it within a legal framework. Carefully tailored regimes for each drug, taxation used to finance much more research, education and treatment ...' (Morris 2001).

(b) 'Drug problems will not be beaten out of society by yet harsher laws, lectured out of society by yet more hours of "health education", or treated out of society by yet more drug experts. There is a place, however, for legislation and education and treatment.' (Royal College of Psychiatrists 1987).

SUPPORT AGENCIES

Outreach workers

There are three main kinds of outreach worker in the field of substance rehabilitation. Some, mainly nurses, are employed professionals. Others are unpaid or paid scripted users or ex-users. Whatever their background, the aim of these workers is to facilitate access to caring services for individuals who want to deal with a substance use problem. An example of how outreach work might be carried out is given in Box 36.6.

Professional outreach workers

These workers are usually nurses; some have dual qualifications in general and mental health nursing. They work independently of the alcohol and/or drug advisory service and their main function is to provide health education and health delivery at the 'grass roots' level. Advice on general care issues, substance use and safe practice is given with the aim of increasing the number of substance users coming forward to seek professional help.

Existing scripted users: unpaid

These outreach workers already live, work and socialise with other users. Their aim is to deliver a health promotion message, e.g. harm minimisation and HIV/AIDS advice, and to promote the idea that local agencies are 'user friendly'.

Ex-users and existing users: paid

In most cases employed by alcohol and/or drug advisory services, these individuals are detached youth workers

Box 36.6

Outreach work: an example

The outreach worker may go to a pub or dance club. During the evening, the worker may meet up with an existing contact, who during the course of a conversation may introduce the worker to an associate who would like to talk (this form of contacting is often referred to as 'snowballing'). This individual may be experiencing substance use problems or problems with their GP. In the case of a health care problem, the worker may be able to facilitate 'harm minimisation' (see below). For example, the user may be advised to go for a health check or for HIV/AIDS and hepatitis B and C testing, or may be informed about how to obtain clean 'works'. In some cases, the worker undertakes these tasks, dealing with the problem on street level.

As the user's trust develops, the worker may bring a colleague along to a meeting or encourage attendance at a clinic. This process gradually leads to a deeper level of care and involvement with the community drug team.

dealing with all welfare aspects of substance use. Their aim is to increase levels of understanding, to give information on safer substance-using practices and to encourage attendance at substance clinics for appropriate interventions.

Harm minimisation

Harm minimisation is a form of intervention that has given rise to much controversy. It is a process by which substance users are advised on safe methods of substance use, rather than being urged to abstain. The user is offered blood tests and health checks, is given advice on safer using practices and is supplied with clean paraphernalia and condoms. The underlying philosophy is that while it may be impossible to eradicate the illegal use of substances, it is nonetheless beneficial for individuals and society to make existing substance use as safe as possible (see Ch. 37).

Needle exchange schemes Usually operated by drug and/or alcohol advisory services, these schemes aim to distribute clean needles, syringes and containers (paraphernalia) with a view to preventing the sharing of equipment and thus reducing the spread of infection. These schemes allow for access to paraphernalia, health promotion materials and advice, e.g. on cleaning of equipment and on safe sexual practice.

Some pharmacists, GPs and community psychiatric nurses offer this service. Needle exchange schemes also facilitate the safe disposal of used paraphernalia and help to maintain the link between the user and agencies.

Voluntary and professional agencies

Local services

Most health districts have a drug and/or alcohol advisory service, usually staffed by specialist nurses, social workers and administrators. Other professionals such as health promotion officers, occupational therapists, doctors/consultants and probation officers may be attached to the team.

These teams offer help, advice, information, health education, treatment and counselling for the substance user, the family or close associates and health care professionals. Some districts have a similar, voluntary service staffed by trained counsellors. Many voluntary services provide a range of alternative therapies, e.g. acupuncture and/or massage, as part of the treatment package. Contact with these services can be made via the Yellow Pages, citizens' advice bureaux, occupational health, community mental health and primary care teams. Some regional alcohol and/or drug treatment units still operate, offering outpatient and inpatient treatment, usually on a 6-week basis. However, access to these may be difficult to obtain and usually requires a doctor's recommendation.

National bodies

Technical information and advice relating to voluntary services may be obtained by making contact with the following organisations (see 'Useful websites and addresses', p. 1167):

- Alcohol Concern
- Drugscope
- Nursing Council on Alcohol (NCA)
- Re-Solv
- The Addictions Forum.

Support groups

Statutory and voluntary drug and/or alcohol advisory services may offer group therapy in a variety of formats. Membership of these groups may be open or closed, and may be for men only, women only or mixed. Some aim for total abstinence, others for controlled use. Some groups are set up to provide support for family members.

- 'Drinkline' is organised on lines similar to 'Weight-watchers'. Total abstinence is not a requirement.
- Alcoholics Anonymous (AA) and Narcotics Anonymous (NA) are self-help organisations offering individual and group support. Total abstinence is required.
- Al-Anon, Al-Ateen and Families Anonymous are run on similar lines to AA and NA groups and provide self-help for the families and friends of substance users.
- Tranquilliser support groups have also been established to offer support and encouragement to individuals during the often long and difficult process of withdrawal.

Additional programmes undertaken by drug and/or alcohol advisory services may include group psychotherapy, social skills training, relaxation, family therapy, education and prevention, and telephone support. Most teams are able to access intensive residential courses, 'dry' hostels and other care facilities. Each of these offers a particular philosophy of care. The service provider usually agrees admission following assessment.

36.10 The Department of Health (1999) suggests that all workers should have knowledge of the services and facilities available to them and how to access these. Produce your own 'resource catalogue' using the information and addresses contained within this chapter. In addition, to increase your familiarity with the services available in your own health district, carry out the following project:

(a) Research all local resources that may assist you in the care of your patient, whether this would be with advice, help, information or statistics. Don't forget self-help groups and counselling services such as the Samaritans, as well as mother-and-toddler groups, which may provide much-needed support for a mother under stress.

(b) Prepare a file card or computer database on each group, listing the contact name, address, telephone number and type of help offered.

CONCLUSION

This chapter has attempted to provide an introduction for the nurse to the many issues surrounding the care of individuals who use substances and who may or may not have a problem with that use. While work with these individuals can constitute a specialism within nursing, the need for nurses in every field to be aware of the signs and the consequences of substance use cannot be overemphasised (Prime Minister's Strategy Unit 2004).

Substance use problems occur in every age group and social class. Within the family, substance use problems may

have serious implications not only for the individual directly affected, but also for the spouse or partner and children. Indeed, the nurse may first identify the existence of substance use not through contact with the substance user, but through interactions with family members (see Case History 36.1). It is vital that nursing interventions, undertaken in response to substance use, are based on an assessment not only of the individual but also of the family circumstances.

As in many areas of nursing, prevention and education show the way forward (Watson 2000). When averting or changing from substance use, be that use problematic or otherwise, individuals must be given adequate information on which to base free and informed decisions. Nurses working with substance users may find that, in order to be more responsive to the needs of the individual, they must venture beyond traditional clinical settings into outreach work. In any event, interventions will demand a holistic approach in which the unique identity of the individual is paramount, and in which all aspects of physical, mental and social well-being are addressed by the cooperative efforts of a multidisciplinary and multiagency team.

Nurses are in a privileged position by virtue of their close and frequent contact with the individual. They are often seen as the 'human face' of community and hospital health services and are perceived to be 'on the patient's side' — practical, approachable and down-to-earth. As a result, nurses are well placed to listen to, support, advise and inform, and nursing the substance-using individual can offer a particularly challenging and rewarding context for the practice of these invaluable skills.

36.11 Now that you have read through the chapter, repeat exercise 36.1, taking note of the following:

- Have your feelings changed? If so, in what way? What new information influenced this change?
- Are there any areas that you feel you need to investigate further? If so, what are these and what sources could you use?

INTRODUCTION — THE 21ST CENTURY GLOBAL CONTEXT

It may seem strange that 16 years since work on the first edition for this book started, there continues to be a chapter devoted to one infectious disease. Nurses around the world now deal with other diseases, some newly emergent, like severe acute respiratory syndrome (SARS) (Waters 2003), and others with a more enduring presence in our care such as hepatitis C (Gungabissoon 2003) and methicillin-resistant *Staphylococcus aureus* (MRSA) (RCN 2004). However, there is still much to learn from human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS). At their appearance nearly 25 years ago, fever hospitals and the specialist qualification of fever nurse were being disbanded in affluent and so-called 'developed' countries. Young, fit people did not die of infectious disease in great numbers and perhaps a degree of hubris and of complacency had set in. AIDS changed all that.

Since AIDS was first recognised, great advances have taken place in the treatment of people with HIV and its related illnesses. Undoubtedly, the main advance is in the expansion and sophistication of combination (multiple) therapies. In the early days of the emergence of the disease, people diagnosed with AIDS would live only weeks or months, whereas the improved therapies have led to the survival of some patients for over 10 years and some over 20 years, and to many more patients being cared for outside hospital.

The reader is directed to the British HIV Association website and their HIV treatment guidelines (British HIV Association 2003) and to the United Nations 2004 Report on the global AIDS epidemic (UN 2004).

In terms of new endeavour, emphasis is now on the practical implementation of treatment for the vast numbers of people with HIV and its related illnesses in financially poor and developing countries, particularly in Africa. Progress is slow, but gathering momentum. The World Health Organization's (2003a) '3 by 5' campaign, which aimed to treat 3 million people by 2005, is in stark contrast to previous ideals and policies, whose counsel of despair was that only prevention was a possibility in non-affluent countries. Jong-wook Lee, Director-General of the World Health Organization (WHO), speaking of the '3 by 5' initiative, states:

> *Lack of access to antiretroviral therapy (ART) is a global health emergency … To deliver antiretroviral treatment to the millions who need it, we must change the way we think and change the way we act.*
>
> *WHO 2003b*

Another advance has been the development of the legal and regulatory framework between countries and within the workplace, in relation to people with HIV and their abilities, rights and duties regarding travel and employment. Dimond (2003) discusses the law, HIV and employees, and the All-Party Parliamentary Group on AIDS (2003) examines migration and HIV (Singh 2003). In the UK, the main policy

theme is that people with HIV should be able to travel and work without interference or harassment and, in most circumstances, have their confidentiality maintained.

The story of AIDS emerged in the USA where five men died of *Pneumocystis carinii* pneumonia (PCP), a rare infection (Shilts 2000). The only characteristics they had in common were their young age, their gender and the fact that they were homosexual. Later that year a patient with similar symptoms and characteristics died in a London hospital (Adler 2001). The condition we now call acquired immune deficiency syndrome (AIDS) had arrived. In 1983–84, in France and the USA, the causative agent, a virus from the family of retroviruses (see p. 1171), was isolated. This virus was found to infiltrate and destroy human helper T lymphocytes, which promote both the ability of B-lymphocyte-derived plasma cells to produce antibodies and the activation of killer T lymphocytes, the $CD8^+$ cytotoxic cells, which are able to attack and kill those cells infected with viruses. The viruses which cause AIDS are known as the human immunodeficiency viruses.

This chapter will present the main historical features of the advent of HIV/AIDS, along with a profile of the retrovirus. It will address the social and economic implications of HIV/AIDS and the effect of the disease on patients and their carers. Testing will be highlighted, together with concomitant ethical and practical dilemmas. The final sections of the chapter will consider the clinical manifestations of HIV/AIDS, giving details of the treatments currently available. The contribution of nurses to the care of individuals with HIV/AIDS will be discussed. Whilst reading this chapter, the reader should remember that the person with HIV/AIDS will spend most of their time at home and not in hospital or other formal care settings.

By setting HIV/AIDS, at the outset, in a wide social context, this chapter intends to emphasise that HIV/AIDS is both a clinical and a sociopolitical issue. It is hoped that nurses, armed with the information provided by this chapter, will be able to develop a knowledgeable and empathetic mode of practice with people who have HIV and related problems.

Definitions

In order to use the correct terminology relating to HIV/AIDS, it is helpful to understand how this terminology developed.

The syndrome

The only clinical factor linking the original patients with AIDS was the fact that they were so profoundly immunosuppressed, that microorganisms which generally inhabit the body harmlessly took the opportunity to replicate wildly, disseminate and cause clinical illness, e.g. *Pneumocystis carinii* pneumonia (PCP). Until that time, this infection was seen only occasionally, in patients who were immunosuppressed with diseases such as leukaemia or whose immunity was suppressed as a side-effect of medication. These types of illness and neoplastic events, which only manifest themselves in persons who have a severely compromised immune system, are referred to as 'opportunistic diseases' and they are the hallmark of the syndrome now referred to as AIDS. As this immunosuppressed state was not a primary, e.g. congenital, but a secondary immunodeficiency, it was called acquired immune deficiency (the main linking clinical factor) syndrome, i.e. a group of recognised clinical signs. In time it would be recognised that this particular immunodeficiency was secondary to specific viral infection.

Human immunodeficiency virus (HIV)

The retroviruses, now called human immunodeficiency viruses, were isolated and designated the causative agents of AIDS. A blood test which could detect antibodies to HIV following infection was developed in 1985. An individual who becomes infected with HIV will respond by producing antibodies in a process known as seroconversion. When a person is found to have HIV antibodies, they are said to be HIV antibody-positive or, less correctly, HIV-positive (HIV+) and are considered to be infected with HIV.

Since the discovery of HIV, a major strain variation within the species human immunodeficiency viruses — HIV 2 — has been identified. It is most commonly found in certain countries on the west coast of Africa and in west India. HIV 2 is less able to be transmitted from an infected mother to her child, i.e. vertical transmission, and infection with HIV 2 is generally associated with a longer incubation period to an AIDS-defining illness (Adler 2001).

AIDS diagnosis

A patient is diagnosed as having AIDS only if they are HIV antibody-positive and have one of the designated infections or diseases associated with AIDS. The classification of these diseases devised by the Centers for Disease Control (CDC 1987) in the USA is used globally. Also current is the *World Health Organization Clinical Staging System for HIV Infection and Disease* (WHO 2003c, see Box 37.1). This system attempts to address some of the anomalies which the CDC system presented. A helpful explanation of the staging system is given in Pratt (2003).

It is important to understand the following relationship between HIV antibodies and AIDS. Everybody who has AIDS is HIV antibody-positive, but not everybody who is HIV antibody-positive has AIDS. It should also be pointed out that an individual who has a positive HIV antibody status may sometimes become ill without being diagnosed as having AIDS. This may be because they have not yet contracted one of the infections or diseases on the classified list but are ill for some other reason, or because they are experiencing side-effects of, for instance, antiretroviral treatment.

Nurses will meet many people who have at some time been diagnosed as having AIDS but who are presently well. A patient may have an AIDS-defining illness, be treated for it, recover and no longer be considered to have AIDS. This is increasingly common as people with the syndrome survive longer. When the author began working in the field, death 18 months to 2 years after diagnosis was the 'norm'. Now one may meet individuals who have survived 10–20 years. Thus the term AIDS as an 'illness label' can be unhelpful, and even misleading, because it does not necessarily reflect how the person is at a given moment. For nurses in particular, the term has little relevance. It is more helpful to consider the term 'persons living with HIV infection' rather than AIDS or HIV patients. The term conveys

Box 37.1

WHO staging system for HIV infection and disease in adults and adolescents

Clinical stage I

1. Asymptomatic
2. Persistent generalised lymphadenopathy

Performance scale 1: asymptomatic, normal activity

Clinical stage II

3. Weight loss, <10% of body weight
4. Minor mucocutaneous manifestations, e.g. seborrhoeic dermatitis, prurigo, fungal nail infections, recurrent oral ulcerations, angular cheilitis
5. Herpes zoster within the last 5 years
6. Recurrent upper respiratory tract infections, e.g. bacterial sinusitis

And/or performance scale 2: symptomatic, normal activity

Clinical stage III

7. Weight loss, >10% of body weight
8. Unexplained chronic diarrhoea, >1 month
9. Unexplained prolonged fever (intermittent or constant), >1 month
10. Oral candidiasis (thrush)
11. Oral hairy leukoplakia
12. Pulmonary tuberculosis within the past year
13. Severe bacterial infections, i.e. pneumonia, pyomyositis

And/or performance scale 3: bedridden <50% of the day during the last month

Clinical stage IV

14. HIV wasting syndrome, as defined by the Centers for Disease Control and Prevention[a]
15. *Pneumocystis carinii* pneumonia
16. Toxoplasmosis of the brain
17. Cryptosporidiosis with diarrhoea >1 month
18. Cryptococcosis, extrapulmonary
19. Cytomegalovirus disease of an organ other than liver, spleen or lymph nodes
20. Herpes simplex virus infection, mucocutaneous >1 month, or visceral any duration
21. Progressive multifocal leukoencephalopathy
22. Any disseminated endemic mycosis, i.e. histoplasmosis, coccidioidomycosis
23. Candidiasis of the oesophagus, trachea, bronchi or lungs
24. Atypical mycobacteriosis, disseminated
25. Non-typhoid *Salmonella* septicaemia
26. Extrapulmonary tuberculosis
27. Lymphoma
28. Kaposi's sarcoma
29. HIV encephalopathy, as defined by the Centers for Disease Control and Prevention[b]

And/or performance scale 4: bedridden >50% of the day during the last month

Note: both definitive and presumptive diagnoses are acceptable.
[a]HIV wasting syndrome: weight loss of >10% of body weight, plus either unexplained chronic diarrhoea (>1 month) or chronic weakness and unexplained prolonged fever (>1 month).
[b]HIV encephalopathy: clinical findings of disabling cognitive and/or motor dysfunction interfering with activities of daily living, progressing over weeks to months, in the absence of a concurrent illness or condition other than HIV infection which could explain the findings.

Reproduced with permission from the World Health Organization (2003c).

a continuum from the moment of infection to end-stage disease and death with early, middle and late events and issues affecting individuals.

Issues surrounding terminology

HIV/AIDS has become a deeply politicised disease phenomenon. The nurse, as educator and advocate, must be sensitive to the sociopolitical issues surrounding HIV/AIDS and its description. The patient has the right to expect that nurses will use terminology that is appropriate and technically correct, promotes well-being, is not stigmatising and does not give offence.

Although the term AIDS has limited clinical usefulness, it is still the term commonly used by the media and the public. Also common are the terms 'the AIDS virus' and 'the HIV virus'. Neither is strictly correct and nurses should use 'HIV' instead.

It is now generally accepted that 'person/s living with AIDS' (PLWA) or HIV is a more acceptable term than 'AIDS patient'. The latter term is inappropriate as an individual may live a normal life for long periods without recourse to medical or nursing care. Calling an individual a 'victim' raises questions of guilt or innocence and, along with 'sufferer', implies that they are powerless to help themselves.

VIRUSES AND NORMAL IMMUNOLOGY

The reader is referred to Chapter 16 for an outline of normal immunology.

Viruses

Viruses are not complete organisms. They can survive only as part of 'host' cells. Unlike bacteria, fungi, protozoa and other infective agents, all of which are complete and independently viable, viruses cannot replicate (multiply/reproduce) by themselves. They are also very small and cannot be seen by a light microscope. Viruses are made up of a core of nucleic acid, i.e. DNA or RNA, never both, and are enveloped in a protein shell.

Retroviruses

These viruses, to which HIV belongs, contain RNA. They have the ability to infiltrate the DNA of the host cell and implant their genetic material there, after which the host cell will have the capability to reproduce HIV.

DNA is present in all organisms. It plays a central part in heredity and, because of its structure, the two interwoven strands of nucleotides, connected by hydrogen bonds, can replicate, carrying the genetic blueprint to the next generation of cells. RNA is made up of a single strand of nucleotides and is involved in protein synthesis. It provides the genetic blueprint of some viruses, including HIV. HIV infects a variety of cells that contain the $CD4^+$ host cell receptors, including T lymphocytes of the helper subset. The presence of additional host cell receptors is known to be necessary in order for HIV to attach itself to, and infect a cell.

The importance of this disruption of the T lymphocytes must be understood within the context of the normal immune response (see Ch. 16). The various types of white blood cell have interlinking but quite distinct cell-mediated responses to seek and destroy invading microorganisms

Box 37.2

The normal immune response

Warning
In response to the invading microorganism, helper T cells orchestrate defences by releasing chemicals which stimulate other cells of the immune system.

Preparation
Activated by these chemical signals, other kinds of T cells (cytotoxic cells and lymphokine producers) begin to proliferate, while B lymphocytes multiply and become plasma cells which start to manufacture antibodies.

Attack
Activated T cells and antibodies are released into the circulation, where they specifically target and destroy the invading organism.

Stand down
Once the foreign organism is routed and the infection is under control, the activity of the immune system is reduced, perhaps partly through the action of suppressor T lymphocytes.

and malignant cells. For a stage-by-stage summary of this process, see Box 37.2. Given the essential role played by helper T cells in the immune system, it is clear that their invasion and destruction by HIV will have devastating results.

For further information on retroviruses, see Chapters 2 and 3 in Pratt (2003).

THE TRANSMISSION OF HIV

Modes of transmission

The first stage of HIV infection occurs when the individual is infected with HIV through an exchange of body fluids and/or blood with an infected individual. Sexual contact and blood-to-blood contact are known as 'horizontal' methods of transmission, i.e. they move 'across' from one individual to another.

Transmission through sexual contact

Unprotected vaginal or anal intercourse is the most common means by which HIV can be transmitted from an infected to a non-infected person. It is difficult to determine absolutely whether other intimate sexual activities, e.g. oral sex, can transmit the virus as they do not often occur in isolation. However, some individual cases have been reported (Rothenberg et al 1998). There is much debate in the scientific and secular worlds about which sexual activities are the most 'dangerous'. Until recently, anal sex was considered to be most risky. Also, women were thought to be more at risk from penis/vagina sex than men. More recent findings are leading to a re-examination of these assumptions, and the scientific debate is not conclusive (Stine 2000).

It is important, therefore, to inform patients that they may be at risk from any intimate sexual contact.

Transmission through blood and blood products

Blood transfusions The spread of HIV in Western countries that have sophisticated blood transfusion services has been greatly reduced since the rigorous screening of donors was instituted in most countries in 1985. In the UK it is now reckoned that there is a risk factor of less than one transmission in a million units of blood. This means fewer than three transmissions a year.

The best-known recipients of blood products are those suffering from haemophilia and those with other blood-clotting disorders. Before 1985, many thousands of such individuals became infected through blood products. Since 1985, these products have been heat treated. The treatment is totally successful but reduces the efficacy of the products, such that more of them are required.

Blood transmission through sharing of equipment HIV transmission can occur through the sharing of syringes, needles and other blood-giving equipment. In Western countries this commonly occurs through the illicit, intravenous (i.v.) use of drugs. Here the probability of infection is often increased by the user 'flushing' the syringe with their blood before injection. In poorer countries, it also occurs where there is reuse of medical equipment and insufficient sterilising facilities. The mode of transmission is the same in both cases.

Percutaneous 'needlestick' injuries There have been very few proven cases of infection by this mode. A study of 3000 incidents where individuals were exposed to HIV puts the risk of seroconversion from a contaminated needlestick at 0.3%. Only 92 cases of occupational infection with HIV have been reported worldwide (Sistrom et al 1998, Babcock & Fraser 2003, Nursing and Midwifery Council 2003a).

Transmission through skin piercing procedures Transmission is certainly a theoretical risk from procedures such as tattooing (Greif et al 1999), and cases have been reported of transmission by body piercing (Armstrong 1998) and skin grafting.

Transmission through other bodily fluids Infection with HIV takes place only when there is sufficient concentration of the virus. Infection through saliva, for instance, is therefore considered unlikely. Worldwide retrospective studies have shown that the number of workers contracting the virus through urine, faeces or saliva, for example, has been extremely small (Jeffries 1997).

Mother-to-child transmission

This form of transmission is known as 'vertical' transmission, i.e. 'from' an infected mother to her child in the womb or during delivery, when the mother's blood and the child's blood become mixed. There is a possibility that transmission through amniotic fluid and ('horizontally') through breast milk may also take place (Gibb et al 2003).

From birth until 11–18 months, the baby will carry the mother's antibodies including HIV. Therefore, all babies born to HIV-infected mothers are found to be HIV antibody-positive. At about 11–18 months, the baby will lose the

mother's antibodies and go on either to being HIV antibody-negative, i.e. not carrying the virus, or to developing their own antibodies, i.e. being infected in their own right. A few of these babies go on to become HIV antibody-negative but positive to another test which isolates antigen (particles of the actual virus), so that they are carrying the virus but not the antibodies.

For further information, see Newberry & Kelsey (2003).

At the beginning of the HIV epidemic it appeared that approximately 50% of children born to HIV antibody-positive mothers became infected in their own right. In countries where there are good antenatal facilities and the mother remains well throughout pregnancy, the rate of transmission from mother to child is dramatically lower. If the mother's immune system is robust, if she is treated in the last trimester and has an early elective caesarean section, transmission is reduced to less than 1% (De Cock et al 2000, WHO 2000).

Stages of HIV infection

The dormant or asymptomatic stage

In HIV-related illness, two main processes take place in the infected person's body:

- HIV destroys the helper T cells and replicates itself
- The body's immunity is inexorably weakened and is attacked by other infections. The body becomes increasingly unable to combat these attacks.

Since viruses cannot multiply by themselves, they need to use the cell-building material of their host cells in order to reproduce themselves (see Fig. 37.1). When HIV enters the bloodstream, it attaches itself to the outer cell membrane of the helper T lymphocyte. Following this, it breaks into the cell and releases its genetic blueprint, which has the ability to replicate itself.

The disease process may then go no further for several months or even years. The person is infected with HIV and may or may not have produced antibodies. This may take 3 months or more. If they have seroconverted and started to produce antibodies, they may or may not have become ill. If they did become ill with acute seroconversion illness (CDC phase A), the usually mild and very common flu-like symptoms were probably not recognised by the individual or their physician as a sign of HIV infection. The helper T-lymphocyte blood count will still be normal and therefore the immune system will remain unaffected. The patient will continue to be well. This stage, often called the dormant stage, is referred to as 'Clinical stage one: 1 – Asymptomatic' in the World Health Organization staging system (WHO 2003c).

In time, the infected T cells will start to replicate new HIV retroviruses. Although it is unclear what triggers this process, it seems that, if an individual keeps generally well and leads a healthy lifestyle, the stage at which HIV starts to replicate and destroy the T cells may be delayed. A clearer finding is that, in conditions of deprivation and poor health, the illness seems to progress more quickly.

The replication stage

The first process At some point after HIV has been incorporated into the helper T lymphocyte, it begins to replicate itself within the cell walls using the cell's own material. The new viruses aggregate, start to destroy the outer cell membrane and break out of the helper T cell, encased in membrane stolen from the host cell and clinging onto the remnants of the cell. This is known as 'budding' (see Fig. 37.1). At this stage, the host cell dies. The new viruses then disperse throughout the bloodstream, infecting other helper T lymphocytes, and the process begins again.

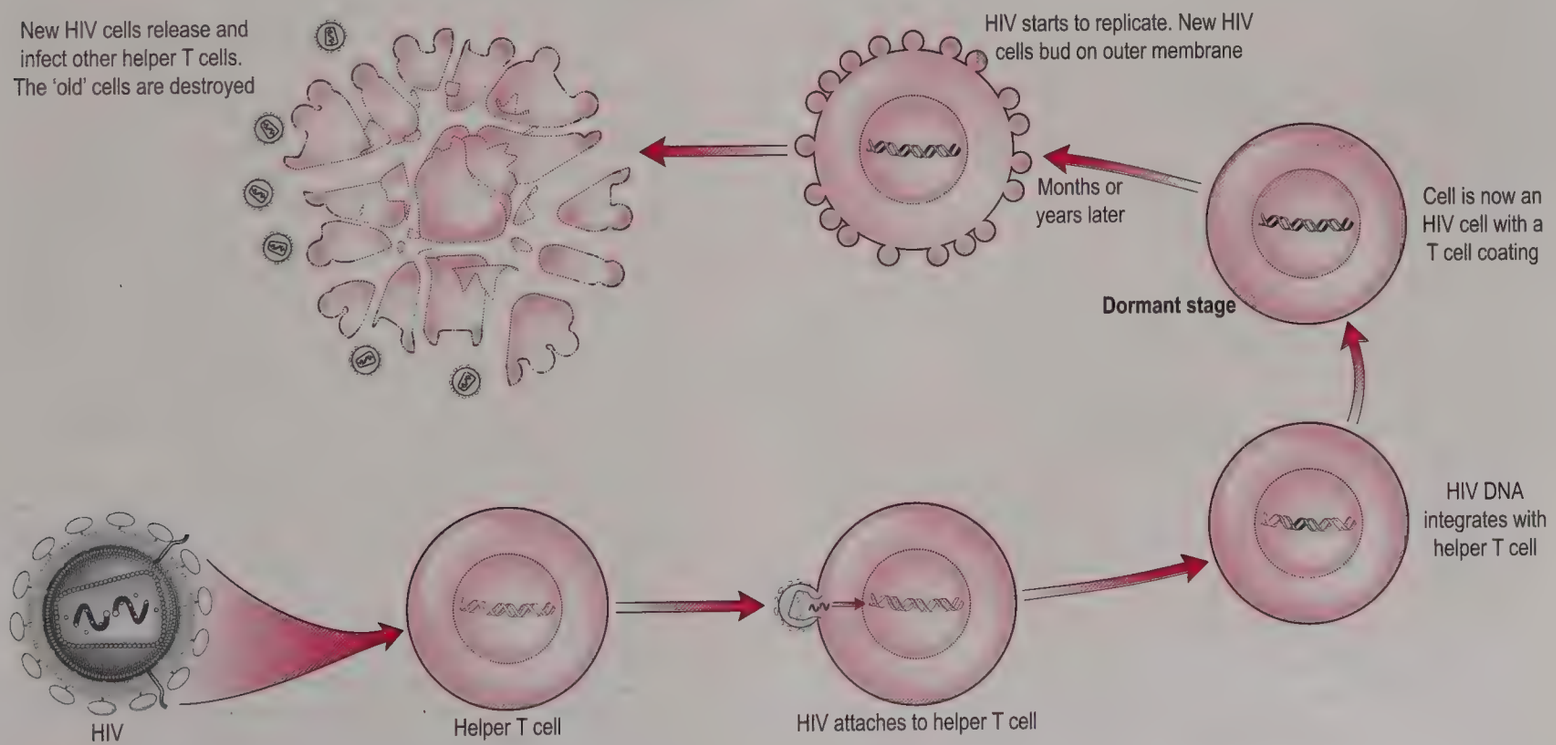

Fig. 37.1 The human immunodeficiency virus in action.

The second process begins when helper T cells have been infected to the degree that the number of normal, healthy helper T cells begins to fall markedly. At this point the body's immune response to other infections will begin to be compromised. From the clinician's viewpoint, this is a significant stage, as the depletion of normal helper T cells can be measured in a blood sample ($CD4^+$ T cell count, see Appendix 1).

Also significant is the ratio between the helper T lymphocytes and the cytotoxic T lymphocytes, which is thought to assist in the 'stand down' phase of the normal immune response (see Box 37.2). Normally, the ratio is 1.5 helpers to 1.0 suppressor cytotoxic cells; however, as the number of healthy helper cells decreases, this ratio changes. This will have a detrimental effect on the immune system. It is also one of the diagnostic signs used to confirm the presence of HIV-related illness. In other forms of immune deficiency illnesses, both helper and suppressor cell levels fall, and so the ratio between them remains roughly the same.

As the helper T cell level falls, the body will become more susceptible to other infections. The individual may at first experience rather vague symptoms, progressing to debilitating but not life-threatening conditions and finally to serious illness and death. Information on the specific diseases which may appear is given later in the chapter.

A typical profile of HIV infection is shown in Figure 37.2. How HIV/AIDS actually manifests itself will vary dramatically from one person to another. Many people with extremely low helper T cell counts may seem healthy; others with what should be a 'good' count will be extremely ill. The nurse must rely on observations of and discussions with the patient in assessing their condition, rather than on abstract clinical indicators alone.

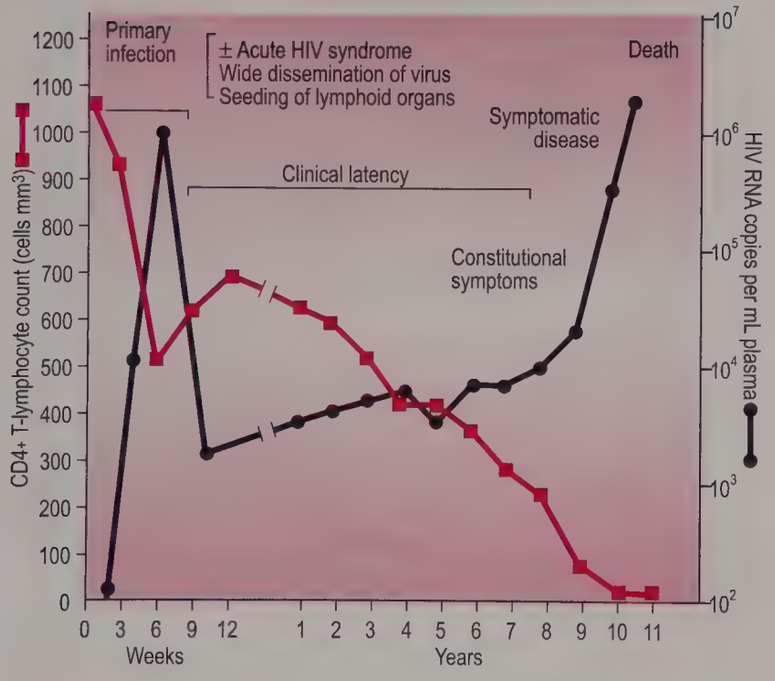

Fig. 37.2 The course of HIV infection. (Adapted from Pratt 2003.)

POLITICAL AND SOCIAL IMPLICATIONS OF HIV/AIDS

AIDS has been referred to as 'the real global terrorist' of the present and compared to the great plagues of the past in that it appears to be spreading unchecked and has, as yet, no cure. Like other infectious diseases which have reached epidemic or pandemic proportions, HIV/AIDS has given rise to a great deal of fear and stigmatisation. In formulating health and social policies in response to AIDS, governments have a duty not only to safeguard the health and well-being of their populations as a whole, but also to protect the rights of those individuals affected by the disease.

The foundation for political and social responses to HIV/AIDS is provided by the work of epidemiologists, who define the disease, describe its typical progression and determine its national and international incidence. Also relevant is its prevalence within particular groups. On the basis of these findings, predictions are made as to the future impact of the disease (Barker & Rose 1998). Armed with this knowledge, nursing, medical and scientific practitioners, along with the individuals and groups affected, endeavour to raise awareness of HIV/AIDS and to lobby governments to take appropriate action.

Although cases of HIV infection were known in 1981, it was not until 2 or 3 years later that HIV appeared officially to be recognised as a threat to the whole community. Various media campaigns were instigated from 1985 onwards and the first full debate in the UK was held in the House of Commons in November 1986 (Hansard 1986).

Some of the questions and issues raised by the epidemiology of HIV/AIDS are listed in Box 37.3.

Box 37.3

Questions and issues raised by HIV/AIDS

- In developing countries, particularly Africa, HIV affects mainly heterosexual people. In the West, with some notable exceptions, the prevalence appears to be overwhelmingly among homosexual men and intravenous drug users. Why is the pattern so different, given that HIV is now present in all sections of the population in the West?
- In many cities in the USA and Africa, the prevalence of HIV among young heterosexuals is rising dramatically. It is now the most common cause of death in this group. Will this happen everywhere?
- Given that there is no cure for AIDS, just how effective are education and prevention policies? Some countries, notably the USA, have strict entry laws. What is the case for stringent political action, e.g. restricting the movements of known HIV-positive individuals?
- Is there a case for testing as many people as possible anonymously to get a more accurate profile of what is going on so that policymakers are better able to provide proper services?
- Is the nurse's primary responsibility to the individual patient and to their confidentiality and wishes? If so, what responsibility does the nurse have to protect the public at large? Can both responsibilities be met at the same time?

Political challenges

The most intractable problem presented by HIV to policy makers is the length of time it takes for the disease to manifest itself after an individual becomes infected. This has the following profound epidemiological implications:

- Most people who are infected are not aware of it until they become ill.
- The government figures published regularly related to people with AIDS do not reflect the prevalence of HIV at that moment. They give, at best, an idea of the prevalence 5–10 years ago.
- It is more difficult to gauge specifically who is at risk, although some 'high-risk' activities can be identified, e.g. i.v. drug use, unprotected sexual intercourse.

It is therefore vital that data on AIDS are as specific as possible. In England and Wales, the Health Protection Agency, and in Scotland, Health Protection Scotland (see 'Useful websites', p. 1189) collect, collate and distribute information on the incidence and prevalence of HIV and AIDS.

Until January 1991, the number of reported AIDS cases in the UK was published monthly. The main figure quoted was the cumulative total, i.e. the overall number known since reporting started. Since the implementation of the AIDS (Control) Act 1987 and other measures, it has been possible to gather more specific, local information from hospitals, clinics and health authorities. There is now an annual breakdown of HIV seropositive incidence, cases of AIDS, gender, high-risk activity, e.g. drug use, and age. Internationally, data collection has been improved by the coordination of research projects and the collation of information and there is an annual global AIDS medical conference.

37.1 Obtain national and local AIDS/HIV-related statistics from the Health Protection Agency (England and Wales) or Health Protection Scotland. Analyse trends over the last 5 years.

The impact of HIV/AIDS on health and social services

Although qualified nurses tend to work exclusively in either a hospital or a community setting, it is important to consider HIV in relation to the full range of services available to the (typically young) person living with HIV, particularly in the light of innovations in medication in the mid-1990s and the longer life expectation. The settings in which care is given to individuals with HIV/AIDS may be categorised as follows:

- Hospital care
  - — inpatient ward or hospice
  - — day care
  - — outpatients
- Community care
  - — treatment room: health centre/clinic
  - — home: with a district nurse, health visitor or other practitioner
  - — home: self-care or with family/partner/friends
  - — outreach: residential, e.g. hostels, prisons, caravans
  - — outreach: non-residential, e.g. drop-in centres, street work.

Hospital care At first, HIV care was delivered almost exclusively in the hospital inpatient setting. This was an expensive, labour-intensive and often arguably a 'patient-unfriendly' option. Individuals would spend many days or weeks in hospital per year, sometimes feeling relatively well but requiring, for example, i.v. therapy. The hospital setting is still used for seriously ill patients. However, day care units are now used extensively and often have flexible hours to facilitate patients' work commitments. Day care units and outpatient departments are used as places of treatment, monitoring, counselling and group work as well as traditional consultation.

Community care Most procedures, including continuous i.v. therapy, can now be performed in the patient's home. The author looked after a young person who, having been in prison, was frightened at the thought of being in hospital. Even though the patient lived in a very poor area, in a crowded home with young children, a high standard of nursing care was possible, including the successful care of a gangrenous ulcer. This patient very rarely went into hospital.

Outreach care is now a well-developed area of health and nursing delivery, particularly in relation to HIV and drug misuse, providing drop-in centres where counselling, medical cover, family planning and antenatal care with direct access to the hospital services are available.

HIV has an enormous social impact on both the individual and carers. In order to provide the best possible care, it is essential to have an integrated, multidisciplinary service that addresses social as well as clinical concerns, particularly in discharge planning and follow-up (Pratt 2003). Creating an environment which enables an effective but confidential service is difficult, especially as more agencies become involved in care. The best principle to adopt is a 'need to know' policy of information disclosure, involving the patient at every stage. This sometimes causes problems, as many professionals, quite wrongly, think they have a 'blanket' right to know a patient's details.

Manpower implications

The two main effects that HIV has had on health service manpower are:

- change and extension of roles
- increased workloads and accompanying costs.

Role change has been seen both in hospital and in the community. By the 1970s it was felt that infectious disease nursing as a 'specialty' was no longer needed and infectious diseases hospitals were increasingly used for other purposes. Now infectious disease facilities have once again become necessary. Special provision for people with HIV/AIDS has been built, requiring the supply and educational preparation of a large number of new staff. To date there has been no audit of how many nurses in the UK have been deployed in this field. However, each health authority publishes an annual report on activities and services under the 1987 AIDS (Control) Act.

Costs

Since 1995–96 and the first edition of this text, these implications have changed, particularly as individuals receive combination therapies (see p. 1186) from an earlier stage in their illness, with the result that many remain in better health for longer periods. This has a considerable impact on financial resources but has lessened the need for specialist inpatient facilities. Hospital admissions, mainly for the treatment of devastating opportunistic infections, increase costs considerably. Newer treatments, although expensive, are seen to be cost-effective as they delay the onset of the advanced stages of HIV disease (AIDS) for which care is very expensive (Adler 2003). More people are therefore able to stay well for longer although, despite some remarkable survival stories, the long-term influence of combination therapy (see p. 1186) on the infected population is unknown (Stine 2000). As highlighted in the Introduction, the move to establish combination therapy in poor and developing countries magnifies these challenges considerably (Lo & Bayer 2003, Mandela 2003, WHO 2003b)

Increased workloads

In the community, HIV has had the effect of creating new fields of work for health care practitioners. District nurses, whose main workload lies in caring for older people, now have younger people on their caseloads with a variety of clinical needs.

Increased input by social services is needed by most affected people, at one stage or another, as their situation changes. Typically the individual is young, independent and employed, perhaps living alone, paying a mortgage or rent, and may have no regular partner. As the disease progresses, these circumstances may change rapidly. In units where there is no resident social worker, the nurse may need to act as advisor and advocate in helping the patient to obtain benefits, housing, domestic assistance, meal supplements and other services. For these nurses, the key to success is to identify the appropriate services, without divulging the patient's personal details, and then, with the patient, to approach them for help. Without careful management, this extension of the nursing role can result in staff being 'spread too thinly'.

If one compares HIV therapy with another long-term disease and treatment, e.g. diabetes mellitus and insulin, where many individuals being treated from a young age may expect to live a fully functional life with normal longevity, the situation with HIV is still uncertain, especially as other factors, such as virus mutation with new disease patterns, manifest themselves (Shaw & Mahoney 2003). These patterns include drug resistance.

Statistics from the Health Protection Service show the cumulative total of cases reported for HIV and AIDS up to 2004. Although the greatest proportion of people affected has been homosexual men, the most rapid increase is among heterosexuals. In the UK, heterosexual transmission outstripped homosexual transmission in 2004.

37.2 What are the current statistics on new AIDS cases?

Social implications

The social impact of HIV/AIDS is felt in two ways: on society as a whole, and on the individual as a social being. Here the wider societal implications are first considered.

Consider the following quotation (Connor & Kingman 1989):

> *At least one American senator was heard to say 'somewhere along the way we are going to have quarantine'.*

This typifies the way in which epidemics are often viewed by the makers of social policy. When the management of an epidemic is seen as being analogous to the management of acute illnesses in clinical practice (Barker & Rose 1998), the following equation is made:

> The organism + the individual = the disease + the population = the epidemic.

In this view an intervention must be made to prevent the transformation of 'organism' into 'epidemic'. Theoretically, the options are:

- to kill the organism
- to make the organism inoperative
- to ameliorate the effects of the organism on the individual
- to separate the individual from the organism
- to separate the individual from the population
- to separate affected groups from the rest of the population.

Looking at disease in this way, the reader may see the role of antibiotics and disinfectants to kill the organism, immunisation to make the organism inoperative, symptom control to ameliorate the effects, infection control and health education to separate the individual from the organism, quarantine to separate the individual from the population and banishment/leper colonies to separate groups from the population.

It may be seen that HIV does not present many options. There is no antibiotic at present and no vaccine. As HIV takes a long time to manifest itself and has no very clear presenting features, quarantine and isolation of potential and actual 'victims' are difficult. At present, only the amelioration of the effects, health education and infection control, including, in this case, the use of condoms, are available in the 'battle' against this epidemic.

These options may seem as being very limited, and therein lies the key to public reaction to HIV and AIDS. In the eyes of society, those who have been appointed to protect the population from disease have not come up with a satisfactory solution for HIV/AIDS. This has led to a reaction of fear and a willingness to stigmatise and even scapegoat those with HIV.

Fear It is important for the nurse to appreciate the complex nature of fear. For example, the knowledge that one cannot 'catch' HIV by shaking hands may not be enough to dispel someone's fear of such contact, for along with the fear of actual physical contamination may be the fear of the very idea of the disease. HIV is particularly frightening because there are very few factors which separate an individual from the virus. This in itself may lead people to

distinguish their own behaviour from that of individuals affected by HIV in the hope of confirming their own 'immunity', as in: 'I can't get HIV because I'm not homosexual'. At the same time, this implies that individuals with HIV/AIDS are themselves to blame and that if everyone in society conformed to certain patterns of behaviour then everything would be all right.

Stigmatisation Scapegoats are those chosen by society to take the blame for evil or misfortune. The selection of a scapegoat is either arbitrary or based in prejudice. This is clear in the case of HIV, which can infect anyone, particularly the sexually active. In the Western world, the virus happens to have affected large numbers of homosexual men first, followed by i.v. drug users. In other areas of the world, its epidemiology has followed other patterns. In any event, the appearance of the virus among one group or another has been a matter of historical accident only and has no inherent moral significance. Nonetheless, people with HIV have been stigmatised officially, e.g. by being refused insurance, employment or entry into certain countries, and unofficially, e.g. by physical and verbal abuse. Individuals affected often become isolated, and because they expect abuse they may start to avoid social interaction, thus compounding their isolation and stigmatisation.

Whether the person involved is a gay man, a drug user, a patient's mother or a child in the playground, fear and stigmatisation can have devastating consequences. A thoughtful nurse often makes all the difference.

Effects on the individual The psychological impact of HIV/AIDS is similar to that of other life-limiting illnesses. For a fuller discussion of the psychological implications of life-limiting illness and of palliative care the reader is referred to Chapter 33.

The sick role Individuals diagnosed as being ill are often implicitly or otherwise 'given permission' to behave in certain ways. Conditions which are seen as 'self-inflicted' tend to elicit less sympathy than others. The author has worked with a patient who, while receiving treatment for a malignant illness, became infected with HIV through a blood transfusion. The patient described to carers the shift in attitude which he then perceived. While the diagnosis was 'cancer', a great deal of sympathy was given. When the diagnosis became 'HIV', the sympathy was considerably less.

A patient who eventually becomes ill may think that they are to blame for not keeping fit enough and may feel guilty when forced to leave work or abandon former social roles. The difficulties are compounded when the person, e.g. a young drug user who prostitutes, has a disordered or chaotic lifestyle. Combined with all of their other problems, a positive HIV diagnosis can be devastating.

It is often difficult for the patient to inform relatives of their diagnosis, thus becoming cut off from a potential source of support and practical help. The nurse can often help the patient and the family to achieve a mutually acceptable resolution, but must bear in mind that whereas a family caring for someone with, say, cancer may get support and practical help from neighbours and others, HIV often sets the scene for isolation, guilt, prejudice and despair. This can happen in any terminal illness, but is often a particular problem in HIV.

Philosophical issues for nurses

The problems the patient experiences, as a stigmatised member of society, demand that nurses who seek to help are very clear about their own attitudes and professional philosophy. Central to any philosophy of nursing practice is the patient's right to 'quality health care in an atmosphere of human dignity without regard to age, ethnic or national origin, sex or sexual orientation, religion or presenting illness' (Pratt 2003). Coupled with this is the duty of nurses to look after all patients.

Models of care

The so-called 'medical model' on which much of nursing practice is based, tends not to provide a satisfactory approach to illnesses for which there is no cure. This model works best when the illness can be reduced to a few constituent parts, which can then be treated, eliminated or made ineffective. HIV and AIDS offer little scope for such an approach, although the search for a 'cure' continues. The reductionist medical model tends to be less effective with multifaceted problems, especially those such as AIDS which are heavily influenced by sociopolitical factors.

Western care systems are based on humanist and utilitarian philosophies whereby the individual is respected and recognised as being capable of independent moral judgement and action. While most people accept this sentiment, there is always difficulty in its application, as it tends to be put into practice only when the individual asserts their rights (Downie & Telfer 1980, Scott et al 2003). Those who have difficulty expressing their rights or who are considered as less worthy than others to do so are often treated as second-class citizens. Many people with HIV fall into these categories. Moreover, professionals and society at large may impose what may be called 'existential assumptions' upon a situation. One patient who is thought to be 'going somewhere' or to have 'been someone' may be considered to be more 'worthwhile' than another patient who is 'going nowhere'. So the death of a 'promising' young pianist, say, is considered sadder than the death of a young prostitute. This attitude pervades care delivery as some professionals prioritise their care using these value judgements as well as formal clinical signs (Bishop & Scudder 1990).

Western models of care tend to hold that one person's rights and liberties must not impinge upon another's and that one may not interfere with a person, even for their own good, unless they are violating the rights of other people (Scott et al 2003). In the case of people who are considered members of a 'minority', these principles often work against their right to high-quality care.

Another possible reaction is for the professional to look at a patient in difficulty and say, 'Who am I to interfere with this person's right to choose to live like this?' as if the young, homeless, ill, drug user has made the same kind of choices and been afforded the same opportunities as, for example, the student nurse. This attitude is seen in specific cases where patients are 'left alone', and in general where

whole groups of people are either ignored or given the minimum of care. In a study of homeless men in hostels, Atkinson (2000) describes this minimum care.

Finally, Western care models are structured on materialistic rationalism whereby only what is 'rational' is accepted as being 'real'. The reader is invited to consider how limiting this view is as an approach to someone whose mind, body and spirit are in turmoil. By being too rational, the nurse may become cut off from the patient's real lived experience. The author undertook a study of cancer patients' experience of their 'journeys' through their treatment. A fascinating insight emerged, as often what the patient experienced and needed from the nurse was different from what the nurse thought. One patient expressed this ...

> *The nurse was ever so good. She told me how the treatment would attack the cancer in great detail, but she didn't tell me whether I would wet myself on the way home.*
>
> *Atkinson et al (2002)*

TESTING AND SCREENING

AIDS/HIV testing involves analysis for HIV antibodies. Testing for the actual virus, i.e. testing for HIV core antigen, particles of the virus, is used for clinical prognosis and management, not generally for diagnostic purposes. Blood samples are used at present for all forms of testing, although urine and saliva tests are being developed, especially for use in screening.

Screening The term 'screening' is generally used, in the context of HIV, to refer to the process by which blood samples undergo laboratory analysis by enzyme-linked immunosorbent assay (ELISA). This procedure is carried out on several samples at once and is used to find out the prevalence of HIV antibodies in a batch of samples. The process may stop here, as in the case of anonymous prevalence surveys. The screening assay has a 'built-in' false-positive rate which ensures that there are no false-negative readings. The analysts know the percentage false-positive rate of the assay and so, when confronted with a batch of positive results, can make a mathematical adjustment to get an accurate picture of the prevalence of HIV in the group.

Individual testing While ELISA is an efficient method of mass screening, it is far from satisfactory for testing an individual, for whom a false-positive result would be devastating. Therefore in individual testing, the sample first undergoes ELISA, and then immunoblotting or the Western blotting method, accurate to within thousandths of 1%, to confirm the diagnosis. This method is more complex and is available only in sophisticated laboratories. In poorer countries, samples may undergo repeated ELISA procedures instead of Western blotting to achieve maximum accuracy in difficult circumstances.

Timing

Generally, HIV antibodies are produced between 3 weeks and 3 months after the individual becomes infected with HIV. The timing of a diagnostic test is important. Individuals who have a test which proves negative are often advised to come back for a repeat test. Because of this uncertainty and the personal impact of a positive result, HIV antibody testing should take place only with pre- and post-test counselling.

Forms of testing

There are various forms of HIV testing, some of which have become controversial. All types are defined here so that the reader can differentiate between them and enter into the continuing debate over their efficacy, need and ethics.

Named voluntary testing with pre- and post-test counselling This form occurs when an individual seeks a test following a specific high-risk activity or contact, or when the individual, for reasons of their own, wants to know their sero status. It is available at genitourinary clinics and HIV units, and from some GPs and other community practitioners. People found to be positive are, with their consent, referred to medical/nursing services. Professionals and others agree that this form is the most acceptable, both practically and ethically.

Named voluntary testing with minimal or no counselling Many people go for testing without being given the opportunity to discuss the implications of a positive or negative result. On being found positive, individuals may not be referred to health services. Others, on being found negative, think that they are 'safe' and need not worry or make behavioural changes. It may be seen, therefore, that this form of testing has drawbacks for the individual and is not advisable.

Conditional named 'voluntary' testing Increasingly, organisations, countries giving work permits, and insurance companies are asking applicants to have an HIV antibody test before gaining entry or obtaining services. The clinical value of these tests is doubtful as they are taken in isolation, often without counselling.

Patients on transplant and other medical waiting lists and those attending infertility clinics are often tested as a condition of entry onto waiting lists. This is done mainly in a hospital setting.

Also, an HIV antibody test is increasingly used as part of a battery of tests to determine a diagnosis, especially for ill patients admitted with unusual or vague symptoms or for patients who appear to be from 'high-risk' groups. Nurses must be particularly careful in these cases. It is their legal duty, as well as that of the doctor, to ensure that every patient gives their informed consent for the test. This may be difficult if the patient is very ill. However, this does not change the nurse's legal and professional accountability (Nursing and Midwifery Council 2003b).

Local anonymous HIV seroprevalence surveys These surveys are carried out by hospital departments who use part of blood samples, given for other purposes, to screen for HIV seroprevalence in a given locality or patient group. This is perfectly legal as long as the patients are informed that this procedure may be carried out. The sample has to be made anonymous and the result is not given to the patient.

Controversy has arisen surrounding this form of testing, particularly when the results are published in medical journals and the media. This is because relatively small numbers of patients are highlighted. For example, 1000 or so pregnant women may be screened, of whom 15 are shown to be HIV antibody-positive. Some publications may break this down even further and state that, of these 15, eight came from a particular place. This narrows down the numbers so much that many people are of the opinion that it compromises anonymity.

National Anonymous Survey of the Seroprevalence of HIV This is an ongoing survey directed by the Department of Health and organised by the Health Protection Agency. As in local surveys, surplus blood from patient samples is used. Again the patients do not have to give specific consent, but they must be informed that their blood may be used. This is done via a multilingual poster campaign and through the nursing and medical professions. The samples are made anonymous, but certain pieces of information, such as gender, age and geographical area, remain with the sample. The various governmental and professional organisations concerned, including nursing and midwifery, meet in a special forum to monitor and improve the project. The results are published nationally with a breakdown of regions and other groups.

Advantages and disadvantages of anonymous testing

Voluntary, informed testing with counselling allows the HIV seropositive individual to be referred to the appropriate services. Ethically and practically, this form is best for patient and professional carer alike. However, in the public perception, the risk of HIV appears to centre around minority groups. Most people do not feel they are at risk. Of those who do feel some risk, most do not think they need to be tested.

Anonymous testing is the compromise that has emerged to satisfy, on the one hand, the need of professionals to find out how many people are, or are likely to be, affected and, on the other, the personal and civil liberties of individuals. Some professionals argue that not enough political effort has been made to increase the uptake of voluntary named testing. As HIV care improves, it is becoming clearer that the earlier an individual knows the diagnosis and is referred to medical and nursing services, the better.

This presents one of the ethical dilemmas of anonymous testing. As the number of anonymous positive samples increases, it will become apparent that, for instance, X number of pregnant women and their babies are affected, but nothing can be done for them because they are unknown. Another objection made by some is that testing babies is an underhand way of testing mothers and that as the number of known but unnamed HIV-positive babies increases, the government will be forced to establish Draconian measures such as mandatory testing for all mothers. Many professionals would argue, however, that the more we know about national and local prevalence, the more we can target services.

In these matters, the rights of the individual must be balanced against the rights of the community. Nurses are bound to uphold the rights of the individual, but they also have a duty towards the community. These obligations are not mutually exclusive, but require that the issues are considered from every viewpoint. The professional bodies provide guidelines on many of the more contentious issues. It may be fair to say, however, that nurses should generally 'err' on the side of the individual patient, for the nurse is sometimes their only advocate (Nursing and Midwifery Council 2003b)

Targeted screening Until the National Survey, screening took place almost exclusively in specialist areas and among particular groups who were considered 'high risk'. Although the information gleaned from this work was useful, it was incomplete, yielding little knowledge about the population at large. Moreover, HIV would always seem to affect mainly homosexuals or drug users if most of the samples continued to be taken from those groups.

'Opt out' testing In some areas of the UK, this has been introduced as part of antenatal screening and sexually transmitted infection screening. The client has to say they do not wish the test, otherwise it will be carried out.

Counselling

While a comprehensive guide to counselling cannot be presented here, the following offers a few basic principles:

- Counselling is a helpful tool, among other tools, which may be used to assist the patient. It is not an end in itself. One person with AIDS half-jokingly remarked: 'Nurses are so keen to counsel me, it seems they forget I have practical needs. Sometimes I feel I'm being counselled to death!'.
- Counselling is not advice-giving. Patients often ask: 'What would you do, nurse?', but the nurse must seriously consider the relevance of their reply. Advice of the 'If I were you ...' type is rarely appropriate.
- Counselling is not about getting the patient to do the 'right' thing; for example, a young, pregnant, HIV-seropositive woman cannot be 'counselled' to have, or not to have, an abortion.
- Counselling is about helping someone come to their own decisions.
- Counselling is an exploration made by two people of issues and problems. The counsellor is an equal partner whose personal opinion is very often not relevant, although it may come up in the course of the conversation.
- It is difficult to counsel and do something else. On many occasions nurses gain the patient's confidence in the process of delivering clinical and personal services. This is a good entry into the counselling relationship, as is the provision of accurate information. To achieve the equality necessary, it is advisable to be in a neutral place on an eye-to-eye level. This is difficult if the patient is lying down with few clothes on with the nurse standing over them!
- Good counselling does not have to take a long time. Some practitioners think counselling is 'rather fancy' and too time-consuming for the busy clinical situation. This is not the case. Effective counselling can be

achieved in half an hour or less, especially if the counsellor gives the individual their undivided attention.
- Know your limitations. During a session it may become apparent to the counsellor that they are getting into areas where one or both parties feel they cannot cope or are out of their depth. There is no shame in this. Seek appropriate help. No one is supposed to have all the answers.

Pre- and post-test counselling

Nurses are often asked to give pre- and post-test counselling. It is essential that the nurse is proficient in attempting this. Courses are now available in many authorities. Counselling in other clinical areas, especially oncology, genetics and palliative care, can provide very good experience. The counsellor must have sound clinical knowledge, as unusual questions which are worrying the patient will often be encountered.

Pre-test counselling will involve the following:

- Establishing why the individual wants to be tested. Many people come armed with misconceptions. Clinical factors must also be established. A patient of the author's came seeking the test and a termination of pregnancy. She thought her partner was HIV-positive and that her baby would die of AIDS. When she was investigated it was found that she was, in fact, not pregnant. Her partner's HIV status was not known, but because she had been worrying, she had imagined the very worst.
- Exploring the 'pros and cons', for that individual, of having the test. Is it appropriate? Should they wait for 3–6 months? Have they been at risk?
- Considering the implications of a positive result. Most people come for a negative result, in order to be reassured.

Most dedicated test centres offer a next day, and some a same day, result service. Ideally the same counsellor should give the person the result, but in the hospital setting the result is often given by the doctor.

If the result is negative, it is important that the individual knows how to avoid risk in the future and whether it is advisable to come back for a repeat test in, for example, 6 months' and 1 year's time. If the result is positive, the counsellor may want to be accompanied by a colleague who can be on hand to assist. There is no good way of divulging such devastating news. Experts in the field often say that every time they have to do so, it is different and that it does not get easier.

37.3 When helping a person in distress with a condition such as HIV, black-and-white answers seldom fit. Here are some true situations. How can you help?

Remember: What you think is 'right' may not help you or the patient.

(a) A patient is found to be HIV-positive. He understands the 'duty' he has to tell his partner but does not know how to do it and 'cannot go through with it'. How do you help him?

(b) A patient who is demonstrating signs of serious illness has been advised to have the HIV test. She does not want to and asks you as the nurse to help her. What do you do?

(c) A colleague of yours receives a needlestick injury from a suspected drug user. There is pressure to test the drug user to see if he has HIV. What is your view of the matter?

(d) A patient with HIV tells you that he is scared of becoming ill and wants to die now. Is he depressed? Is there any hope? How do you cope when you can't say 'It'll be all right'?

(e) A patient tells you of a 'high-risk' activity he has engaged in. You want to help him. How do you reassure him without lying? On the other hand, how do you tell him the truth without panicking him or making him behave rashly?

In all of these situations, where do your 'loyalties' lie? To whom are you accountable or responsible — the patient, the public, the government, yourself, your profession?

HEALTH EDUCATION AND PROMOTION IN HIV

Caplan's (1961) classic model describes health education and promotion as having three parts:

- *primary* — preventing occurrence of the disease; providing education, raising awareness, giving information
- *secondary* — detecting disease early; screening, performing individual testing
- *tertiary* — preventing deterioration of individuals affected, giving support.

These general aims must be responsive to the physical, mental, emotional, spiritual and societal needs of the individual (Catalan 1999, Ewles & Simnett 2003).

Health promotion in HIV/AIDS entails more than raising general public awareness through mass media campaigns. It can also involve such activities as providing assertiveness training for individuals affected and helping them to learn self-care and nurturing skills. HIV awareness also has implications for the workplace, raising concerns about working practice and hiring policies. Legal and ethical issues must also be grappled with by nurses working with people who are involved in illicit drug use and prostitution and who consequently face particular difficulties.

To become equipped to operate on so many levels, the reader is urged to read not only 'mainstream' publications on health promotion, such as Ewles and Simnett (2003), but also books which demonstrate particular perspectives. Stine (2000) presents not only the clinical reality but also provides extracts from the media about experience, politics and ethical dilemmas. These may help the reader to take a more analytical view of large-scale media campaigns.

Elements of health promotion

Targeting the 'audience'

The way in which HIV educators convey their message sometimes seems to contradict the message itself. For example, the maxim that 'there are no high-risk groups, only high-risk activities' is generally 'targeted' at drug users, prostitutes and gay men, which may amount to ideological double talk.

The labelling of whole groups as being 'at risk' is not precise. A gay man, for example, is not at risk if he refrains

from unprotected sexual intercourse. An i.v. drug user who does not share injecting equipment is also not at risk from HIV, although impure street drugs are themselves a risk. These individuals are not at risk merely because they can be labelled 'gay' or 'drug user'; rather, people are at risk if they undertake a high-risk activity.

Advertisers and health educators, however, record that certain groups have certain behaviour patterns in common. It makes sense, therefore, to target these groups with certain services and messages, always remembering that general patterns will not fully reflect the complexity of individuals.

Initiatives vary and take on cultural differences around the world, from the 'light touch' of fun days and health awareness messages on beer mats, to in-depth and detailed information provided for particular groups of individuals displaying high-risk behaviour, e.g. pregnant women who use illicit drugs intravenously. It should be remembered that individuals move through different groups. A good example in this context is the young, adult holidaymaker whose behaviour, during most of the year, would not be considered at risk but who may be considered high risk when on holiday. Several initiatives around the world address this issue.

The right medium and the right message

Leaflets are frequently used in various kinds of information campaigns because they are very simple to distribute. Most people in the UK can read, and by means of leaflets, information can be placed unequivocally in the hands of the target audience. Unfortunately, research over the years has shown that people tend not to read unsolicited leaflets. While they can be an excellent written adjunct to a spoken session, leaflets are of limited use 'cold'.

The first public message from the UK government came in the form of an open letter from the Chief Medical Officer at the Department of Health, warning of the risks of HIV. This message was published in all the national newspapers. Following this, there was a leaflet drop to every household in the UK and a poster and television campaign. The commercials and posters carried the slogan 'Don't die of ignorance' but did not go into clinical detail. They were designed to raise awareness. The National AIDS Helpline was set up where people could, and still can, phone free to speak to a trained telephone counsellor.

Although the early health promotion approaches did prompt some reduction in high-risk behaviour, research subsequently showed that general messages warning of danger and giving non-specific information were of limited efficacy. Over the years, mass media messages have therefore become much more specific, aiming at particular individuals and behaviour groups.

Although HIV education through the mass media has some degree of effectiveness, this kind of communication, no matter how expert, always has a high degree of 'wastage'. Even the most successful television advertising campaigns can only expect to 'reach', i.e. to elicit sales from, 2% of the adult population. However, as long as this form of health promotion is successful in influencing the behaviour of some people for their own benefit and that of the larger community, mass media information campaigns must continue to constitute a vital part of the battle against HIV.

37.4 Some people feel that health promotion needs to change radically as its HIV-related messages, such as those about 'safer sex', are not getting through to those at risk. What is your evaluation of current HIV-related health messages?

The nurse's role

Given the limitations of mass communications in influencing behaviour, nurses must take every opportunity to make general messages relevant to the patients in their care. Nurses have always been involved in assisting patients to understand their treatment, and in answering their questions in terms that can be understood. In doing so, they require sound clinical knowledge together with an understanding of the patient's needs, lifestyle and expectations, as obtained from the nursing assessment.

One of the nurse's greatest advantages as a health educator lies in the opportunities to be with the patient for long periods of time in a position of trust. Many other health care professionals see the patient only during short visits and often have to work harder to establish a rapport (Bishop & Scudder 1990). Nevertheless, the nurse may still experience difficulty in discussing sexual matters and sexuality with patients. Public campaigns are restricted by legislation and 'public taste', and it may be left to the nurse to provide more explicit information. Personal value judgements, embarrassment and questions of status may present obstacles. Answering questions on, for example, oral sex from a person of a different sexual persuasion to oneself may be difficult. Speaking to an underage person who is sexually active may be embarrassing and raise ethical questions. Many practitioners become expert at putting up verbal and non-verbal barriers so that such discussions are avoided.

Despite this potential for awkwardness or discomfort, it is clear, given the devastating effects of HIV, how important it is for nurses to fulfil their obligations as health educators. It is strongly suggested that the reader find an expert practitioner who can act as a role model and mentor. Attending an education course may also help. It is not suggested the nurse must necessarily change their opinion about certain issues or that they must agree with what each patient has to say. However, caring must be unconditional, answering to the patient's needs regardless of the nurse's personal values.

A mentor can also help the less experienced practitioner to deal with difficult, sometimes ethical, issues. Patients sometimes give the nurse information about past actions which places the nurse in a difficult position. In such cases, nurses at all levels should seek advice, whilst ensuring that patient confidentiality is maintained. Under the Nursing and Midwifery Council guidelines (2004), the nurse is judged both on confidentiality and on the accounts given of personal actions in a difficult situation. To give an example, the author once looked after an HIV antibody-positive 15-year-old individual who was having penetrative sex with an underage female partner who lived with her parents. The situation was discussed and acted upon, keeping the confidentiality of all parties. The 15-year-old was assisted to approach the partner and her parents accompanied by nursing staff. Although, in this case, the medical consultant had the power to make an approach without consent,

sensitive work with the patient made this unnecessary and a good working relationship was maintained.

Nurses, particularly those working as health advisors within sexual health services, have an extremely important role in HIV. Partner notification work, for example, requires a sensitive and expert approach.

Health educators are sometimes faced with the dilemma that encouraging safe practice and encouraging someone to break the law seem to amount to the same thing. For example, nurses are now involved in giving drug users clean needles and syringes. This practice has government and professional support. Is it correct, however, for the nurse to tell the patient how to inject safely or to use one form of drug instead of another? (see Ch. 36). In the face of a bleak prognosis, the practitioner may see no option but to fall back on the pragmatic principle of 'harm reduction' rather than to insist upon an ideal. In such a situation the nurse should seek guidance and support from management (Crouch 2003, Johnson 2003, Donovan 2004).

Group work Nurses are increasingly becoming involved in working with groups, particularly in the community. These may be self-help groups or people attending a clinic for a particular service. Whether the nurse personally sets up the group, or 'piggy-backs' a service onto an existing group, the results can be significant. By speaking to a small number, answering questions members of the group want to ask and offering individuals the opportunity to speak in private afterwards, the nurse can make health education messages personally relevant.

For further information on the formal and informal intricacies of setting up groups, agendas and action plans, see Ewles & Simnett (2003).

CLINICAL MANIFESTATIONS AND MANAGEMENT OF HIV/AIDS

People with HIV disease rarely get all of the diseases associated with AIDS (see Box 37.1), and often those that do occur manifest one at a time. The precise course of the illness is virtually impossible to predict. A number of patients of the author seemed so close to death in late 1987 that it seemed cruel to persist with medication; however, between 2000 and 2004, the author has seen or heard news of some of them, although others have died.

The treatment of AIDS is a rapidly developing field. This section will therefore present a matrix of available approaches that can be used by the nurse as a conceptual and practical framework as the medical and nursing management of HIV/AIDS advances.

Approaches to nursing care

Pratt (2003) provides detailed strategies and philosophies for ward and service management. The author has used a process based on Roy's adaptation model (Andrews & Roy 1997) which takes into account the following aspects of the patient's illness experience:

- physiological adaptation — clinical signs, disease process
- self-concept adaptation — anxiety, aggression, grief, social belonging
- role function adaptation, e.g. as a parent, a partner, a worker — sense of failure, sense of conflict
- interdependency adaptation — loneliness, rejection, social interaction.

These four 'adaptive modes' are placed in the context of three 'stimuli':

- focal, e.g. the surrounding facilities, services available; other people
- contextual, e.g. space available, distance to toilet, room temperature
- residual, e.g. personal beliefs, prejudices, personal qualities.

The nurse applying this model, having identified a clinical problem, e.g. the patient's sudden inability to walk, will consider not only the medication and treatment but also the patient's ability to function and adapt. This is then put alongside the practicalities of the stimuli. Are the facilities at home suitable? How far is it to the toilet? Can the patient cope with a commode in the front room? Will they let their partner look after them?

Roy's model is also useful as it helps the nurse consider all the adaptations needed to make an individual service effective. Does the present service or nursing procedure need to change? Does the environment suit the patient? Does the patient need to modify their lifestyle? How can the nurse foster the necessary changes? The adaptation model encourages a flexible approach by nurse and patient in both hospital and community care settings.

People with HIV may present with seemingly minor problems which cannot always be diagnosed or predicted. For example, an individual may suffer weight loss, difficulty in swallowing, anorexia, night sweats, lethargy, mouth ulcers, diarrhoea and/or constipation. In addition to this, they may become depressed and desperate, as such conditions, even if not in themselves life threatening, can be very distressing. A patient of the author's had, over 2 years, contracted two serious bouts of PCP. He had borne these very well. However, he became severely depressed some time later when he was back at work. Having contracted oral thrush, he could not swallow properly and was losing weight. This made him feel powerless and he said it was worse than the 'serious' illnesses. Such examples serve to remind the practitioner that the seriousness of a condition cannot be judged strictly by clinical criteria. Moreover, by taking notice of even the smallest signs and taking action, nurses can help many patients remain alive. Many HIV-related conditions, if diagnosed early, respond well to treatment.

Infection control

For general principles of infection control, the reader is referred to Chapter 16. The essence of infection control with HIV is to use standard infection control precautions (SICPs) to protect the patient who will be at increased risk of health care associated infection (HAI) (Wilson 2001). Care should be taken with all body fluids, and gloves and aprons should be used for intimate procedures. Because of the damaged

immune system, the patient may be more at risk from the nurse than the other way round.

For further information on HIV-related infection control, see Chapter 14 in Pratt (2003).

In the home, basic hygiene is to be encouraged and clothes and bedding should be washed in a washing machine. Disposal of medical waste should be carried out in accordance with local nursing policies and procedures. Needles and syringes found in the street are the responsibility of the Environmental Health Department, although health care professionals finding them have a duty to minimise the risk of injury to themselves and others where possible.

CONDITIONS, TREATMENTS AND SPECIFIC NURSING INTERVENTIONS

What follows is a description of the main presenting infections, conditions and treatments associated with HIV and AIDS (see Box 37.1).

For further information, the following are recommended: Pratt (2003) for discussion of nursing strategy; Stine (2000) and Shaw & Mahoney (2003) for an American perspective. Shaw and Mahoney also have a very helpful presentation by answering stated questions, e.g. 'What do you do ...', as well as sections on other infections and complementary therapies.

At present there is no vaccine against AIDS. Research is advancing and expectations of a vaccine to provide immunity against HIV are still cited by various establishments as being from 5 to 10 years away. Although there are various treatments which ameliorate the effects of viruses, there has never been anything in the nature of a broad-spectrum antibiotic which actually kills viruses. Antiviral agents which suppress HIV will be discussed later.

Possibilities for fighting and killing the virus are therefore limited. The best success has been in the area of symptomatic control, i.e. stopping or slowing the associated diseases and conditions which can kill the patient. The other main aim of care is to improve the patient's quality of life. There is thus a similarity between AIDS nursing and oncology and palliative care.

At the beginning of the epidemic, the life expectancy of someone diagnosed as having AIDS ranged from a few weeks to 2 years. Patients receiving care, particularly those in affluent countries, can now live for 10 years or more. As described earlier, when comparing HIV disease with other life-threatening conditions such as cancer or diabetes mellitus, which similarly depend on symptomatic control but for which there is a much longer life expectancy, it becomes apparent that the care of HIV-related illness continues to be in a developing stage.

The general progress of HIV-related illness is represented in Figure 37.2 (p. 1174).

Phases of HIV and AIDS

Phase A: acute seroconversion illness

In most individuals this illness is not recognised. It may be seen 2–6 weeks after exposure to HIV. Not everyone infected with HIV gets this flu- or glandular fever-like condition. It may be associated with joint pain and other non-specific signs. A skin rash is sometimes seen, as are swollen lymph glands; these usually reduce after some time. At this stage the body will be producing HIV antibodies (seroconversion). A few individuals may also show early signs of HIV affecting the central nervous system, particularly the layers of the brain, e.g. encephalopathy, meningitis (see Ch. 9).

Treatment of seroconversion illness is symptomatic and does not usually take place in hospital. For the alert doctor and nurse, the illness may be a useful diagnostic warning, rather as the presence of a thirst and boils suggests diabetes. However, the signs are very similar to those of many minor infections.

Phase B: antibody-positive phase

B-1: asymptomatic HIV infection As HIV has only been recognised for approximately 25 years, one can only state that the period between infection and the onset of clinical signs may be anything from a few weeks to 20+ years. From this fact it may be seen that procedures such as contact tracing are not as simple or effective as in other sexually transmitted disease, as the asymptomatic period commonly covers much of an individual's sexually active life.

B-2: persistent generalised lymphadenopathy (PGL) or lymphadenopathy syndrome (LAS) This condition is sometimes the one which alerts medical services to investigate for HIV. The individual presents with swollen glands of more than 1 cm which persist for longer than 12 weeks. Although the individual may have swollen inguinal glands, they must also have other affected glands. Other reasons for swollen glands must be discounted before a diagnosis is given. As this is often the 'introductory' stage of HIV illness, monitoring of helper T cells and suppressor T cells (via the $CD4^+$ T-cell procedure; see Appendix 1) and other investigations may begin. It is at this stage that the individual may be tested for HIV for the first time.

Phase C

This phase refers to a period in an individual's illness career where they may contract a variety of well-known conditions, but not major, life-threatening, opportunistic infections or cancers. Common bacterial, viral and fungal infections frequently occur and are often marked by their persistence and virulence. Oral and genital herpes or athlete's foot are good examples. In a normally healthy person, these conditions would resolve within a few days. In phase C, the duration of the infection is lengthened and the whole foot, for instance, may become affected. Other conditions such as oral hairy leukoplakia are sometimes seen.

Loss of weight may be seen at this stage. This may be due to a specific mechanical problem, such as mouth ulcers, or from persistent low-grade attacks from infections. At this stage a significant drop may be seen in the helper T cells. In day-to-day practice, nurses should bear in mind that young, healthy people should overcome common infections quickly without them becoming widespread. Any persistent condition, e.g. coughing, loss of weight, should be noted. While thrush (*Candida albicans*) is common in the vagina, it is

very uncommon in the mouth of a young healthy person. Such an occurrence should immediately alert the practitioner to the fact that the individual may have an underlying condition such as HIV.

The nurse working with diagnosed patients should also be aware that, since the positive diagnosis, the individual will have been dreading the onset of illness. When weight loss, mouth ulcers or fungal infections occur, the patient may become acutely anxious, considering themselves to be in imminent danger of pain or death. Other professionals, such as clinical psychologists, can assist the patient during these periods. Involvement of the patient in all stages of decision making and treatment right from the start will assist them to take control of their condition and reduce any feeling of helplessness.

Box 37.4 summarises treatments and medications used in various conditions associated with Phase C.

Phase D: AIDS — constitutional disease, opportunistic infections, secondary cancers

Constitutional disease: HIV wasting syndrome The diagnosis of AIDS depends on an individual being diagnosed as HIV antibody-positive, plus being diagnosed as having one of the life-threatening opportunistic infections or secondary cancers associated with HIV. However, a third criterion has come more to the fore, namely the constitutional or systemic condition known as HIV wasting syndrome. This has arisen from the experience in Africa, where AIDS is called 'slim disease'. In the West, it is also increasingly recognised that some individuals become extremely ill, losing excessive amounts of weight, more than 10% body mass, and suffering from morbid weakness and loss of function with or without having the 'label' of one of the listed conditions. In the USA, 19% of adults with AIDS are diagnosed as having HIV wasting syndrome (Kirton 2003).

The causes of HIV wasting syndrome may be mechanical or systemic. As mentioned before, people lose weight if there are factors such as mouth ulcers and sickness which deter them from eating. Malabsorption may also be seen and may be due to the presence of a lesion such as Kaposi's sarcoma in the gut or to a more generalised dysfunction. In all these cases the patient is starved of nutrients.

Wasting may also occur as a result of metabolic changes. As in cancerous conditions, the body may go from its normal balance of catabolism and anabolism into a catabolic crisis in which body mass is 'burnt up' at an increased and dangerous rate, often causing irreparable damage. These patients may recover some weight but they often do not recover muscle mass (Stine 2000, Shaw & Mahoney 2003).

Supervised nutritional rehabilitation is therefore necessary. This may include nutritional supplements and more invasive therapy such as continuous or intermittent parenteral feeding. However, it is as well to remember that the nurse can play a life-saving role in the attention given to the ordinary nutritional service to the patient.

Opportunistic infections: protozoal Some of the protozoal infections which may occur in AIDS are as follows.

Pneumocystis carinii pneumonia (PCP; pneumocystosis) Approximately 60% of individuals contract PCP as the first AIDS-related infection. Because the vast majority of people diagnosed as having AIDS have been unaware of their HIV status, many people who have contracted PCP for the first time present not to specialist units but to Emergency Departments, GPs' offices and other non-specialist areas.

Box 37.4

Key nursing care issues

Diarrhoea
Immediate monitoring of hydration and nutrition should start with the help of a dietitian.

Weight loss
Measurements of muscle and fat loss should be included in the care programme. Eating patterns should be discussed along with ways of increasing intake, e.g. taking frequent, smaller meals and perhaps supplementary feeds such as Ensure.

Fluid and electrolyte replacement is essential. Codeine phosphate, loperamide hydrochloride and diphenoxylate hydrochloride may be useful, but it is emphasised that medication should always be given in combination with dietary monitoring and therapy (see Chs 20 and 21).

Herpes simplex
Aciclovir is used. Prophylactic doses may also be given.

Herpes zoster
Mouth and lip care are important to prevent cracking and secondary infection. Soothing lotions and loose clothing may be appropriate for attacks of shingles. Sleep, fluid intake and diet should be monitored.

Seborrhoeic dermatitis/skin care
Salicylic acid and tar-based lotions are used. Low-dose steroids and steroid/antibiotic/antifungal combinations, e.g. clobetasone butyrate (Trimovate) are sometimes used for short periods. Responding to the individual patient's discomfort is important. Giving attention to small details in order to alleviate the irritation of skin conditions is one of the most appreciated nursing services (see Ch. 12).

Tinea pedis
Miconazole and clotrimazole creams are used topically. Systemic griseofulvin is used if the infection is persistent. Keeping the feet dry and comfortable can be helped by such measures as drying with a cool hair dryer and leaving the end of the bed covers loose.

Oral candidiasis
Nystatin antifungal topical drops may be used. However, oral thrush is often persistent in HIV illness, in which case systemic fluconazole is used (see Ch. 15). Mouth care is vital, as is a high fluid intake. Some patients find mouth rinsing with benzydamide hydrochloride, which has anaesthetic properties, helpful. Others rinse with fizzy water or diet cola to relieve discomfort, a valued practice that is not yet supported by research evidence.

Oral hairy leukoplakia
Aciclovir is used. Mouth care is again essential.

Ongoing support
Nurse-led clinics are now an important source of support, particularly around the time of starting highly active antiretroviral therapy (HAART).

Based on data from Pratt (2003) and Shaw & Mahoney (2003).

Although PCP is the most common cause of death in AIDS, the organism responsible, *Pneumocystis carinii* (now also known as *Pneumocystis jiroveci*), can be found, quite normally, in most human beings. However, in health, the immune system keeps the population of the organism at an acceptable level. When the immune system is compromised, the level rises and causes severe, life-threatening pneumonia. The individual usually presents with a 2–5 week history of increasing shortness of breath, weakness and dry cough; cyanosis is often seen (Stine 2000, Adler 2001, Pratt 2003).

A variety of drugs is used in the treatment of PCP: co-trimoxazole for mild to moderate episodes and pentamidine isetionate for moderate to severe episodes. Aerosolised pentamidine may be used as a treatment and as a prophylactic measure.

Cryptosporidiosis This condition has some notoriety because of the sometimes devastating diarrhoea it causes and because high levels of the organism in the general water supply are often reported in the news. It is caused by a protozoan which is normally present in small quantities in the water supply. In immunocompromised patients, it rises to high levels in the gastrointestinal tract and causes diarrhoea. The loss of fluid can be as much as 10–20 L/day, although less virulent attacks are also seen.

Cryptosporidiosis is generally seen only in patients who are already very ill and have suffered other infections. It is very difficult to manage this condition at home, as i.v. fluid replacement and constant bowel movements will need attention. For the patient, this condition may mean an extremely poor state of health and hospitalisation. In its worst form, it is an extremely distressing condition for both the patient and carers. There is no specific curative therapy for this infection. Highly active antiretroviral therapy (HAART; see p. 1186) is associated with clinical improvement. Treatment with antidiarrhoeals, oral or i.v. rehydration and nutritional support will be required.

Toxoplasmosis The causative protozoan is sometimes associated with cats and raw meat, although it does not generally manifest itself as a disease in healthy people. Its most common manifestation is cerebral toxoplasmosis. The organism causes space-occupying lesions in the brain. These create cerebral oedema and raised intracranial pressure. The patient suffers the usual signs of these conditions: paralysis and unconsciousness (see Ch. 9). Toxoplasmosis is often fatal and treatment must be prolonged as relapses are almost inevitable. The main medication is co-trimoxazole, or dapsone with pyrimethamine. In the most serious cases, constant nursing attention is needed as the patient's condition may deteriorate rapidly (Stine 2000, Adler 2001, Pratt 2003).

Opportunistic infections: viral The most common of these are described below.

Herpes simplex virus This condition has been mentioned in association with early phases, where it occurs in its less virulent forms. Serious and life-threatening forms, e.g. encephalitis, are sometimes seen, affecting the central nervous system (Pratt 2003). Aciclovir is used in treatment.

Cytomegalovirus (CMV) This virus is encountered in general practice and in midwifery, where it is known to cause spontaneous abortion. In HIV-related illness it is most commonly seen causing CMV retinitis. Small 'cotton buds' are seen on the retina on examination. The patient may then rapidly become blind, a deterioration which can occur in the space of a few days. Treatment with ganciclovir, foscarnet sodium or cidofovir i.v. is given. These may be given in the hospital setting, but increasingly are given at home. Improvement is seen with treatment but relapse occurs in almost all cases.

CMV retinitis can have a devastating affect on both the patient's morale and state of mind. Two of the author's patients decided to stop all treatment once they became blind, whereupon other illness and death followed quite quickly. This demonstrated to the author the vital importance of the patient's will to live when combating HIV-related illness.

Progressive multifocal leucoencephalopathy (PML) This unusual disease is caused by JC virus, a type of papovavirus, and results in demyelination. Conditions most likely to be seen are blindness, hemiparesis, ataxia and aphasia (Adler 2001). Antiretroviral therapy with zidovudine-containing regimens may provide dramatic improvement in this late-stage, crippling condition (Pratt 2003).

Opportunistic infections: bacterial The following bacterial infections may be seen in people with AIDS (see also Ch. 16).

Mycobacterium tuberculosis (TB) Tuberculosis is now increasingly seen in patients with HIV and is often associated with poor social conditions and increasingly in vulnerable groups such as asylum seekers. Prisons around the world have seen an increase in TB prevalence, particularly where there is a high prevalence of HIV. Prisoners with HIV are affected, as are other vulnerable inmates. Treatment is with rifampicin, isoniazid, ethambutol and pyrazinamide for a 2-month induction phase and with rifampicin and isoniazid for a 4-month continuation phase. TB in the general population, when treated, is not generally life threatening. Patients with HIV who are infected with TB, however, are often made even weaker by the condition (United Nations 2004).

Salmonellosis As with other compromised and vulnerable individuals, this infection, generally associated with food poisoning, poses a particular danger to people with HIV. Scrupulous care should be taken in food preparation and delivery. Patients should avoid undercooking foods such as eggs and poultry. Hand hygiene is also important (see Ch. 16). Treatment is with chloramphenicol, ampicillin or amoxicillin.

Mycobacterium avium complex (MAC) People in advanced stages of HIV illness are sometimes found to have atypical mycobacteria in their lungs. MAC has become less common since the widespread use of combination antiretroviral therapy (HAART).

Opportunistic infections: fungal

Candidiasis is sometimes seen in virulent manifestations in people with advanced HIV illness. Infection may extend from the mouth to the alimentary tract. Vaginal candidiasis may be particularly persistent and distressing. Nystatin vaginal pessaries and other conventional treatments are used.

Cryptococcus is a systemic fungal condition. Treatment is with amphotericin and fluconazole. Two others are *histoplasmosis*, which affects the lungs, liver and gastrointestinal tract, and *coccidioidomycosis*, which affects any organ, including the brain (Pratt 2003).

Infestation Strictly speaking, infestation is not associated with HIV. However, it should be pointed out that if a patient with HIV happens to become infested with lice or scabies, particularly the variety known as Norwegian scabies, the infection may be particularly virulent, with several thousand times as many mites on the skin as in a patient who is not immunocompromised. Norwegian scabies occasionally strikes hospitals and institutions.

Secondary cancers The immune system has the function, not only of fighting infection, but also of fighting and inhibiting malignant cells. The following two forms of cancer are associated with HIV and an AIDS diagnosis.

Kaposi's sarcoma (KS) This purplish skin cancer was previously seen only in older men of certain races, e.g. Jewish men. With the advent of AIDS in the Western world, it was one of the first manifestations of the condition. As with the opportunistic infections, it is not seen in all patients. As a skin condition it is very disfiguring, particularly when on the face. If it remains in small patches, treatment is often confined to cosmetic camouflage. However, it sometimes forms constricting bands on the skin, e.g. around the ankle. Internally, it may also lead to gastrointestinal obstruction and it is sometimes found in the lungs and other internal organs. Patients with visceral or advanced KS are treated with radiotherapy or systemic chemotherapy. With widespread adoption of safer sex practices and the introduction of HAART, the incidence of KS has declined dramatically (Adler 2001).

Non-Hodgkin's lymphomas (B-cell lymphomas, undifferentiated lymphomas) These cancers are seen in much higher numbers among people with AIDS than in the general population. They are found in the central nervous system, the bone marrow and the gastrointestinal tract. They are often rapidly fatal and treatment is often not successful. Various chemotherapies may be used (see Ch. 31).

Neurological disease; HIV encephalopathy HIV neurological disease is not an opportunistic infection. It is the human immunodeficiency virus directly affecting the central nervous system, including the covering of the brain. It may manifest early on as peripheral neuropathy, in its many forms, and later progress to affect the individual's personality and lucidity. Eventually the person may suffer dementia. One of the problems in diagnosing this condition is that changes in computed tomograms (CT scans) do not necessarily accompany changes in behaviour; it is possible for a patient with a normal CT to experience dementia.

Acute viral encephalitis can occur in late symptomatic HIV disease caused by reactivation of latent cytomegalovirus (CMV) or herpes simplex virus (HSV) infection.

Nursing care of the various conditions associated with neurological disease and encephalopathy is often challenging in terms of both short- and long-term care. Remissions can occur but there can be periods of despair for the individual. One of the author's patients, who refused to be cared for in hospital, having spent long periods in prison and being afraid of institutions, was cared for at home. He began to suffer from forgetfulness, personality changes and eventually showed signs of dementia. This was distressing for him, as he often had insight into his condition; in these lucid periods he would sometimes say he wanted to end his life.

On a more optimistic note, however, HIV neurological disease does appear to respond well to antiviral therapy. Many patients show a marked improvement as well as a slowing down of the advancement of the disease.

Antiretroviral therapy

Since the mid-1990s, antiretroviral treatment has developed significantly and made a considerable impact in reducing HIV-related morbidity and mortality. Treatment aims to reduce the plasma HIV RNA level — the viral load; Table 37.1 shows medication currently available in the UK. These medications target two specific viral enzymes necessary for HIV replication: reverse transcriptase and protease. Fusion inhibitors prevent HIV attaching to receptor sites on the surface of host cells that HIV targets for infection, and entering the cells.

Highly active antiretroviral therapy (HAART)

The normal treatment pattern is with a combination of three, four or five medications, occasionally six in 'salvage' therapy. HAART is started in all symptomatic patients, in those who have a high rate of viral replication and before irreversible damage to the immune system occurs. A range of serious side-effects is associated with these medications and adherence to HAART is a major issue. Adverse effects include kidney and liver toxicity, hyperglycaemia, raised plasma levels of triglycerides and cholesterol, lipodystrophy, hypersensitivity reactions and peripheral neuropathy. The

Table 37.1 Antiretroviral medication used in the UK, 2004

Generic name	Proprietary name
Nucleoside reverse transcriptase inhibitors	
Emtricitabine	Emtriva
Didanosine	Videx
Lamivudine/zidovudine	Combivir
Lamivudine	Epivir
AZT	Retrovir
Lamivudine/zidovudine/abacavir	Trizivir
Stavudine	Zerit
Abacavir	Ziagen
Zalcitabine	Hivid
Nucleotide reverse transcriptase inhibitors	
Tenofovir	Viread
Non-nucleoside reverse transcriptase inhibitors	
Efavirenz	Sustiva
Nevirapine	Viramune
Protease inhibitors	
Amprenavir	Agenerase
Nelfinavir	Viracept
Lopinavir/ritonavir	Kaletra
Ritonavir	Norvir
Indinavir	Crixivan
Saquinavir soft gel caps	Fortovase
Saquinavir hard gel caps	Invirase
Fusion inhibitors	
Enfuvirtide	Fuzeon

commitment to HAART is for life and GPs and practice nurses particularly have an important role in supporting patients in adhering to these challenging medication regimens. There have been advances to improve pill burden and once-daily regimens are now popular. Antiretroviral medications are also extremely expensive and ways of reducing costs are being explored.

For further information on side-effects and adherence to antiretroviral therapy, see Loveday (2003).

CONCLUSION

HIV and its related diseases continue to challenge health services throughout the world. The irony, described earlier, of discontinuing the specialism of fever nurses, just when AIDS was first recognised, as though infectious disease were yesterday's problem, has been further compounded by the emergence of widespread resistant tuberculosis and hepatitis C. In future years, perhaps AIDS and other intractable infectious diseases will be considered together rather than as separate and distinct specialties.

Whatever the future of AIDS as a specialty, it will remain important that nurses stay involved with their patients and not aloof. More than ever before, nurses appreciate that they are privileged to be admitted into the trust of their patients. In the field of HIV, as in other palliative care, nurses become very deeply involved in their patients' lives and in their experience of dying (McIntyre 2001).

The nursing care of people with HIV has seen a real growth in innovative practice. Work with drug users, prisoners, prostitutes and other marginalised people has meant that nurses are increasingly working in non-traditional areas, using new procedures. Many myths have been shattered, particularly with regard to the amount of sophisticated equipment that was thought necessary to provide care. High-level nursing care is now given in the poorest areas and in the most difficult of circumstances across the world (Coleblunders et al 2000, Fleck 2003, Kawonza 2003). What is also interesting, and encouraging, is that the move to treatment of AIDS in developing and poor countries has also supported the strengthening of palliative care globally (Stjernsward 2002, Kikule 2003).

Family recognition People with HIV and AIDS, as with the rest of the population, have a variety of domestic arrangements and relationships, and the nurse would do well to take the widest view of the terms 'family' and 'next of kin'. It is distressing to watch courtesy and kindness being shown to the 'official' family and next of kin, who may be estranged, while the patient's lifelong partner and the people they choose to spend every day with are pushed out of the picture. The author has seen this happen to both homosexual and heterosexual patients. In such matters, the nurse should take the lead from the patient and not entirely from the admission form.

Spirituality does not always manifest itself as the embracing of a formal religion. When an individual is seriously ill, they may 'plug into the infinite' in many ways. One of the author's patients found solace in a trip to the opera. Another, who had gone blind, particularly loved sweet-smelling flowers. As an aspiring professional, I used to be rather contemptuous of what I considered sentimental or superstitious behaviour. Experience, however, has taught me some wisdom.

Grieving and the nurse — a personal reflection

Many patients I have cared for have now died. The oldest was 70, the youngest 18. I remember them all, and each one has enhanced my practice. As I write this chapter, their memory is close by, their faces very clear in my mind. I remember when each one died, and each time was an emotional experience. There is some debate as to whether it is a good thing to hang onto disturbing memories. My experience is that it is not a question of deliberately hanging on. When one becomes deeply involved in an individual's living and dying, their memory will live on. It is the nurse's role to bear witness to those memories and to the present experience of each patient alive today. This may be emotional sometimes, but it is not depressing. It is a positive attitude which improves care delivery.

The great and often arduous journey of people with HIV-related illness was brought home to me in late 2003. I was in the kitchen of my home when I heard a familiar voice on the television in the other room. Memories flooded back as I remembered the fun and experiences I had with the owner of that voice. At the time, 14 years previously, this great man, who was HIV positive, and I were often called 'The Twins'. We were both very big (6'4" and over 20 stone) and challenged in the beauty stakes. We would joke about keeping big and alive and would encourage other people to eat. I smiled at the memories and was pleased to hear his voice.

I went in to watch the programme and saw a stranger. How could this worn, thin man be the voice and physique of my friend? It was definitely him, his passion and spirit identified him, but the lines of his struggle were etched in his face. He was talking about how, after many years of relentless treatment, he and many others sometimes took 'holidays' from their treatment, not from despair but for respite. So progress continues to be made, but the experience for the individual is very difficult.

Progress in bringing active treatment to poor and developing countries, rather than adhering to the monolithic position of 'prevention is the only game in town', is becoming a practical reality. Some major companies and employers pay for the treatment of their workers. One executive, interviewed on the BBC Radio 4 business programme in late 2003, stated that this was not charity, but the protection of his workforce, up to a quarter of whom, in some areas, were HIV positive.

In 2005 it was announced that a former minister of the UK government had been HIV positive since 1987. The individual was prompted to make this knowledge public when Nelson Mandela, speaking in 2005 at the funeral of his son, who had died from AIDS, called for the ending of the stigma and secrecy surrounding HIV and AIDS.

Despite these developments, in Northern Europe, there is a decline in articles about HIV in many mainstream journals. Nurses and others do meet people with HIV, but not in great numbers, especially in hospital settings. This situation should not deceive. It is thought-provoking and chilling to consider that, had this terrible disease not taken the lives

of affluent white people in the Northern Hemisphere, it might not appear in a book like this at all. I leave the reader with the words of Nelson Mandela (2003) giving the British Red Cross Humanity Lecture.

HIV/AIDS is having a devastating impact on families, communities, societies and economies. Decades have been chopped from life expectancy and young child mortality is expected to more than double in the most severely affected countries of Africa. AIDS is clearly a disaster, effectively wiping out the development gains of the past decades and sabotaging the future.

It is no less than a war, a world war that affects all of us ultimately. The developing world is, as in so many other cases, suffering the worst while having the least resources to deal with the threat.

APPENDICES

Appendix 1 1193

Appendix 2 1201

APPENDIX 1

TESTS AND INVESTIGATIONS

The following tests and investigations should be seen as terms defined rather than processes described and are used to supplement and clarify reference made to them in the text.

Actigraph

An actigraph or accelerometer is a small electronic device, usually worn on the non-dominant wrist. It is approximately the size of a wrist watch and measures sleep indirectly through its recording of arm movements. Actigraphy is based on the principle that arm movements are linked to wakefulness and not to sleep, thus fewer arm movements are associated with sleep and a greater number of arm movements denote wakefulness. Increasingly, nurses are using actigraphs to monitor patients' sleep.

Amniocentesis

This is a diagnostic procedure performed by inserting a hollow needle through the abdominal wall into the uterus and withdrawing a small amount of fluid from the sac surrounding the fetus. Amniotic fluid contains cells that are normally shed from the fetus. Samples of these cells are obtained by withdrawing some amniotic fluid. The chromosome analysis of these cells can be performed to determine abnormalities.

Angiography

This involves the injection of contrast medium to outline blood vessels. The contrast is injected and rapid serial X-ray films are taken. The presence and location of aneurysms and other blood vessel anomalies such as stenosis are demonstrated. Angiography is not without risk and its performance may be delayed in the patient who is in a poor clinical condition.

Arterial blood gases (ABGs)

This involves a sample of blood being taken from an artery. The blood is analysed and gives arterial oxygen tensions (P_aO_2), the arterial carbon dioxide tension (P_aCO_2) and oxygen saturation. In addition, blood pH, standard bicarbonate and base excess are also estimated.

Arteriography

A radio-opaque dye is injected into an artery and a series of X-rays are taken to show the path of the dye in the arteries and pinpoint any obstruction to blood flow.

Arthroscopy

The direct examination of a joint by the surgical insertion of an arthroscope. The procedure can be performed on an outpatient basis and is used in the diagnosis of injuries. Although it is most commonly used for the knee joint, arthroscopic techniques can also be used for the hip, shoulder, wrist and ankle.

Barium studies

When plain radiography is inadequate to study an area of interest, contrast media can be used. Barium sulphate is an aqueous suspension, which is non-irritant and radiodense. Administered orally or rectally, it allows the gastrointestinal tract to stand out when viewed through a fluoroscope or on a radiograph. Barium studies of the gastrointestinal tract can help in the diagnosis of disorders such as peptic ulceration, malignant tumours, diverticulitis and colitis.

Biopsy

The excision of a small area of tissue for diagnostic purposes. Often used in the diagnosis of breast disease.

Blood count

Calculation of the number of red blood cells, white blood cells and platelets in a litre of blood. A differential blood count is the estimation of the relative proportion of the different blood cells in the blood.

Blood film

Microscopic examination of the cellular components of the blood, i.e. red and white blood cells and platelets.

Red cells

Size: Usually 7 μm in diameter

- Microcytic — smaller than normal
- Normocytic — normal size
- Macrocytic — larger than normal
- Anisocytic — inequality in size.

Shape: Poikilocytic — marked irregularity in shape.
Colour:

- Hypochromic — red cells contain less haemoglobin than normal, resulting in a pale colour
- Normochromic — normal amount of haemoglobin in red blood cells and therefore normal colour.

White cells

Size: Usually 10–15 μm in diameter.
Structure:

- Staining characteristics of granules are different for neutrophils, eosinophils and basophils
- Excessive nuclear lobulation in neutrophils (indication of megaloblastic anaemia, iron deficiency, renal failure).

Cell differentiation between different granulocytes, lymphocytes and monocytes can be performed and commented on in the blood film report.

Platelets

Size: 2–4 μm in diameter.
Structure: Smaller or larger than average occur in certain haematological conditions, e.g. large platelets occur in thrombocytopenia due to platelet loss or destruction or postsplenectomy.

Brodie–Trendelenburg test

This is a test for varicose veins. The patient lies on their back and raises their leg to empty the veins. A tourniquet is applied just below the saphenous opening. The patient is then stood up and the tourniquet removed in 60 s. Normally the vein should fill from below within 35 s with the tourniquet in situ. Earlier filling indicates incompetence of a communicating vein. If, on release, the veins fill rapidly from above, this is due to incompetent saphenofemoral valves.

Bronchoscopy

Endoscopic examination of the trachea and larger bronchi. It is indicated in patients with haemoptysis, suspected lung cancer and chest infections which are not defined by other investigations.

Cardiotocography

The simultaneous monitoring of the fetal heart rate and maternal uterine contractions as a means of monitoring fetal well-being.

$CD4^+$ T-lymphocyte cell counts

Laboratory estimates of the number of $CD4^+$ T lymphocytes in peripheral blood are generally reported as the number of cells per cubic millimetre (cells/mm^3). These estimates and their trends to decrease or increase over time comprise one of the most important laboratory assessments predicting HIV disease progression and response to antiviral therapy.

Cholecystography

Radiological examination of the gall bladder using a radio-opaque contrast medium taken orally. A normal liver will usually remove the radio-opaque medium from the bloodstream and store and concentrate it in the gall bladder. Radiographs taken will show the dye-filled gall bladder as a dense shadow. Gallstones may be seen as filling defects. This technique will not outline the gall bladder when the serum bilirubin concentration is elevated (>34 mmol/L), as insufficient contrast medium is excreted. Although oral cystography is a reliable means of detecting gallstones in non-jaundiced patients, it has been largely superseded by ultrasonography.

Chorionic villus sampling (CVS)

CVS is a prenatal test that involves taking a tiny tissue sample from outside the sac where the fetus develops. The tissue is tested to diagnose or rule out certain birth defects. The test is generally performed between 10 and 12 weeks after a woman's last menstrual period. This investigation may be offered when there is an increased risk of chromosomal or genetic birth defects, and parents would like test results as early in pregnancy as possible. CVS is not routinely offered to all pregnant women because the test carries a small risk of miscarriage, and possibly other complications.

Computerised (axial) tomography (CT scan)

The patient lies on a couch and the head is placed in an opening in the front of the scanner. A series of X-rays are beamed through the patient's head in transaxial slices of various sizes and, depending upon the density of the tissue, are either transmitted or absorbed. Those that are transmitted are detected by a battery of sensitive crystals and this information is then fed to a computer, which creates an image of the scanned structures, e.g. brain tissue. Once one 'sweep' is complete, the machine moves through 1° until an 180° arc has been completed. CT scanning may reveal alterations in tissue density, displacement of structures and abnormalities. Certain types of lesion are better demonstrated with the use of contrast enhancement; this involves the injection of an intravenous contrast and then scanning the patient as already described.

Coombs' test

Test to detect antibodies to red blood cells:

- *direct Coombs' test* detects those bound to the red blood cells
- *indirect Coombs' test* detects those not bound to the red blood cells but circulating in the serum.

Countercurrent immunoelectrophoresis (CCIE)

A laboratory method for the detection of specific antibodies or antigens.

Creatinine clearance

This is a calculation to assess the kidneys' ability to remove creatinine from the blood and hence provide a guide to how well the kidneys are working. The creatinine clearance reflects the glomerular filtration rate (GFR).

Relying on simple measurement of the serum creatinine as an assessment of renal function can overestimate GFR by up to 19%. Several factors may influence creatinine production and so the Cockcroft and Gualt formula uses age, sex, weight and plasma creatinine to correct for these, and provide a more accurate assessment of renal function and estimated GFR. However, in recent years, other formulae such as the Modification of Diet in Renal Disease (MDRD) equation have been proposed (Levey et al 1999) to provide a more accurate assessment of GFR by taking factors such as ethnicity into account.

C-reactive protein (CRP)

CRP is a type of protein produced by the liver that is present only during acute inflammation. It gives a general indication of acute inflammation in the body, rather than identifying a specific cause of this inflammation.

Culture (bacterial)

The specimen material is smeared onto a culture medium plate (containing nutrients and moisture), and then incubated at 37°C to allow any bacteria present to grow and multiply. After 18–24 h the culture plate is examined and bacteria can be identified.

Cystography/cystourography

Via a urinary catheter, the bladder is filled to capacity with contrast medium and X-rayed, revealing any bladder abnormalities. The catheter is then removed to observe the function of the bladder and upper urethra during micturition — a cystourogram.

Cystometry

This investigation measures changes in the pressure in the bladder. A urinary catheter is inserted and the bladder drained. Water at body temperature is then introduced into the bladder at a slow and constant rate and, in response to the increasing volume, the bladder pressure is recorded using a pressure-measuring device, which produces a cystometrogram.

Cytology

Cytology is the study of the structure and function of cells, both normal and abnormal. Body cells may be collected by a variety of methods, e.g. from a specimen of urine or sputum, scraped from a skin lesion or from the cervix during a Papanicolaou smear test, or from aspirate of a lump or bone marrow. The cells are then examined microscopically for abnormalities.

Echocardiography

A non-invasive technique which uses pulses of high-frequency sound (ultrasound) emitted from a transducer to evaluate cardiac anatomy, pathology and function. The procedure involves an operator applying a lubricant to the skin surface of the chest wall and moving the transducer or probe back and forth by hand across the surface.

Electroencephalography (EEG)

A graphic recording of the electrical activity of the brain. Electrodes are attached to the scalp and the electrical activity is noted with a sensitive recorder. Patients prone to seizures will demonstrate an abnormal waveform even while seizure-free.

Enzyme-linked immunosorbent assay (ELISA)

A laboratory method for the detection of specific antibodies or antigens.

Erythrocyte sedimentation rate (ESR)

Measurement of the height of red blood cells at the foot of a column of blood after the blood has been left standing in the narrow tube for 1 h (normal value <10 mm).

Evoked responses

In this test, one of the sensory systems is artificially stimulated and the response noted with the use of appropriately placed electrodes, which detect disturbances of conduction. Visual evoked responses are obtained by asking the patient to look at a reversing checkboard pattern or flashing lights. Electrodes placed on the scalp over the occipital lobes will detect if there is any delay in conduction along the optic pathway, such as may occur in a patient with multiple sclerosis.

Fine-needle aspiration (FNA)

A means of tissue diagnosis by withdrawing fluid or tissue from a swelling, e.g. in the neck.

Glucose tolerance test

Measurement of the body's ability to handle appropriately the excess sugar presented after drinking a high glucose drink. Patient fasts overnight. In the morning 75 g glucose is given in 300 mL water. Blood glucose is measured before and 2 h after ingestion of glucose. Diabetes mellitus confirmed if glucose level >11.1 mmol/L.

Gonioscopy

Gonioscopy is performed to assess the angle of the eye, between the cornea and iris. A narrowed angle is indicative of closed-angled glaucoma.

The eye is anaesthetised with short-acting eye drops. A contact lens in which an angled mirror has been incorporated (gonioscope) is lubricated with methylcellulose eye drops and applied to the cornea. The eye is then examined through a slit lamp.

Haemoglobin estimation

Estimation of the amount of haemoglobin present in 100 mL of blood (normal values: men, 13.5–17.5 g/dL; women, 11.5–15.5 g/dL).

Haemostasis (clotting) tests

Activated partial thromboplastin time (APTT) A coagulation test of the intrinsic and common clotting pathways. Phospholipid, calcium and kaolin are added to citrated plasma. The clotting time depends on the presence of the components of the intrinsic pathway. Abnormalities in the test result from deficiencies of intrinsic and common pathway factors (normal result: 30–40 s).

Prothrombin time (PT) Tests the extrinsic pathway of blood coagulation. The test requires the presence of functional quantities of factor VII and vitamin K-dependent factor X. The result is expressed as the ratio of patient:control — the international normalised ratio (INR). (Normal result: clot forms in 13 s; normal ratio: 1.0–1.3.)

Thrombin clotting time (TT) Tests the final reaction in the final pathway, i.e. fibrinogen converted to fibrin (normal value: 14–16 s).

Bleeding time Test for abnormal platelet function. Time taken to stop bleeding after making a standardised superficial skin incision, e.g. with a lancet (normal value: 3–8 min).

Immunocoagglutination

A laboratory method for the detection of specific antibodies or antigens.

Immunodiffusion

A laboratory method for the detection of specific antibodies or antigens.

Immunoelectrophoresis

A laboratory method for the detection of specific antibodies or antigens.

Intravenous cholangiography

Contrast medium, given intravenously, is excreted into the biliary system. Serial radiographs are taken. However, this technique is not commonly used as results are often of poor quality, are of no value in jaundiced patients and also carry a small but significant risk of an anaphylactic reaction to the contrast medium. As a result, methods that allow direct injection of the contrast into the biliary tree are preferred, e.g. percutaneous transhepatic cholangiography (PTC), endoscopic retrograde cholangiopancreatography (ERCP), operative cholangiography and T-tube cholangiography.

Intravenous fluorescein angiography

This technique is used as an aid in the diagnosis and treatment of many of the vascular disorders of the retina. A 5 mL i.v. injection of 10% fluorescein sodium is given into a vein in the arm. A series of photographs are taken through a dilated pupil at timed intervals, using a fundal camera. Any defect in the retinal vessels will show up as a leakage of dye or occlusion of the vessel. The patient may feel nauseated after the procedure.

The patient should be informed that the sclera and skin will take on a yellow colour for about 24 h and that urine will be greenish for 24–48 h as the dye is excreted through the kidneys. Diabetic patients who carry out urine testing should be advised to test their blood sugar instead, as the dye can affect the results obtained by urine test strips.

Lumbar puncture

This is the most common neurological investigation. It involves the insertion of a sterile needle and trocar between lumbar vertebrae 3 and 4, or 4 and 5, and the withdrawal of a quantity of cerebrospinal fluid (CSF) for analysis. The procedure is usually performed in the ward under local anaesthetic. The lumbar CSF pressure may also be measured prior to the removal of CSF. The normal constituents of CSF and their values may be altered in the presence of a disorder, e.g. the number of red blood cells in the CSF following subarachnoid haemorrhage will be markedly elevated.

Magnetic resonance imaging (MRI)

This investigation is based on the use of a magnetic field and radio pulse waves, instead of traditional irradiation. The patient lies on a couch and is then completely enclosed in a tunnel within the scanner. A strong magnetic field is applied and the nuclei within the tissues, which were previously spinning in a random fashion, line up in a north–south magnetic field orientation. A radio pulse wave is introduced at a right angle to the magnetic field and the nuclei are tipped out of alignment, causing uniform resonance. The pulse waves are stopped and the resonating nuclei will return to their previous state. Minute radiofrequency signals are given off as the nuclei enter this relaxed state and these are monitored by the scanner. By pre-programming the computer to simulate a non-uniform magnetic field, the positively charged particles in different parts of the magnetic field will resonate at different speeds. Variable radio pulse waves result in differences in the emission of radiofrequency data. The computer assimilates the data and constructs a tissue image.

This type of scanning has a particular use in detecting cerebral and spinal oedema, and cerebral and spinal blood flow-related disorders, such as infarction, haemorrhage and arteriovenous malformation. In musculoskeletal conditions and injuries it is used to detect soft tissue problems such

as a torn cruciate ligament in the knee or a disc protrusion in the vertebral column.

Mammogram

A mammogram is an X-ray examination of the breast. Usually two views of the breast tissue are taken under compression.

Mantoux test

An intradermal injection of tuberculin purified protein derivative (PPD), which is a sterile preparation 'made from the heat-treated products of growth and lysis of the mycobacterium' (DH 1996). The result is read after 48–72 h. A positive result is described as induration of at least 5 mm diameter at the injection site. This indicates that the individual has sensitivity to the tuberculin protein, and a strong reaction may indicate active disease.

Mean corpuscular haemoglobin (MCH)

This is the average concentration of haemoglobin in a red blood cell (normal range: 30–35 g/dL).

Mean corpuscular or cell volume (MCV)

The average red cell volume — normal: 85 fl (range 75–95 fl).

Microscopy

Direct visualisation of microorganisms using a light microscope or an electron microscope (uses a beam of electrons rather than light rays).

Orthopantomogram (OPT)

Panoramic radiograph giving consistent image quality, usually of mandible or maxilla, for suspected neoplasia. Also in maxillofacial surgery for middle third fracture of facial bones.

Packed cell volume (PCV) or haematocrit

This test measures the relative red cell mass to plasma, i.e. the proportion of the blood sample composed of packed red blood cells to plasma (normal values: men, 40–52%; women, 36–48%).

Paul–Bunnell (monospot) test

A method of determining the diagnosis of infectious mononucleosis (glandular fever), which may result from the Epstein–Barr virus (EBV). During the second week of the infection, specific EBV IgM antibodies indicate recent infection by the virus.

Pleural aspiration

This involves the percutaneous drainage of fluids or air and is indicated in pleural effusions, pneumothorax or empyema. It may be diagnostic or therapeutic.

Polysomnography

Polysomnography is a diagnostic investigation in which a number of physiological variables are measured, via sensor leads, and recorded while the individual is asleep. These include eye and jaw muscle movements, leg muscle movements and brain electrical activity.

Positron emission tomography (PET) scan

A computerised radiographic technique that employs radioactive substances to examine the metabolic activities of various body structures. It involves the injection into the bloodstream of a solution containing a very short-lived radioactive agent which then emits positively charged particles — positrons. These combine with negatively charged electrons normally found in body cells and emit gamma rays. It is these rays that are picked up by the PET computer and converted to colour-coded images that indicate the intensity of metabolic activity of the organ involved.

PET scans have proved useful in studying the blood flow and metabolism in the heart and blood vessels, in diagnosing and studying cancer, in understanding the biochemical activity in the brain in such disorders as multiple sclerosis and Parkinson's disease, and in demonstrating which parts of the brain are active when people are in pain.

Precipitin test

A laboratory method for the detection of specific antibodies or antigens.

Pulmonary function test (PFT)

A useful test in the diagnosis of respiratory disorders and in measuring and monitoring the severity and course of a disease.

Radioallergosorbent test (RAST)

A laboratory method for the detection of specific antibodies or antigens.

Radioimmunoassay (RIA)

A laboratory method for the detection of specific antibodies or antigens.

Radioisotope scanning

Radioisotope scans involve the use of small amounts of various radioactive substances, which are differentially taken up by normal and abnormal (malignant) tissue. The most common radioisotope scans are those of the liver, brain and bones. The radioisotope is injected intravenously, and the scan occurs several hours later. Patients should be reassured that the radioactivity of their bodies during this waiting time is minimal and that they are not a danger to others.

Red cell mass

Estimation of the total volume of circulating red cells performed by labelling a sample of the patient's own red blood cells with isotope ^{51}Cr or ^{99m}Tc. A measured amount is reinjected and a sample is taken after a specific period of time when the dilution can be calculated (normal value: men, 25–35 mL/kg; women, 20–30 mL/kg).

Renography

A radiological study to assess renal function. Some elements that the kidneys normally concentrate and excrete can be labelled with radioactive isotopes. These are administered intravenously and the function of the kidneys can be traced by recording the rate at which the isotopes are removed from the blood and passed into the urinary collecting system.

Reticulocyte count

The number of reticulocytes in the peripheral blood (normal range: 0.2–2.0% of red blood cells).

Schiller test

Iodine 3.5% is applied to the cervix and will stain normal cells of the cervix. Abnormal cells will not pick up the colour because they do not contain glycogen.

Schilling test

Estimation of the gastrointestinal absorption of radioactive vitamin B_{12} (normal range >10% of administered oral dose in 24-h urine sample).

Sensitivity

A test used to determine which antibiotics will kill the bacteria in the specimen. The antibiotic-impregnated discs are placed over a film of cultured bacteria on a culture plate and the plate read some hours later. A zone of inhibition around the disc indicates that the organism is sensitive to that antibiotic. If an organism is resistant, there will be growth right up to the disc.

Sentinel node biopsy

Radioactive colloid is injected into a tumour before surgery. Passage of the colloid through the lymphatic system adjacent to the tumour is scanned by a digital gamma camera (lymphoscintigraphy). During subsequent surgery (within 24 h), use of both a gamma probe and blue dye identifies the first echelon lymph node encountered. This node is excised and examined immediately by a pathologist (frozen section). Presence or otherwise of tumour cells dictates whether further excision of lymph glands is indicated. Used mainly in breast carcinoma, malignant melanoma and oral and oropharyngeal squamous cell carcinoma when the tumour is readily accessible prior to surgery. If the sentinel node is negative, the patient may be spared unnecessary surgery involving lymphatic dissection (Ross et al 2002).

Serology

The examination of blood serum, often to ascertain if infection is present by identifying antigen/antibody.

Sialogram

Radiograph following injection of contrast medium into a salivary duct and gland.

Skeletal survey X-rays

A skeletal survey involves X-rays of the skull, spine, ribs, pelvis and the femoral and humeral heads, enabling detection of primary bone tumours and bone metastases from other tumours.

T-cell immunophenotyping (CD4 T-cell subsets)

This procedure, used particularly for patients with HIV disease, shows the level of healthy T-helper cells the patient has. This is a vital prognostic tool. The test uses a monoclonal antibody, which binds to a specific antigen on the T_4 helper cells. The test counts these and presents them as a ratio of the total T cells.

Tonometry

Tonometric tests measure intraocular pressure (IOP). The normal range is 12–20 mmHg.

Applanation tonometry Fluorescein and anaesthetic drops are instilled prior to this procedure. A prism attached to a slit lamp (or a portable Perkins' tonometer) is used to flatten a defined area of the cornea. The greater the force required to flatten the area, the higher the IOP.

Non-contact (air puff) tonometry uses a computerised instrument to direct a fine, high-pressure jet of air onto the cornea. The increase in force progresses linearly until the cornea becomes flat. At this point the cornea acts like a mirror and reflects light to a photoelectric sensor, which immediately shuts off the puff of air. The force required to flatten the cornea is recorded and converted into an IOP reading.

Tumour markers

Some malignant tumours produce substances that can be detected in the blood. These may serve as 'markers' of the presence or recurrence of the tumour, and sometimes as an indicator of its size and, therefore, response to treatment. For example, alpha-fetoprotein (AFP) and beta-human chorionic gonadotrophin (BhCG) are produced by testicular tumours, and acid phosphatase by prostatic tumours.

Ultrasound

The use of high frequency sound waves through a hand-held transducer to image soft tissues, particularly useful when examining breast tissue.

Urethroscopy

The endoscopic examination of the male urethra and prostate gland.

Urinary flow rate

The voiding flow rate is measured using specially equipped facilities which allow the patient to void in privacy but where a machine can record the characteristics of the flow. The test will identify such things as peak flow, average flow and total flow time.

Urine protein:creatinine ratio

Proteinuria can be assessed from a single (early morning) urine sample and this can provide a reliable predictor (in people who do not have diabetes mellitus) of deterioration of renal function and fall in GFR (Ruggenenti et al 1998, Keane et al 1999). This test is reported to be more reliable than the traditional 24 h urine collection.

Ventilation perfusion scan (VQ scan)

The intravenous injection of radioisotope to outline the distribution of pulmonary perfusion. Xenon-133 gas is inhaled into the lung and, using the two scans, a pulmonary embolus can be seen to cause a lowering of perfusion relative to ventilation.

Videofluoroscopy

Video recording of the swallowing mechanism, using fluorescent fluid.

Water depletion test (diabetes insipidus)

Fluids are withheld for 8–12 h or until 3% of the body weight has been lost. Regular measurements of plasma and urine are taken. The inability to increase urinary specific gravity and osmolality in response to water depletion is indicative of diabetes insipidus. The test must be closely supervised as the patient will experience excessive thirst. The test is terminated if signs of tachycardia, hypotension or obvious dehydration occur.

APPENDIX 2

NORMAL VALUES

Notes on international system of units (SI units)	1201
Biochemical values	1201
Haematological values	1206

NOTES ON INTERNATIONAL SYSTEM OF UNITS (SI UNITS)

Examples of basic SI units

Length	metre (m)
Mass	kilogram (kg)
Amount of substance	mole (mol)
Energy	joule (J)
Pressure	pascal (Pa)

Examples of decimal multiples and submultiples of SI units

Factor	Name	Symbol
10^{6}	mega-	M
10^{3}	kilo-	k
10^{-1}	deci-	d
10^{-2}	centi-	c
10^{-3}	milli-	m
10^{-6}	micro-	μ
10^{-9}	nano-	n
10^{-12}	pico-	p
10^{-15}	femto-	f

Volume The basic SI unit of volume is the cubic metre (1000 litres). Because of its convenience the litre is used as the unit of volume in laboratory work.

Mass concentration (e.g. g/L, mcg/L) is used for all protein measurements, for substances which do not have a sufficiently well-defined composition and for serum vitamin B_{12} and folate measurements.

SI units are not employed for enzymes, nor usually for immunoglobulins.

BIOCHEMICAL VALUES

Reference ranges are largely those used in the Department of Clinical Biochemistry, the Lothian University NHS Division. These can vary from laboratory to laboratory, depending on the assay method used and other factors; this is especially the case for the enzyme assays. Although the SI system of units is widely used in the UK, units of measurement can vary and lead to laboratory differences.

No details are given of the collection requirements which may be critical to obtaining a meaningful result.

Unless otherwise stated, reference ranges apply to adults; *values in children may be different.*

Table A2.1 Arterial blood analysis

	Reference range	
Analysis	**SI units**	**Non-SI units**
Bicarbonate	21–27.5 mmol/L	21–27.5 meq/L
Hydrogen ion	36–44 nmol/L	pH 7.36–7.44
Pa CO_2	4.4–6.1 kPa	33–46 mmHg
Pa O_2	12–15 kPa	90–113 mmHg
Oxygen saturation	Normally >97%	

Table A2.2 Cerebrospinal fluid

	Reference range	
Analysis	**SI units**	**Non-SI units**
Cells	Up to 5 (all mononuclear) cells/mm^3	
Chloride	120–170 mmol/L	120–170 meq/L
Glucose	2.5–4.0 mmol/L	45–72 mg/100 mL
IgG index*	<0.65	—
Total protein	100–400 mg/L	0.01–0.04 g/100 mL

*A crude index of increase in IgG attributable to intrathecal synthesis.

Table A2.3 Reference values in venous serum for the more common analytes in adults

Analysis	Reference range	
	SI units	Non-SI units
α_1-Antitrypsin	1.7–3.2 g/L	170–320 mg/100 mL
Alanine aminotransferase (ALT)	10–40 U/L	—
Albumin	36–47 g/L	3.6–4.7 g/100 mL
Alkaline phosphatase	40–125 U/L	—
Amylase	<100 U/L	—
Aspartate aminotransferase (AST)	10–35 U/L	—
Bilirubin (total)	2–17 μmol/L	0.12–1.0 mg/100 mL
Calcium	2.12–2.62 mmol/L	4.24–5.24 meq/L or 8.50–10.50 mg/100 mL
Carboxyhaemoglobin	Not normally detectable Up to 1.5% in non-smokers	—
Ceruloplasmin	150–600 mg/L	15–60 mg/100 mL
Chloride	95–107 mmol/L	95–107 meq/L
Cholesterol (total)[1]		
HDL-cholesterol		
Male	0.5–1.6 mmol/L	19–62 mg/100 mL
Female	0.6–1.9 mmol/L	23–74 mg/100 mL
Copper	13–24 μmol/L	83–153 μg/100 mL
Creatine kinase (total)		
Male	30–200 U/L	—
Female	30–150 U/L	—
Creatine kinase (MB isoenzyme)	Normally <6% of total CK	—
Creatinine	55–120 μmol/L	0.62–1.36 mg/100 mL
Ethanol	Not normally detectable	
	65–87 mmol/L (Marked intoxication)	300–400 mg/mL
	87–109 mmol/L (Stupor)	400–500 mg/mL
	>109 mmol/L (Coma)	>500 mg/100 mL
Ferritin		
Male	17–300 μg/L	17–300 ng/mL
Female	14–150 μg/L	14–150 ng/mL
Gamma-glutamyl transferase (GGT)		
Male	10–55 U/L	—
Female	5–35 U/L	—
Glucose (fasting)[2]	3.6–5.8 mmol/L	65–104 mg/100 mL
Glycated haemoglobin (HbA_1)	5.0–6.5%	—
Immunoglobulin A	0.5–4.0 g/L	50–400 mg/100 mL
Immunoglobulin G	5.0–13.0 g/L	500–1300 mg/100 mL
Immunoglobulin M		
Male	0.3–2.2 g/L	30–220 mg/100 mL
Female	0.4–2.5 g/L	40–250 mg/100 mL
Iron		
Male	14–32 μmol/L	78–178 μg/100 mL
Female	10–28 μmol/L	56–156 μg/100 mL

Table A2.3 Reference values in venous serum for the more common analytes in adults *(Continued)*

Analysis	Reference range	
	SI units	Non-SI units
Iron-binding capacity	45–72 μmol/L	251–402 μg/100 mL
Lactate	0.4–1.4 mmol/L	3.6–12.6 mg/100 mL
Lactate dehydrogenase (total)	230–460 U/L	—
Lead[3]	<1.0 μmol/L	<21 μg/100 mL
Magnesium	0.75–1.0 mmol/L	1.5–2.0 meq/L or 1.82–2.43 mg/100 mL
Osmolality	280–290 mmol/kg	280–290 mosm/L
Phosphate (fasting)	0.8–1.4 mmol/L	2.48–4.34 mg/100 mL
Potassium (plasma)	3.3–4.7 mmol/L	3.3–4.7 meq/L
Potassium (serum)	3.6–5.1 mmol/L	3.6–5.1 meq/L
Protein (total)	60–80 g/L	6–8 g/100 mL
Sodium	132–144 mmol/L	132–144 meq/L
Total CO_2	24–30 mmol/L	24–30 meq/L
Transferrin	2.0–4.0 g/L	0.2–0.4 g/100 mL
Triglycerides (fasting)	0.6–1.7 mmol/L	53–150 mg/100 mL
Urate		
Male	0.12–0.42 mmol/L	2.0–7.0 mg/100 mL
Female	0.12–0.36 mmol/L	2.0–6.0 mg/100 mL
Urea	2.5–6.6 mmol/L	15–40 mg/100 mL
Zinc	11–22 μmol/L	72–144 μg/100 mL

[1] Cholesterol (total)

Ideally	<5.2 mmol/L	<200 mg/100 mL
Mild increase	5.2–6.5 mmol/L	200–250 mg/100 mL
Moderate increase	6.5–7.8 mmol/L	250–300 mg/100 mL
Severe increase	>7.8 mmol/L	>300 mg/100 mL

(as defined by the European Atherosclerosis Society)

[2] Values quoted for venous plasma or serum

[3] In children — Up to 0.5 μmol/L — Up to 10 μg/100 mL

Table A2.4 Reference values for the more common analytes in urine

Analysis	Reference range	
	SI units	Non-SI units
Albumin[1]		
Calcium	1.2–3.7 mmol/24 h (low calcium diet) Up to 12 mmol/24 h (normal diet)	2.4–7.4 meq/24 h Up to 24 meq/24 h
Copper	Up to 0.6 μmol/24 h	Up to 38 μg/24 h
Cortisol	9–50 μmol/mol creatinine	30–160 μg cortisol/g creatinine
Creatinine	10–20 mmol/24 h	1130–2260 mg/24 h
5-hydroxyindole-3-acetic acid (5-HIAA)	<60 μmol/24 h	<11.5 mg/24 h
Metadrenalines		
Normetadrenaline	0.4–3.4 μmol/24 h	73–620 μg/24 h
Metadrenaline	0.3–1.7 μmol/24 h	59–335 μg/24 h
Oxalate		
Male	80–490 μmol/24 h	7.2–44 mg/24 h
Female	40–320 μmol/24 h	3.6–29 mg/24 h
Phosphate	15–50 mmol/24 h	465–1548 mg/24 h
Potassium[2]	25–100 mmol/24 h	25–100 meq/24 h
Protein	Up to 0.3 g/L	Up to 0.03 g/100 mL
Sodium	100–200 mmol/24 h	100–200 meq/24 h
Urate	1.2–3.0 mmol/24 h	202–504 mg/24 h
Urea	170–600 mmol/24 h	10.2–36.0 g/24 h

[1]Albumin/creatinine ratio (ACR) and urinary albumin excretion rate (AER) are used to detect microalbuminuria, i.e. excessive albumin excretion in patients with diabetes mellitus, which is of predictive value in identifying patients at risk of progression to diabetic nephropathy. The test should only be carried out in the absence of overt proteinuria (dipstix negative).

ACR

Reference range: <3.5 mg albumin/mmol creatinine (<31 μg albumin/mg creatinine)
'Borderline': 3.5–10 mg albumin/mmol creatinine (31–88 μg albumin/mg creatinine)
Positive test: >10 mg albumin/mmol creatinine (>88 μg albumin/mg creatinine)

AER

Reference range: <20 μg albumin/min
Microalbuminuria: 20–200 μg albumin/min

[2]The urinary output of electrolytes such as sodium and potassium is normally a reflection of intake. This can vary widely, especially on a cultural, worldwide basis. The values quoted are more appropriate to a 'Western' diet.

Table A2.5 Hormones in serum

Hormone	Reference range	
	SI units	Non-SI units
Adrenocorticotrophic hormone (ACTH) (plasma)	7–51 ng/L (0700–1000 h)	—
Cortisol	150–550 nmol/L (at 0800 h) <200 nmol/L (at 2200 h)	5.5–20 μg/100 mL <73 μg/100 mL
Follicle-stimulating hormone (FSH)		
Male	1.5–9.0 U/L	—
Female*	3.0–15 U/L (early follicular) Up to 20 U/L (mid-cycle) >30 U/L (postmenopausal)	— — —
Gastrin (plasma)	Up to 120 ng/L	Up to 12 ng/100 mL
Growth hormone (GH)	Variable, up to 50 mU/L	—
Insulin	Highly variable and interpretable only in relation to plasma glucose and body habitus	—
Luteinising hormone (LH)		
Female*	2.5–9.0 U/L (early follicular) Up to 90 U/L (mid-cycle) >20 U/L (postmenopausal)	— — —
Male	1.5–9.0 U/L	—
Oestradiol-17β		
Female	110–180 pmol/L (early follicular) 550–1650 pmol/L (mid-cycle) 370–770 pmol/L (luteal) <150 pmol/L (postmenopausal)	30–49 pg/mL 150–449 pg/mL 101–209 pg/mL <41 pg/mL
Male	<200 pmol/L	<54 pg/mL
Parathyroid hormone (PTH)	10–65 ng/L	1.0–6.5 ng/100 mL
Progesterone		
Male	<2.0 nmol/L	<0.63 μg/L
Female	<2.0 nmol/L (follicular) >15 nmol/L (mid-luteal) <2.0 nmol/L (postmenopausal)	<0.63 μg/L >4.7 μg/L <0.63 μg/L
Prolactin (PRL)	60–390 mU/L	—
Testosterone		
Male	10–30 nmol/L	2.88–8.64 ng/mL
Female	0.4–2.8 nmol/L	0.12–0.81 ng/mL
Thyroid-stimulating hormone (TSH)	0.15–3.5 mU/L	—
Thyroxine (free) (free T_4)	10–27 pmol/L	777–2098 pg/100 mL
Triiodothyronine (T_3)	1.0–2.6 nmol/L	65–169 ng/100 mL
TSH receptor antibodies (TRAb)	<7 U/L	—

*Luteal phase values similar to follicular phase.

Notes

1. A number of hormones are unstable, and collection details are critical to obtaining a meaningful result. Refer to local hospital handbook.
2. Values in the table are only a guideline; hormone levels can often only be meaningfully understood in relation to factors such as sex (e.g. testosterone), age (e.g. FSH in women), time of day (e.g. cortisol) or regulatory factors (e.g. insulin and glucose, PTH and Ca^{2+}). Also, reference ranges may be critically method dependent.

HAEMATOLOGICAL VALUES

Table A2.6 Haematological values

Analysis	Reference range SI units	Non-SI units
Bleeding time (Ivy)	Less than 8 min	
Body fluid (total)	50% (obese)–70% (lean) of body weight	—
Intracellular	30–40% of body weight	—
Extracellular	20–30% of body weight	—
Blood volume		
Male	75 ± 10 mL/kg	—
Female	70 ± 10 mL/kg	—
Coagulation screen		
Prothrombin time	8.0–10.5 s	—
Activated partial thromboplastin time	26–37 s	—
Erythrocyte sedimentation rate*		
Adult male	0–10 mm/h	—
Adult female	3–15 mm/h	—
Fibrinogen	1.5–4.0 g/L	0.15–0.4 g/100 mL
Folate		
Serum	1.5–20.6 µg/L	1.5–20.6 ng/mL
Red cell	95–570 µg/L	95–570 ng/mL
Haemoglobin		
Male	130–180 g/L	13–18 g/100 mL
Female	115–165 g/L	11.5–16.5 g/100 mL
Haptoglobin	0.3–2.0 g/L	0.03–0.2 g/100 mL
Leucocytes (adults)	4.0–11.0 × 10^9/L	4.0–11.0 × 10^3/mm^3
Differential white cell count		
Neutrophil granulocytes	2.0–7.5 × 10^9/L	2.0–7.5 × 10^3/mm^3
Lymphocytes	1.5–4.0 × 10^9/L	1.5–4.0 × 10^3/mm^3
Monocytes	0.2–0.8 × 10^9/L	0.2–0.8 × 10^3/mm^3
Eosinophil granulocytes	0.04–0.4 × 10^9/L	0.04–0.4 × 10^3/mm^3
Basophil granulocytes	0.01–0.1 × 10^9/L	0.01–0.1 × 10^3/mm^3
Mean cell haemoglobin (MCH)	27–32 pg	—
Mean cell volume (MCV)	78–98 fl	—
Packed cell volume (PCV) or haematocrit		
Male	0.40–0.54	—
Female	0.37–0.47	—
Platelets	150–350 × 10^9/L	150–350 × 10^3/mm^3
Red cell count		
Male	4.5–6.5 × 10^{12}/L	4.5–6.5 × 10^6/mm^3
Female	3.8–5.8 × 10^{12}/L	3.8–5.8 × 10^6/mm^3
Red cell life-span (mean)	120 days	—
Red cell life-span $T^1/_2$ (^{51}Cr)	25–35 days	—
Reticulocytes (adults)	25–85 × 10^9/L	25–85 × 10^3/mm^3
Vitamin B_{12}	130–770 pg/mL	—

*Higher values in older patients are not necessarily abnormal.

GLOSSARY

Achalasia. A failure of the smooth muscle of the gastrointestinal tract to relax. The cause is unknown, but it occurs due to degeneration of the ganglionic cells. The failure is most notable in the lower oesophagus which fails to relax with swallowing.

Active cycle of breathing technique (ACBT). Breathing and coughing exercises to help the prevention of postoperative respiratory complications:

Deep breaths — hold for 3 s

Relaxed breaths

Huffs

Coughs

Relaxed breaths

Repeat __ times every hour: left side lying, right side lying, sitting upright

Adjuvant therapy. Any therapy which is deliberately planned in conjunction with another form of therapy, e.g. adjuvant chemotherapy following surgery for breast cancer.

Advocate. An aspect of the nursing role essential to humanistic care whereby the nurse assists the patient to make decisions in a self-determined manner.

Aerobic. Able to live and function in the presence of oxygen.

Affective. Refers to affect, an outward manifestation of a person's feelings or emotions.

Afferent nerve fibre. This is the sensory nerve fibre which runs from the tissues to the central nervous system.

Alleles. Alternative forms of a gene or DNA sequence occurring at the same locus on homologous chromosomes.

Allodynia. 'Pain due to a stimulus which does not normally provoke pain' (IASP 1986, p. S217).

Alport's syndrome. A rare inherited problem which has a combination of effects. Most commonly the kidneys are affected, with nephritis and the gradual development of kidney failure. Hearing may also be affected and very rarely there may also be problems with the platelets in the blood. It is more common in boys.

Amsler grid. A square grid used to detect macular distortion and abnormalities for people with early age-related macular degeneration. The individual focuses their vision on a central dot and notes any irregularities in the appearance — 'straightness' — of the lines.

Anaerobic. Able to live and function in the absence of oxygen.

Aneuploid. Chromosome number that is not an exact multiple of the haploid set; for example, $2n - 1$ or $2n + 1$.

Angiogenesis. The growth of new blood vessels. This is an important natural process occurring in the body, both in health and in disease. In cardiovascular disease, if the body is unable to generate adequate collateral blood vessels or mount a sufficient angiogenesis response, the oxygen-starved muscle is at risk of death. Therapeutic angiogenesis is being used to stimulate new blood vessel growth. This is done by delivering angiogenic proteins or their genes into the muscle or by using a specially designed laser to drill tiny channels into the muscle in order to stimulate new blood vessel growth.

Antihistamine labyrinthine sedatives. Sedatives that have an anti-inflammatory action and also reduce the levels of dizziness and nausea.

Antinociceptive. Something that helps to reduce or stop the response to noxious stimulation.

Antiseptic. A chemical solution, which will reduce and prevent growth of microorganisms on skin.

Antroscopy. Endoscopic examination of the maxillary sinuses.

Appraisal. The individual's assessment of a stressful situation and how it will affect them.

Arteriogram. A radio-opaque dye is injected into an artery and a series of X-rays taken to show the path of the dye in the arteries and to pinpoint any obstruction to blood flow.

Ascites. An abnormal collection of fluid in the peritoneal cavity.

Aseptic. Prevention from contamination with microorganisms utilising certain techniques. Includes sterile conditions on human tissues, on materials and in rooms, obtained by excluding/removing/killing organisms in the environment or on the people involved.

Atherosclerosis. A complex disease characterised by the growth of smooth muscle cells and the build-up of lipid

lesions within the intima of the arteries. It is a dynamic inflammatory process with phases of stability and instability.

Atopy. Hereditary tendency to a clinical hypersensitivity state.

Attico-antral disease. Bone erosion of the middle ear, caused by chronic infection.

Auriscope. An instrument which incorporates magnification and illumination, and can be used for examining the ear.

Autogenic drainage. A self-drainage technique which utilises controlled expiratory airflow (tidal breathing) to mobilise secretions consisting of three phases: 1) unsticking the peripheral secretions by breathing at low lung volumes (slow deep air movement); 2) collecting the mucus from central airways by breathing at low to mid lung volumes (slow mid-range air movement); 3) evacuating the mucus from the central airways by breathing at mid to high lung volumes (shallow air movement).

Autonomy. To act with self-determination.

Autosome. Any chromosome other than the sex chromosomes.

B-scan. An ultrasonography test to clinically assess ocular and orbital diseases. Used to detect vitreal or retinal abnormalities.

Biofeedback. Presentation of immediate visual or auditory information about usually unconscious body functions.

Buchanan laryngectomy bib protector. A humidifying covering for the stoma of a laryngectomy.

Bulbospongiosum. Muscle that evacuates the bulb of the urethra. Responds to manual compression of the urethral bulb to prevent postmicturition dribbling in men.

Bulla. Large visible collection of fluid more than 1 cm in diameter.

Burrow. Tunnel in the skin caused by a parasite (scabies).

Carcinoid syndrome. 'Carcinoids' is an old term for tumours of the neuroendocrine cells of the gut. They usually arise from the terminal ileum but can originate from anywhere along the gut and also from the bronchial epithelium ('bronchial carcinoids'). The most common site for carcinoid tumours is the appendix, followed by the rectum and ileum. The tumours are usually slow growing, with the malignant potential dependent on the origin of the primary. In approximately 10–20% of cases they are associated with the 'carcinoid syndrome', symptoms of which include diarrhoea, flushing and (rarely) asthma due to active secretion of a variety of agents by the carcinoid. Prominent among these is 5-hydroxytryptamine (5-HT or serotonin) which is metabolised in the liver to 5-hydroxyindole acetic acid (5HIAA) and excreted in the urine. Diagnosis is based on finding elevated levels of 5HIAA in a 24-h urine collection (Bloom & Hammond 1995). The diarrhoea may be profuse with several litres/day being excreted and is associated with abdominal cramps. Flushing of the face and neck is paroxysmal and usually unprovoked, although it is often associated with exertion, alcohol intake and eating. It may also be associated with palpitations and postural hypotension. In general, the carcinoid syndrome is only seen when the tumour has metastasised to the liver, allowing for serotonin and other agents to leak into the general circulation. Occasionally other hormones such as ACTH may be secreted ectopically.

Cardiac troponins. Proteins bound to the thin filaments of the contractile apparatus of the myocytes in cardiac muscle. There are three cardiac troponins — T, I and C — and it is now becoming routine to measure the levels of troponin T and I in clinical practice. Both these cardiac troponins are released into the blood within 3 h of myocardial injury, peaking at 12 h. They have 100% sensitivity for diagnosing myocardial damage. They are also useful for risk stratification as they are of prognostic value in acute coronary syndromes.

Carotid sinus massage. Gentle massage of the carotid sinus in the neck which increases vagal tone, inhibits sinus node firing and slows atrioventricular (AV) conduction. It may slow or terminate an arrhythmia. It is also useful to differentiate between arrhythmias. For example, carotid sinus massage will slow down but not terminate atrial flutter whereas it will break the cycle of tachycardias that are produced by a re-entry circuit mechanism as it blocks AV node conduction.

Carrier. Healthy person possessing a mutant gene in heterozygous form; also refers to a person with a balanced chromosomal translocation.

Catheter ablation. The delivery of radiofrequency energy to an area of the myocardium via a catheter inserted peripherally and fed into the chambers of the heart. The discharged energy is directed to a specific site after careful mapping in order to target the cells responsible for accessory pathways and arrhythmias.

Causalgia. 'A syndrome of sustained burning pain, allodynia and hyperpathios after a traumatic nerve lesion' (IASP 1986, p. S218).

Cholangiocarcinoma. Cancer of the bile ducts.

Choledocholithiasis. Stones in the bile ducts.

Cisplatin-based. Chemotherapeutic agents of similar chemical structure and use as cisplatinum, e.g. carboplatin.

Clean. Devices or surfaces being free of visible soil, organic and inorganic contamination, by the use of either physical action, e.g. scrubbing with a surfactant or detergent and water, or an energy-based process (e.g. ultrasonic cleaners) with appropriate chemical agents.

Cognitive. Pertaining to mental processes involved in perceiving, thinking, learning and judging. Involves functions associated with orientation, attention, memory, language and visuospatial ability.

Cohort nursing. Sharing of an area by a particular group of patients, for example with the same infectious organism.

Collaborative relationships. Relationships within which the nurse, the patient and the patient's significant others work together as a cohesive team with shared responsibilities.

Colonisation. The presence and multiplication of microorganisms without tissue invasion or damage.

Comedone. Plug of sebum and keratin in the pilosebaceous gland.

Communicable. A disease that can be transmitted from one person to another.

Complementary therapies. Diverse therapeutic practices and diagnostic systems which do not necessarily adhere to, or in some cases oppose, the principles guiding conventional, scientific medicine, e.g. acupuncture, aromatherapy and homeopathy.

Contamination. The soiling or pollution of inanimate objects or living material with harmful, potentially infectious or other unwanted material, for example organic matter or microorganisms.

Coping. The various strategies individuals utilise to deal with the effects of stress in their lives.

Corneal melt. Also known as corneal thinning resulting from inflammation, infection or degeneration.

C-reactive protein. An abnormal protein which appears in the blood in the active phase of many diseases, e.g. bacterial infections, myocardial infarction and malignancy. It is expressed as 0 (normal) to +5.

Creatinine. A waste product of normal muscle metabolism which is normally excreted by the kidneys. When kidney function is reduced, the level of creatinine in the blood rises and the amount cleared by the kidneys (creatinine clearance) falls. Normal range of serum creatinine in men is 60–120 μmol/L and women 45–90 μmol/L. Normal creatinine clearance is approximately 125 mL/min.

Cross-infection. Infection that is acquired from microorganisms on other people or in the environment.

Crust. Dried exudate on skin (serum, blood, pus).

CT scanning. Computed tomography (CT) imaging, also known as 'CAT scanning' (computed axial tomography). CT scanning has the ability to image a combination of soft tissue, bone and blood vessels. As X-rays pass through the body they are absorbed or attenuated (weakened) at differing levels, creating a matrix or profile of X-ray beams of different strength. This X-ray profile is registered on film, thus creating an image. In the case of CT, the film is replaced by a banana-shaped detector which measures the X-ray profile.

Curettage. The scraping of tissue from a cavity using an instrument known as a 'curette'. Scrapings of the endometrium of the uterus are analysed in a pathology laboratory to aid diagnosis.

Cycloplegics. A medication group of eye drops which dilate the pupil and paralyse the ciliary muscle.

Cytogenetics. Branch of genetics devoted to the cellular constituents concerned in heredity, i.e. in chromosomes. Clinical cytogenetics is a specific branch of cytogenetics concerned with the relations between chromosomal abnormalities and pathogenic conditions, e.g. leukaemias.

Decerebration. Characterised by extension and pronation of the arms, extension of the legs and plantar flexion (i.e. hyperextension of all limbs). The condition may progress to opisthotonos.

Decontamination. All of the elements included with the cleaning, disinfection and sterilisation processes.

Decortication. Characterised by hyperflexion and adduction of the upper limbs, and hyperextension, internal rotation and plantar flexion of the lower limbs. It occurs when there is severe damage to the cerebral hemispheres or the internal capsule.

Demography. The study of populations and their characteristics, e.g. age, gender, density, distribution, migration, income and dependency.

Depolarisation. The electrical activation of myocardial cells as a result of changes in the cell membrane permeability. This produces marked shifts in ion concentrations inside and outside the cell, with the inside of the cell becoming negatively charged. As myocardial cells are so tightly bound, stimulation of any single cell causes the impulse to spread to all adjacent cells.

Dermatitis artefacta. Psychological problem where patient presents with self-induced skin lesions.

Dermatome. An area of skin mainly innervated by a particular spinal cord segment.

Desmopressin. Artificial antidiuretic hormone. In spray form, used intranasally for short relief of symptoms of nocturnal enuresis.

Differentiation. The development process during which immature cells and tissues become more complex and specialised.

Diploid. Normal state of human somatic cells containing two haploid sets of chromosomes (2n).

Disability. Any long-term or permanent loss or reduction in functional capacity which can affect an individual's ability to perform activities; can be experienced physically and/or psychologically and has social dimensions.

Disinfection. A process to reduce the number of viable microorganisms, but which may not necessarily inactivate some microbial agents, such as certain viruses and bacteria spores. Disinfection may not achieve the same reduction in microbial contamination levels as sterilisation.

Disseminated disease. Disease which is distributed over a considerable area of the body, e.g. metastatic cancer.

Distal intestinal obstruction syndrome (DIOS). Episodes of complete or partial intestinal obstruction associated with colicky pain, bloating and constipation.

Dominant. Trait expressed in people who are heterozygous for a particular gene.

Dysmorphobia. Patient complains of severe skin problems but investigations are normal. Often associated with clinical depression and delusions of body image.

Dysmorphology. Study of malformations arising from abnormal embryogenesis.

Dyspareunia. Difficult and/or painful sexual intercourse experienced by the woman. The discomfort may be described as superficial or deep.

Dysthymia. Chronic unipolar depression which tends to occur in older people with multiple debilitating, physical and psychosocial problems.

Echocardiogram. A non-invasive technique which uses pulses of high-frequency sounds (ultrasound) emitted from a transducer to evaluate cardiac anatomy, pathology and function. The procedure involves an operator applying a lubricant to the skin surface of the chest wall and moving the transducer or probe back and forth by hand across the surface.

Electrophoresis. Movement of charged particles through a liquid medium in response to changes in an electrical field. The pattern of migration can be recorded as bands on an electrophoretogram. It can be used to identify serum proteins and in the diagnosis of certain blood disorders, e.g. myeloma.

Embolism. The plugging of a blood vessel by material which has been carried through the larger vessels by the bloodstream. Usually due to fragments of a clot, but can be due to other factors such as a mass of air bubbles or bacteria.

Emollients. Agents that soften and soothe skin.

Empowerment. An enabling process whereby individuals are encouraged to think, make decisions and act as autonomously as possible.

Endarterectomy. Surgery to remove plaque build-up that causes narrowing (stenosis) in the artery. The blood flow through the narrowed area may need to be temporarily re-routed (shunted). Re-routing is done by placing a tube in the vessel above and below the narrowing. Blood flows around the narrowed area during the surgery. The artery is opened and the plaque is carefully removed, often in one piece. A vein from the leg may be sewn (grafted) on the artery to widen or repair the vessel. The shunt is removed, and the artery and skin incisions are closed.

Endemic. Cases of a disease that regularly appears in the population with little variation in incidence.

Endogenous. Microorganisms originating from within the body or produced from internal causes.

Epidemic. When an unusually high incidence of an endemic infection occurs, or occurrence of an infection not usually seen in a population.

Equianalgesic. A specified drug dose or route of administration that will give about the same analgesic effect as another specified drug dose or route. The term is often applied to an equianalgesic chart. This chart is useful to help maintain the same level of analgesia when changing the type of drug and/or the route of administration. Morphine is usually used as a standard for comparison. This chart can be used, for example, to see how much pethidine would have the same effect as 10 mg morphine. It also shows how much of an oral dose would be needed to equate in analgesic effect to a previous i.m. or i.v. dose, or vice versa.

Erythema. Redness of skin caused by vascular dilatation.

Excimer laser (EXCIted diMER). A treatment using laser energy to correct refractive errors (myopia or astigmatism) by altering corneal tissue.

Excoriation. Superficial abrasion caused by scratching.

Exfoliation. Shedding of tissue in layers.

Exogenous. Microorganisms originating outside the body or produced from external causes.

Extravasation. Accidental infiltration of vesicant/irritant fluids/medications into subcutaneous tissues surrounding the site of administration.

Fabry's disease. An inherited metabolic disease in which a glycolipid (ceramide trihexoside) accumulates in the organs and tissues, impairing function of kidneys and other organs.

Fine-needle aspiration (FNA). A means of tissue diagnosis by withdrawing fluid or tissue from a swelling, e.g. in the neck.

Fissure. Linear split in the epidermis.

Fomites. Inanimate objects or material on which disease-producing agents may be conveyed, for example bedding, clothes and soft furnishings.

Gastrocolic reflex. Sensory stimulation arising on entry of food into the stomach, resulting in strong peristaltic waves in the colon.

Genetic marker. A gene or DNA sequence having a known location on a chromosome and associated with a particular gene or trait. Genetic markers associated with certain diseases can be detected in the blood and used to determine whether an individual is at risk of developing a disease.

Gonadal mosaicism. Presence of a mutation in germline but not somatic cells, which results in transmission of a genetic disorder by a healthy person.

Haemolysis. The breakdown of red blood cells with the liberation of haemoglobin.

Haemorrhagic telangiectasia. A group of leaking dilated capillaries, often obvious on the surface of the skin.

Haemostasis. The homeostatic process which prevents the loss of blood from the vascular system and ensures the patency of the blood vessels.

Handicap. Limitation of activity persisting as a residual effect of impairment.

Haploid. Normal state of gametes, containing one set of chromosomes (n).

Haplotype. Particular set of alleles at closely linked loci on a single chromosome that are inherited together.

Hepatic encephalopathy. A neuropsychiatric syndrome present only in significant liver disease. Features can range from barely detectable changes in ability to concentrate through to violent behaviour and eventually coma.

Herd immunity. When a population is protected against an infectious disease through development of immunity, usually considered such when at least 60% of the population are known to be immune.

Heterozygote. Person possessing different alleles at a particular locus on homologous chromosomes.

HLA -B27 (human leucocyte antigen -B27). A blood test to detect gene/antigen compatibility and autoimmune disease, used for uveitis.

Homologous. Chromosomes that pair at meiosis and contain the same set of gene loci.

Homozygote. Person having two identical alleles at a particular locus on homologous chromosomes.

Hydrocephalus. An excess of cerebrospinal fluid inside the skull due to an obstruction to normal cerebrospinal fluid absorption.

Hyperpathia. 'A painful syndrome, characterised by increased reaction to a stimulus, especially a repetitive stimulus, as well as an increased threshold' (IASP 1986, p. S219).

Hypertrophy. Increase in size which takes place in an organ as a result of an increased amount of work demanded of it.

Impairment. Any disturbance of the body's structure and function.

Implantable venous reservoir. A small device placed under the skin. It empties into a blood vessel and makes it easier to give intravenous drugs and to take blood for tests.

Incubating. The time taken by microorganisms to develop signs and symptoms of infection from when they first make contact with a host.

Infestation. Presence of animal parasites in or on the human body.

Intra-aortic balloon pump. Intra-aortic balloon counterpulsation is a mechanical means of supporting the acutely failing left ventricle. The balloon is introduced under local anaesthetic, usually via the femoral artery, into the descending thoracic aorta. During diastole the balloon is inflated with helium and blood is driven out of the aorta into the distributing arteries. The balloon is deflated at the end of diastole just prior to the opening of the aortic valve, reducing afterload and left ventricular work.

Intracellular sperm injection (ICSI). Process of injecting a harvested single sperm into a harvested single ovum. The fertilised egg is returned to the female via the vagina to develop normally in the womb.

Iontophoresis. A treatment used for hyperhidrosis, excessive sweating. Iontophoresis is the introduction, by means of an electric current, of ions of soluble salts into the tissues of the body. This then 'plugs' the sweat ducts or disrupts the sweat gland, which in turn disrupts secretion of sweat.

Irritant. Medication/solution which has the potential to cause pain or irritation at the site of administration.

Isometric exercises. Exercises that increase muscle tension by applying pressure against stable resistance, e.g. making a limb push against an immovable object.

Karyotype. Description of the chromosomes present in somatic cells.

Laparoscopy. The surgical procedure of insertion of a fibreoptic endoscope, known as a 'laparoscope', into the abdominal cavity for the purpose of examination of the pelvic organs and carrying out surgical procedures such as biopsies, aspiration of cysts, collection of ova from ripened follicles, division of adhesions or ligation of the uterine tubes for sterilisation.

Lemniscal tract. Transmits impulses for more discriminating touch and pressure sensations.

Leucophoresis. Laboratory procedure in which white blood cells are separated by electrophoresis for identification and evaluation of the types of cells and their properties.

Locus. Site of a specific gene or DNA sequence on a chromosome.

Macule. Non-palpable localised area of change in skin colour.

Meconium ileus. Obstructed bowel due to impacted tenacious meconium. Associated in newborns with a diagnosis of cystic fibrosis.

Meiosis. Cell division during gametogenesis resulting in haploid gametes.

Melaena. Black tarry stools due to the presence of partly digested blood from further up in the digestive tract. Melaena is not apparent in an adult unless 500 mL of blood has entered the gut.

Mendelian disorder. Inherited disorder due to a defect in a single gene.

Meridians. In Eastern medicine these are believed to be connected channels through which energy (or *ki*) flows throughout the body. Each meridian is linked to an organ or psychophysical function, and its *ki* can be contacted at certain points along its path. For example, in acupuncture these are the places where needles would be placed.

Mesencephalon. The midbrain (which is one of three parts of the brain stem), lying just below the cerebrum and just above the pons.

Mesenteric adenitis. Inflammation of the lymph glands in the membranous support of the intestines: the mesentery. This condition must be ruled out when diagnosing appendicitis.

Metastases. The transfer of disease from one organ or part of the body to another not directly connected with it. Most commonly used to describe secondary growth of malignant tumours.

Microscopic endothelial sperm aspiration. Removal of sperm under anaesthetic, directly from the testes.

Mitosis. Cell division occurring in somatic cells resulting in diploid daughter cells.

MMR vaccination. Measles, mumps and rubella vaccination.

Mortality. A measure of causes of and age at death for a given population which can provide information on changes in life expectancy but may not indicate quality of life experienced.

MUGA scanning. A multigated acquisition scan (MUGA scan) is a nuclear scan that evaluates the pumping function of the ventricles.

Multiple Endocrine Neoplasia Type I (MEN I). MEN I is a syndrome characterised by the combined occurrence of tumours of the parathyroid glands, pancreatic islet cells and the anterior pituitary. Parathyroid tumours occur in 95% of patients with MEN I. Approximately 90% of these patients present with hypercalcaemia. Pancreatic islet cell tumours, of which gastrinomas are the most common, occur in 40% of MEN I patients and are an important cause of morbidity and mortality. Anterior pituitary tumours, usually prolactinomas, occur in 30% of MEN I patients. Other tumours associated with MEN I include

adrenal tumours, carcinoid tumours, lipomas and angiofibromas (Thakker 1998).

Multiple Endocrine Neoplasia Type II (MEN II). MEN II is characterised by the association of Medullary Thyroid Carcinoma (MTC), phaeochromocytomas and parathyroid tumours. There are three clinical variants: MEN IIa, MEN IIb and MTC-only. The most common is MEN IIa, with almost all patients having MTC and which in 50% of patients is also associated with phaeochromocytomas and in 20% of patients with parathyroid tumours. MEN IIb is characterised by the occurrence of MTC and phaeochromocytomas without parathyroid tumours and represents 5% of all MEN II cases. In addition, patients with MEN IIb have Marfan's syndrome, mucosal neuromas, medullated corneal fibres and intestinal autonomic ganglion dysfunction, leading to multiple diverticulae and an enlarged colon (Thakker 2004).

Mutation. Change in the structure of DNA.

Neoplasm. Any new and abnormal growth, a tumour. Neoplasms may be benign or malignant.

Nephrotoxicity. The degree to which a substance may impair kidney function.

Neuralgias. 'Pain in the distribution of a nerve or nerves' (IASP 1986, p. S220).

Neuroendocrine tumours (NET). Neuroendocrine tumours are a group of tumours that arise from endocrine glands or from endocrine islets within glandular tissue, e.g. the thyroid or pancreas or endocrine cells in the digestive and respiratory tract (Kaltsas et al 2004). See also Carcinoid syndrome, above.

Neutropenia. Reduction in number of neutrophils, usually less than 1×10^9 cells/L, resulting in the neutropenic patient being highly susceptible to infection.

Nociceptor. This is a receptor which responds to noxious stimuli or injury.

Nodule. Small node or node-like structure.

Nulliparous. A woman who has not borne a child.

Nystagmus. Rapid and involuntary movements of the eyes which may be vertical, horizontal or rotatory. The condition may be congenital and associated with poor sight or may occur due to disorders in the part of the brain responsible for movements and coordination. Vestibular nystagmus results when there is labyrinthine damage in the ear.

Opisthotonos. Arching of the back with backward flexion of the head and feet. This posture occurs when there is damage to the midbrain and pons. Opisthotonos can also occur in meningitis, due to severe inflammation of the meninges.

Orthopantomogram (OPT). Panoramic radiograph giving consistent image quality, usually of mandible or maxilla, for suspected neoplasia. Also in maxillofacial surgery for middle third fracture of facial bones.

Ototoxicity. The degree to which a substance may cause damage to the ear.

Palliative therapy. Therapy used to treat distressing symptoms and improve quality of life where no cure is thought possible, e.g. radiotherapy to painful bone metastases.

Pancytopenia. Reduction in the number of red blood cells, neutrophils and platelets, i.e. there is an anaemia, neutropenia and thrombocytopenia.

Pandemic. An infectious disease causing a worldwide outbreak.

Papule. Circumscribed disc-shaped elevated area of skin less than 1 cm in diameter.

Paraprotein. Any of the incomplete monoclonal immunoglobulins that occur in plasma cell disorders, e.g. myeloma.

Parasite. An organism that lives in or upon another, obtaining nourishment from this host site, but without providing any benefit to the host.

Parous. Having given birth to a child.

Passive exercise. The moving of parts of the body, e.g. a limb, by an outside force, with no voluntary contribution by the individual.

Paterson–Kelly/Plummer–Vinson syndrome. A combination of dysphagia, glossitis and nutritional iron deficiency anaemia. Dysphagia is caused by a fibrous web in the post-cricoid region of the oesophagus. Oral iron therapy usually leads to complete recovery.

Pathogenic. A microorganism's ability to invade, cause harm and produce disease within a host.

Patulent. The external sphincter lacks tone and is open, due to a grossly overloaded rectum.

Phenomenological. Offering an account of the person's own experience as a unique event or phenomenon.

Phenotype. Physical or biochemical characteristics of a person reflecting genetic constitution and environmental influence.

Photophobia. Inability to expose the eyes to light.

Piston effect. Movement of catheter up and down within the urethra.

Plaque. Palpable elevation of the skin more than 2 cm in diameter.

Plasmapheresis. Removal of plasma from previously withdrawn blood by centrifugation; the blood is then reinfused into the donor or another client who requires red cells. Used as treatment to reduce viscosity of blood where viscosity is high.

Pluripotent or stem cell. A blood stem cell is the original blood cell from which all other blood cells are derived.

Polycystic ovary syndrome (PCOS). PCOS is a syndrome characterised by excessive androgens and ovulatory dysfunction. It is the most common endocrinopathy in premenopausal women. Approximately 95% of women who present with hirsutism have PCOS. Symptoms, which often arise around the time of puberty but can occur any time, e.g. after gaining weight or stopping the oral contraceptive pill, include oligomenorrhoea and/or amenorrhoea, hirsutism, obesity and infertility (Azziz 2005).

Polymerase chain. Method of amplification of specific DNA sequences.

Proband. Index case through which a family is identified.

Prognosis. A forecast of the probable course and outcome of a condition and the prospects of a recovery.

Proprioceptors. Any sensory nerve ending, such as those located in muscles, tendons, joints and the vestibular apparatus, that respond to stimuli regarding movement and spatial positions.

Pruritus. Itching that may result from many skin and systemic disorders. In liver disease, the cause of the itching is unclear, although the deposition of bile salts is implicated.

Pseudocyst. An abnormal dilated space which resembles a cyst but has no epithelial lining, e.g. pancreatic pseudocyst where the sac contains pancreatic enzymes, debris and blood within a lining of inflammatory tissue.

Purpura. Extravasation of blood from the capillaries into the skin or onto or into the mucous membranes. Appears as small red dots (petechiae) or large bruises.

Pustule. Visible collection of pus.

Quality assurance. An ongoing process of assuring the client of a specific standard of excellence through measurement and evaluation of a product or service.

Quality audit. A systematic and independent examination of the effectiveness of the quality system or its parts.

Radionuclide ventriculography. A non-invasive procedure that uses radioactive tracers to make heart chambers and blood vessels visible. A radioactive isotope is injected into the vein. Commonly used isotopes include technetium and thallium. Radioactive isotopes attach to red blood cells and pass through the heart in the circulating blood. The radioactive isotope can then be traced through the heart using special cameras or scanners. The images may be synchronised with an electrocardiogram.

Recession and resection. The weakening and strengthening of extraocular muscles, by moving their attachment to the sclera backwards or forwards, in order to correct a squint.

Recombination. Crossing-over between homologous chromosomes at meiosis which separates linked loci.

Response. A psychological or physiological reaction to stimulation.

Reticular. From the Latin word reticulus (net-like), meaning a Roman gladiator who fought with a net.

Roger's crystal spray. A glass atomiser with saline to spray at the tracheostomy stoma or bib protector, in order to moisten it.

Salpingolysis. The breaking down of adhesions in a uterine tube.

Salpingostomy. The surgical opening of the uterine tubes for reparative procedures following inflammatory disease or sterilisation. The aim is to restore patency to the tubes by anastomoses of the cut ends from either side of the blockage.

Saltatory conduction. A means of increasing the speed of nerve conduction, whereby the impulse 'jumps' from one node of Ranvier to the next.

Sclerotherapy. The injection of an irritant substance into varicose veins, which causes thrombophlebitis and encourages obliteration and subsequent scarring of the tissue.

Sheehan's syndrome. The pituitary gland, which enlarges during pregnancy, becomes very susceptible to any compromise to its blood supply. Sheehan's syndrome occurs when there is haemorrhagic infarction of the enlarged postpartum pituitary gland following a severe hypotensive crisis, usually due to excessive blood loss, e.g. postpartum haemorrhage, which results in hypopituitarism.

Sialogram. Radiograph following injection of contrast medium into salivary duct and gland.

Sjögren's syndrome. An autoimmune disease attacking and destroying the body's own moisture-producing glands. The main symptoms are dry eyes and dry mouth, as well as dryness of joints and major organs.

Slit lamp. A slit lamp is a binocular microscope which illuminates and magnifies the ocular structures with a narrow band of light, facilitating examination for accurate diagnosis.

'Sounds'. Medical probes of different sizes used to explore or expand a cavity, e.g. dilatation of the urethra.

Spider telangiectasis. A localised collection of distended blood capillaries arising from a central point, thereby resembling a spider's web (also known as 'spider naevi').

Spinothalamic tract. Transmits impulses for crude touch, pain and temperature sensations.

Spore. Some microorganisms develop a casing to protect themselves in inhospitable conditions. Spores cannot multiply but can survive for long periods during such times.

Staging. A process of identifying the stage of progression of a disease, e.g. the size of a tumour and the extent of any spread.

Sterilisation. The process of rendering an individual incapable of reproduction. Female sterilisation is most commonly carried out via a laparoscopic procedure. The uterine tubes are occluded by the application of clips, cautery, thermal coagulation or laser vaporisation with photocoagulation.

Stimulus. Any factor such as heat, light, cold or medication that will cause a response in a person or an organism. The term can also apply to any event causing emotional distress.

Stoma button. A small Silastic appliance, approximately 2.5 cm in length. It has an external flange and is designed to sit firmly in a laryngectomy stoma in the same way as would a laryngectomy tube.

Stomatitis. Inflammation of the oral mucosa.

Support and supervision. Regular contact with another person undertaking similar clinical work with the purpose of sharing and learning from difficult or painful situations.

Synapse. The point of communication between two adjacent neurones.

Thalamus. A collection of grey matter located within the forebrain or prosencephalon.

Thrombocytopenia. Reduced number of platelets, usually less than 100×10^9 cells/L, which can result in the occurrence of purpura and spontaneous bleeding.

Thrombosis. Formation of a blood clot within the blood vessels or the heart. The indirect cause is usually some damage to the smooth lining of the blood vessels brought about by inflammation or the result of atheroma.

Titration. A method whereby the amount of solute in a solution can be measured. The solution is added in small measured quantities to a known volume of a standard solution until the required reaction occurs.

Trait. Recognisable phenotype due to a genetic character.

Transactional. Representing an interaction between the perception of the person and the object of the person's stress.

Transcription. Production of messenger RNA from DNA sequence in gene.

Transient microorganisms. Microorganisms which may be present on or in the body under certain conditions and for certain lengths of time and may be picked up from other people or the environment during activities; they are easier to remove by mechanical friction than resident microorganisms.

Transjugular Intrahepatic Portosystemic Stent Shunt (TIPSS). A method of treating portal hypertension by inserting a metal mesh tube (stent) through the liver which joins two large veins, the portal vein and hepatic vein, allowing blood to flow through the liver, thereby relieving portal hypertension which causes the varices. This stent remains in place permanently.

Translocation. Transfer of chromosomal material between two non-homologous chromosomes.

Transmyocardial laser revascularisation (TMR). TMR uses a laser beam to improve blood flow to heart muscle, often relieving symptoms in people who are no longer good candidates for surgery or angioplasty. It does not require stopping the heart and is done through a small incision instead of through open-chest surgery. This technique is usually only undertaken when persistent, severe angina cannot be controlled with medication or treated with bypass surgery or percutaneous coronary intervention (PCI).

Trichotillomania. Compulsive plucking of hair — often a transient compulsive habit, but can be a sign of disturbed behaviour.

Trisomy. Cells containing one more than the normal diploid set of chromosomes (2n + 1).

Variceal banding. Via endoscopy, the varices in the oesophagus are viewed and a rubber band inserted round each of these varices. This occludes the blood supply in these veins and they eventually disappear.

Ventricular assist device. This is a device that provides temporary circulatory support in heart failure in order to promote optimum myocardial tissue recovery. Ventricular assist devices partially bypass either the left or right ventricle using an artificial pump that maintains systemic circulation. A median sternotomy is made, blood is diverted away from the heart, bypasses the ventricle and is returned to the patient.

Ventrosuspension. The round ligaments of the pelvis may be folded, ligated, plicated or transplanted at operation with the aim of pulling the retroverted uterus forward.

Vesicant. Medication or solution which has corrosive properties and therefore the potential to cause tissue destruction in the event of extravasation.

Vesicle. Small visible collection of fluid less than 1 cm in diameter.

Viability. The capacity of a fetus for living a separate existence from its mother. A fetus is considered viable or capable of survival from the 24th week of pregnancy. This viability is recognised and safeguarded in the Human Fertilisation and Embryology Act 1990.

Videofluoroscopy. Video recording of swallowing mechanism, using fluorescent fluid, an 'action X-ray'.

Virulence. The level of activity of pathogenic microorganisms that contributes to the harm or infection that may occur.

Weal. Circumscribed, elevated area of cutaneous oedema.

Wilson's disease. An inborn defect of copper metabolism that results in free copper being deposited in the liver, causing jaundice and cirrhosis. Deposits can also occur in the brain, resulting in intellectual impairment. The condition is treated with penicillamine, a derivative of penicillin, which chelates (binds) the copper in order to remove excess from the body.

ELSEVIER

Nursing Practice

Hospital and Home

The Adult

THIRD EDITION

The most comprehensive UK Adult Nursing core text, now in its third edition, for the next generation of nurses...

This best-selling textbook has been revised and updated to present the knowledge and skills required for competent, evidence-based nursing practice, whilst maintaining the thorough approach that was welcomed in the first two editions. It remains the core text of choice for students of adult nursing.

The third edition continues to reflect the issues and challenges for nursing practice in an era of rapid developments in diagnosis, therapy and care. As always, the importance of the patient as partner in care is emphasised.

The three-section format which has proved so effective is retained, progressing as it does from a broad systems approach to more detail on specific patient concerns and nursing issues. Ample cross-referencing encourages links between the sections:

SECTION ONE:
Care of patients with common disorders

SECTION TWO:
Common patient problems and related nursing care

SECTION THREE:
now entitled - Nursing patients with special challenges.

Key features of the text:

- Care priorities and pathways
- Personal accounts of the lived experience of illness
- Pauses for reflection
- Clear illustrations
- Research abstracts
- Comprehensive referencing
- Further reading, web sites and addresses

This text is an invaluable resource, not only for student nurses, but also for qualified nurses, those returning to practice and nurse educators.

From students who used the previous editions of the book ....

- My class call it "the nursing bible"
- Fantastic book for student nurses
- Well written, easy to follow and very informative
- A mine of information
- Heavy to carry but not heavy to read!

From nurses who use it as a resource in practice ....

- The book is easy to use and a good reference tool
- Just what I need on return to practice after a five-year gap
- Very comprehensive
- Excellent source when qualified
