Genetic engineering has provided hope for blood products. Initially, recombinant erythropoietin was developed for treatment of anemias and facilitation of autologous blood donation (see Chapter 57). In 1992, a human recombinant hemoglobin (rHb 1.1) was designed as a blood substitute.[119] With the use of genetic engineering techniques, it was made from *Escherichia coli*. It functions as normal hemoglobin in terms of oxygen-carrying capacity, but it does not require crossmatching, nor does it transmit disease or become rapidly outdated. How much recombinant material can be tolerated by humans remains to be determined. Unfortunately, this caused arteriolar vasoconstriction from nitric oxide scavenging. While arterial blood pressure was sustained, it was at the expense of severe vasoconstriction of microvascular structures, which is not beneficial for organ perfusion. Recently, rHbg 2.0, which minimizes nitric oxide scavenging, caused little arteriolar vasoconstriction when compared with rHbg 1.1 and diaspirin crosslinked hemoglobin.[120,121] It is hoped that studies of these newer hemoglobin solutions will lead to new synthetic blood products in humans.

An example of a product that appears to be the initial one possibly approved for routine clinical practice is Hemopure.[122] It is from ultrapurified bovine RBCs that have been glutaraldehyde polymerized. It has a higher P_{50} (i.e., 43 instead of 26 mm Hg), which means that it should deliver oxygen to the tissues at least as well, if not better, than human RBCs.[122] It has the added advantage of not requiring type and crossmatch and not transmitting infectious agents such as HIV and hepatitis virus.[121,122] These, of course, are typical characteristics of most synthetic blood products (Table 55-16). Many clinical trials have been safely conducted with a few possibly minor complications, the significance of which are not clear. Complications include a slight increase in mean arterial blood pressure and a decrease in cardiac index, which presumably may be from nitric oxide. Hemopure has been approved for routine clinical use in South Africa. Its indication will probably be treatment of acute anemia in some type of surgery. Most of the clinical trials have shown a decreased use of allogeneic blood transfusions.[123]

However, the most recent information regarding HBOCs is not encouraging. Natanson and associates[124] performed a cumulative meta-analysis on 16 trials involving five different products and 3711 patients. They concluded that there was a significant increased risk of myocardial infarction and death when HBOCs were given. An accompanying editorial by Fergusson and McIntyre[125] concluded that a 30% increased risk of death and a 3-fold increase in the risk of myocardial infarction should preclude any additional studies. Furthermore, there was a consistency of harm among all of the technologies (e.g., cross-linked, polymerized, or conjugated). In essence, investigators must demonstrate that HBOCs are at least as effective in reducing mortality or serious morbidity as the current standards of care. I have reluctantly concluded that use of synthetic blood (HBOCs) is not likely with the current technologic approaches.

Table 55-16 Comparison of Synthetic Blood in General with Allogeneic Blood

Parameter	Synthetic	Allogeneic
Oxygen delivery	Rapid and consistent	Dependent on 2,3-DPG
Risk of disease transmission	None	See Table 55-9
Storage	Room temperature Stable efficacy	Refrigeration Loss of efficacy
Shelf life	1-3 years	42 days
Preparation	Ready to use	Crossmatch
Compatibility	Universal	Type specific
Duration of action	1-3 days	60-90 days

Informed Consent

Before any transfusion is given, informed consent should be obtained from the patient or guardian (see Chapter 10). What constitutes consent varies across the United States and is still changing. If a patient is damaged by a transfusion administered without a valid consent, damages may be recovered even though the defendant did everything properly.[124] During the past decade, the public has demanded to know more about transfusions. A dramatic example was the passage of the Paul Gann Blood Safety Act in California. This law mandates that patients be informed of the risks of blood transfusions and of any alternatives. This law has apparently already had a restrictive impact on transfusion practice in California.[126] The rapid changes in transfusion medicine probably dictate an intense, ongoing educational process for clinicians who administer blood products to ensure that they are compliant with current laws and regulations.

56 Coagulation

Key Points

1. Under normal physiologic conditions, clot formation requires participation of vascular endothelium, platelets, and plasma-mediated hemostasis.
2. Tissue factor (extrinsic pathway) initiates plasma-mediated hemostasis, whereas factor XI (intrinsic pathway) amplifies the response.
3. Thrombin generation proves the key regulatory enzymatic step in hemostasis.
4. Platelets participate in clot formation as (1) anchoring sites for coagulation factor activation complexes; (2) delivery "vehicles" releasing hemostatically active proteins; and (3) major structural components of the clot.
5. A carefully performed history of bleeding remains the most effective means for identifying bleeding and thrombotic tendencies.
6. Thrombosis is potentiated by stasis, vascular endothelial injury, and underlying hypercoagulable conditions.
7. Heparin-induced thrombocytopenia (HIT) comprises a heparin-mediated autoimmune response potentiating platelet activation as well as venous and arterial thromboses.

Normal Hemostasis

Hemostasis comprises cellular and biochemical processes that limit blood loss resulting from injury, maintain intravascular blood fluidity, and promote revascularization of thrombosed vessels after injury. Normal physiologic hemostasis necessitates a delicate balance between procoagulant pathways responsible for generation of a stable localized hemostatic "plug" and counterregulatory mechanisms inhibiting thrombus formation beyond the injury site. Vascular endothelium, platelets, and plasma coagulation proteins play equally important roles in this process. Failure to maintain balance commonly leads to excessive bleeding or pathologic thrombus formation.

Vascular endothelial injury, mechanical or biochemical, leads to platelet deposition at the injury site, a process often referred to as primary hemostasis. Although primary hemostasis may prove adequate for a minor injury, control of more significant bleeding necessitates stable clot formation incorporating cross-linked fibrin—a process mediated by activation of plasma clotting factors and often referred to as secondary hemostasis. Although the terms *primary* and *secondary hemostasis* remain relevant for descriptive and diagnostic purposes, advances in understanding cellular and molecular processes underlying hemostasis suggest a far more complex interplay between vascular endothelium, platelets, and plasma-mediated hemostasis than is reflected in this model.

Vascular Endothelial Role in Hemostasis

Under normal conditions, vascular endothelium provides a nonthrombogenic surface to promote blood fluidity. Healthy endothelial cells possess antiplatelet, anticoagulant, and profibrinolytic effects to inhibit clot formation.[1] Negatively charged vascular endothelium repels platelets and produces prostacyclin (PGI_2) and nitric oxide (NO), which are potent platelet inhibitors.[2] Adenosine diphosphatase (ADPase) synthesized by vascular endothelial cells degrades adenosine diphosphate (ADP), another potent platelet activator. Given these endogenous antiplatelet effects, nonactivated platelets do not adhere to healthy vascular endothelial cells. Vascular endothelium further expresses several inhibitors of plasma-mediated hemostasis, including thrombomodulin (an indirect thrombin inhibitor), heparin-like glycosaminoglycans, and tissue factor pathway inhibitor (TFPI).[3] Finally, vascular endothelium synthesizes tissue plasminogen activator (t-PA), which is responsible for activating fibrinolysis—a primary counterregulatory mechanism limiting clot propagation.

Despite these natural defense mechanisms to inhibit thrombus generation, a variety of mechanical and chemical stimuli may shift the balance such that the endothelium promotes clot formation. Damage to vascular endothelial cells exposes the underlying extracellular matrix (ECM) including collagen, von Willebrand factor (vWF), and other platelet-adhesive glycoproteins.[4,5] Platelets bind to and are activated by exposure to ECM

components. Exposure of tissue factor, constitutively expressed by fibroblasts in the ECM, activates plasma-mediated coagulation pathways to generate thrombin and, ultimately, fibrin clot. Certain cytokines (i.e., interleukin-1, tumor necrosis factor, and γ-interferon) and hormones (i.e., desmopressin acetate or endotoxin) induce prothrombotic changes in vascular endothelial cells, including synthesis and expression of vWF, tissue factor, plasminogen activator inhibitor (PAI-1, an inhibitor of fibrinolysis), as well as downregulate normal antithrombotic cellular and biochemical pathways.[6,7] Thrombin, hypoxia, and high fluid shear stress induce prothrombotic vascular endothelial changes. Increased vascular endothelial synthesis of PAI-1 and associated inhibition of fibrinolysis have been implicated in the prothrombotic state and high incidence of venous thrombosis after surgery.[8,9]

Platelets and Hemostasis

Platelets contribute a critical role in hemostasis. Derived from bone marrow megakaryocytes, nonactivated platelets circulate as discoid anuclear cells.[10] The platelet membrane is characterized by numerous receptors and a surface-connected open canalicular system serving to increase platelet membrane surface area as well as to provide rapid communication between the platelet interior and external environment.[11] Under normal circumstances, platelets do not bind vascular endothelium; however, when injury exposes ECM, platelets undergo a series of biochemical and physical alterations characterized by three major phases: adhesion, activation, and aggregation.

Exposure of subendothelial matrix proteins (i.e., collagen, vWF, fibronectin) allows for platelet adhesion to the vascular wall. vWF proves particularly important as a bridging molecule between ECM and platelet glycoprotein Ib/factor IX/factor V receptor complexes.[12] Absence of either vWF (von Willebrand disease) or glycoprotein Ib/factor IX/factor V receptors (Bernard-Soulier syndrome) results in a clinically significant bleeding disorder.

As platelets adhere along the ECM, a series of physical and biochemical changes occur termed *platelet activation.* Platelets contain two specific types of storage granules: alpha granules and dense bodies.[11] Alpha granules contain numerous proteins essential to hemostasis and wound repair, including fibrinogen, coagulation factors V and VIII, vWF, platelet-derived growth factor, and others. Dense bodies contain the adenine nucleotides ADP and adenosine triphosphate (ATP) as well as calcium, serotonin, histamine, and epinephrine. During the activation phase, platelets release granular contents, resulting in recruitment and activation of additional platelets as well as propagation of plasma-mediated coagulation.[13] During activation, platelets undergo structural changes to develop pseudopod-like membrane extensions and to release physiologically active microparticles, with both mechanisms serving to increase dramatically platelet membrane surface area. Redistribution of platelet membrane phospholipids during activation exposes newly activated glycoprotein platelet surface receptors and phospholipid binding sites for calcium and coagulation factor activation complexes, which is critical to propagation of plasma-mediated hemostasis.[14]

During the final phase of platelet aggregation, activators released during the activation phase serve to recruit additional platelets to the site of injury. Newly active glycoprotein IIb/IIIa receptors on the platelet surface bind fibrinogen to provide for cross-linking with adjacent platelets (platelet aggregation).[15] The importance of these receptors is reflected by the bleeding disorder associated with their hereditary deficiency: Glanzmann thrombasthenia.

Plasma-Mediated Hemostasis

Plasma-mediated hemostasis, the coagulation cascade, might best be summarized as an amplification system to accelerate thrombin generation from an inactive precursor (i.e., prothrombin). Trace plasma proteins, activated by exposure to tissue factor or exposure to foreign surfaces, initiate a cascading series of reactions culminating in conversion of soluble fibrinogen to insoluble fibrin clot.[16] Thrombin generation, the "thrombin burst," represents the key regulatory step in this hemostatic process. Thrombin not only generates fibrin but also activates platelets and mediates a host of additional processes affecting inflammation, mitogenesis, and even downregulation of hemostasis.[17]

Traditionally, the "coagulation cascade" describing plasma-mediated hemostasis has been depicted as intrinsic and extrinsic pathways, both of which culminate in a common pathway where fibrin generation occurs.[18] Although this cascade model has proved an oversimplification, it remains a useful descriptive tool for organizing discussions of plasma-mediated hemostasis (Fig. 56-1). Coagulation factors are, for the most part, synthesized hepatically and circulate as inactive proteins termed *zymogens.* The somewhat confusing nomenclature of the classic coagulation cascade derives from the fact that inactive zymogens were identified using Roman numerals assigned in order of discovery. As the zymogen is converted to an active enzyme, a lower-case letter "a" is added to the Roman numeral identifier. For example, inactive prothrombin is referred to as factor II, whereas active thrombin is identified as factor IIa. Some numerals were subsequently withdrawn or renamed as our understanding of the biochemistry underlying hemostasis evolved.

The coagulation cascade characterizes a series of enzymatic reactions in which inactive precursors—zymogens—undergo activation to amplify the overall reaction. Each stage of the cascade requires assembly of membrane-bound activation complexes, each composed of an enzyme (activated coagulation factor), substrate (inactive precursor zymogen), cofactor (accelerator/ catalyst), and calcium.[19] Assembly of these activation complexes occurs on phospholipid membranes (most often platelet or microparticle membranes) that serve to localize and concentrate reactants. In the absence of phospholipid membrane anchoring sites, activation of coagulation factors slows dramatically, further serving to localize clot generation to injury sites.

Extrinsic Pathway of Coagulation

The extrinsic pathway of coagulation, widely recognized as the initiating step in plasma-mediated hemostasis, begins with exposure of blood plasma to tissue factor.[20] Tissue factor is prevalent in subendothelial tissues surrounding vasculature; however, under normal conditions the vascular endothelium minimizes contact between tissue factor and plasma coagulation factors. After vascular injury, small concentrations of factor VIIa circulating in

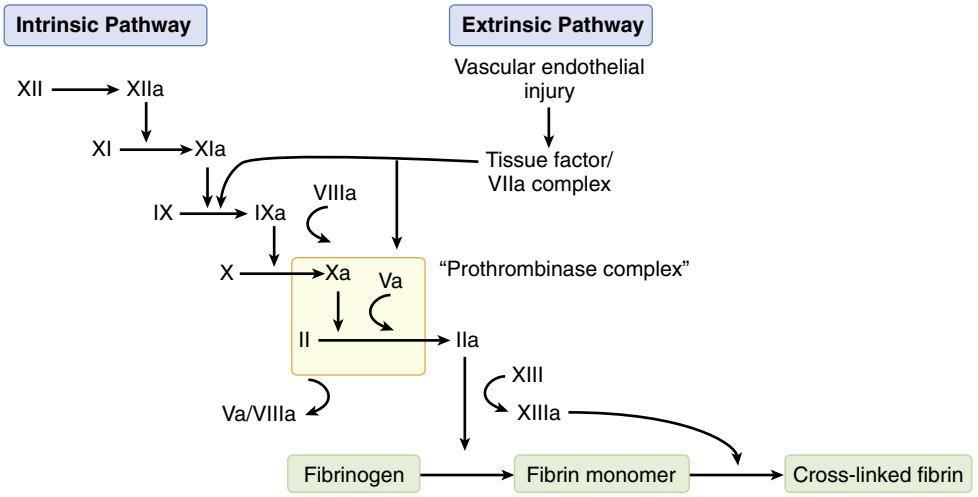

Figure 56-1 Depiction of the classic coagulation cascade incorporating extrinsic and intrinsic pathways of coagulation. *(From Slaughter TF: The coagulation system and cardiac surgery. In Estafanous FG, Barash PG, Reves JG [eds]: Cardiac Anesthesia: Principles and Clinical Practice, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2001, p 320, with permission.)*

plasma form phospholipid-bound activation complexes with tissue factor, factor X, and calcium to promote conversion of factor X to Xa.[21] Recently, the tissue factor/factor VIIa complex has been demonstrated to activate factor IX of the intrinsic pathway, further demonstrating the key role of tissue factor in initiating hemostasis.[22]

Intrinsic Pathway of Coagulation

Classically, the intrinsic or contact activation system was described as a parallel pathway for thrombin generation by way of factor XII. However, the rarity of bleeding disorders resulting from contact activation factor deficiencies led to our current understanding of the intrinsic pathway as an amplification system to propagate thrombin generation initiated by the extrinsic pathway.[22] Recent cell-based models of coagulation suggest that thrombin generation by way of the extrinsic pathway is limited by a natural inhibitor, tissue factor pathway inhibitor (TFPI).[23] However, small quantities of thrombin generated before neutralization of the extrinsic pathway activate factor XI and the intrinsic pathway. The intrinsic pathway subsequently amplifies and propagates the hemostatic response to maximize thrombin generation (Fig. 56-2). Although factor XII may be activated by foreign surfaces (i.e., cardiopulmonary bypass circuits or glass vials), the intrinsic pathway appears to play a minor role in initiation of hemostasis. Proteins of the intrinsic pathway may, however, contribute to inflammatory processes, complement activation, fibrinolysis, kinin generation, and angiogenesis.[22,24]

Common Pathway of Coagulation

The final pathway, common to both extrinsic and intrinsic coagulation cascades, depicts thrombin generation and subsequent fibrin formation. Signal amplification through both extrinsic and intrinsic pathways culminates in formation of prothrombinase complexes (phospholipid membrane bound activation complexes)

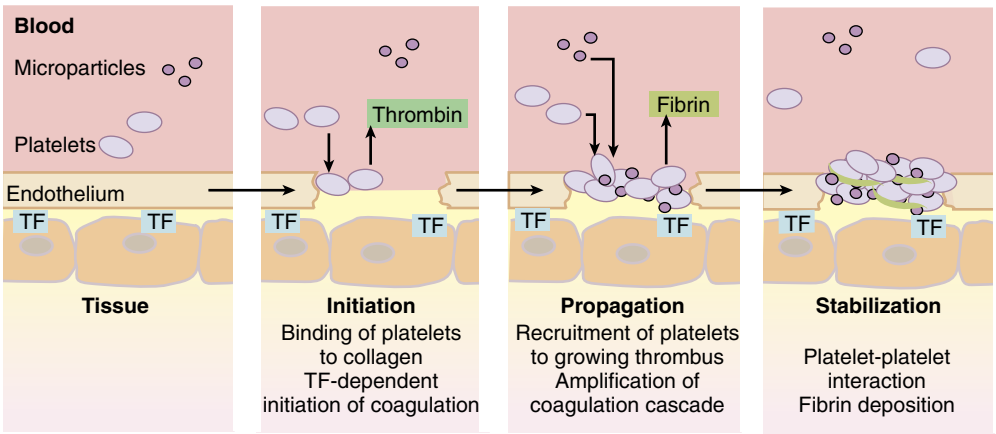

Figure 56-2 Clot formation at vascular injury site. Vascular injury exposes subendothelial tissue factor initiating plasma-mediated hemostasis via the extrinsic pathway. The intrinsic pathway further amplifies thrombin and fibrin generation. Platelets adhere to exposed collagen to undergo activation, resulting in recruitment and aggregation of additional platelets. *(From Mackman N, Tilley RE, Key NS: Role of extrinsic pathway of blood coagulation in hemostasis and thrombosis. Arterioscleros Thromb Vasc Biol 27:1688, 2007, with permission.)*

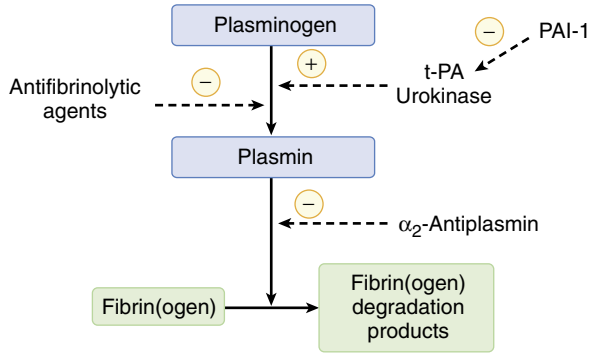

Figure 56-3 Principal mediators of fibrinolysis. *Dashed lines* depict sites of action for promoters and inhibitors of fibrinolysis. *(From Slaughter TF: The coagulation system and cardiac surgery. comprised of factor Xa, factor II (prothrombin), factor Va (cofactor), and calcium ions.[25] Prothrombinase complexes mediate the thrombin burst—a surge in thrombin generation from the inactive precursor prothrombin. Thrombin proteolytically cleaves fibrinopeptides A and B from fibrinogen molecules to generate fibrin monomers, which polymerize into fibrin strands (i.e., fibrin clot).[25] Finally, factor XIIIa, a transglutaminase activated by thrombin, covalently crosslinks fibrin strands to produce an insoluble fibrin clot resistant to fibrinolytic degradation.[26] Again, thrombin generation is the key enzymatic step regulating hemostasis.[27] Not only does thrombin activity mediate conversion of fibrinogen to fibrin, but it also activates platelets, converts inactive cofactors V and VIII to active conformations, activates factor XI and the intrinsic pathway of coagulation, upregulates cellular expression of tissue factor, and stimulates vascular endothelial expression of PAI-1 to downregulate fibrinolytic activity.[17,27]

Intrinsic Anticoagulant Mechanisms

Once activated, regulation of hemostasis proves essential to limit clot propagation beyond the injury site. One simple, yet important, anticoagulant mechanism derives from flowing blood and hemodilution. The early platelet/fibrin clot proves highly susceptible to disruption by shear forces within flowing blood. Blood flow further limits localization and concentration of both platelets and coagulation factors such that a critical mass of hemostatic components may fail to coalesce.[25,28] However, later in the clotting process more robust counterregulatory mechanisms are necessary to limit clot propagation. Four major counterregulatory pathways have been identified that appear particularly crucial for downregulating hemostasis: fibrinolysis, TFPI, the protein C system, and serine protease inhibitors.

The fibrinolytic system comprises a cascade of amplifying reactions culminating in plasmin generation and proteolytic degradation of fibrin and fibrinogen. As with the plasma-mediated coagulation cascade, inactive precursor proteins are converted to active enzymes, necessitating a balanced system of regulatory controls to prevent excessive bleeding or thrombosis (Fig. 56-3). The principal enzymatic mediator of fibrinolysis, plasmin, is generated from an inactive precursor, plasminogen.[29] *In vivo*, plasmin generation most often is initiated by release of t-PA or urokinase from vascular endothelium. Thrombin provides a potent stimulus for t-PA synthesis.[27] Factor XIIa and kallikrein of the intrinsic pathway activate fibrinolysis after exposure to foreign surfaces. The presence of fibrin accelerates plasmin generation.[30] Rapid inhibition of free plasmin also limits spread of fibrinolytic activity. In addition to enzymatic degradation of fibrin and fibrinogen, plasmin inhibits hemostasis by degrading essential cofactors V and VIII as well as reducing platelet glycoprotein surface receptors essential to adhesion and aggregation.[31] Fibrin degradation products possess mild anticoagulant properties as well.

TFPI inhibits the tissue factor/factor VIIa complex and thereby the extrinsic coagulation pathway, which is responsible for initiation of hemostasis. TFPI and factor Xa form phospholipid membrane-bound complexes that incorporate and inhibit tissue factor/factor VIIa complexes.[3] Most TFPI is bound to vascular endothelium but may be released into circulation by heparin administration. Heparin further catalyzes TFPI inhibitory activity.[32] As TFPI rapidly extinguishes tissue factor/VIIa activity, the critical role of the intrinsic pathway to continued thrombin and fibrin generation becomes apparent.[22]

The protein C system proves particularly important in downregulating hemostasis because it inhibits thrombin as well as the essential cofactors Va and VIIIa. Thrombin initiates this inhibitory pathway by binding a membrane-associated protein, thrombomodulin, to activate protein C.[33] Protein C, complexed with the cofactor protein S degrades both cofactors Va and VIIIa. Loss of these critical cofactors limits formation of "tenase" and "prothrombinase" activation complexes essential to formation of factor X and thrombin, respectively. Thrombin, once bound to thrombomodulin, is inactivated and removed from circulation, providing another mechanism by which protein C downregulates hemostasis.[33]

The most significant serine protease inhibitors regulating hemostasis include antithrombin (AT) and heparin cofactor II. Antithrombin binds to and inhibits thrombin as well as factors IXa, Xa, XIa, and XIIa. Heparin cofactor II inhibits thrombin alone. Although the precise physiologic role for heparin cofactor II remains uncertain, antithrombin plays a major role in downregulating hemostasis.[34] Heparin, a catalyst accelerator, binds antithrombin to promote inhibition of targeted enzymes.[35] Heparin-like glycosaminoglycans, located on vascular endothelial cells, provide inhibitory sites for thrombin and factor Xa *in vivo*.

Disorders of Hemostasis

Evaluation of Bleeding Disorders

Few would argue the importance of assessing bleeding risk preoperatively; however, appropriate methods for ascertaining this risk remain subject to debate. Although routine coagulation testing of all surgical patients preoperatively intuitively may be appealing, this approach lacks predictive value for bleeding disorders and certainly lacks cost effectiveness.[36] A carefully performed history of bleeding remains the single most effective predictor for perioperative bleeding.

A well-conducted history should focus on prior bleeding episodes experienced by the patient.[37] Does the patient have a history of "excessive" bleeding in association with trauma or prior surgery? Were blood transfusions or reoperation required to control the bleeding? A history suggestive of a bleeding disorder might include frequent epistaxis of a severity necessitating

"packing the nasal passage" or surgical intervention. Oral surgery and dental extractions prove a particularly good test of hemostasis due to high concentrations of fibrinolytic activity in the oral cavity. Von Willebrand's disease not infrequently manifests as menorrhagia, and postpartum hemorrhage commonly occurs in women with underlying disorders of hemostasis.[38] A history of spontaneous hemorrhage (nontraumatic) proves particularly concerning when associated with joints (hemarthroses) or deep muscles. Identification of a bleeding disorder at an early age or in family members suggests an inherited, as opposed to acquired, condition.[39] A careful medication history including direct questions relating to consumption of aspirin-containing nonprescription drugs, herbs, and fish oil may prove noteworthy. Finally, inquiries regarding coexisting diseases should be included (i.e., renal, hepatic, thyroid, bone marrow disorders, and malignancy).

For most patients, a thoughtfully conducted bleeding history will eliminate need for preoperative laboratory-based coagulation testing. Regardless, there remain several valid reasons for preoperative coagulation testing. Should the preoperative history or physical examination reveal signs or symptoms suggestive of a bleeding disorder further laboratory-based assessment of coagulation would be indicated. Preoperative screening tests of coagulation may be indicated, despite a negative history, in cases in which major surgery commonly associated with significant bleeding is planned (i.e., cardiopulmonary bypass). Finally, preoperative testing may prove justified in settings in which the patient is unable to provide a bleeding history preoperatively. Should evidence of a bleeding disorder be detected preoperatively, underlying mechanisms must be ascertained if possible before proceeding with surgery.

Inherited Bleeding Disorders

Although inherited disorders of hemostasis may involve platelet function, plasma-mediated hemostasis, or fibrinolytic pathways, von Willebrand's disease characterized by quantitative or qualitative deficiencies of vWF proves the most common of inherited bleeding disorders.[38] Variants include types I and III with varying quantitative vWF deficiencies and type II comprising a collection of qualitative defects affecting vWF function. Under normal conditions, vWF plays a critical role in platelet adhesion to ECM. vWF further acts as a carrier molecule preventing proteolytic degradation of factor VIII in free plasma.[40] Classically, patients with von Willebrand's disease describe a history of easy bruising, recurrent epistaxis, and menorrhagia, all characteristic of defects in primary (i.e., platelet mediated) hemostasis. In more severe cases (i.e., type III vWD), concomitant reductions in factor VIII may lead to serious spontaneous hemorrhage, including hemarthroses, which is common in hemophilia. Laboratory testing often demonstrates mild to moderate prolongation of the activated partial thromboplastin time (aPTT), prolonged bleeding time, decreased immunoreactive vWF concentrations, and reduced platelet aggregation in response to ristocetin.[38,41] Increasingly, the PFA-100 and similar *ex-vivo* platelet function tests have replaced bleeding times in assessing for vWD.[42] Measurable reductions in factor VIII activity may occur in severe cases. Mild cases of vWD often respond to desmopressin acetate (DDAVP); however, given a significant bleeding history, specific replacement of vWF and factor VIII with select factor VIII concentrates (i.e., Humate-P: Armour Pharmaceuticals, Kankakee, IL) may be indicated.[43,44]

Although relatively uncommon, the hemophilias merit consideration given their diverse clinical presentation. Hemophilia A, characterized by variable degrees of factor VIII deficiency, is an X-linked inherited bleeding disorder most frequently presenting in childhood as spontaneous hemorrhage involving joints or deep muscles or both. Hemophilia A occurs with an incidence of 1:5000 males; however, nearly one third of cases represent new mutations with no family history.[45] In mild cases, patients with hemophilia may not be identified until later in life, often after unexplained bleeding with surgery or trauma. Classically, laboratory testing in patients with hemophilia reveals prolongation of the aPTT, whereas the prothrombin time (PT) and bleeding time remain within normal limits. Specific measurement of factor VIII:C is required to confirm the diagnosis and to clarify the severity of factor VIII deficiency. Mild cases of hemophilia A may be treated with desmopressin; however, in most cases perioperative management of these patients necessitates consultation with a hematologist and administration of recombinant or purified factor VIII concentrates.[43,46] An increasingly common complication of hemophilia, particularly in the case of hemophilia A, has been development of alloantibodies directed against the factor VIII protein. In cases of high titer antibodies, administration of factor VIII concentrates may fail to control bleeding. Several approaches have reduced bleeding in these patients, including substitution of porcine factor VIII, administration of "activated" or "nonactivated" prothrombin complex concentrates, or treatment with recombinant factor VIIa (NovoSeven, Novo Nordisk, Copenhagen, Denmark) (see Chapter 57).[44,47] Also inherited as an X-linked disorder, hemophilia B (i.e., Christmas disease) occurs in approximately 1:40,000 and necessitates blood component replacement with factor IX concentrates.

Acquired Bleeding Disorders

A detailed account of acquired hemostatic disorders is beyond the scope of this discussion; however, given that a limited number of drugs and coexisting medical conditions account for the majority of acquired bleeding disorders, these conditions merit consideration. Heparin, warfarin, and fibrinolytic drugs historically accounted for most serious drug-induced bleeding complications (Table 56-1).[48,49] More recently, antiplatelet drug therapy further has complicated perioperative management (Table 56-2).[49-52] Unfractionated heparin comprises a heterogeneous mixture of membrane-associated glycosaminoglycans derived from either bovine or porcine mucosal tissues. Specificity and potency of unfractionated heparin varies by molecular weight, which ranges between 5,000 and 30,000 daltons.[35] Heparin derives its anticoagulant effect by interacting with plasma antithrombin, which in turn inhibits serine proteases participating in plasma-mediated hemostasis.[34] The half-life of heparin is 1 to 2 hours and varies directly with total dose. Heparin is cleared from the circulation both renally and hepatically. Most often, heparin's anticoagulant effect is monitored using the aPTT with a target prolongation of one and one-half to two times control, commonly used for treatment of venous thrombosis.[53] At heparin concentrations exceeding measurement limits of the aPTT, such as during cardiopulmonary bypass or interventional cardiovascular procedures, the activated clotting time (ACT) provides an alternative,

Table 56-1 Anticoagulant Agents

Drug	Site of Action	Route	Plasma Half-life	Excretion	Antidote	Stop before Procedure	Prolongation of PT/aPTT
Unfractionated heparin	IIa/Xa	IV/SC	1.5 hr	Hepatic	Protamine	6 hr	No/Yes

albeit less sensitive, measure of heparin anticoagulation.[54] Heparin's anticoagulant effect is rapidly reversible by protamine administration.[55]

More recently, low-molecular-weight heparins (LMWHs) have gained favor as a result of reduced dosing frequency and the lack of need for monitoring. Owing to shorter saccharide chain lengths, LMWHs exhibit reduced inhibitory activity toward thrombin while retaining factor Xa inhibitory activity.[56] Theoretically, LMWHs should be associated with reduced bleeding tendencies. Regardless, LMWHs have a more predictable pharmacokinetic response, fewer effects on platelet function, and a reduced risk for heparin-induced thrombocytopenia (HIT). Although monitoring of LMWHs is not performed routinely, the PT and aPTT most often are unaffected, necessitating measurement of anti–factor Xa activity. Furthermore, should rapid reversal of LMWH prove necessary, protamine proves only partially effective.[57]

Oral anticoagulant therapy in the form of coumarin derivatives, interferes with hepatic synthesis of vitamin K–dependent coagulation factors: factors II, VII, IX, X, protein C, and protein S.[58] Specifically, coumarin inhibits carboxylation of glutamic acid residues essential for anchoring coagulation factor activation complexes to phospholipid membranes. Coumarin therapy is monitored using the INR (International Normalized Ratio) system derived from the PT. Generally, an INR of 2 to 3 is considered reflective of adequate anticoagulation.[53] In most cases, excessive coumarin anticoagulation is managed by withholding drug administration. However, given a half-life of 2 to 4 days,

Table 56-2 Antiplatelet Agents

more rapid reversal in perioperative settings may be needed. Vitamin K administered orally or parentally in doses of 1 to 2 mg reverses coumarin anticoagulation.[58] More rapid reversal may be achieved by administration of plasma or prothrombin complex concentrates.[59] Recombinant factor VIIa also has proved effective at reversing coumarin-associated bleeding.

Despite relatively short half-lives and increasing fibrin specificity, fibrinolytic drug administration continues to be associated with significant bleeding potential. Bleeding after fibrinolytic drugs proves multifactorial in origin, resulting from proteolytic degradation of fibrin and fibrinogen, proteolysis of cofactors V and VIII, and digestion of platelet glycoprotein surface receptors.[29] In addition, both fibrin and fibrinogen degradation fragments impair platelet function and inhibit assembly of fibrin monomers into strands. Once the fibrinolytic agent is cleared from plasma, antifibrinolytic drugs prove of limited benefit. Therapy must rely on selective repletion of platelet and plasma protein constituents. In many cases, cryoprecipitate will be administered to replace fibrinogen and platelet infusions will be needed to compensate for qualitative platelet dysfunction. Plasma infusions may be required to replete plasma coagulation factors, particularly cofactors V and VIII.

Liver Disease

Hemostatic defects associated with hepatic failure prove complex and multifactorial. Severe liver disease impairs synthesis of coagulation factors, impedes clearance of activated clotting and fibrinolytic proteins, and produces quantitative and qualitative platelet dysfunction. Laboratory findings commonly associated with liver disease include a prolonged PT, possible prolongation of the aPTT, and thrombocytopenia.[60] Prolongation of bleeding time reflects qualitative defects in platelet adhesion and aggregation. Treatment of bleeding in the setting of liver disease most often is based on laboratory abnormalities. Plasma and platelets frequently are administered for acute bleeding. Low fibrinogen concentrations may necessitate cryoprecipitate administration. In addition, low-grade fibrinolysis may benefit from antifibrinolytic drug administration in select settings.

Renal Disease

Platelet dysfunction commonly occurs in association with chronic renal failure, as reflected by a prolonged bleeding time and propensity for bleeding associated with surgery or trauma. Underlying mechanisms appear multifactorial and may include accumulation of guanidinosuccinic acid and nitric oxide in uremic plasma.[61] In addition, red blood cell concentration has been speculated to play a role as correction of anemia results in shortened bleeding times, presumably related to the role of red blood cells in causing platelet margination along the vessel wall under laminar flow conditions.[28] Both dialysis and correction of anemia have been reported to shorten bleeding times in patients with chronic renal failure. Traditionally, cryoprecipitate administration occurs in this setting; however, desmopressin (0.3 μg/kg) and conjugated estrogens similarly may shorten bleeding times.[43] Risks associated with these therapies, and the predictive value of bleeding time for subsequent hemorrhage, remain unclear.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) comprises a pathophysiologic hemostatic response to tissue factor/factor VIIa complex exposure and activation of the extrinsic pathway of coagulation. Numerous underlying disorders may precipitate DIC, including trauma, amniotic fluid embolus, malignancy, sepsis, or incompatible blood transfusions.[62] Most often, DIC presents clinically as a diffuse bleeding disorder associated with consumption of coagulation factors and platelets during widespread microvascular thrombotic activity. Underlying fibrinolysis, providing a counterregulatory mechanism to maintain vascular integrity, proves common as well. Laboratory findings typical of DIC include reductions in platelet count, prolongation of the PT, aPTT, and thrombin time (TT), and elevated concentrations of soluble fibrin and fibrin(ogen) degradation products. Chronic DIC states have been identified with relatively normal screening tests of coagulation accompanied by elevated concentrations of soluble fibrin and fibrin(ogen) degradation products.[63] Management of DIC requires alleviating the underlying condition precipitating hemostatic activation. Otherwise, treatment includes selective blood component transfusions to replete coagulation factors and platelets consumed in the process. Antifibrinolytic therapy generally is contraindicated in DIC owing to potential for catastrophic thrombotic complications.

Prothrombotic States

Thrombophilia, a propensity for thrombotic events, most often manifests clinically in the form of venous thrombosis (frequently deep venous thrombosis of the lower extremity).[64] As with bleeding disorders, thrombophilia may result from inherited or acquired conditions (Table 56-3). In the majority of cases, a precipitating event may be identified.[65] For example, thrombotic complications often occur after surgery, during pregnancy, and in association with obesity or underlying malignancy.[66] Random screening of asymptomatic patients for thrombotic risk has not proved cost effective or clinically efficacious.[67,68] As with bleeding disorders, a careful history focusing on prior thrombotic events, family history of thrombosis, and concurrent drug therapy offers greater predictive value than random screening.

Common Inherited Thrombotic Disorders

Although understanding of thrombotic disorders from a biochemical and molecular level remains limited at present, careful testing may identify an underlying heritable thrombotic

Table 56-3 Hypercoagulable States and Risk for Perioperative Thrombosis

High Risk

Postoperative prothrombotic state
Malignancy
Immobilization

predisposition in as many as 50% of patients with venous thromboembolism.[69] Relatively common inherited conditions underlying prothrombotic tendencies include single point mutations in genes for factor V (factor V Leiden) or prothrombin (prothrombin G20210A). In the case of the factor V Leiden mutation, the essential cofactor Va acquires resistance to degradation by protein C.[70] This simple alteration in balance between hemostasis and the protein C counterregulatory system induces a prothrombotic tendency present in approximately 5% of the population. In the case of the prothrombin gene mutation, increased prothrombin concentrations in plasma again generate a hypercoagulable state. Less common inherited forms of thrombophilia include deficiencies of antithrombin, protein C, and protein S.[34] Inherited forms of thrombophilia are characterized by highly variable penetrance affected by blood type, sex, and other confounding variables. In the absence of coexisting precipitating conditions, absolute thrombotic risk secondary to a heritable thrombophilia proves limited.[71] In the presence of a family history or test abnormality suggesting thrombophilia with no history of thrombosis, risks associated with long-term preventive anticoagulation may outweigh potential benefits. After a thrombotic complication, however, these patients most often are managed with life-long anticoagulation.

Common Acquired Thrombotic Disorders

Antiphospholipid Syndrome

Antiphospholipid syndrome describes an acquired autoimmune disorder characterized by venous and/or arterial thromboses as well as recurrent pregnancy loss. This syndrome may occur secondarily to autoimmune disorders such as systemic lupus erythematosus or rheumatoid arthritis, or it may occur in isolation. Characteristically, antiphospholipid syndrome results in mild prolongation of the aPTT and positive testing for lupus anticoagulant or anticardiolipin antibodies.[72] Despite the prolonged aPTT, antiphospholipid syndrome poses no increased bleeding risk but rather increases the potential for thrombosis. Antibodies associated with antiphospholipid syndrome interfere with phospholipids common to many laboratory-based tests of coagulation. Isolated prolongation of an aPTT in a preoperative patient merits consideration of the diagnosis of antiphospholipid syndrome. Patients with this syndrome who have experienced a thrombotic complication are at increased risk for recurrent thrombosis and most often are managed by life-long anticoagulation.[73]

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia describes an autoimmune-mediated drug reaction occurring in as many as 5% of patients receiving heparin therapy. As opposed to other drug-induced thrombocytopenias, HIT results in platelet activation and potential for venous and arterial thromboses.[74,75] Evidence suggests that HIT is mediated by immune complexes (composed of IgG antibody, platelet factor 4 [PF4], and heparin) that bind platelet Fcγ receptors to activate platelets. Anti-PF4/heparin antibodies may "activate" vascular endothelium, monocytes, and macrophages by upregulating tissue factor expression (Fig. 56-4). Patients developing HIT during heparin therapy experience substantially increased risk for thrombosis (odds ratio 20-40, absolute risk 30%-75%).[74,75]

In most cases, HIT manifests clinically as thrombocytopenia occurring 5 to 14 days after initiating heparin therapy. However, with prior heparin exposure, thrombocytopenia or thrombosis may occur within 1 day. In some reported cases, thrombosis occurred simultaneously with thrombocytopenia, providing no warning. Although HIT remains a clinical diagnosis, laboratory testing provides confirmatory evidence. Both functional (i.e., serotonin platelet release assays or heparin-induced platelet aggregation) and quantitative (i.e., solid-phase enzyme-linked immunosorbent assays [ELISA]) tests for PF4/heparin

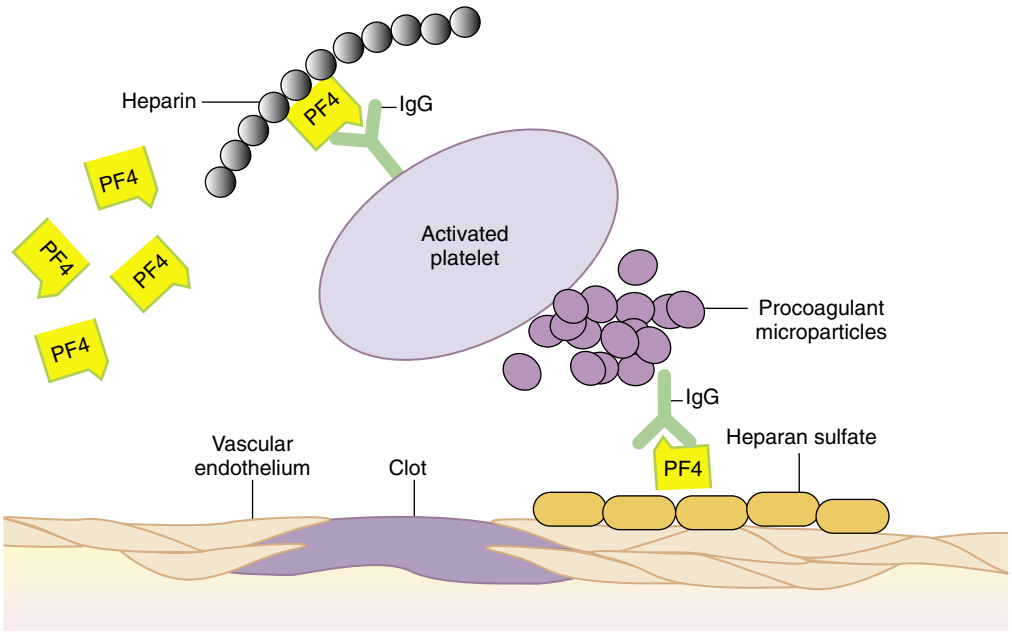

Figure 56-4 Mechanisms underlying thrombosis in heparin-induced thrombocytopenia (HIT). Immune complexes composed of heparin, platelet factor 4 (PF4), and antibodies bind to platelet surface Fcγ receptors to activate platelets. PF4/heparin immune complexes further activate vascular endothelium, monocytes, and macrophages to increase tissue factor expression. *(From Slaughter TF, Greenberg CS: Heparin-associated thrombocytopenia and thrombosis: Implications for perioperative management. Anesthesiology 87:669, 1997, with permission.)*

immune complexes prove beneficial.[75] Recent evidence suggests that PF4/heparin antibodies alone, in the absence of thrombocytopenia or thrombosis, may predict adverse outcomes.[76,77]

A diagnosis of HIT should be entertained for any patient experiencing thrombosis or thrombocytopenia (absolute or relative [≥ 50% reduction in platelet count]) during or after heparin administration. In cases in which HIT is suspected, heparin must be discontinued immediately (i.e., including unfractionated heparin, heparin-bonded catheters, heparin flushes, LMWH). Alternative non-heparin anticoagulation must be administered concurrently. In most cases, a direct thrombin inhibitor (i.e., bivalirudin, lepirudin, argatroban) is substituted for heparin until adequate prolongation of the INR may be achieved with warfarin.[78,79] Typically, PF4/heparin immune complexes clear from the circulation within 3 months. If possible, patients experiencing HIT should avoid future exposure to unfractionated heparin; however, several reports describe subsequent limited perioperative reexposure to unfractionated heparin after laboratory testing to ensure absence of PF4/heparin immune complexes.

Monitoring Coagulation

Traditionally, perioperative coagulation monitoring has focused on (1) preoperative testing to identify patients at increased risk for perioperative bleeding and (2) intraoperative monitoring of heparin therapy during cardiac and vascular surgery. As discussed previously, routine preoperative coagulation testing lacks either predictive value or cost efficacy.[80] However, in patients with a history suggestive of a bleeding disorder or whose surgery may be associated with a high incidence of bleeding or coagulopathy, baseline preoperative coagulation testing may be advisable.

Given the widely acknowledged pharmacokinetic and pharmacodynamic response to heparin, monitoring anticoagulation during cardiac and vascular surgery remains common. Patient-specific factors affecting response to heparin include age, weight, intravascular volume, and plasma/membrane concentrations of antithrombin, heparin cofactor II, platelet factor 4, and other heparin binding proteins. Therefore, patients experience widely divergent anticoagulant responses to identical weight-based doses of heparin. Regardless, monitoring of heparin anticoagulation must be performed if only to prevent the rare, but potentially lethal, complication resulting from inadvertent failure to administer heparin before cardiopulmonary bypass or vascular surgery.

The ideal test of perioperative coagulation would prove simple to perform, accurate, reproducible, diagnostically specific, and cost effective. No current coagulation monitor meets these expectations; however, integrating results from multiple forms of monitoring may provide valuable diagnostic insight into perioperative coagulopathies.

Common Laboratory-Based Measures of Coagulation

Activated Partial Thromboplastin Time

The aPTT assesses integrity of the intrinsic and common pathways of plasma-mediated hemostasis. It measures the time required in seconds for clot formation to occur after mixing a sample of patient plasma with phospholipid, calcium, and an activator of the intrinsic pathway of coagulation (i.e., celite, kaolin, silica, or ellagic acid). In most cases, coagulation factor deficiencies are detectable at factor concentrations below 30% to 40% of normal; however, aPTT reagents vary in sensitivity to factor concentrations, necessitating institutional specific determination of "normal" ranges.[81] Prolongation of the aPTT is evaluated further with mixing studies to determine whether delayed clot formation is attributable to a coagulation factor deficiency or an inhibitor (i.e., heparin, antiphospholipid antibody, fibrin split products). The mixing study is performed by mixing the patient's plasma sample with "normal" donor plasma. In the case of a coagulation factor deficiency, time to clot formation will correct and sequential assays for specific coagulation factor concentrations allow for identification of the deficiency. A common means of confirming heparin prolongation of the aPTT is to perform a thrombin clotting time (TCT). In this test, the patient's citrate-containing plasma sample is mixed with thrombin and time to clot formation is measured in seconds.[39] The most common mechanism underlying prolongation of the TCT is presence of heparin or a direct thrombin inhibitor anticoagulant; however, dysfibrinogenemia or fibrin(ogen) degradation products also may impair clot formation in this setting.

Prothrombin Time

The PT assesses integrity of the extrinsic and common pathways of plasma-mediated hemostasis. It measures time required in seconds for clot formation to occur after mixing a sample of patient plasma with tissue factor (thromboplastin) and calcium. As with the aPTT, thromboplastin test reagents vary in sensitivity, limiting the ability to compare results between laboratories. Given the importance of monitoring PT results for patients on long-term warfarin therapy, the INR was introduced as a means of normalizing PT results among different laboratories.[81] Thromboplastin reagents are tested against an international recombinant standard and assigned an international sensitivity index (ISI) based on results. The INR subsequently is calculated as INR = (patient PT/standard PT)^{ISI} in which the "standard PT" represents the geometric mean of multiple normal samples from the testing laboratory. Institution of the INR substantially reduced interlaboratory variations in the PT. As with the aPTT, prolongation of the PT is assessed further with mixing studies.

Platelet Count and Bleeding Time

The platelet count remains a standard component in screening for coagulation abnormalities. Automated platelet counts are performed in bulk using either optical- or impedance-based measurements. Recommendations regarding optimal platelet counts prove somewhat arbitrary; however, platelet counts exceeding 100,000/μL usually are associated with normal hemostasis. Abnormally low platelet counts merit further assessment, including a visual platelet count using a blood smear. Sample hemodilution and platelet clumping are common causes for false low platelet counts. EDTA-induced platelet clumping, a common artifact explaining thrombocytopenia, may be identified by manually counting platelets or by substituting a citrate anticoagulant, as opposed to EDTA common to platelet collection vacutainers.

Although the bleeding time, as a test of platelet dysfunction, has lost much of its popularity in the past 10 years, many clinicians continue to rely on bleeding time assessment as a measure of platelet function and primary hemostasis. With the use of a commercial template cutting device and a sphygmoma-

nometer adjusted to 40 mm Hg venous pressure, bleeding times of 2 to 10 minutes on the anterior forearm are considered normal. Limitations of the bleeding time include poor reproducibility, time needed to perform the test, and potential for scarring. Furthermore, the bleeding time is affected by numerous confounding variables, including skin temperature, skin thickness, age, ethnicity, anatomic test location, and a host of other factors.[82] In general, the bleeding time has not proved predictive of bleeding and for that reason its use as a preoperative screening test to assess bleeding risk is not recommended.

Common Point-of-Care Measures of Coagulation

Although laboratory-based measures of coagulation remain the mainstay of preoperative coagulation testing, increasing availability of sensitive and specific point-of-care coagulation monitoring may soon offer opportunities to direct blood component and hemostatic drug therapy more specifically without delays inherent to standard laboratory testing. Commercially available point-of-care monitors applicable in the perioperative setting may be considered in four broad categories: (1) functional measures of coagulation or assays that measure the intrinsic ability of blood to generate clot; (2) heparin concentration monitors; (3) viscoelastic measures of coagulation; and (4) platelet function monitors.

Functional Measures of Coagulation

The activated coagulation time (ACT), described by Hattersley in 1966 as a variation of the Lee-White whole blood clotting time, employs a contact activation initiator, typically celite (diatomaceous earth) or kaolin, to accelerate clot formation and reduce time for assay completion. Kaolin is recommended for use in patients receiving the antifibrinolytic drug aprotinin because celite ACTs in this setting are subject to artifactual prolongation.[83] Failure to appreciate this drug-mediated effect may result in inadequate heparin administration if using celite ACT measurements with aprotinin. Whether high plasma concentrations of aprotinin may affect the kaolin ACT remains unclear.

Current commercial ACT monitors automate clot detection. One of the more widely available ACT monitors uses a glass test tube containing a small magnet (Hemochron; International Technidyne, Inc., Edison, NJ). After adding sample blood, the tube is placed into the analyzer and the tube is rotated slowly at 37°C, allowing the magnet to maintain contact with a proximity detection switch. As fibrin clot forms, the magnet becomes entrapped and dislodged from the detection switch, thereby triggering an alarm to signal completion of the ACT. Another ACT device uses a "plumb bob" flag assembly that is raised and released repeatedly to settle in the sample vial containing blood and contact activator (Hepcon and ACT II; Medtronic Blood Management, Parker, CO). With clot formation, the descent rate of the flag through the blood sample slows, triggers an optical detector, and sets off an alarm to signal completion of the ACT.

The ACT in normal individuals is 107 ± 13 seconds (mean ± SD). However, the time at which a patient's "baseline" ACT is measured influences the result.[83] After surgical incision, baseline ACT may decrease. Because the ACT measures clot formation by way of intrinsic and common pathways, heparin and other anticoagulants prolong time to clot formation; however, the ACT proves somewhat resistant to platelet dysfunction and thrombocytopenia.

ACT testing remains a popular perioperative coagulation monitor because of its simplicity, low cost, and linear operating response at high heparin concentrations. Limitations of ACT monitoring include lack of sensitivity at low heparin concentrations and poor reproducibility.[83] ACT tubes containing heparinase improve sensitivity for detecting low heparin concentrations. Further limitations of the ACT include artifactual prolongation of results with hemodilution or hypothermia and the fact that ACT values beyond 600 seconds exceed the linear response range for the assay. Duplicate measurements improve results; however, newer electrochemically based ACT analyzers (ISTAT; Abbott Laboratories, Chicago, IL) improve reproducibility such that single ACT determinations may prove adequate.

The high-dose thrombin time (HiTT) (International Technidyne, Edison, NJ) provides an alternative functional measure of heparin anticoagulation. Primarily employed in cardiac surgical settings, the HiTT assay contains high thrombin concentrations to cleave fibrinogen directly and generate fibrin clot.[84] Given excess thrombin concentrations, clot formation occurs independently of plasma coagulation factors other than fibrinogen. As a result, HiTT is prolonged by heparin (or other thrombin inhibitors), extreme degrees of hypofibrinogenemia or dysfibrinogenemia, and high concentrations of fibrin split products (as occur with fibrinolysis). During most surgical procedures requiring heparin administration, HiTT prolongation will correlate with heparin anticoagulant effect.

Heparin Concentration Measurement

Protamine titration remains the most popular point-of-care method for determining heparin concentration in perioperative settings. Protamine, a strongly basic polycationic protein, directly inhibits heparin in a stoichiometric manner. In other words, 1 mg of protamine will inhibit 1 mg (approximately 100 U) of heparin, thereby forming the basis for protamine titration as a measure of heparin concentration. As increasing concentrations of protamine are added to a sample of heparin-containing blood, time to clot formation decreases until the point at which the protamine concentration exceeds heparin concentration to delay clot formation. If a series of blood samples with incremental doses of protamine are analyzed, the sample in which the protamine and heparin concentrations are most closely matched will clot first. In this manner, protamine titration methodology allows for heparin concentration estimation. Assuming that the heparin-protamine titration curve for an individual patient remains constant throughout the operative period, protamine titration methods may estimate heparin doses required to achieve a desired plasma heparin concentration or the protamine dose needed to reverse a given heparin concentration in blood.[54] Current point-of-care heparin concentration monitors employ automated measurement techniques (Hepcon HMS; Medtronic Blood Management, Parker, CO). Advantages of heparin concentration measurement include sensitivity for low heparin concentrations as well as relative insensitivity to hemodilution and hypothermia. In addition, heparin concentration measures are unaffected by aprotinin.

A major limitation of heparin concentration monitoring is failure to assess directly for an anticoagulant effect. To use an extreme example, consider a patient with a homozygous deficiency of antithrombin; in this setting, heparin concentration

determination alone would fail to identify the lack of anticoagulant effect after heparin administration.

Viscoelastic Measures of Coagulation

Initially developed in the 1940s, viscoelastic measures of coagulation have undergone a resurgence in popularity. The unique aspect of viscoelastic monitors lies in their ability to measure the entire spectrum of clot formation from early fibrin strand generation through clot retraction and eventual fibrinolysis. The thromboelastograph (TEG) (Haemoscope, Niles, IL), developed by Hartert in 1948, uses a small 0.35-mL blood sample placed into a disposable cuvette within the instrument. The cuvette is maintained at a temperature of 37°C and continuously rotates around an axis of approximately 5 degrees. A metal piston attached by a torsion wire to an electronic recorder is lowered into the blood within the cuvette. As clot formation occurs, the piston becomes enmeshed within the clot and rotation of the cuvette is transferred to the piston, torsion wire, and electronic recorder.[85]

Although variables derived from the TEG tracing do not coincide directly with laboratory-based tests of coagulation, the TEG depicts characteristic abnormalities in clot formation and fibrinolysis. Various parameters describing clot formation and lysis are identified and measured by the TEG. For example, the R value (reaction time) measures time to initial clot formation (normal, 7.5 to 15 minutes). Comparable to the whole blood clotting time, addition of a contact activator such as celite or kaolin to the sample cuvette reduces time to results. The R value may be prolonged by a deficiency of one or more plasma coagulation factors or inhibitors such as heparin. Maximum amplitude (MA) provides a measure of clot strength and may be decreased by either qualitative or quantitative platelet dysfunction or decreased fibrinogen concentration. Normal MA is 50 to 60 mm. The alpha angle and K (BiKoatugulierung or coagulation) values measure rate of clot formation and may be prolonged by any variable slowing clot generation such as a plasma coagulation factor deficiency or heparin anticoagulation.[86]

The Sonoclot (Sienco, Inc., Wheat Ridge, CO) provides an alternative viscoelastic measure of coagulation. In contrast to the TEG, Sonoclot immerses a rapidly vibrating probe into a 0.4-mL sample of blood. As clot formation occurs, impedance to probe movement through the blood increases and generates an electrical signal and characteristic clot "signature." The Sonoclot may be used to derive the ACT, as well as to provide information regarding clot strength and fibrinolysis.

Both the TEG and Sonoclot generate characteristic diagrams by translating mechanical resistance to sensor movement in a blood sample to a waveform. One of the more common applications for the TEG has been real-time detection of excess fibrinolysis during liver transplantation. The TEG also may prove beneficial in differentiating surgically related bleeding from that of a coagulopathy. More widespread application of viscoelastic coagulation monitoring has been hindered by lack of specificity associated with abnormal findings and qualitative assay interpretation.[86] Digital automation of these instruments has simplified and improved reproducibility.

Platelet Function Monitors

Assessment of platelet function has proved challenging for a number of reasons. Historically, tests of platelet function have proved costly, time consuming, and technically demanding. Platelet dysfunction may occur as a result of diverse inherited or acquired disorders affecting surface receptors involved in adhesion or aggregation, storage granules, internal activation pathways, phospholipid membranes, or other mechanisms.[51] Lack of standardized quality controls necessitates use of local donors' blood to establish normal control ranges. Furthermore, even established tests such as platelet aggregation lack performance standardization resulting in widely varying results among laboratories. Complicating assessment further is the fact that platelets are highly susceptible to activation or desensitization during sample collection, transport, storage, and processing.

Although viscoelastic measures of coagulation (i.e., TEG/Sonoclot) may detect severe platelet dysfunction, sensitivity and specificity are limited. The standard laboratory-based method for identifying qualitative platelet dysfunction remains optical aggregometry performed using specific platelet agonists and samples of platelet-rich plasma. Flow cytometry employing fluorescent-labeled antibodies provides another sensitive method for quantitating platelet activation, responsiveness, and surface receptor availability.[87] Despite representing standards of care, these measures remain technically challenging, costly, and time-consuming laboratory-based assays.

Fortunately, an increasing array of platelet function assays specifically designed as point-of-care instruments are available.[88,89] As a measure of primary hemostasis, the PFA-100 (Platelet Function Analyzer; Dade International Inc, Miami, FL) increasingly has replaced the bleeding time in assessment of primary hemostasis. Unique among both laboratory-based and point-of-care platelet function monitors, the PFA-100 incorporates high-shear conditions to simulate small vessel injury in the presence of either ADP or epinephrine, both potent platelet activators.[90] Time to clot–mediated aperture occlusion is reported as "closure time." The PFA-100 has proved effective in detecting von Willebrand's disease as well as aspirin-mediated platelet dysfunction. This instrument, as a component of a standardized screening protocol, reduces time to identify and classify platelet dysfunction. Limitations of the PFA-100 include interference by thrombocytopenia and hemodilution.

The HemoSTATUS (Medtronic Blood Systems, Parker, CO) platelet function test exploits the ability of platelet activating factor (PAF) to accelerate clot formation of the kaolin-activated ACT. HemoSTATUS testing is performed on the Medtronic HMS coagulation analyzer employing a 6-channel kaolin ACT cartridge preloaded with serially increasing concentrations of PAF. A clot ratio is determined for each individual patient assay based on the ratio of the PAF-accelerated ACT to the standard ACT. An individual patient's clot ratio is compared with a maximal clot ratio derived from normal volunteers to provide a relative measure of platelet function. In the presence of platelet dysfunction, higher concentrations of PAF are required to achieve a comparable PAF-activated ACT. In cardiac surgery, investigators demonstrated a relationship between platelet dysfunction and postoperative bleeding.[83] Furthermore, the maximal clot ratio as determined by HemoSTATUS improved after desmopressin or platelet administration. Other investigators, however, failed to identify a relationship between platelet dysfunction as measured by HemoSTATUS and postoperative bleeding.

The Rapid Platelet Function Analyzer (RPFA; Accumetrix, San Diego, CA) is an automated turbidimetric whole blood platelet function assay that assesses ability of activated platelets to bind

fibrinogen-coated polystyrene beads. On addition of the whole blood test sample, thrombin receptor activating peptide (TRAP) directly activates platelets within the sample to stimulate glycoprotein IIb/IIIa platelet surface receptor expression. As activated platelets bind and aggregate fibrinogen-coated beads, light transmission through the sample increases to generate a signal. Although the RPFA is simple to operate and provides a rapid bedside measure of platelet function, a baseline reference measurement is required for each patient to calculate the extent of subsequent changes in platelet function.[88] Potential applications of this methodology in the perioperative setting remain unclear.

Plateletworks (Helena Laboratories, Beaumont, TX) employs a hemocytometer to perform automated platelet counts on whole blood samples collected in the presence and absence of platelet-stimulating agonists such as collagen or ADP. The difference in platelet counts before and after agonist addition provides a direct measure of platelet aggregation (i.e., platelet responsiveness) and is reported as "% aggregation." Preliminary investigations demonstrated reasonable correlations between platelet counts performed with the Ichor hematology analyzer and laboratory-based instruments.[88] In addition, the Plateletworks assay proved effective in identifying platelet dysfunction in the setting of glycoprotein IIb/IIIa antagonists and appears to correlate relatively well with laboratory-based measures of platelet aggregation.

Employing a sample of whole blood, the Hemodyne Hemostasis Analyzer (Hemodyne, Richmond, VA) measures platelet contractile force, the force produced by platelets during clot retraction, and clot elastic modulus, a measure of clot rigidity. In preliminary investigations, platelet contractile force was reduced after cardiopulmonary bypass and modestly correlated with perioperative blood loss.

Advances in our understanding of hemostasis and thrombosis at the molecular level have contributed directly to recent biotechnologic innovations in point-of-care testing. Further advances in point-of-care coagulation monitoring offer the opportunity for clinicians to make informed decisions about transfusion therapy and hemostatic drug administration to minimize perioperative bleeding. In considering any point-of-care coagulation testing, one must recognize that results will not necessarily mirror those reported from laboratory-based testing. Reagent sensitivities vary from manufacturer to manufacturer and even one lot of reagent to another. In addition, point-of-care testing typically relies on whole blood samples for testing as opposed to laboratory-based testing using plasma or processed platelets. A final consideration for which point-of-care platelet function testing provides a particularly relevant example is that monitors from different manufacturers measure differing aspects of platelet- or plasma-mediated hemostasis. In the case of platelet function monitors, a dozen instruments purport to measure "platelet function." However, using different instruments one may obtain results varying from "severe" platelet dysfunction to "no platelet dysfunction" in a single sample of blood. Before adopting any point-of-care monitoring, an understanding of the quality assurance requirements, test methodology, and concomitant strengths and weaknesses will be essential to benefit patient care.

57 Autologous Transfusion, Recombinant Factor VIIa, and Bloodless Medicine

Key Points

1. Reinfusion of shed blood was employed as early as 1818. Preoperative donation of autologous blood was advocated in the 1930s when the first blood banks were established. Autologous transfusion has grown in popularity in response to the increase in complex operative procedures and new technologic advances that allow its safe use.
2. The two primary reasons for employing autologous transfusion are avoidance of complications associated with allogeneic transfusion and conservation of blood resources.
3. The three types of autologous blood transfusion are preoperative autologous donation (PAD), acute normovolemic hemodilution (ANH), and intraoperative and postoperative blood recovery (salvage).
4. PAD became accepted as a standard practice in certain elective surgical settings such as total joint replacement surgery, so that by 1992 more than 6% of the blood transfused in the United States was autologous. Subsequently, substantial improvements in blood safety have been accompanied by a decline in PAD as well as an interest in ANH as an alternative, lower cost strategy.
5. The criteria for autologous donors are not as stringent as those for allogeneic donors. Transfusion service policies, implemented under the auspices of hospital transfusion committees, differ regarding collection and use of autologous blood with positive viral markers. It is common practice to preclude the blood reactive for hepatitis B surface antigen and human immunodeficiency virus because of concerns for the safety of both patients and personnel. Contraindications include evidence of infection and risk of bacteremia, scheduled surgery for correction of aortic stenosis, and unstable angina.
6. Although autologous blood collections have become popular, the costs associated with their collection are higher than those associated with the collection of allogeneic blood.
7. ANH is the removal of whole blood from a patient while restoring the circulating blood volume with an acellular fluid shortly before an anticipated significant surgical blood loss. The chief benefit of ANH is the reduction of red blood cell losses when whole blood is shed perioperatively at lower hematocrit levels after ANH is completed.
8. Because there is no good evidence that either PAD or ANH is effective at eliminating allogeneic blood transfusions, these autologous blood collection techniques cannot be considered cost-effective alternatives to allogeneic blood.
9. The term *intraoperative blood collection* or *recovery* describes the technique of collecting and reinfusing blood lost by a patient during surgery. The oxygen-transport properties of recovered red blood cells are equivalent to stored allogeneic red blood cells. The survival of recovered blood cells appears to be at least comparable to that of transfused allogeneic red blood cells.
10. Postoperative blood collection denotes the recovery of blood from surgical drains followed by reinfusion, with or without processing. Postoperative autologous blood transfusion is practiced widely but not uniformly.
11. Fibrin glue is derived from a source of fibrinogen and factor XIII (fibrin-stabilizing factor), in which a solution of fibrinogen is mixed with a solution of thrombin and applied to a surgical field. These preparations represent additional allogeneic blood donor exposure. Patients should be made aware of the potential complications as well as the potential benefits.
12. Recombinant factor VIIa (rfVIIa) has been approved for treatment of bleeding in hemophilia patients with inhibitors. It has also been successful in patients without hemophilia with acquired antibodies against factor VIII (acquired hemophilia). Pharmacologic doses of rfVIIa enhance the thrombin generation on already activated

platelets and, therefore, may also be of benefit in providing hemostasis in other situations, such as those characterized by profuse bleeding and impaired thrombin generation.

13. Bloodless medicine and surgery is defined using a team approach that reduces blood loss and employs the best available alternatives to allogeneic transfusion therapy while focusing on the provision of the best possible medical care to all patients. Some patients, however, object to receiving blood or blood products as part of their medical treatment on religious grounds or because of concern about the safety of blood transfusions, regardless of their religious background.

There are three types of autologous blood transfusion: preoperative autologous donation (PAD), acute normovolemic hemodilution (ANH), and intraoperative and postoperative blood recovery (blood salvage). The advantages, disadvantages, applications, and complications vary with the techniques being used.

The two primary reasons for employing autologous transfusion are avoidance of complications associated with allogeneic transfusion and conservation of blood resources. Patients with rare blood phenotypes or alloantibodies can benefit from autologous transfusion because compatible allogeneic blood may not always be available.[1] Potential complications of allogeneic transfusion that can be eliminated or minimized when autologous blood is administered include acute and delayed hemolytic reactions, alloimmunization, allergic and febrile reactions, and transfusion-transmitted infectious diseases. Intraoperative blood recovery may be the only option for providing a sufficient volume of compatible blood when severe, rapid blood loss occurs. ANH provides the only practical source of fresh whole blood.

The role of autologous blood procurement in surgery remains in evolution, based on improved blood safety, increased blood costs, and emerging pharmacologic alternatives to blood transfusion.[2-4] PAD became accepted as a standard practice in certain elective surgical settings such as total joint replacement surgery, so that by 1992 more than 6% of the blood transfused in the United States was autologous.[5] Subsequently, substantial improvements in blood safety have been accompanied by a decline in PAD (Table 57-1) as well as an interest in ANH as an alternative, lower cost strategy.[6] Nevertheless, public perception of blood safety and the reluctance to accept allogeneic blood transfusion in the elective transfusion setting,[7] along with emerging blood inventory shortages, continue to give autologous blood procurement strategies an important role in the surgical arena.

Preoperative Blood Donation

Patient Selection

The criteria for autologous donors are not as stringent as those for allogeneic donors. The American Association of Blood Banks (AABB) Standards for Blood Banks and Transfusion Services requires that the donor-patient's hemoglobin (Hb) be no less than 11 g/dL or the hematocrit (Hct) be less than 33% before each donation.[8] There are no age or weight limits. Patients may donate 10.5 mL/kg, in addition to testing samples. Donations may be scheduled more than once a week, but the last should occur no less than 72 hours before surgery to allow time for restoration of intravascular volume and for transport and testing of the donated blood.

Transfusion service policies, implemented under the auspices of hospital transfusion committees, differ regarding collection and use of autologous blood with positive viral markers. It is common practice to preclude use of blood reactive for hepatitis B surface antigen and the human immunodeficiency virus because of concerns for the safety of both patients and personnel. Some hospitals accept and transfuse autologous blood with any positive viral markers, and denying patients infected with human immunodeficiency virus the opportunity to receive their own blood could be a violation of the Americans with Disabilities Act.[9] Candidates for preoperative collection are stable patients scheduled for surgical procedures in which blood transfusion is likely. For procedures that are unlikely to require transfusion (i.e., a maximal surgical blood ordering schedule [MSBOS] does not suggest that crossmatched blood must be available),[10] the use of preoperative blood collection is not recommended.

Table 57-1 Collection and Transfusion of Autologous Blood* in the United States

Source	1980	1986	1989	1992	1994	1997	1999	2001
Transfused autologous (% of all blood units)	N/A	N/A	369 (3.1%)	566 (5.0%)	482 (4.3%)	421 (3.7%)	367 (3.0%)	359 (2.6%)

In selected patient subgroups, preoperative collection of autologous blood can significantly reduce exposure to allogeneic blood. Preoperative autologous collections should be considered for patients scheduled for procedures in which they are likely to receive transfusion, such as major orthopedic procedures, vascular surgery, cardiac or thoracic surgery, and radical prostatectomy.[11] The most common surgical procedures for which autologous blood is predonated are total joint replacements.[12] Autologous blood should not be collected for procedures that seldom (<10% of cases) require transfusion, such as cholecystectomy, herniorrhaphy, vaginal hysterectomy, and uncomplicated obstetric delivery.[13]

In special circumstances, preoperative autologous blood collection can be performed for patients who would not ordinarily be considered for autologous donation. Availability of medical support is important in assessing patient suitability. With suitable volume modification, parental cooperation, and attention to preparation and reassurance, pediatric patients can participate in preoperative collection programs.[14] Patients with significant cardiac disease are considered poor risks for autologous blood donation. Despite reports of safety in small numbers of such patients who underwent autologous blood donation,[15] the risks that are associated with autologous blood donation[16] in these patients are greater than estimated current risks of allogeneic transfusion.[4,5] Table 57-2 summarizes the medical contraindications to a patient's participation in an autologous blood donation program.[17] The collection of autologous blood from women during routine pregnancy is unwarranted,[18] because blood is so seldom needed. PAD can be considered for women with alloantibodies to multiple or high-incidence antigens or with placenta previa or other conditions placing them at high risk for antepartum or intrapartum hemorrhage.[13] AABB Standards no longer permit allogeneic transfusion of unused autologous units ("crossover") because autologous donors are not, in the strictest sense, volunteer donors.[8]

Attempts to stratify patients into groups at high and low risk for needing transfusion based on the baseline level of hemoglobin and on the type of procedure show some promise. In a Canadian study using a point score system, 80% of patients undergoing orthopedic procedures were identified to be at low risk (<10%) for transfusion, and therefore autologous blood procurement for these patients would not be recommended.[19] However, one problem with algorithms that consider the estimated blood loss and preoperative hematocrit is that blood losses are difficult to measure[20] or predict because specific surgical procedures performed even by the same surgeon can be accompanied by a wide range of blood loss.

Table 57-2 Contraindications to Participation in Autologous Blood Donation Programs

1. Evidence of infection and risk of bacteremia
2. Scheduled surgery to correct aortic stenosis
3. Unstable angina
4. Active seizure disorder
5. Myocardial infarction or cerebrovascular accident within 6 months of donation
6. Patients with significant cardiac or pulmonary disease who have not yet been cleared for surgery by their treating physician
7. High-grade left main coronary artery disease
8. Cyanotic heart disease
9. Uncontrolled hypertension

The Role of Aggressive Phlebotomy and the Use of Erythropoietin

The efficacy of PAD is dependent on the degree to which the patient's erythropoiesis increases the production of red blood cells (RBCs).[21] The endogenous erythropoietin response and compensatory erythropoiesis are suboptimal under "standard" conditions of 1 blood unit donated weekly. As shown in Table 57-3, weekly PAD is accompanied by an expansion in RBC volume of 11% (with no oral iron supplementation) to 19% (with oral iron supplementation), which is not sufficient to prevent increasing anemia in patients undergoing PAD. If the erythropoietic response to autologous blood phlebotomy does not maintain the patient's hematocrit level during the donation interval, the donation of autologous blood actually may be harmful[22,23] by causing perioperative anemia and an increased likelihood of allogeneic blood transfusion. A mathematical model[22] has been published to demonstrate the relationship between anticipated surgical blood losses, the desired hematocrit, and the need for autologous blood donation.

In contrast to autologous blood donation under "standard" conditions, studies of "aggressive" autologous blood phlebotomy (twice weekly for 3 weeks, beginning 25 to 35 days before surgery) have demonstrated that endogenous erythropoietin levels do increase, along with enhanced erythropoiesis representing RBC volume expansion of 19% to 26% (see Table 57-3). Exogenous (pharmacologic) erythropoietin therapy to further stimulate erythropoiesis (up to 50% RBC volume expansion[24-26]) during autologous phlebotomy has been approved in Canada and Japan but not in the United States.[27] Perisurgical erythropoietin therapy is approved worldwide for anemic (Hct < 39%) patients scheduled for noncardiac, nonvascular surgeries.

Transfusion Trigger

Disagreement exists about the proper hemoglobin/hematocrit level ("transfusion trigger") at which autologous blood should be given (see Chapter 55).[28] Autologous blood transfusion recipient risks are given in Table 57-4. Perhaps autologous and allogeneic blood transfusion triggers should be similar, because the mortality risks related to allogeneic blood are less than risks of mortality from administrative errors that are associated with both autologous and allogeneic blood.[29]

Preoperative Collection of Components

Preoperative or intraoperative collection of platelet-rich plasma during cardiopulmonary bypass surgery may improve hemostasis and decrease allogeneic exposures.[28] Preoperative collection of autologous platelets, especially in cardiac surgery, is often impractical because patients may be taking antiplatelet drugs; surgery is often scheduled on an emergency basis; and relatively low numbers of platelets are harvested.

Table 57-3 Endogenous Erythropoietin-Mediated Erythropoiesis*

		RBC (mL)		Net RBC		
	Patients (*n*)	Removed (Donated)	Produced	Expansion (%)	Iron Therapy	Reference
Standard Phlebotomy	108	522	351	19	PO	36
	22	590	220	11	None	33
	45	621	331	17	PO	33
	41	603	315	16	PO, IV	33
Aggressive Phlebotomy	30	540	397	19	None	34
	30	558	473	23	PO	34
	30	522	436	21	IV	34

Cost-Effectiveness

Although autologous blood collections have become popular, the costs associated with their collection are higher than those associated with the collection of allogeneic blood. The continued need for autologous blood programs has been questioned because the reduced risk of allogeneic blood transfusions has made PAD poorly cost effective.[30,31]

Acute Normovolemic Hemodilution (ANH)

ANH is the removal of whole blood from a patient while restoring the circulating blood volume with an acellular fluid shortly before an anticipated significant surgical blood loss. To minimize the manual labor associated with hemodilution, the blood should be collected in standard blood bags containing anticoagulant on a tilt-rocker with automatic cutoff via volume sensors. The blood is then stored at room temperature and reinfused during surgery after major blood loss has ceased, or sooner if indicated. Simultaneous infusions of crystalloid (3 mL crystalloid for each 1 mL of blood withdrawn) and colloid (dextrans, starches, gelatin, albumin [1 mL for each 1 mL of blood withdrawn]) have been recommended.[32] Blood units are reinfused in the reverse order of collection since the first unit collected; therefore, the last unit transfused has the highest hematocrit and concentration of coagulation factors and platelets. While this technique has been primarily developed and utilized in Europe, increasing interest in the United States has led to data[3] that show promise in the use of ANH as an alternative method of autologous blood procurement. Augmented hemodilution (replacement of ANH collected in part by synthetic oxygen carriers) is an integral part of many phase III studies designed to obtain U.S. Food and Drug Administration (FDA) approval for artificial oxygen carriers.

Physiologic Considerations

Conserved Red Blood Cell Mass

The chief benefit of ANH is the reduction of RBC losses when whole blood is shed perioperatively at lower hematocrit levels after ANH is completed.[33] Mathematical modeling has suggested that severe ANH to preoperative hematocrit levels of less than 20%, accompanied by substantial blood losses, would be required before the red cell volume "saved" by ANH would become clinically important.[34] A clinical analysis of patients who had undergone "minimal" ANH (representing 15% or less of patients' blood volume) estimated that only 100 mL of RBCs (the equivalent of ½ unit of blood) was "saved" under these conditions.[35] With moderate hemodilution (target hematocrit levels of 28%), the "savings" becomes more substantial. The removal of 3 blood units in a patient who subsequently underwent a blood loss of 2600 mL resulted in surgical RBC losses "saved" by hemodilution of 215 mL, or the equivalent of 1 allogeneic blood unit (Fig. 57-1).[36] This RBC

Table 57-4 Advantages and Disadvantages of Autologous Blood Donation

Advantages	Disadvantages
Prevents transfusion-transmitted disease	Does not affect risk of bacterial contamination
Prevents red cell alloimmunization	Does not affect risk of ABO incompatibility error
Supplements the blood supply	Is more costly than allogeneic blood
Provides compatible blood for patients	Results in wastage of blood not transfused with alloantibodies
Prevents some adverse transfusion reactions	Increased incidence of adverse reactions to autologous donation
Provides reassurance to patients concerned about blood risks	Subjects patient to perioperative anemia and increased likelihood of transfusion

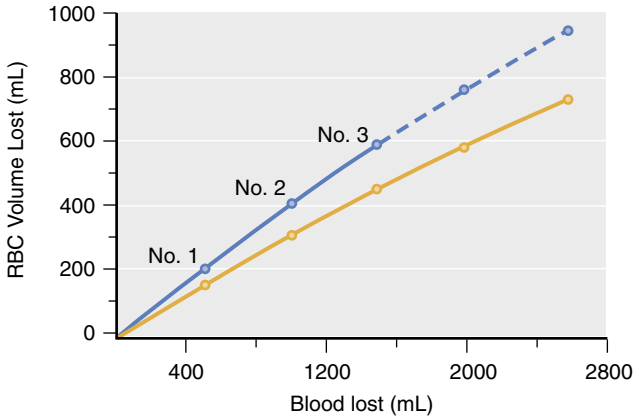

Figure 57-1 The relationship between whole blood volume (mL) lost (*abscissa*) and red blood cell (RBC) volume lost (*ordinate*) in a 100-kg patient undergoing hemodilution: RBC volume lost with 2800 mL whole blood lost intraoperatively after hemodilution of 1500 mL whole blood (*solid blue line*); RBC volume lost with 2800 mL whole blood lost during hemodilution at each of three 500 mL volumes (*solid orange line*); cumulative RBC volume lost intraoperatively, derived for 2800 mL whole blood lost if hemodilution had not been performed (*blue dashed line*). A net of 215 mL reduction in RBC volume lost with hemodilution is illustrated by the divergence of the two curves. (*From Goodnough LT, Grishaber JE, Monk TG, et al: Acute normovolemic hemodilution in patients undergoing radical suprapubic prostatectomy: A case study analysis. Anesth Analg 78:932-937, 1994, with permission.*)

volume approaches the RBC volume expansion generated by autologous blood predonation under standard phlebotomy conditions.

The benefit of ANH as determined in a mathematical model[32] is illustrated in Figure 57-2. An adult with an estimated 5-L blood volume and an initial hematocrit of 40%, with surgical blood losses of up to 3000 mL would result in a hematocrit level that would remain 25% postoperatively without an autologous blood intervention. This level is generally considered safe for patients without known risk factors. In this model, the performance of ANH with initial hematocrit levels of 40% to 45% would allow up to 2500 to 3500 mL of surgical blood loss; yet the nadir level of hematocrit could be maintained at 28%.

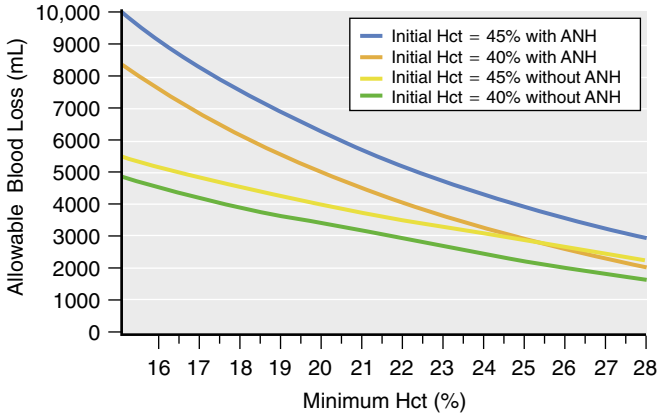

Figure 57-2 The maximum allowable blood loss in a patient with a blood volume of 5000 mL and an initial hematocrit level of 45% (*blue and yellow lines*) or 40% (*green and orange lines*), with and without acute normovolemic hemodilution (ANH). (*From Goodnough LT, Brecher ME, Monk TG: Acute normovolemic hemodilution in surgery. Hematology 2:413-420, 1992, with permission.*)

Improved Oxygenation

Withdrawal of whole blood and replacement with crystalloid or colloid solution decreases arterial oxygen content, but compensatory hemodynamic mechanisms and the existence of surplus oxygen-delivery capacity make ANH safe. A sudden decrease in RBC concentration decreases blood viscosity, thereby decreasing peripheral resistance and increasing cardiac output. If cardiac output can effectively compensate, oxygen delivery to the tissues at a hematocrit of 25% to 30% is as good as, but no better than, oxygen delivery at a hematocrit of 30% to 35%.[37]

Preservation of Hemostasis

Because blood collected by ANH is stored at room temperature and is usually returned to the patient within 8 hours of collection, there is little deterioration of platelets or coagulation factors. The hemostatic value of blood collected by ANH is of questionable benefit for orthopedic or urologic surgery because plasma and platelets are rarely indicated in this setting. Its value in protecting plasma and platelets from the acquired coagulopathy of extracorporeal circulation in cardiac surgery (known as "blood pooling") is better established.[38]

Clinical Studies

Prospective, randomized studies in radical prostatectomy,[39] knee replacement,[40] and hip replacement[41] suggest that ANH can be considered equivalent to PAD as a method of autologous blood procurement. Additional, selected clinical trials of ANH are summarized in Table 57-5.[42-48] Reviews[49] and commentaries[50] on the merits of ANH have been published. When ANH and reinfusion are accomplished in the operating room by on-site personnel, the procurement and administration costs are minimized. Blood obtained during ANH does not require the commitment of the patient's time, transportation, costs, and loss of work time that can be associated with PAD. The wastage of PAD units (approximately 50% of units collected)[13] also is eliminated with ANH. Additionally, autologous blood units procured by ANH require no inventory or testing costs. Because the blood never leaves the patient's room, ANH minimizes the possibility of an administrative or clerical error that could lead to an ABO-incompatible blood transfusion and death, as well as bacterial contamination associated with prolonged storage at 4°C.

Some practical considerations are important regarding an ANH program. Decisions about ANH should be based on the surgical procedure and on the patient's preoperative blood volume and hematocrit, target hemodilution hematocrit, and other physiologic variables. The institution's policy and procedures and the mechanisms for educating staff should be established and periodically reviewed.

There should be careful monitoring of the patient's circulating volume and perfusion status during the procedure. Blood must be collected in an aseptic manner, ordinarily into standard blood collection bags with citrate anticoagulant. Units must be properly labeled and stored. The label must contain, at a minimum, the patient's full name, medical record number, date and time of

Table 57-5 Selected Clinical Trials of Acute Normovolemic Hemodilution (ANH)

collection, and the statement "For Autologous Use Only." Room temperature storage should not exceed 8 hours. If more time elapses between collection and transfusion, the blood should be stored in a monitored refrigerator. Suggested criteria for patient selection are listed in Table 57-6.

Cost-Effective Analysis of ANH versus PAD

Because there is no good evidence that either PAD or ANH is effective at eliminating allogeneic blood transfusions, autologous blood collection techniques cannot be considered cost-effective alternatives to the use of allogeneic blood. The majority of the trials evaluating the efficacy of ANH compare this blood conservation technique to PAD because autologous blood donation is considered to be a "standard of care" for many elective surgical procedures in the United States and many patients request its use. Medicolegal concerns may also prevent the inclusion of a treatment arm consisting of only allogeneic blood transfusion because blood safety acts in several states mandate that physicians discuss autologous blood options before elective surgical procedures.[3] All of these studies found ANH to be equivalent to PAD in eliminating the need for allogeneic blood transfusions and suggest that ANH and PAD are equivalent for avoiding allogeneic blood transfusions during elective surgery.[51] Long-term outcomes including anesthesia and surgery times, intraoperative hemodynamic values, and length of hospital stays were also equivalent in PAD and ANH.

Because ANH and PAD appear to have equivalent efficacy, it is not possible to do a cost-effectiveness evaluation comparing these autologous transfusion modalities. However, if two interventions have equivalent outcomes but different costs, medical economists often perform a cost minimization analysis to determine the least-cost alternative.[52] Despite the fact that only a few studies include economic evaluations comparing the cost of autologous blood techniques, all of these studies demonstrate that ANH is much less costly than PAD.[51] ANH can, therefore, be considered a cost-minimizing technique for procuring autologous blood before elective surgery.

Table 57-6 Criteria for Selection of Patients for Acute Normovolemic Hemodilution

1. Likelihood of transfusion exceeds 10% (i.e., blood requested for crossmatch according to a maximum surgical blood order schedule)
2. Preoperative hemoglobin level of at least 12 g/dL
3. Absence of clinically significant coronary, pulmonary, renal, or liver disease
4. Absence of severe hypertension
5. Absence of infection and risk of bacteremia

Intraoperative Blood Collection

The term *intraoperative blood collection* or *recovery* describes the technique of collecting and reinfusing blood lost by a patient during surgery. The oxygen-transport properties of recovered RBCs are equivalent to those of stored allogeneic RBCs. The survival of recovered RBCs appears to be at least comparable to that of transfused allogeneic RBCs.[53] Intraoperative collection is contraindicated when certain procoagulant materials (e.g., topical collagen) are applied to the surgical field, because systemic activation of coagulation may result. Microaggregate filters (40 ∝m) are most often used, because recovered blood may contain tissue debris, small blood clots, or bone fragments.

Cell washing devices can provide the equivalent of 12 units of banked blood per hour to a massively bleeding patient.[53] Data regarding adverse events of reinfusion of recovered blood have been published.[54] Air embolus is a potentially serious problem. Three fatalities from air embolus were reported over a 5-year interval to the New York State Department of Public Health, for an overall fatality risk of 1 in 30,000.[30] Hemolysis of recovered blood can occur during suctioning from the surface instead of from deep pools of shed blood. For this reason, manufacturers' guidelines recommend a maximum vacuum setting of no more than 150 mm Hg: one study found that vacuum settings as high as 300 mm Hg could be used, when necessary, without causing excessive hemolysis.[55] Patients exhibit a level of plasma-free hemoglobin that is usually higher than after allogeneic transfusion. The clinical importance of free hemoglobin in the concentrations usually seen has not been established, although excessive free hemoglobin may indicate inadequate washing. Positive bacterial cultures from recovered blood are sometimes observed;

however, clinical infection is rare.[56] Most programs use machines that collect shed blood, wash it, and concentrate the RBCs. This process typically results in 225-mL units of saline-suspended RBCs with a hematocrit of 50% to 60%.

Clinical Studies

As with PAD and ANH, collection and recovery of intraoperative autologous blood should undergo scrutiny with regard to both safety and efficacy. A controlled study in cardiothoracic surgery demonstrated a lack of efficacy when transfusion requirements and clinical outcomes were followed.[56] A second study found that only a minority of patients undergoing major orthopedic and cardiac surgery achieved cost equivalence with intraoperative blood recovery using semi-automated instruments compared with banked blood.[57] Although the collection of a minimum of one blood unit equivalent is possible for less expensive (with unwashed blood) methods, at least two blood unit equivalents need to be recovered using a cell-recovery instrument (with washed blood) to achieve cost-effectiveness.[58] The value of intraoperative blood collection is apparent for vascular surgeries with large blood losses, such as aortic aneurysm repair and liver transplantation.[59] However, a prospective, randomized trial[58] of intraoperative recovery and reinfusion in patients undergoing aortic aneurysm repair showed no benefit in a reduction of allogeneic blood exposure. The value of this technology may be in cost savings and blood inventory considerations in patients with substantial blood losses.

Medical Controversies

Collection devices that neither concentrate nor wash shed blood before reinfusion increase the risk of adverse effects. Shed blood has undergone varying degrees of coagulation/fibrinolysis and hemolysis, and infusion of large volumes of washed or unwashed blood has been described in association with disseminated intravascular coagulation.[59] In general, blood collected at low flow rates or during slow bleeding from patients who are not systemically anticoagulated will have undergone coagulation and fibrinolysis and will not contribute to hemostasis on reinfusion. The high suction pressure and surface skimming during aspiration and the turbulence or mechanical compression that occurs in roller pumps and plastic tubing make some degree of hemolysis inevitable. High concentrations of free hemoglobin may be nephrotoxic to patients with impaired renal function. Many programs limit the quantity of recovered blood that may be reinfused without processing. To minimize hemolysis, the vacuum level should ordinarily not exceed 150 mm Hg, although higher levels of suction may occasionally be needed during periods of rapid bleeding.

An alternative approach is to collect blood in a canister system designed for direct reinfusion and then to concentrate and wash the recovered RBCs in a blood bank cell washer. Intraoperatively collected and recovered blood must be handled in the transfusion service laboratory like any other autologous unit. The unit should be reinfused through a filter.

Some practical considerations for cell recovery programs are listed in Table 57-7. If collected under aseptic conditions with a saline-wash device and if properly labeled, blood may be stored at room temperature for up to 4 hours or at 1° to 6°C for up to 24 hours, provided that storage at 1° to 6°C is begun within 4 hours of ending the collection.[8] Note that the allowable interval of room temperature storage is shorter for recovered blood (4 hours) than for ANH blood (8 hours). Storage times are the same for recovered blood whether unwashed or washed.

Table 57-7 Practical Considerations for Intraoperative Cell Recovery, Storage, and Reinfusion

1. If not transfused immediately, units collected from a sterile operating field and processed with a device for intraoperative blood collection that washes with 0.9% saline, USP, shall be stored under one of the following conditions prior to initiation of transfusion:
   a. At room temperature for up to 4 hours after terminating collection
   b. At 1-6°C for up to 24 hours, provided that storage at 1-6°C is begun within 4 hours of ending the collection.
2. Transfusion of blood collected intraoperatively by other means shall begin within 6 hours of initiating the collection.
3. Each unit collected intraoperatively shall be labeled with the patient's first name, last name, and hospital identification number; the date and time of initiation of collection and of expiration; and the statement "For Autologous Use Only."
4. If stored in the blood bank, the unit shall be handled like any other autologous unit.
5. The transfusion of shed blood collected under postoperative or post-traumatic conditions shall begin within 6 hours of initiating the collection.

Postoperative Blood Collection

Postoperative blood collection denotes the recovery of blood from surgical drains followed by reinfusion, with or without processing.[60] In some programs, postoperative shed blood is collected into sterile canisters and reinfused, without processing, through a microaggregate filter. Recovered blood is dilute, is partially hemolyzed and defibrinated, and may contain high concentrations of cytokines. For these reasons, most programs set an upper limit on the volume (e.g., 1400 mL) of unprocessed blood that can be reinfused. If transfusion of blood has not begun within 6 hours of initiating the collection, the blood must be discarded.

Clinical Studies

The evolution of cardiac surgery has been accompanied by broad experience in postoperative conservation of blood. Postoperative autologous blood transfusion is practiced widely but not uniformly. Prospective and controlled trials have disagreed over the efficacy of postoperative blood recovery in cardiac surgery patients; at least three such studies have demonstrated lack of efficacy,[61,62] whereas at least two studies have shown benefit.[63] The disparity of results in these studies may be explained, in part, by differences in transfusion practices. Modification of physician transfusion practices may have been an uncredited intervention in these blood conservation studies.

In the postoperative orthopedic surgical setting, a number of reports have similarly described the successful recovery and reinfusion of washed[64] and unwashed[65] wound drainage blood from patients undergoing arthroplasty. The volume of reinfused

drainage blood has been reported to be as much as 3000 mL and averages more than 1100 mL in patients undergoing cementless knee replacement.[65] Because the RBC content of the fluid collected is low (hematocrit levels of 20%) the volume of RBCs reinfused is often small.[66] A prospective, randomized study of postoperative salvage and reinfusion in patients undergoing total knee or hip replacement found no differences in perioperative hemoglobin levels or allogeneic blood transfusions between patients who did or did not have joint drainage devices.[67]

The safety of reinfused unwashed orthopedic wound drainage has been controversial. Theoretical concerns have been expressed regarding infusion of potentially harmful materials in recovered blood, including free hemoglobin, RBC stroma, marrow fat, toxic irritants, tissue or methacrylate debris, fibrin degradation products, activated coagulation factors, and complement. Although two small studies have reported complications,[68,69] several larger studies have reported no serious adverse effects when the drainage was passed through a standard 40-∝m blood filter.[64,65,70]

The potential for decreasing exposure to allogeneic blood among orthopedic patients undergoing postoperative blood collection, whether washed or unwashed, is greatest for cementless bilateral total knee replacement, revision hip or knee replacement, and long-segment spinal fusion. As in the case of intraoperative recovery, blood loss must be sufficient to warrant the additional cost of processing technology.[71] As in selection of patients who can benefit from PAD and ANH, prospective identification of patients who can benefit from intraoperative and postoperative autologous blood recovery is possible if patients' preoperative hemoglobin level, anticipated surgical blood losses, and the perioperative "transfusion trigger" are taken into account.

Fibrin Glue

Fibrin glue and fibrin gel are blood derivatives rather than pharmacologic agents, but their increasing use as an intervention in surgical hemostasis and blood conservation deserves mention. Fibrin glue is derived from a source of fibrinogen and factor XIII (fibrin-stabilizing factor), in which a solution of fibrinogen is mixed with a solution of thrombin and applied to a surgical field.[72] These agents can be applied directly to wounds that display diffuse microvascular bleeding or can be used to seal vascular grafts. It is important to note that these preparations represent additional allogeneic blood donor exposure. Alternatively, the source of fibrinogen and factor XIII can be derived from as little as 40 mL of the patient's autologous blood.[73]

Patients should be made aware of the potential complications as well as the potential benefits of its use.[74] One case of anaphylactic reaction after a total of only 8 mL of fibrin glue administration[75] and one case of human immunodeficiency virus transmission[76] have been described. A solvent-detergent–treated fibrin glue preparation is now available.[77] Reports of two cardiac surgery patients who presented with acquired thrombin or factor V inhibitors, each of whom had been previously exposed to bovine thrombin,[78] cause concern over the potential toxicities associated with the use of either allogeneic or autologous fibrin sealants. Issues of informed consent for administration of these blood products and criteria for their use need to be addressed.

Recombinant Factor VIIA

Recombinant factor VIIa (rfVIIa) has been approved for treatment of bleeding in hemophilia patients with inhibitors. Pharmacologic doses of rfVIIa have been found to enhance the thrombin generation on activated platelets and, therefore, may also likely be of benefit in providing hemostasis in other (nonapproved) situations characterized by profuse bleeding and impaired thrombin generation,[79] such as in patients with thrombocytopenia and in those with functional platelet defects.[80,81] Additionally, it has been used successfully in a variety of less well-characterized surgical bleeding situations with dilutional or consumptive coagulopathies and in patients with impaired liver function.[82-84] Policies for the approval of rfVIIa therapy in nonapproved settings should therefore undergo periodic review and revision as relevant new information and data are generated.[85] Because of the recent trends in rfVIIa usage in nonapproved settings, significant concerns about its safety, efficacy, and costs have arisen. Additionally, dosing of rfVIIa for these potentially broad clinical applications is not standardized.

Complex Surgery and Traumas Resulting in Profuse Bleeding

A hemostatic effect has been demonstrated after the administration of rfVIIa in a limited number of patients after trauma and bleeding.[82,83] Seven trauma patients treated with rfVIIa after failure of conventional measures to achieve hemostasis[83] reported cessation of diffuse bleeding and correction of abnormal coagulation assays; three of the seven patients died of reasons other than bleeding or of thromboembolism.

Anecdotal case reports have been published that describe the successful use of rfVIIa in patients with substantial perisurgical bleeding. The experience of rfVIIa use in trauma with excessive bleeding as well as in profuse postoperative bleeding, based largely on case reports, has indicated a hemostatic effect of rfVIIa given in doses ranging from 20 to 120 ∝g/kg. The issue of preemptive, preoperative rfVIIa (40-90 ∝g/kg) was studied in nine patients with coagulopathy and urgent neurosurgical intervention.[86] Post-rfVIIa coagulation parameters normalized as early as 20 minutes after infusion, with no noted procedural or operative complications. No associated thromboembolic complications were observed. Subsequently, a prospective, randomized study of rfVIIa (20 ∝g/kg or 40 ∝g/kg) versus placebo perioperatively in 36 patients undergoing radical retropubic prostatectomy found that the cohorts receiving rfVIIa had substantially less median operative blood loss compared with placebo (1235 mL, 1089 mL, and 2688 mL, respectively).[87] This study was not powered to demonstrate reductions in blood transfusions.

In single center series, 51 patients undergoing rfVIIa therapy for intractable blood loss after cardiac surgery were compared with 51 matched controls.[88] The authors found that bleeding 1 hour after therapy was reduced in the treated cohort, compared with the control cohort. No differences in serious adverse events were noted. A subsequent review from the same institution of 114 cardiac surgery patients who received rfVIIa compared with 541 concurrent patients who did not receive rfVIIa concluded that rfVIIa is not associated with increased risk

of adverse events and early treatment may be associated with better outcomes.[89] A second series of rfVIIa in 53 patients during cardiac surgery found a significant decrease in doses of all blood products.[90] However, a third series of 24 patients treated with rfVIIa for refractory bleeding after cardiac surgery, compared with 24 matched controls, found no differences in red blood cells or plasma units transfused over a 24-hour period.[91]

Recently, a pilot study of 20 patients undergoing complex noncoronary cardiac surgery who were randomized to receive either placebo or rfVIIa (90 ∝g/kg) prophylactically after completion of cardiopulmonary bypass and reversal of heparin found a significantly reduced need for allogenic transfusion in the cohort who received rfVIIa.[92] However, a pediatric study of 76 pediatric patients undergoing surgery for congenital heart disease found no benefit of rfVIIa (40 ∝g/kg) prophylaxis as determined by chest closure time after cardiopulmonary bypass.[93]

Two randomized placebo-controlled trials of rfVIIa as adjunctive therapy for control of bleeding in trauma patients were published.[94] In an analysis of 143 patients with blunt trauma, the percentage of patients alive at 48 hours receiving more than 20 units of RBCs was reduced from 33% to 14% ($P = .03$). For 143 patients with penetrating trauma, the reduction from 19% to 7% was not significant ($P = .08$). No differences in serious adverse events between the rfVIIa-treated and placebo cohorts were observed.

Dose

A retrospective review of 40 patients with coagulopathic bleeding in a variety of medical and surgical settings from 13 hospitals in an Internet-based database (excluding history of coagulopathy and trauma patients) who received rfVIIa (15 to 180 ∝g/kg, with 38 patients receiving fewer than five doses) found that 32 (80%) achieved complete ($n = 18$) or partial ($n = 14$) cessation of bleeding.[95] Responses occurred in all dose ranges, without any evidence of a dose-response effect; the percentages of complete, partial, or no response were not different at doses of less than 70 ∝g/kg, 70 to 90 ∝g/kg, or more than 90 ∝g/kg (Fig. 57-1). Significantly fewer blood products were administered after rfVIIa therapy. Twenty-three (58%) patients died, reflecting the unstable clinical status of the patients at the decision point for considering rfVIIa therapy. On the basis of this study, we have recommended a nonweight dosage strategy in which a 4.8-mg vial administered to an adult patient weighing 50 to 100 kg represents a 100-∝g/kg to 50-∝g/kg dose.[85]

Patients Receiving Oral Anticoagulant Therapy

One report describes the use of rfVIIa in seven adult patients with prolonged international normalized ratio (INR), three of whom required surgery. The doses administered ranged from 20 to 90 ∝g/kg, and all patients were reported to have a positive outcome.[96] These observations indicate that rfVIIa may be used to reverse the effect of warfarin (Coumadin) or other vitamin K–antagonist therapy in cases in which the administration of vitamin K alone has been found to be insufficient. Two published reports of 15 total patients treated with rfVIIa for reversal of excessive anticoagulation with warfarin support a dosage of 20 ∝g/kg, or 1.2 mg for an adult patient.[97,98] A recent review of 12 patients with acute warfarin-associated intracranial hemorrhage over this same time period at one institution, all of whom received rfVIIa (30 to 135 ∝g/kg) as well as vitamin K (10 mg/day · 3) and fresh frozen plasma (1307 ± 652 mL) for treatment, found that treatment was associated with rapid correction of the INR and that single doses appeared safe in this high-risk population.[99]

Patients with Impaired Liver Function

A multicenter trial studied 71 patients with advanced liver disease who were undergoing laparoscopic liver biopsy.[100] The patients were randomized to receive one of four doses of rfVIIa (5, 20, 80, or 120 ∝g/kg); 48 (74%) of 65 patients achieved hemostasis within 10 minutes. One thrombotic event and one case of disseminated intravascular coagulation were reported, not believed by the authors to be related to rfVIIa therapy. Despite these complications, the authors concluded that laparoscopic liver biopsy can be performed safely and reliably by using rfVIIa in patients in whom the standard procedure might be contraindicated because of coagulopathy.

The safety and efficacy of rfVIIa in patients with cirrhosis with upper gastrointestinal hemorrhage was studied in a randomized study of 245 patients with a composite primary endpoint, including failure to control bleeding within 24 hours after first dose, failure to prevent rebleeding within 24 hours to 5 deaths, or death within 5 days.[101] There were no significant differences found between the placebo compared with the rfVIIa (8 doses at 100 mg/kg over 30 hours) cohorts: failures on composite endpoint were 16% and 14%, respectively ($P = .72$). Similarly, a randomized, controlled study of patients with cirrhosis who underwent partial hepatectomy found no benefit to rfVIIa compared with placebo when the volume of blood products administered, or percentage of patients transfused, was analyzed.[102] Finally, no value for peri-adjuvant rfVIIa was found in patients undergoing liver transplantation, when compared with placebo.[103]

Patients with Normal Hepatic Function

A prospective, randomized, double-blind multicenter study evaluated the efficacy of two different doses of rfVIIa compared with placebo on RBC transfusions for adult patients without cirrhosis undergoing partial hepatectomy.[104] Mean RBC volume transfused was 1024, 1354, and 1036 mL for placebo, 20 ∝g/kg rfVIIa, and 80 ∝g/kg rfVIIa, respectively ($P > .05$). Similarly, there were no differences in percentage of patients transfused and in intraoperative blood losses. Serious adverse events were not different.

Patients with Hemorrhagic Stroke

A recent prospective, randomized, double-blind placebo-controlled trial of three doses of rfVIIa compared with placebo was reported in patients presenting with acute (<4 hr) hemorrhagic stroke.[105] At 24 hours after treatment, the percentage of patients showing expansion was 28%, 16%, 14%, and 11% for the placebo, 40 ∝g/kg, 80 ∝g/kg, and 160 ∝g/kg, respectively ($P < .05$

treatment cohorts versus placebo). Percentage of patients with mortality was 29%, 18%, 18%, and 19%, respectively ($P < .05$, treatment cohorts versus placebo). Impairment scored at 90 days was also improved in the treatment cohorts compared with placebo. A follow-up, clinical trial (placebo, 40 ∝g/kg, and 80 ∝g/kg) failed to show any benefit for rfVIIa compared with placebo.[106]

Safety

Of the more than 170,000 standard doses of rfVIIa given after its approval (almost all to patients with hemophilia and inhibitors), only rare (<1:11,300) thrombotic events have been reported.[79] Thrombotic complications have also been reported with rfVIIa therapy in patients without inhibitors to factor VIII or IX. An acute cerebrovascular accident and death occurred in a clinical trial of rfVIIa (90 ∝g/kg) before and after minor surgery or dental procedures in patients with factor XII deficiency.[107] The last of 10 patients enrolled in an open label trial, dose-escalation trial to prevent rebleeding after subarachnoid hemorrhage developed middle cerebral artery thrombosis after receiving rFVIIa.[108] In a high-risk trauma population, 3 of 40 (7.5%) patients who were deemed at high risk for thrombosis developed thrombotic complications after receiving rfVIIa.[109]

Although SAE and thrombotic events have been distributed evenly among treatment and placebo cohorts in several large randomized clinical trials of patients undergoing radical prostatectomy,[87] trauma,[96] upper gastrointestinal bleeding,[101] or partial hepatectomy,[107] there was an uneven distribution of thromboembolic events in the clinical trial of patients with hemorrhagic stroke[107]; total events were 2 (2%), 7 (6%), 4 (5%), and 10 (10%) for the placebo, 40, 80, and 160 ∝g/kg cohorts, respectively. Most of these events were arterial, including thrombotic stroke and myocardial infarction. Whether these serious adverse events are attributed to rfVIIa or to a population at risk for these events will need to be determined in a follow-up clinical trial.

A summary of thromboembolic events reported to the FDA from March 1999 to December 2004 indicated a total of 151 events in settings with unlabeled indications.[110] These included deep venous thrombosis (42), cerebrovascular accidents (39), acute myocardial infarctions (34), pulmonary thromboembolus (32), arterial thrombosis (26), and clotted devices (10). Thirty-eight percent of cases had concomitant use of other hemostatic agents. In 36 (72%) of 50 reported deaths, rfVIIa was listed as the probable cause. The authors concluded that randomized clinical trials are necessary to demonstrate safety and efficacy of rfVIIa in nonapproved settings. A subsequent report analyzed safety data from 13 clinical trials in patients treated with rfVIIa for cirrhosis, trauma, or reversal of anticoagulant therapy.[111] The authors reported thrombotic adverse events in 5.3% of patients who received placebo, compared with 6.0% in patients who received rfVIIa ($P = .57$).

In cardiac surgery patients, cohort-matched studies[87,88] and a systematic review[112] found no differences in serious adverse events in patients treated with rfVIIa. We reported a patient who had a fatal thrombosis after administration of activated prothrombin complex concentrate who had also received two doses of rfVIIa more than 6 hours earlier, while supported by extracorporeal membrane oxygenation.[113] Because of this experience, we recommend that patients should not receive combination therapy with both activated prothrombin complex concentrate and rfVIIa.

On the basis of these reports, use of activated factor concentrates should be used with caution in patients with known hypercoagulability (e.g., history of thrombotic complications, established thrombotic disorders such as factor V Leiden, antiphospholipid syndrome) or who have excessive bleeding in the setting of disseminated intravascular coagulation or other states of generalized activation of the hemostatic system (e.g., after cardiac surgery, patients on extracorporeal membrane oxygenation or ventricular assist devices) based on the potential for development of localized or systemic intravascular thrombosis.

In summary, dose, timing, and safety of rfVIIa have yet to be defined in this diverse patient population and formal prospective trials are needed. Consensus-based recommendations on the use of rfVIIa in nonapproved settings have been developed.[114] The decision on when and where to use rfVIIa for patients with uncontrolled bleeding continues to be one that must be made by individual physicians, assisted by their hospital pharmacotherapeutic or transfusion committees.[115]

Bloodless Medicine

Some patients object to receiving blood or blood products as part of their medical treatment. Many of these individuals are Jehovah's Witnesses and refuse the transfusion of another person's blood based on strict interpretations of both Old and New Testament texts that refer to the sanctity of blood.[116] This religious group currently has over 6 million active and 14 million associated followers worldwide, and its publications are translated into over 200 different languages. In the 1980s, bloodless medicine programs were started at the request of Jehovah's Witness patients who wanted hospitals where they could receive the best medical care and have their desire to avoid allogeneic blood transfusions respected.[116]

Recently, a substantial proportion of the population in the United States, regardless of their religious background, has voiced concern about the safety of blood transfusions. A telephone survey found that only 61% of the respondents believed the blood supply in the United States was safe, and 33% said that they would refuse blood transfusions if hospitalized.[7] In the past decade, public concern about problems with the blood supply and shortages in the availability of volunteer blood donors have also led to the development of bloodless medicine centers.

Bloodless medicine and surgery is defined as a team approach "that reduces blood loss and uses the best available alternatives to allogeneic transfusion therapy while focusing on the provision of the best possible medical care to all patients."[1] The objectives of a bloodless medicine program should include "providing leadership within an institution for bloodless medicine and being the advocate for patients not accepting transfusion."[117] All clinicians should realize that a philosophy of blood management that incorporates the avoidance of unnecessary blood transfusions in all patients is appropriate even if a bloodless medicine center does not exist at their institutions.[1] The general principles of surgical and anesthetic bloodless management are detailed in Table 57-8.[118]

Table 57-8 Surgical and Anesthetic Principles of Bloodless Medicine Management

Preoperative Assessment and Planning
Management of anemia
Management of anticoagulation and congenital and drug-induced coagulopathies
Prophylactic interventional radiology and embolization
Prescribing and scheduling of cell salvage apparatus
Restricted diagnostic phlebotomy
Intraoperative Blood Conservation
Meticulous surgical hemostasis
Blood salvage
Hemodilution
Pharmaceutical enhancement of hemostasis
Maintenance of normothermia
Surgical positioning to minimize blood loss and hypertension
Postoperative Blood Conservation
Blood salvage
Tolerance of anemia
Optimum fluid and volume management
Restricted diagnostic phlebotomy
Adequate analgesia, maintenance of normothermia
Maintain appropriate fluid resuscitation. Significant normovolemic anemia is well tolerated in hemodynamically stable patients.
In actively bleeding patients, the first management priority must be to stop the bleeding. Avoid attempts to normalize blood pressure until bleeding is stopped.
Prevent or treat coagulation disorders promptly.
Oral or parenteral iron may be used to improve iron stores. Exogenous erythropoietin therapy effectively increases RBC mass.
Hematology and Oncology
Aggressive exogenous erythropoietin therapy and iron therapy for the prophylaxis of anemia
Individualized chemotherapy protocols to minimize hematologic toxicity
Pharmacologic prophylaxis and treatment of bleeding
Tolerance of anemia
Restricted diagnostic phlebotomy

RBC, red blood cell.

Summary

A substantial proportion of patients in the United States consider the administration of an allogeneic blood transfusion to have a bad outcome. Autologous transfusion regimens are reported to decrease allogeneic transfusion requirements in surgical patients, but the cost-effectiveness of all of these techniques remains in question. Further research to define the indications for, and limitations of, each autologous technique is needed. Clinical trials that evaluate combinations of several blood conservation techniques may be necessary if the goal is to eliminate the need for allogeneic blood transfusions in the future.

58 Anesthesia and Treatment of Chronic Pain

Key Points

1. The normal physiology of neuronal function, receptors, ion channels, and plasticity is altered by persistent pain.
2. Because of the large number of sources and manifestation of chronic pain, classification needs to include cancer-related, non–cancer-related, neuropathic, inflammatory, arthritis, and musculoskeletal pain.
3. Interdisciplinary management of chronic pain must include specialists in psychology, physical therapy, occupational therapy, and anesthesiology.
4. Drugs used for chronic pain are multiple and include opioids, nonsteroidal anti-inflammatory drugs and antipyretic analgesics, serotonin receptor ligands, antiepileptics, antidepressants, topical analgesics (e.g., nonsteroidal anti-inflammatory drugs, capsaicin, local anesthetics, opioids), other analgesics, and adjuvants such as local anesthetics, α_2-agonists, baclofen, botulinum toxin, antiemetics, laxatives, novel drugs such as cannabinoids, and ion channel blockers.
5. Interventional management of chronic pain includes the use of diagnostic blocks, therapeutic blocks, continuous catheter techniques, and stimulation techniques such as acupuncture, transcutaneous electrical nerve stimulation, and spinal cord stimulation.
6. Perioperative management of patients with chronic pain involves the use of opioid and nonopioid analgesics; evaluation for dependence, addiction, and pseudo-addiction; and practical considerations.

Physiologic Changes in Patients with Persistent Pain

Excitatory Mechanisms

Pain may be roughly divided into two broad categories: physiologic and pathologic pain. Physiologic (acute, nociceptive) pain is an essential early warning sign that usually elicits reflex withdrawal and thereby promotes survival by protecting the organism from further injury. In contrast, pathologic (e.g., neuropathic) pain is an expression of the maladaptive operation of the nervous system; it is pain as a disease.[1] Physiologic pain is mediated by a sensory system consisting of primary afferent neurons, spinal interneurons and ascending tracts, and several supraspinal areas. Trigeminal and dorsal root ganglia give rise to high-threshold Aδ and C fibers innervating peripheral tissues (skin, muscles, joints, viscera). These specialized primary afferent neurons, also called nociceptors, transduce noxious stimuli into action potentials and conduct them to the dorsal horn of the spinal cord (Fig. 58-1). When peripheral tissue is damaged, primary afferent neurons are sensitized or directly activated (or both) by a variety of thermal, mechanical, and chemical stimuli. Examples are protons, sympathetic amines, adenosine triphosphate (ATP), glutamate, neuropeptides (calcitonin gene–related peptide, substance P), nerve growth factor, prostaglandins, bradykinin, proinflammatory cytokines, and chemokines.[2,3] These agents lead to opening (gating) of cation channels in the neuronal membrane. Such channels include the capsaicin-, proton-, and heat-sensitive transient receptor potential vanilloid 1 (TRPV1) or the ATP-gated $P2X_3$ receptor. Gating produces an inward current of Na^+ and Ca^{2+} ions into the nociceptor terminal. If this depolarizing current is sufficient to activate voltage-gated Na^+ channels (e.g., $Na_V1.8$), they too will open, thus further depolarizing the membrane and initiating a burst of action potentials that are then conducted along the sensory axon to the dorsal horn of the spinal cord.[3,4] Thereafter, these impulses are transmitted to spinal neurons, the brainstem, the thalamus, and the cortex.[5,6]

Transmission of input from nociceptors to spinal neurons that project to the brain is mediated by direct monosynaptic contact or by multiple excitatory or inhibitory interneurons. The central terminals of nociceptors contain excitatory transmitters such as glutamate, substance P, and neurotrophic factors that activate postsynaptic *N*-methyl-D-aspartate (NMDA), neurokinin,

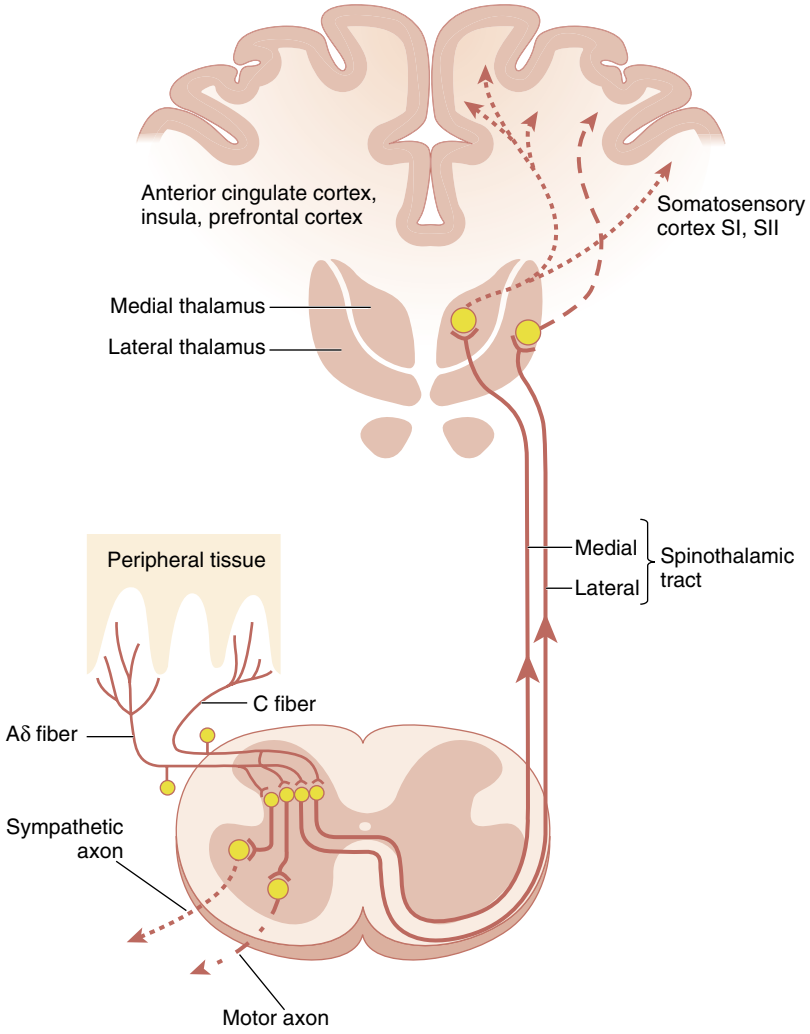

Figure 58-1 Nociceptive pathways. For details see text. *(Adapted from Brack A, Stein C, Schaible HG: Periphere und zentrale Mechanismen des Entzündungsschmerzes.* In *Straub RH [ed]: Lehrbuch der klinischen Pathophysiologie komplexer chronischer Erkrankungen, vol 1. Göttingen, Germany, Vandenhoeck & Ruprecht, 2006, pp 183-192.)*

and tyrosine kinase receptors, respectively. Repeated nociceptor stimulation can sensitize both peripheral and central neurons (activity-dependent plasticity). In spinal neurons such a progressive increase in output in response to persistent nociceptor excitation has been termed "wind-up." Later, sensitization can be sustained by transcriptional changes in the expression of genes coding for various neuropeptides, transmitters, ion channels, receptors, and signaling molecules (transcription-dependent plasticity) in both nociceptors and spinal neurons. Important examples include the NMDA receptor, cyclooxygenase-2 (COX-2), Ca^{2+} and Na^{+} channels, and cytokines and chemokines expressed by neurons and glial cells.[7,8] In addition, physical rearrangement of neuronal circuits by apoptosis, nerve growth, and sprouting occurs in the peripheral and central nervous systems.[1,5] For ethical reasons, animal studies are limited to several days or weeks, but human chronic pain usually lasts for months or years. Therefore, animal models do not mirror the truly chronic clinical situation and are more cautiously termed "persistent pain." Human brain-imaging studies have begun to investigate changes in patients with neuropathic pain, phantom pain, postherpetic neuralgia, back pain, and other chronic pain syndromes. However, with the exception of primary headaches, functional imaging has not yet provided reproducible findings specific for the disease or a pathophysiologic basis for these syndromes.[9]

Inhibitory Mechanisms

Concurrent with the events just described, powerful endogenous mechanisms counteracting pain unfold both in the periphery and in the central nervous system. In injured tissue this occurs by interactions between leukocyte-derived opioid peptides and peripheral nociceptor terminals carrying opioid receptors[10,11] and by the action of anti-inflammatory cytokines.[2] Inflammation of peripheral tissue leads to increased expression, axonal transport, and enhanced G protein coupling of opioid receptors in neurons of the dorsal root ganglia. These phenomena are dependent on sensory neuron electrical activity, production of proinflammatory cytokines, and the presence of nerve growth factor within the inflamed tissue.[12] In parallel, opioid peptide–containing immune cells extravasate and accumulate in the inflamed tissue.[13,14] These cells upregulate the gene expression of opioid peptide precursors[15] and the enzymatic machinery for their processing into functionally active peptides.[16] In response to stress, corticotropin-

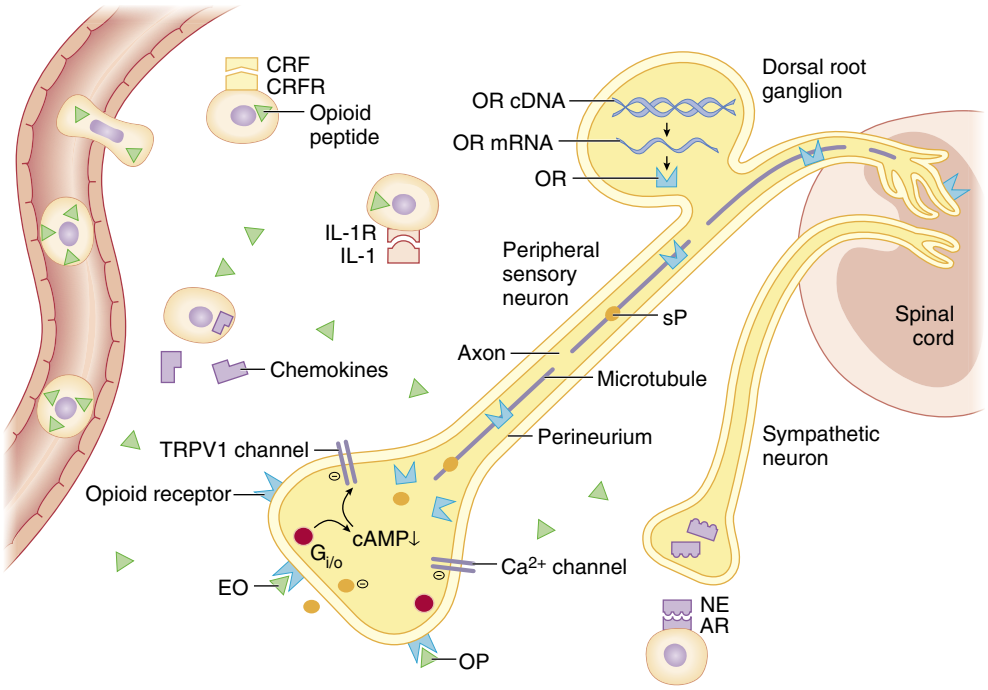

Figure 58-2 Endogenous antinociceptive mechanisms within peripheral injured tissue. Opioid peptide–containing circulating leukocytes extravasate on activation of adhesion molecules and chemotaxis by chemokines. Subsequently, these leukocytes are stimulated by stress or releasing agents to secrete opioid peptides. For example, corticotropin-releasing factor (CRF), interleukin-1β (IL-1), and norepinephrine (NE, released from sympathetic neurons) can elicit release of opioid by activating their respective CRF receptors (CRFR), IL-1 receptors (IL-1R), and adrenergic receptors (AR) on leukocytes. Exogenous opioids (EO) or endogenous opioid peptides (OP) (*green triangles*) bind to opioid receptors (OR), which are synthesized in dorsal root ganglia and transported along intra-axonal microtubules to the peripheral (and central) terminals of sensory neurons. The subsequent inhibition of ion channels (e.g., TRPV1, Ca^{2+}) (see Fig. 58-3 and text) and release of substance P (sP) result in antinociceptive effects. cAMP, cyclic adenosine monophosphate. *(Adapted from Rittner HL, Machelska H, Stein C: Leukocytes in the regulation of pain and analgesia. J Leukoc Biol 78:1215-1222, 2005.)*

releasing factor, cytokines, chemokines, or catecholamines, leukocytes secrete opioids, which then activate peripheral opioid receptors and produce analgesia by inhibiting the excitability of nociceptors or the release of excitatory neuropeptides, or both (Fig. 58-2).[17,18] The clinical relevance of these mechanisms has been shown in studies demonstrating that patients with knee joint inflammation express opioid peptides in immune cells and opioid receptors on sensory nerve terminals within synovial tissue. After knee surgery, such patients exhibited significantly enhanced postoperative pain and analgesic consumption when the interaction between opioid peptides and receptors was blocked by intraarticular application of the antagonist naloxone.[19,20]

In the spinal cord, inhibition is mediated by the release of opioids, γ-aminobutyric acid (GABA), or glycine from interneurons, which then activate presynaptic opioid or GABA receptors (or both) on central nociceptor terminals to reduce the release of excitatory transmitters. In addition, opening of postsynaptic K^+ or Cl^- channels by opioids or GABA, respectively, evokes hyperpolarizing inhibitory potentials in the dorsal horn neurons. During ongoing nociceptive stimulation, spinal interneurons upregulate gene expression and the production of opioid peptides.[21,22] Powerful descending inhibitory pathways from the brainstem also become active by operating mostly through the noradrenergic, serotonergic, and opioid systems. A key region is the periaqueductal gray matter. It projects to the rostral ventromedial medulla, which then projects along the dorsolateral funiculus to the dorsal horn.[23] Integration of signals from excitatory and inhibitory neurotransmitters with cognitive, emotional, and environmental factors (see later) eventually results in the central perception of pain. When the intricate balance among biologic, psychological, and social factors becomes disturbed, chronic pain can develop.

Clinical Definitions, Prevalence, and Classification of Chronic Pain

Definitions

The International Association for the Study of Pain (IASP) defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[24] This classification further states that pain is always subjective and that it is a sensation in part of the body. At the same time it is unpleasant and therefore also has an emotional component. Many people report pain in the absence of tissue damage or any probable pathophysiologic cause. There is usually no way to distinguish their experience from that attributable to tissue damage. If patients regard their experience as pain or if they report it in the same ways as pain caused by tissue damage, it should be accepted as pain. This definition avoids tying pain to a

stimulus. Nociception alone, or activity induced in peripheral sensory neurons (nociceptors) and higher nociceptive pathways by a noxious stimulus, is not pain. Pain is always a psychological state, even though it often has a proximate physical cause.[24] Chronic pain is defined as "pain of a duration or intensity that adversely affects the function or well-being of the patient" by the American Society of Anesthesiologists.[25] The IASP defines it as "pain without apparent biological value that has persisted beyond the normal tissue healing time usually taken to be 3 months."[26] The presence or extent of chronic pain often does not correlate with the documented tissue pathology.

Prevalence

Beyond these general definitions, there is no common understanding of the characteristics of a chronic pain patient, which may be one reason why estimates of pain prevalence differ greatly from one publication to another. Heterogeneous populations, the occurrence of undetected comorbidity, different definitions of chronic pain, and different approaches to data collection result in estimates of prevalence ranging from 20% to 60%. The data available indicate a higher prevalence in women and the elderly (usually musculoskeletal pain).[27,28] Chronic pain has enormous socioeconomic cost. In the United States alone, annual expenditures amount to $150 billion for health care, disability compensation, lost workdays, and related expenses. Similar figures have been reported by other countries.[29,30]

Classification

It is traditional to distinguish between malignant (related to cancer and its treatment) and nonmalignant (e.g. neuropathic, musculoskeletal, inflammatory) chronic pain. However, little evidence suggests that different somatic or psychological mechanisms warrant such a distinction.[31] Cancer patients tend to have more serious health restrictions and are prescribed more opioids and other medications than patients with chronic nonmalignant pain. Some studies suggest that patients with nonmalignant pain report higher pain scores, expect more pain relief than cancer patients, and believe that higher pain scores would result in increases in medication.[32] Nonmalignant chronic pain is frequently classified into inflammatory (e.g., arthritic), musculoskeletal (e.g., low back pain), headaches, and neuropathic pain (e.g., postherpetic neuralgia, phantom pain, complex regional pain syndrome [CRPS], diabetic neuropathy, human immunodeficiency virus–associated neuropathy). The chief symptoms of neuropathic pain include spontaneous lancinating, shooting, or burning pain; hyperalgesia; and allodynia; or any combination of such pain.[33] Cancer pain can originate from invasion of the tumor into tissues densely innervated by primary afferent neurons (e.g., pleura, peritoneum) or directly into a peripheral nerve plexus. In the latter, neuropathic symptoms may be predominant. A problem in the treatment of cancer pain is a lack of correlation between the patient's self-reporting and assessment of the clinical staff. In some studies the patient's pain may have been underestimated by medical staff and family members, which may have resulted in poor pain control.[34] Many therapies for cancer are associated with severe pain. For example, cytoreductive radiotherapy or chemotherapy frequently causes painful oral mucositis, especially after bone marrow transplantation.[35]

Biopsychosocial Concept of Chronic Pain

Cancer and noncancer patients with chronic pain have in common the complex influences of biologic (tissue damage), cognitive (memory, expectations), emotional (anxiety, depression), and environmental factors (reinforcement, conditioning). Many patients have limited mobility, lack of motivation, depression, anger, anxiety, and fear of reinjury, characteristics that hamper return to normal work or recreational activities. Such patients may become preoccupied with pain and somatic processes, which may disrupt sleep and cause irritability and social withdrawal. Other cognitive factors such as patients' expectations or beliefs (e.g., perceived inability to control the pain) influence psychosocial and physical functioning. Pain behavior such as limping, medication intake, or avoidance of activity is subject to operant conditioning; that is, it responds to reward and punishment. For example, pain behavior may be positively reinforced by attention from a spouse or health care provider (e.g., by inadequate use of nerve blocks or medications). Conversely, such behavior can be extinguished when it is disregarded and incremental activity is reinforced by social attention and praise.[36,37] Respondent learning mechanisms (i.e., classic conditioning) may also contribute to chronicity.[38] Other issues often coexist, such as substance abuse problems, family dysfunction, and conflicts with legal or insurance systems. Consequently, care seeking is an integral feature of the pain experience, and excessive use of the health care system ensues. The interplay between these biologic, psychological, and social factors results in the persistence of pain and illness behavior.[37,38] Treating only one aspect of this complex syndrome is obviously insufficient. Therefore, a biopsychosocial concept of pain has been adopted. This concept was first described by Engel in 1959 but was implemented into daily practice only recently, especially with regard to chronic pain patients.[39,40] With the help of this concept it is possible to understand why chronic pain may exist without obvious physical cause or why pathologic somatic findings may remain unnoticed by the patient. Interestingly, recent studies have shown that the experience and regulation of social and physical pain may share a common neuroanatomic basis.[41] In a multimodal approach, management of pain addresses physical, psychological, and social skills and underscores patients' active responsibility to regain control over life by improving function and well-being.[38,42]

Interdisciplinary Management of Chronic Pain

The anesthesiologist John J. Bonica was the first to appreciate the need for a multidisciplinary approach to chronic pain. Bonica's early experiences in and after World War II convinced him that complex pain problems could be treated more effectively when different disciplines contribute their specialized knowledge and skills to the common goal of making a correct diagnosis and developing the most effective therapeutic strategy. The first multidisciplinary facility was put into practice at the Tacoma General

Hospital, followed by the University of Washington in 1960. From 1970 through 1990, the number of pain management facilities continued to increase, mostly directed by anesthesiologists in North America and Europe. Such comprehensive pain centers should have personnel and facilities to evaluate and treat the biomedical, psychosocial, and occupational aspects of chronic pain and to educate and teach medical students, residents, and fellows. Guidelines for desirable characteristics of pain treatment facilities have been published by the IASP.[43] Multidisciplinary and multimodal management results in increased physical and psychosocial function, reduced health care use, and vocational rehabilitation.[40,44] Meta-analyses have shown that such programs offer the most efficacious and cost-effective evidence-based treatment of chronic nonmalignant pain.[30,45,46] Treatment of chronic pain without an interdisciplinary approach is inadequate and may lead to misdiagnosis (e.g., overlooking psychological processes in presumed diskogenic back pain or overlooking a somatic etiology in a presumed "psychogenic" pain disorder).[47] Moreover, conventional monomodal approaches such as pharmacotherapy alone only perpetuate the expensive, futile, and endless search for medical solutions.[30,42]

The core team consists of a pain management physician (anesthesiologist with subspecialty training), a psychologist, a physical therapist, and an occupational therapist. Depending on local circumstances, this team may be supplemented by administrators, nurse specialists, and pharmacists. The initial screening of the patient by members of the core team determines what other specialists will be needed for complete assessment. After this evaluation, the patient is presented to the entire core team and a comprehensive treatment plan is developed. This plan is tailored to the patient's needs, abilities, and expectations, with a focus on establishing measurable treatment goals for the patient. For some patients, education and medical management may suffice, whereas for others, an intensive full-day rehabilitation program conducted over a period of several weeks may be needed. To foster patient compliance, open discussion of treatment goals with regard to the patient's anticipations is essential. Many patients expect complete resolution of the pain and return to full function, a goal that may not be achievable. In many cases, realistic options are a reduction in pain; improved physical function, mood, and sleep; development of active coping skills; and return to work. Thus, rehabilitation rather than cure is the most appropriate therapeutic option.[30,48]

Psychology

The role of the psychologist includes initial assessment and treatment approaches such as education, cognitive-behavioral therapy, and relaxation training. Assessment of the patient addresses the sensory, affective, cognitive, behavioral, and occupational dimensions of the pain problem. An extensive (biographic) history, behavioral analysis, and the use of questionnaires are obligatory. Most questionnaires include scoring systems for pain intensity (e.g., numerical or visual analog scales), pain behavior (e.g., West Haven–Yale Multidimensional Pain Inventory), multidimensional pain quality, cognitive coping, fear (e.g., State Trait Anxiety Inventory), depression, and other associated symptoms. Indications for psychological pain management are relevant somatization, depressive disorders, inadequate coping, drug abuse, and high levels of pain behavior reinforced by the environment (e.g., family members). The type of therapy depends on the pain syndrome. For instance, chronic headache, inflammatory rheumatic pain, and unspecific back pain specifically benefit from behavioral therapy,[38,49] which usually means a complete change of view for the patient from a purely passive recipient of curative treatment to an active, self-reliant approach to functional restoration, vocational rehabilitation, and reduced health care use despite pain. Thus, pain reduction alone is no longer the focus of therapy.[42]

Physical Therapy

The role of the physical therapist includes initial evaluation of the musculoskeletal system, assessment of the patient's workplace and home, education in active physical coping skills, and management of the physical rehabilitation process. An intensive exercise program with emphasis on responsibility of the patient for self-management is an integral part of comprehensive programs for chronic nonmalignant pain.[30,40,44] Improving fitness, mobility, and posture counteracts the effects of disuse and complements behavioral treatment. The physical therapist encourages the adoption of regular exercise into daily life, facilitates repeated exposure to movement as much as possible despite pain, and reinforces education on the biopsychosocial model of pain management. Different techniques of exercise such as muscle conditioning, aerobics, and others are efficacious in improving endurance and reducing pain, disability, and fear avoidance behavior.[50-53] On the other hand, passive treatments such as massage or chiropractic interventions are not beneficial.[54,55] The regimen of graded exercise follows the original concept of Fordyce and colleagues.[36] Patients are instructed to find a baseline tolerance level for each exercise. Next, a program of improvement is negotiated and agreed upon. Patients note improvement on a daily basis and are required to complete the exercise plan regardless of how they feel. Thus, control over exercise behavior is contingent on the plan rather than pain because exercise and pain are disconnected. Individual motivation is an important factor in determining how well patients learn to manage pain.[56]

Occupational Therapy

The occupational therapist teaches the patient to achieve life goals despite pain and to overcome the limitations imposed by pain. Initial assessment includes a history of working life and place, family life, and daily activities, as well as physical examination to determine range of motion and the presence of movement disorders or deformities that might hinder performance. The primary therapeutic objectives are reduction of pain and associated disability, promotion of optimal function in everyday life, and encouragement of meaningful family, social, and work relationships.[57] An important target is supporting return to work by the patient, including specific work conditioning.[58] The chance of returning to work after a period of sick leave from low back pain, for example, apparently decreases over time, thereby generating enormous cost to society through wage compensation, social support, and loss of production.[29,59] Barriers to return to work

include job dissatisfaction and perceptions of the impact of work on the cause of the pain.[60] Together with the patient, the occupational therapist should develop a program to increase self-esteem, restore self-efficacy, and promote optimal occupational and recreational function despite pain.

Anesthesiology

The role of the anesthesiologist in the treatment of chronic pain has changed considerably over the last decades. "Nerve block practices" have been replaced by interdisciplinary pain management centers. In this context the anesthesiologist acts as a physician-educator, not only as a technical expert. The challenge is to optimally combine regional anesthesia skills and pharmacologic knowledge with the psychosocial components of chronic pain to render more comprehensive pain management services. Anesthesiologists need to use their expertise in pharmacotherapy, nerve blocks, and skilled techniques within the broad-based biopsychosocial approach. The focus is not only on reducing pain but also on decreasing disability, improving quality of life, and enhancing function. It is of crucial importance to recognize that the conventional way of administering medication "as needed" or to use nerve blocks for short-term pain relief may reinforce pain behavior and the patient's belief in an underlying physical abnormality that is best managed by biomedical procedures.[42] Moreover, false expectations are maintained, such as the notion that the patient should be the passive recipient rather than an active participant in the process, and false assumptions are promoted, such as the belief that pain is the primary problem in the patient's life. This approach neglects psychosocial factors, perpetuates the expensive and futile search for unidimensional biomedical solutions, and promotes iatrogenic somatization, medicalization, and high health care use by chronic pain patients.[42] The role of the anesthesiologist within the interdisciplinary team differs depending on the type of patient being treated. Cancer and acute pain management demand the full range of the anesthesiologist's technical skills and pharmacologic knowledge. In chronic nonmalignant pain, the anesthesiologist's abilities as an educator, coach, and motivator are far more important. As a member of the interdisciplinary team, the anesthesiologist has to reinforce and maintain the biopsychosocial focus, respond appropriately to somatic concerns, and manage medications. In concert with other members of the team, the anesthesiologist uses motivational strategies to encourage the patient to attain self-managed reactivation goals in the physical, psychosocial, recreational, and vocational domains. At the same time, the anesthesiologist's presence provides "white coat credibility" and is essential to avoid the patient's pejorative conclusion that the pain is "all in my head." The anesthesiologist monitors the patient's physical status, potential development of new medical problems, and medications. In addition, the anesthesiologist provides real-time reassurance and education regarding the absence of any relevant abnormality and the minimal role of surgery and conveys medical information to make informed choices. The anesthesiologist plays a crucial role within the multidisciplinary team in directing the patient toward a multimodal pain treatment plan. This is reflected by the fact that the majority of pain therapists worldwide are anesthesiologists. In the described clinical setting, anesthesiologists work closely with other health care professionals, thereby gaining added recognition outside the operating room.[42]

Drugs Used for Chronic Pain

Analgesic drugs interfere with the generation or transmission (or both) of impulses after noxious stimulation of the nervous system (nociception). This can occur at both the peripheral and central levels of the neuraxis. The therapeutic goal is to diminish the perception of pain. Analgesics are used to modulate either the generation of noxious chemicals (e.g., prostaglandins) or the activation of neuronal receptors or ion channels transducing or transmitting noxious stimuli (e.g., peptide, kinin, monoamine receptors, Na^+ channels). Drugs currently used for chronic pain include opioids, nonsteroidal antiinflammatory drugs (NSAIDs), serotonergic compounds, antiepileptics, and antidepressants (Table 58-1). Other classes, such as adrenergic receptor agonists, excitatory amino acid receptor (e.g., NMDA) antagonists, neurotrophin antagonists, neuropeptide (e.g., calcitonin gene–related peptide) receptor antagonists, kinin receptor antagonists, prostaglandin E receptor (EP) antagonists, cannabinoids, and ion channel (e.g., TRP, P2X) blockers, are currently under investigation but are not yet used routinely. Local anesthetics are used for local and regional anesthetic techniques. Mixed drugs combine different mechanisms, such as inhibition of noradrenaline reuptake and opioid agonist effects (tramadol) or opioid agonist and NMDA antagonist effects (ketamine). Various routes of drug administration (e.g., oral, intravenous, subcutaneous, intrathecal, epidural, topical, intra-articular, transnasal) can be used, depending on the clinical circumstances. Chronic pain requires a multidisciplinary approach that encompasses various pharmacologic and nonpharmacologic (psychological, physiotherapeutic) treatment strategies (see the earlier section "Interdisciplinary Management of Chronic Pain").

Opioids

Opioids act on heptahelical G protein–coupled receptors. Three types of opioid receptors (μ, δ, κ) have been cloned. Additional subtypes (e.g., μ_1, μ_2, δ_1, δ_2), possibly resulting from gene polymorphisms, splice variants, or alternative processing, have been proposed. Opioid receptors are localized and can be activated at all levels of the neuraxis, including the peripheral and central processes of primary sensory neurons (nociceptors), spinal cord (interneurons, projection neurons), brainstem, midbrain, and cortex. All opioid receptors couple to G proteins (mainly G_i/G_o) and subsequently inhibit adenylyl cyclase, decrease the conductance of voltage-gated Ca^{2+} channels, or open rectifying K^+ channels, or any combination of these effects (Fig. 58-3, upper panel). These effects ultimately result in decreased neuronal activity. Prevention of Ca^{2+} influx inhibits the release of excitatory (pronociceptive) neurotransmitters. A prominent example is suppression of release of substance P from primary sensory neurons both within the spinal cord and from their peripheral terminals within injured tissue. At the postsynaptic membrane, opioids produce hyperpolarization by opening K^+ channels, thereby preventing excitation or propagation of action potentials in second-order projection neurons. In addition, opioids inhibit sensory neuron–specific tetrodotoxin-resistant Na^+ channels, TRPV1 channels, and excitatory postsynaptic currents evoked by glutamate receptors (e.g., NMDA) in the spinal cord. The result is decreased transmission of nociceptive stimuli at all levels of the neuraxis

Table 58-1 Analgesic Drugs, Targets, Mechanisms, and Side Effects

Drugs	Targets	Mechanisms	Functional Consequences	Side Effects
Opioids	G protein–coupled μ-, δ-, κ-receptors	↓ cAMP ↓ Ca^{2+} currents ↑ K^+ currents	↓ Excitability of peripheral and central neurons ↓ Release of excitatory neurotransmitters	μ, δ: sedation, nausea, euphoria/reward, respiratory depression, constipation κ: dysphoria/aversion, diuresis, sedation
NSAIDs	Cyclooxygenases (COX-1, COX-2)	↓ Prostaglandins ↓ Thromboxanes	↓ Sensitization of sensory neurons ↑ Inhibition of spinal neurons	Nonselective: gastrointestinal ulcers, perforation, bleeding, renal impairment COX-2: thrombosis, myocardial infarction, stroke
Serotonin agonists	G protein–coupled 5-HT receptors 5-HT_3: ion channels	↓ cAMP (5-HT_1) ↑ cAMP ($5\text{-HT}_{4\text{-}7}$) ↑ PLC (5-HT_2)	↓ Release of excitatory neuropeptides ↓ Neurogenic inflammation ↑ Vasoconstriction	Myocardial infarction, stroke, peripheral vascular occlusion
Antiepileptics	Na^+, Ca^{2+} channels GABA receptors	↓ Na^+ currents ↓ Ca^{2+} currents ↑ GABA receptor activity	↓ Excitability of peripheral and central neurons ↓ Release of excitatory neurotransmitters	Sedation, dizziness, cognitive impairment, ataxia, hepatotoxicity, thrombocytopenia
Antidepressants	Norepinephrine/5-HT transporters Na^+, K^+ channels	↓ Norepinephrine/5-HT reuptake ↓ Na^+ currents ↑ K^+ currents	↓ Excitability of peripheral and central neurons	Cardiac arrhythmia, myocardial infarction, sedation, nausea, dry mouth, constipation, dizziness, sleep disturbance, blurred vision

cAMP, cyclic adenosine monophosphate; COX, cyclooxygenase; GABA, γ-aminobutyric acid; 5-HT, 5-hydroxytryptamine; NSAIDs, nonsteroidal anti-inflammatory drugs; PLC, phospholipase C.

and profoundly reduced perception of pain. Endogenous opioid receptor ligands are derived from the precursors proopiomelanocortin (encoding β-endorphin), proenkephalin (encoding met-enkephalin and leu-enkephalin), and prodynorphin (encoding dynorphins). These peptides contain the common Tyr-Gly-Gly-Phe-Met/Leu sequence at their amino terminals, known as the opioid motif. β-Endorphin and the enkephalins are potent antinociceptive agents acting at μ- and δ-receptors. Dynorphins can elicit both pronociceptive and antinociceptive effects via NMDA receptors and κ-opioid receptors, respectively. A fourth group of tetrapeptides (endomorphins) with yet unknown precursors do not contain the pan-opioid motif but bind to μ-receptors with high selectivity. Opioid peptides and receptors are expressed throughout the central and peripheral nervous systems, in neuroendocrine tissues, and in immune cells.[61]

The opioids commonly available (morphine, codeine, methadone, fentanyl and its derivatives) are μ-agonists. Naloxone is a nonselective antagonist at all three receptors. Partial agonists must occupy a greater fraction of the available pool of functional receptors than full agonists to induce a response of equivalent magnitude. Mixed agonist/antagonists (buprenorphine, butorphanol, nalbuphine, pentazocine) may act as agonists at low doses and as antagonists (at the same or a different receptor type) at higher doses. Such compounds typically exhibit ceiling effects for analgesia, and they may elicit an acute withdrawal syndrome when administered together with a pure agonist. All three receptors (μ, δ, κ) mediate analgesia, but with differing side effects. μ-Receptors mediate respiratory depression, sedation, reward/euphoria, nausea, urinary retention, biliary spasm, and constipation. κ-Receptors mediate dysphoric, aversive, sedative, and diuretic effects but do not mediate constipation. δ-Receptors mediate reward/euphoria and, to a lesser degree, respiratory depression and constipation. Tolerance and physical dependence may occur with prolonged administration of pure agonists, and abrupt discontinuation or administration of an antagonist can result in a withdrawal syndrome (see also the later section "Perioperative Management of Patients with Chronic Pain").

Tolerance describes the phenomenon that the magnitude of a given drug effect decreases with repeated administration of the same dose or that increasing doses are needed to produce the same effect. Tolerance is not synonymous with dependence (see "Perioperative Management of Patients with Chronic Pain"). All effects of opioids (e.g., analgesia, nausea, respiratory depression, sedation, constipation) can be subject to the development of tolerance, albeit to different degrees. For example, tolerance to respiratory depression, sedation, and nausea often develops faster than tolerance to constipation or miosis[62,63] (see also the later section "Other Analgesics and Adjuvants"). Incomplete cross-tolerance between opioids or genetic differences may explain the clinical observation that switching drugs ("opioid rotation") is occasionally useful in patients with inadequate pain relief or intolerable side effects.[64] Opioid-induced adaptations occur at multiple levels in the nervous and other organ systems, beginning with direct modulation of opioid receptor signaling and extending to complex neuronal networks, including learned behavior. Proposed mechanisms involved in pharmacodynamic tolerance include opioid receptor–G protein uncoupling, decreased receptor internalization/recycling, and increased sensitivity of the NMDA receptor (see Fig. 58-3, lower panel).[61,65] In addition, pharmacokinetic (e.g., altered distribution or metabolism of the opioid) and learned tolerance (e.g., compensatory skills developed during mild intoxication) and increased nociceptive stimulation by tumor growth, inflammation, or neuroma formation are possible reasons for increased dose requirements.[62,66] There is a

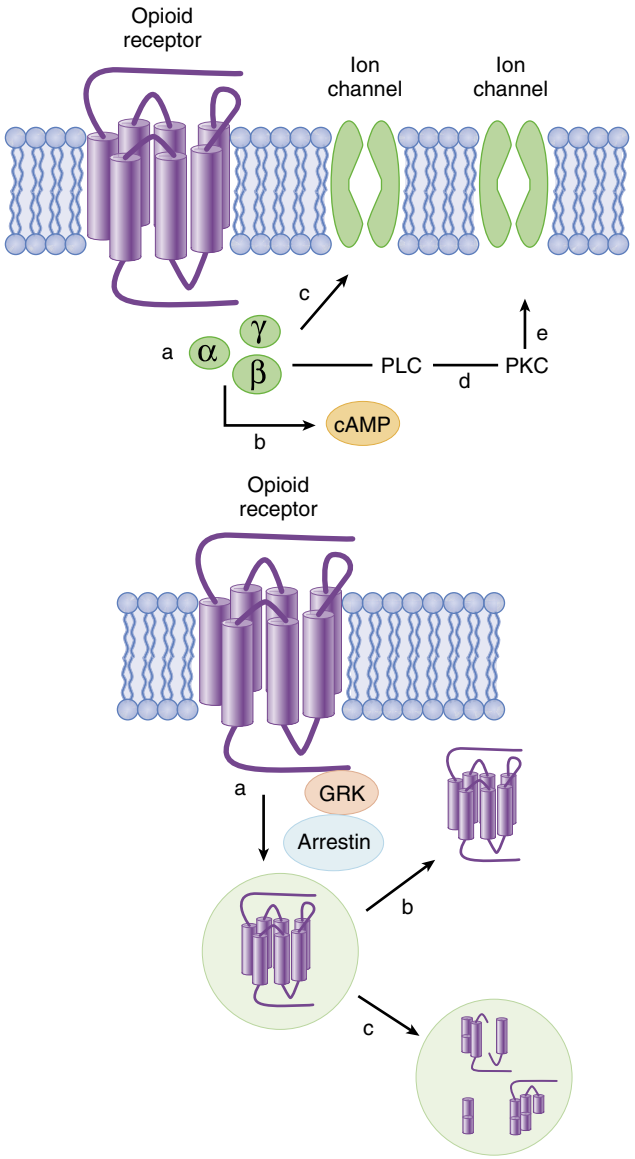

Figure 58-3 Opioid receptor signaling and recycling. **Upper panel,** Opioid ligands induce a conformational change at the receptor that allows coupling of G proteins to the receptor. The heterotrimeric G protein dissociates into active Gα and Gβγ subunits (a) that can inhibit adenylyl cyclase and reduce cyclic adenosine monophosphate (cAMP) (b), decrease the conductance of voltage-gated Ca^{2+} channels, or open rectifying K^+ channels (c). In addition, the phospholipase C (PLC)/phosphokinase C (PKC) pathways can be activated (d) to modulate Ca^{2+} channel activity in the plasma membrane (e). **Lower panel,** Opioid receptor desensitization and trafficking are activated by G protein–coupled receptor kinases (GRK). After binding of arrestin, the receptor is in a desensitized state at the plasma membrane (a). Arrestin-bound receptors can then be internalized via a clathrin-dependent pathway and either be recycled to the cell surface (b) or degraded in lysosomes (c). *(Adapted from Zöllner C, Stein C: Opioids. Handb Exp Pharmacol 177:31-63, 2007.)*

lack of carefully controlled clinical studies that unequivocally demonstrate pharmacodynamic tolerance to opioid analgesia in patients.[67]

There is ongoing debate whether opioids may paradoxically induce hyperalgesia.[68] However, on closer scrutiny of the data available it appears that most of these studies have in fact shown withdrawal-induced hyperalgesia, a well-known phenomenon after abrupt cessation of opioids (see also the later section "Perioperative Management of Patients with Chronic Pain"). At ultrahigh doses, occasionally encountered in patients with extreme cancer pain, singular cases of allodynia have been observed and attributed to the neuroexcitatory effects of opioid metabolites.[69] There is no conclusive evidence that hyperalgesia occurs during the perioperative or chronic administration of regular opioid doses in patients.[68]

Opioids are effective in the periphery (e.g., topical or intraarticular administration, particularly in inflamed tissue), at the neuraxis (intrathecal, epidural, or intracerebroventricular administration), and systemically (intravenous, oral, subcutaneous, sublingual, or transdermal administration).[61,70] The clinical choice of a particular compound or its formulation is based on pharmacokinetic considerations (route of administration, desired onset or duration, lipophilicity) and on side effects associated with the respective route of drug delivery.[71,72] Dosages are dependent on patient characteristics, the type of pain, and the route of administration. Systemically and spinally administered opioids can produce similar side effects, depending on the dosage and rostral/systemic redistribution. For intrathecal application, lipophilic drugs are preferred because they are trapped in the spinal cord and less likely to migrate to the brain within cerebrospinal fluid. Adverse side effects can be minimized by careful dose titration and close patient monitoring, or they can be treated by comedication (antiemetics, laxatives) or naloxone. No significant side effects have been reported with the peripheral (e.g., topical) application of small, systemically inactive doses of opioids. Current research aims at the development of systemically applicable opioids with restricted access to the brain.[11,73]

Opioids are the most effective drugs for severe acute and cancer-related chronic pain. The use of opioids in chronic non–cancer-related pain (e.g., neuropathic, musculoskeletal) is not unequivocally supported by adequately powered, blinded, randomized controlled trials (RCTs), and epidemiologic data suggest that opioids do not improve quality of life or functional capacity.[74] Thus far, double-blind placebo-controlled studies have investigated a maximum treatment duration of 8 weeks.[75,76] Only a few RCTs have required strict discontinuation of prestudy nonopioid analgesics to test the effects of a sole opioid medication,[75,77-80] and several others have examined an unspecified mixture of opioid and nonopioid drugs. The maximum reduction in pain scores was 17% in comparison to placebo, a clinically nonsignificant effect. More important outcome parameters such as psychosocial factors, quality of life, and functional status have been investigated in just a few trials.[75-79,81,82] Only one study using opioids alone[78] and two using mixed drugs[82,83] showed modest improvement. The well-known adverse side effects of opioid medication (nausea, sedation, constipation, dizziness, etc.) were reported in all these studies and led to the dropout of significant numbers (up to 58%) of subjects. Thus, consistent with the multifactorial nature of chronic pain, it is highly questionable whether opioids alone can produce an analgesic response if, for example, there is a major affective component of the pain or if learned pain behavior is the main problem. In addition, the prevalence of addiction is as high as 50% in patients treated with opioids for chronic nonmalignant pain.[84,85] The central point to keep in mind is that the entire patient must be evaluated, not just the pain.[86] The target of intervention is not only the source of nociception (if at all identifiable) but also suffering, dysfunction, psychosocial factors, and dependence on the health care system (see earlier). Thus, the use of opioids as a sole treatment modality in chronic nonmalignant pain is not recommended.

Nonsteroidal Anti-inflammatory Drugs and Antipyretic Analgesics

The acidic NSAIDs and the nonacidic antipyretic analgesics (e.g., acetaminophen, phenazones) inhibit COXs, enzymes that catalyze the transformation of arachidonic acid (a ubiquitous cell component generated from phospholipids) to prostaglandins and thromboxanes.[87] Two isoforms, COX-1 and COX-2, are constitutively expressed in peripheral tissues and in the central nervous system. In response to injury and inflammatory mediators (e.g., cytokines, growth factors), both isoforms can be upregulated, which results in increased concentrations of prostaglandins. In the periphery, prostaglandins (mainly PGE_2) sensitize nociceptors by phosphorylation of ion channels (e.g., Na^+, TRPV1) via EP receptor activation. As a result, nociceptors become more responsive to noxious mechanical (e.g., pressure, hollow organ distention), chemical (e.g., acidosis, bradykinin, neurotrophic factors), or thermal stimuli. In the spinal cord, PGE_2 blocks glycinergic neuronal inhibition, enhances excitatory amino acid release, and depolarizes ascending neurons. These mechanisms facilitate the generation of impulses within nociceptors and their transmission through the spinal cord to higher brain areas. By blocking one (selective COX-2 inhibitors) or both enzymes (nonselective NSAIDs), prostaglandin formation diminishes. Subsequently, nociceptors become less responsive to noxious stimuli and spinal neurotransmission is attenuated.

Less severe pain states (e.g., early arthritis, headache) are commonly treated with nonselective NSAIDs (e.g., aspirin, ibuprofen, indomethacin, diclofenac) or antipyretic analgesics (e.g., acetaminophen), mostly used orally. Some agents are available for parenteral, rectal, or topical application. Over-the-counter availability and self-medication have led to frequent abuse and toxicity. Side effects have been attributed to COX-1–induced blockade of thromboxane production and impairment of platelet function (gastrointestinal and other bleeding disorders), decrease in tissue-protective prostaglandins (gastrointestinal ulcers, perforation), decrease in renal vasodilatory prostaglandins (nephrotoxicity), and the formation of highly reactive metabolites (acetaminophen hepatotoxicity). The development of selective COX-2 inhibitors was driven by the assumption that COX-2 expression is selectively induced in inflamed tissue and that the constitutive tissue-protective COX-1 would be spared. It has now become clear that COX-2 expression is constitutive in many tissues (e.g., gastrointestinal epithelium, vascular endothelium, spinal cord) and that inhibition of COX-2 may exacerbate inflammation, impair ulcer healing, and decrease the formation of vasoprotective prostacyclin. Selective COX-2 inhibitors confer an increased risk for thrombosis, myocardial infarction, renal impairment, hypertension, stroke, and liver toxicity. Both classes of COX inhibitors can cause rare anaphylactic reactions. Acetaminophen (paracetamol) has relatively weak anti-inflammatory and antiplatelet activity. It is used for osteoarthritis, headache, and fever.[87]

Serotonergic Drugs

Serotonin (5-hydroxytryptamine [5-HT]) is a monoamine neurotransmitter found in the sympathetic nervous system, in the gastrointestinal tract, and in platelets. It acts on 5-HT receptors expressed at all levels of the neuraxis and on blood vessels. Within the dorsal horn of the spinal cord, serotoninergic neurons contribute to endogenous pain inhibition. With the exception of 5-HT_3 (a ligand-gated ion channel), 5-HT receptors are G protein–coupled receptors. 5-$HT_{1B/1D}$ agonists (triptans) have been studied extensively and are effective against neurovascular (migraine, cluster) headaches. Migraine is thought to be related to the release of neuropeptides (e.g., calcitonin gene–related peptide) from trigeminal sensory neurons innervating meningeal and intracranial blood vessels. This leads to vasodilation, an inflammatory reaction, and subsequent pain. Triptans inhibit neurogenic inflammation via 5-HT_{1D} receptors on trigeminal afferents, with possible additional sites of action on thalamic neurons and in the periaqueductal gray matter. Activation of vascular 5-HT_{1B} receptors constricts meningeal (and coronary) vessels. The latter effects have stimulated a search for nonvasoconstrictor approaches, such as highly selective 5-HT_{1D} and 5-HT_{1F} agonists. However, none of them have demonstrated clinical antimigraine effects thus far.

Triptans can be applied orally, subcutaneously, or transnasally and have been used for the treatment of migraine. All triptans narrow coronary arteries via 5-HT_{1B} receptors by up to 20% at clinical doses and should not be administered to patients with risk factors or coronary, cerebrovascular, or peripheral vascular disease. Some triptans have the potential for significant drug-drug interactions (e.g., with monoamine oxidase inhibitors, propranolol, cimetidine, hepatic P450-metabolized medications, P-glycoprotein pump inhibitors). Rational use of triptans should be restricted to patients with disability associated with migraine.[88]

Antiepileptic Drugs

Antiepileptics are used for the treatment of neuropathic pain resulting from lesions to the peripheral (e.g., diabetes, herpes) or central nervous system (e.g., stroke). Such syndromes have been attributed to ectopic activity in sensitized nociceptors from regenerating nerve sprouts, recruitment of previously "silent" nociceptors, or spontaneous neuronal activity (or any combination of these processes). These events may result in sensitization of primary afferents and subsequent sensitization of second- and third-order ascending neurons. Among the best-studied mechanisms are the increased expression and trafficking of ion channels (e.g., Na^+, Ca^{2+}, TRP) and increased activity at glutamate (NMDA) receptor sites. Mechanisms of action of antiepileptics include stabilization of the neuronal membrane by blockage of pathologically active voltage-sensitive Na^+ channels (carbamazepine, phenytoin, lamotrigine, topiramate), blockage of voltage-dependent Ca^{2+} channels (gabapentin, pregabalin), inhibition of presynaptic release of excitatory neurotransmitters (gabapentin, lamotrigine), and enhancement of the activity of GABA receptors (topiramate).

Antiepileptics have been used for neuropathic pain and for migraine prophylaxis. They are frequently coadministered with antidepressants. Their most common adverse effects are impaired mental (somnolence, dizziness, cognitive impairment, fatigue) and motor function (ataxia), which limit their clinical use, particularly in elderly patients. Serious side effects have been reported, including hepatotoxicity, thrombocytopenia, and life-threatening dermatologic and hematologic reactions. Plasma drug concentrations should be monitored.[88]

Antidepressants

Antidepressants are used for the treatment of neuropathic pain and headache. They include the classic tricyclic compounds, which are divided into nonselective norepinephrine/5-HT reuptake inhibitors (amitriptyline, imipramine, clomipramine, venlafaxine), preferential norepinephrine reuptake inhibitors (desipramine, nortriptyline), and selective 5-HT reuptake inhibitors (citalopram, paroxetine, fluoxetine). The reuptake blockade leads to stimulation of endogenous monoaminergic pain inhibition in the spinal cord and brain. In addition, tricyclic antidepressants have NMDA receptor antagonist, endogenous opioid–enhancing, Na^+ channel–blocking, and K^+ channel–opening effects that can suppress peripheral and central sensitization. Block of cardiac ion channels by tricyclic antidepressants can lead to arrhythmias. The selective 5-HT transporter inhibitors have a different side effect profile and are safer in cases of overdose.

Tricyclic antidepressants require monitoring of plasma drug concentrations to achieve optimal effect and avoid toxicity, unless sufficient pain relief is obtained with low doses (up to 75 mg/day of imipramine or amitriptyline). Patients with ischemic heart disease may have an increased risk for sudden arrhythmia, and patients with recent myocardial infarction, arrhythmia, or cardiac decompensation should not take tricyclic antidepressants at all. Tricyclic antidepressants also block histamine, cholinergic, and adrenergic receptor sites. Adverse events include sedation, nausea, dry mouth, constipation, dizziness, sleep disturbance, and blurred vision.[88]

Topical Analgesics

The topical application of various analgesics is an area of considerable interest because many chronic pain syndromes depend to some degree on the peripheral activation of primary afferent neurons. Localized administration can potentially optimize drug concentrations at the site of pain generation while avoiding high plasma levels, systemic side effects, drug interactions, and the need to titrate doses into a therapeutic range. RCTs have demonstrated the effectiveness of topical NSAIDs, tricyclic antidepressants, capsaicin, local anesthetics, and opioids.[11,73,88]

Topical NSAIDs are typical over-the-counter medications, widely advertised and used for acute and chronic pain. A large number of formulations (cream, gel, ointment) are commercially available, with varying drug delivery to the skin and subcutaneous tissue.[89] Two meta-analyses concluded that topical NSAIDs are effective for a limited period (2 weeks) for chronic musculoskeletal pain[90] but not for osteoarthritis.[91] Local adverse effects included rash and pruritus. A topical tricyclic antidepressant (doxepin) has shown efficacy in a mixed group of patients with neuropathic pain and, as a mouthwash, in patients with chemotherapy-induced oral mucositis. Side effects included burning discomfort.[73]

Capsaicin is the active pungent ingredient in chili peppers. Topically applied capsaicin interacts with nociceptive neurons via the vanilloid receptor (TRPV1). It causes initial activation of these neurons with release of substance P. This is perceived as a burning or itching sensation with a flare response and occurs in a high number (up to 80%) of patients. Desensitization develops after repeated application, probably because of depletion of substance P in sensory neurons. Another potential mechanism is a direct neurotoxic effect that results in the degeneration of small-diameter sensory nerve fibers.[73] Capsaicin is available as 0.025% and 0.075% cream. It was shown to achieve pain relief in patients with postherpetic neuralgia, postmastectomy syndrome, osteoarthritis, and a variety of neuropathic syndromes. A systematic review revealed moderate to poor effectiveness with a number needed to treat of 5.7.[92] One approach to minimizing side effects and enhancing analgesia has been the application of high concentrations (5% to 10%) under regional anesthesia,[93] but the concomitant application of local anesthetics did not prevent capsaicin-induced burning pain.[94] Thus, topical capsaicin may be a supplement for the treatment of neuropathic pain in a small number of patients unresponsive to or intolerant of other therapeutic approaches.

Topical formulations of local anesthetics block Na^+ channels in primary afferent neurons. Blockade of Na^+ channels reduces impulse generation in both normal and damaged sensory neurons. Such neurons exhibit spontaneous and ectopic firing, which possibly contributes to certain conditions of chronic neuropathic pain. Under these conditions, the altered expression, distribution, and function of ion channels along axons are associated with increased sensitivity to local anesthetics. Thus, pain relief can be achieved with local anesthetic concentrations below those that totally block conduction of impulses.[95,96] Controlled studies using lidocaine patches and gels showed pain reduction in patients with postherpetic neuralgia and allodynia.[88,97] In addition, patients with painful diabetic polyneuropathy, CRPS, postmastectomy syndrome, or post-thoracotomy syndrome can achieve relief of pain. Except for skin irritation, there have been no reports of serious side effects. Gel formulations of 5% lidocaine may be useful for the treatment of postherpetic neuralgia or oral mucositis.[98,99]

Topically applied or locally injected opioids produce analgesia by activating opioid receptors on primary afferent neurons. This leads to inhibition of Ca^{2+}, Na^+, and TRPV1 currents, which are activated by inflammatory agents.[61,100] Subsequently, the excitability of nociceptors, propagation of action potentials, and release of proinflammatory neuropeptides (substance P) from sensory nerve endings are inhibited. All these mechanisms result in analgesia or anti-inflammatory effects (or both).[11,61] Other mechanisms accounting for the particular efficacy of peripheral opioids in relieving pain associated with inflammation include upregulation[101] and accelerated centrifugal transport of opioid receptors in sensory neurons,[102] enhanced G protein coupling of peripheral opioid receptors,[103] and facilitation of access of opioid agonists to their receptors by disruption of the perineural barrier.[104] Consistently, clinical studies indicate that perineural application of opioids along uninjured nerves (e.g., axillary plexus) does not reliably produce analgesic effects.[105] In addition, the production and secretion of endogenous opioid peptides from immune cells within inflamed tissue[2,20] appear to produce additive/synergistic interactions[106] rather than cross-tolerance at peripheral opioid receptors.[107] Peripheral opioid administration is regularly used and well documented in the case of perioperative intra-articular morphine[108-111] (www.guideline.gov). Intra-articular morphine also produces analgesia in chronic rheumatoid and osteoarthritis, where its potency was shown to be similar to standard intra-articular steroids and long lasting (up to 7 days), possibly because of morphine's anti-inflammatory activity.[112,113] In observational studies, opioids have been applied locally (e.g., in gels) to treat pain from skin ulcers, cystitis, cancer-related oral mucositis,

corneal abrasion, and bone injury. No significant adverse effects have been reported thus far.[73,99]

Other Analgesics and Adjuvants

Local anesthetics have been used topically, orally, intravenously, in trigger point injections, and in regional anesthetic techniques for selected chronic pain syndromes (see later in the section "Interventional Methods Used for Chronic Pain" and Chapters 30, 51, and 52). Their systemic application (e.g., oral mexiletine) exhibited mixed success in various neuropathies. The evidence to date supports mexiletine as a third-line drug in selected patients with diabetic neuropathy.[88] Meta-analyses indicate that intravenous infusion of local anesthetics is not effective for postherpetic neuralgia but may have short-lasting effects (30 minutes) on other types of neuropathic pain.[114,115] Severe side effects, including arrhythmias, dizziness, nausea, and fatigue, limit the systemic application of local anesthetics.

α_2-Adrenergic receptors are G protein–coupled receptors. Similar to opioids, α_2-agonists (clonidine) lead to opening of K^+ channels, inhibition of presynaptic Ca^{2+} channels, and inhibition of adenylyl cyclase. Thus, like opioids, α_2-agonists reduce release of neurotransmitters and decrease postsynaptic transmission, thereby resulting in an overall inhibitory effect.[116] The evidence available indicates that epidural or systemic clonidine is analgesic in patients with CRPS and neuropathic and cancer pain but that its use is limited by a high incidence of sedation, hypotension, and bradycardia.[88]

Baclofen activates $GABA_B$ receptors presynaptically and postsynaptically, which leads to a decrease in excitatory and an increase in inhibitory neurotransmission. In some reports baclofen was found to exhibit analgesic effects in trigeminal neuralgia and central neuropathic pain. The most common side effects are drowsiness, dizziness, and gastrointestinal distress.[88] Botulinum toxin is assumed to inhibit release of acetylcholine at the neuromuscular junction and to thereby alleviate muscle spasticity. The (unlabeled) use of botulinum toxin injections has produced inconsistent results in relieving headaches[117] and was not effective for myofascial trigger points and orofacial or neck pain.[118-120] Side effects include pain and erythema at the injection site and unintended paralysis of adjacent muscles.[121] Under the assumption of anti-inflammatory activity, steroid injections are frequently used epidurally or perineurally, albeit without convincing evidence of effectiveness (see the later section "Therapeutic Nerve Blocks").

Antiemetics are used to treat nausea, a frequent side effect of analgesics (particularly opioids) and a frequent complaint in cancer patients (also see Chapter 86).[122] Recommendations for the treatment of postoperative nausea and vomiting cannot readily be extrapolated to chronic pain patients. For example, in cancer patients causes other than opioids have to be considered, such as radiotherapy and chemotherapy, uremia, hypercalcemia, bowel obstruction, and increased intracranial pressure. In addition, pain itself, as well as anxiety, can cause nausea. Opioid-related nausea usually diminishes by tolerance within a few weeks. Management guidelines for the treatment of nausea and vomiting are available, and selection of antiemetics should be based on mechanism of action, if possible, although few controlled studies exist.[123-125] The medullary chemoreceptor trigger zone, gastrointestinal stimulation or failure, and vestibular and cortical mechanisms, as well as alterations in taste and smell, may contribute to nausea and vomiting, particularly in cancer patients. Most recommendations for the choice of antiemetic medication include gastrointestinal prokinetics (metoclopramide), phenothiazines (e.g., levomepromazine), dopamine receptor antagonists (e.g., haloperidol), serotonin antagonists (e.g., ondansetron), and antihistamines (e.g., cyclizine). In addition, the use of methylnaltrexone (an exclusively peripherally acting opioid antagonist), dexamethasone (unknown mechanism), the anticholinergic scopolamine, and the neurokinin-1 receptor antagonist aprepitant has been reported. Combinations of antiemetics with different modes of action can be used.[123,124,126] Many of these drugs cause undesirable side effects by themselves. For example, dimenhydrinate and cyclizine produce drowsiness but are especially effective if bowel obstruction, pharyngeal stimulation, or increased intracranial pressure coexists. Cannabinoids and benzodiazepines may be considered for nausea unresponsive to conventional antiemetics, although their efficacy is thought to be comparatively low.[124,127]

Laxatives are indicated when bowel movements are less frequent than three per week and associated with difficulty or discomfort. Risk factors for constipation include opioid medication, older age, advanced cancer, hypokalemia, immobilization, and therapy with tricyclic antidepressants, phenothiazines, anticonvulsants, diuretics, and iron supplements. Opioid-related is not associated with is mediated through intestinal and (partially) through central μ-receptors.[61] It is the most commonly occurring side effect of opioid medications in cancer patients and frequently does not exhibit tolerance. Ample fluid intake, fiber-rich nutrition, and mobilization are nonpharmacologic approaches to prophylaxis. Laxatives include bulk-forming, osmotic, and hyperosmolar agents; substances for colonic lavage; prokinetic drugs; and opioid antagonists. Recommendations usually include lactulose, senna, or polyethylene glycol as a first choice.[123,128] However, lactulose should be avoided in patients with impaired fluid intake, such as the elderly and those with advanced cancer. If insufficient, the agents of first choice may be combined with paraffin or anthraglycosides (bisacodyl). Rectal sorbitol or contrast medium is the choice for the next more intensified step. Prokinetic agents, such as metoclopramide, are sometimes added for refractory constipation. An interesting alternative for opioid-related constipation is opioid antagonists. To avoid central effects antagonizing analgesia or producing withdrawal, oral naloxone and the peripherally restricted antagonists methylnaltrexone and alvimopan were tested. Both demonstrated dose-dependent reversal of constipation.[123,129,130] In patients with malignant bowel obstruction, however, different algorithms have to be followed.[131]

Development of Novel Analgesics

Cannabinoids are currently under intense investigation. Animal and in vitro models have shown that derivatives of tetrahydrocannabinol produce antinociceptive effects and that cannabinoid receptors and their endogenous ligands are expressed in pain-processing areas of the brain, spinal cord, and periphery.[132] Animal studies have shown that peripheral cannabinoid receptors play a particularly prominent role in pain inhibition.[133,134] A meta-analysis of clinical studies concluded that the analgesic effects of cannabinoids are not superior to those of oral opioids such as codeine.[135] Psychotropic side effects, sedation, dizziness, cognitive

impairment, motor deficits, and other adverse effects are major limiting factors in clinical practice.[88,135] Ion channel blockers are also an area of intense research. Examples emerging as potential drug targets include $Na_V1.8$, a Na^+ channel expressed mainly in peripheral nociceptive neurons; $Ca_V2.2$, a voltage-gated Ca^{2+} channel blocked by the conotoxin ziconotide; TRPV1, the capsaicin receptor; and the $P2X_3$ receptor, a ligand-gated cation channel located on peripheral nociceptive neurons.[4,136,137]

Interventional Methods Used for Chronic Pain

The popularity of interventional methods has decreased over time. Although early pain therapists (e.g., Leriche) generally used "blocks" to treat pain,[138] the biopsychosocial concept of chronic pain has led to a much more cautious and judicial use of such techniques (see earlier in the section "Interdisciplinary Management of Chronic Pain"), particularly since most of these techniques are not evidence based. Block therapy alone is not usually curative, but it can facilitate participation in rehabilitation and therefore does have a role in the management of chronic pain. Regardless of which procedure is considered, a consensus on its use has to be reached within the interdisciplinary team.

Diagnostic Nerve Blocks

Neural blockade is thought to be a useful tool to better understand the mechanisms underlying pain in an individual patient and to provide a prognosis for planned neuroablative procedures (particularly in cancer pain) (also see Chapters 52 and 53). Differential blockade aims to selectively block either single peripheral nerves to identify an anatomic pain source or to selectively block only one type of nerve fiber (autonomic versus somatic).[139] Frequently, active and nonactive compounds are injected sequentially to differentiate drug-related from placebo responses. Differential neural blockade can be performed at the peripheral and central (neuraxial) levels. A popular protocol is the sequential intrathecal application of short- and long-acting local anesthetics (or opioids) or increasing concentrations of a local anesthetic, as originally described by Cherry and revised many times since then. Diagnostic neural blockade is used for low back pain, headache, neuropathic pain, and CRPS. Examples include zygapophyseal (facet) joint injections and medial branch blocks,[140] sacroiliac joint injections,[141] trigger point injections, spinal nerve blocks, occipital nerve blocks, and sympathetic blocks.[139] The last may be achieved by injection of local anesthetic at the sympathetic chain (e.g., stellate ganglion) or by intravenous regional infusion of sympatholytic drugs (e.g., phentolamine). However, an extensive review of the experimental and clinical literature concluded that none of these procedures has unequivocally proved to be clinically useful in controlled studies.[139] This was confirmed in recent systematic reviews.[140,141] In particular, the validity of diagnostic nerve blocks is limited by the complexity of factors determining pain perception (see earlier under "Biopsychosocial Concept of Pain" and "Interdisciplinary Management of Chronic Pain"). Furthermore, the assumption that local anesthetics can selectively produce conduction block of only one fiber type in a nerve is probably false.[139,142] Nevertheless, experienced and observant clinicians have found that such procedures may occasionally provide information that is helpful in guiding subsequent therapy. Nerve blockade may still play a role in the comprehensive workup of chronic pain patients, provided that the clinician takes great care in carrying out the technique, interpreting the results, and integrating them into interdisciplinary decisions.[139]

Therapeutic Nerve Blocks

Cancer Pain

Therapeutic nerve blocks are used mostly for the management of cancer-related pain (also see Chapter 52). Here, interventional treatment may represent the fourth step in the World Health Organization analgesic ladder.[143] Ninety percent to 95% of patients with cancer pain usually obtain adequate pain relief from pharmacologic management, and only a small fraction need interventions such as nerve blocks.[144-146] A comprehensive biopsychosocial approach to pain management that carefully balances risks against benefits in individual patients is a prerequisite for successful use of interventional techniques.[147] Therapeutic nerve blocks extend the treatment range when conservative methods fail to achieve tolerable levels of pain or side effects. For example, neuropathic and incidental (breakthrough) pain is sometimes poorly controlled by systemic analgesics and may be an indication for invasive therapy.

In patients with unresectable pancreatic cancer, neurolysis of the celiac plexus is frequently used for treatment of pain (Fig. 58-4). Patients with other upper abdominal malignancies, such as

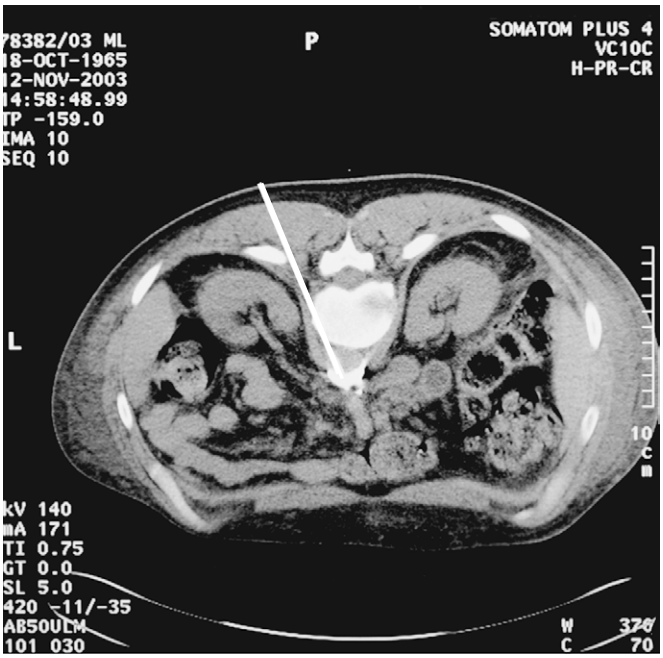

Figure 58-4 Transaortic approach to neurolysis of the celiac plexus with typical dye distribution ventral to the aorta. For details, see text. *(From the authors' archives.)*

hepatic or gastric cancer, may also benefit from this intervention. This technique is based on the assumption that nociceptive stimulation is transmitted along primary afferent fibers that travel with the sympathetic fibers of the splanchnic nerves arising from T5-T12 and with the parasympathetic efferent fibers that together form the celiac plexus. The ganglia are situated in the retroperitoneal space adjacent to the L1 vertebral body. Anatomic landmarks can be identified with the help of computed tomography, fluoroscopy, and ultrasound.[148] The most common techniques include the bilateral transcrural[149] and the unilateral transaortic approaches[150] with the use of alcohol (50% to 100%) or phenol (7% to 12%). In patients undergoing laparotomy, intraoperative neurolysis of the celiac plexus can also be performed.[151] Most centers advocate a diagnostic local anesthetic block to predict the analgesic and side effects (mostly diarrhea and hypotension).[152] A recent systematic review of RCTs comparing neurolytic celiac plexus blockade with standard treatment (oral NSAIDs and morphine) plus sham blockade or sham blockade alone concluded that celiac plexus neurolysis was associated with lower pain scores, decreased morphine use, and reduced constipation, albeit with minimal clinical significance.[153]

Less common sites for neurolysis are the intercostal nerves (e.g., in rib metastasis), the superior hypogastric ganglion, the ganglion impar, and the lumbar sympathetic ganglia (e.g., for pelvic tumors). In perineal pain caused by local infiltration of rectal cancer, intrathecal neurolysis may be considered if bladder and sphincter function is not of concern.[154] An indication for thoracic intrathecal or epidural neurolysis might be advanced lung cancer.[155] As a neurolytic agent, alcohol may be preferred because of its perceived higher success rate and longer duration of pain relief (3 to 6 months) than achieved with phenol (2 to 3 months), although no studies directly comparing these two agents are available. A diagnostic local anesthetic block to predict analgesic and side effects is advocated. Because alcohol is hypobaric and phenol is hyperbaric, the patient needs to be positioned accordingly during intrathecal neurolysis. In many cases pain relief is incomplete, but intake and side effects of opioids decrease. The limited period of pain reduction and the limited possibility of repeat injections are reasons why neurolysis is used mostly in patients with a short life expectancy.[156]

Non–Cancer-Associated Pain

Both the complexity of factors contributing to pain perception and perpetuation (see earlier in the sections "Biopsychosocial Concept of Pain" and "Interdisciplinary Management of Chronic Pain") and the detrimental long-term effects of nerve destruction (neuropathic pain caused by spontaneous ectopic neuronal discharge, upregulation of neuronal ion channels and excitatory amino acid receptors; see earlier in the sections "Physiologic Changes in Persistent Pain" and "Antiepileptic Drugs") caution against neuroablative procedures in patients with non–cancer-related pain. Nonetheless, many practitioners perform radiofrequency ablation or cryoneurolysis at the facet joints and sacroiliac joints, as well as several other destructive procedures.[157] However, such interventions have never been shown to provide long-term pain relief in RCTs.[157,158]

Nondestructive procedures include trigger point, epidural, perineural, and intra-articular injections of local anesthetics or steroids (or both). Steroids are used under the assumption of anti-inflammatory activity. For example, in chronic back or neck pain, injections into facet (or zygapophyseal) joints or along the medial branch from the posterior ramus of the spinal nerve root are frequently performed, but without convincing long-term results.[157] Similarly, injections into the sacroiliac joints or trigger points or occipital nerve blocks show no consistent long-lasting effects.[159-161] Epidural steroids are also used extensively for low back and neck pain but have not been shown to provide long-term pain relief in RCTs.[157] There is no evidence that the addition of other agents such as hyaluronic acid produces better results.[157] Neither preoperative nor postoperative nerve blocks have shown consistent improvement of phantom limb pain.[162] Some evidence from RCTs indicates that epidural or intrathecal steroids combined with local anesthetics can be effective in patients with herpes zoster and postherpetic neuralgia.[163]

Sympathetic nerve blocks with local anesthetics, often carried out as a series, are commonly used for herpes zoster–associated pain and CRPS, but evidence from RCTs is lacking. Some studies were able to demonstrate short-term effects but no clear reduction of the risk for postherpetic neuralgia.[163,164] Similarly, the long-term effectiveness of sympathetic blockade in CRPS has not been demonstrated in RCTs.[165,166] Anecdotal reports have described sympathetic blocks for ischemic pain, such as in peripheral vascular disease or Raynaud's disease.

In contrast with the lack of evidence of long-term effects, interventional techniques can produce short-term pain relief. In the context of interdisciplinary management, such techniques may be used to facilitate initial physical therapy sessions in patients with chronic nonmalignant pain.[157,159,167]

Continuous Catheter Techniques

Continuous drug delivery to the intrathecal or epidural space can be accomplished with programmable implanted pumps, implanted accessible reservoir systems, and tunneled exteriorized catheters. The principal benefit appears to be a reduction in systemic side effects. As with nerve blocks, evidence of effectiveness of these approaches is stronger for cancer pain than for chronic nonmalignant pain.

Cancer Pain

Only a small minority of cancer patients require neuraxial drug delivery because of intolerable side effects and refractory pain with systemic analgesics. The preponderance of evidence supporting this mode of drug delivery is derived from nonrandomized, uncontrolled studies.[148,168] The advantage of the epidural technique is its ubiquitous availability in most anesthesia departments, but disadvantages are the chance of inhomogeneous distribution of the analgesics, high drug volume requirements and possible systemic absorption, and limited duration of therapy as a result of local granuloma formation and technical failure.[148] The intrathecal approach allows homogeneous distribution of analgesics, low-volume injections, control of catheter positioning with aspiration of fluids, and long-term therapy with a minimal infection rate, although case reports on catheter tip inflammatory granulomas have occurred. Usually, morphine (1 to 15 mg dependent on preceding systemic dosage) or hydromorphone is recommended as the drug of first choice. For refractory pain, combinations with bupivacaine, clonidine, ziconotide, and other compounds have been used.[168] This technique should be used

only if the treatment center has the capacity for emergency in-house treatment, 24-hour emergency calls, and adequate home care service with stringent protocols to avoid infections. To transfer the patient from high-dose systemic to intraspinal analgesia, 24-hour monitoring is required. The initial intrathecal morphine dose is about 1% of the oral morphine equivalent. Thereafter, the systemic opioid dose is reduced by 50% and then slowly tapered by 10% daily to avoid withdrawal while at the same time allowing the usual systemic opioid doses as rescue medication.

Non–Cancer-Associated Pain

No RCTs are available, but a number of observational reports describe continuous catheter techniques for chronic nonmalignant pain.[148,169] Most of these studies used intrathecal morphine and some used hydromorphone, baclofen, or ziconotide in patients with chronic low back pain. On average, these patients exhibited increasing daily morphine doses over time and a high incidence (up to 25%) of complications such as catheter obstruction, catheter tip granuloma formation, pruritus, urinary retention, and infection. Effectiveness of these techniques in relieving pain or improving function in comparison with placebo, natural history, or other treatments has not been shown.[148,169]

Stimulation Techniques

Stimulation techniques frequently used in pain management include acupuncture, spinal cord (or dorsal column) stimulation (SCS), and transcutaneous electrical nerve stimulation (TENS). Acupuncture has been popular among patients for a long time and lately also within the medical community. Systematic reviews of sham-controlled studies of migraine prophylaxis and arthritic pain have shown that using traditional Chinese concepts of meridians and specified classic points is as effective as selection of acupuncture points at random.[170,171] The conclusion was that there is no specific effect of acupuncture when compared with standard medical migraine prophylaxis.[170] In osteoarthritis, adequately blinded studies have yielded inconclusive results.[171,172] In rheumatoid arthritis, acupuncture was not recommended.[173] In chronic low back pain, several reviews concluded that in the long term, acupuncture is not more effective than other treatments.[174-176] With respect to pain relief in cancer patients, the data available do not support its effectiveness either.[177]

The idea of modulating neural transmission by electrical stimulation dates back to ancient Rome with the observation that gout pain was alleviated by accidental contact with a torpedo fish. The gate theory of pain in the 1960s proposed that pain perception was influenced by the balance of firing between large and small nerve fibers and that retrograde nonpainful stimulation of large fibers would "close the gate" by adjusting the level of voltage.[148] This prompted the development of TENS, SCS, and various techniques of brain stimulation that have been applied in patients with refractory CRPS or neuropathic, low back, and ischemic pain. None of these methods have been validated by adequately powered and blinded RCTs for chronic pain.[178,179] Unblinded studies suggest that selected patients with CRPS or back pain might benefit from SCS, but controlled trials are needed. Complications include electrode displacement, infection, and battery failure.[179,180] Because it is noninvasive and easy to administer, TENS is used widely. However, systematic reviews of its application for chronic low back pain[181] and painful rheumatoid arthritis or osteoarthritis[182,183] have not yielded conclusive evidence of its effectiveness.

Perioperative Management of Patients with Chronic Pain

Characteristics of Chronic Pain Patients in the Perioperative Period

A chronic pain patient has certain distinctive features important for perioperative management (also see Chapter 87). Altered opioid sensitivity and behavior are the major points to be considered. The preanesthetic visit should therefore include questions regarding chronic pain and regular use of analgesics and adjuvant medication. Although a number of characteristics, including increased opioid demand, underreporting of pain, and noncompliance are known, only a few specific recommendations are available, such as an adequate increase in the opioid dose for analgesia, continuation of preoperative analgesics to prevent withdrawal, and intensive education to strengthen the patient's coping potential. No differences between specific techniques for postoperative analgesia (e.g., systemic, patient-controlled, or regional analgesia) have been shown thus far.

Some unique personality features are possibly relevant in the perioperative period. In the Minnesota Multiphasic Personality Inventory, chronic pain patients scored high on the hypochondria and hysteria scales.[184] The hypochondria scale tests preoccupation with physical discomfort, and the hysteria scale reveals information concerning coping with stress. Both are important parameters indicating a need for the patient to master the perioperative situation and have consequences on patient cooperation. Thus, studies have shown that rates of noncompliance with the patient-controlled analgesia (PCA) technique are increased and the duration of PCA treatment is prolonged.[32] Furthermore, the preoperative intensity of pain alone—independent of the use of analgesics—correlates positively with postoperative pain.[185] Anxiety is another factor that can complicate postoperative recovery. In clinical practice it may be difficult to distinguish normal from maladaptive anxiety, but in general, patients with cancer pain are more likely to be anxious than, for example, cancer patients without pain.[186] In addition, a chronic pain patient, especially one with cancer, is not as confident of recovery as other patients with chronic diseases.[32]

Chronic pain patients are often pretreated with opioids, COX inhibitors, antidepressants, anticonvulsants, or any combination of these treatments. They suffer from prolonged inactivity or neurologic deficits (or both), which increases the risk for adverse events during the perioperative period. Tolerance, drug interactions, and side effects may occur. In addition, inappropriate or excessive medication is commonly observed.[187] Chronic pain patients tend to underestimate and underreport their medication use. Studies suggest that this tendency is more pronounced for opioid analgesics than for other medications and is greater in women than in men.[188] Thus, undertreatment in the perioperative period may be unnoticed and might induce withdrawal, which can result in serious cardiopulmonary strain associated with the neuroexcitatory withdrawal syndrome. Some key issues are summarized in Box 58-1.

Box 58-1 Risk Factors in the Perioperative Management of Chronic Pain Patients

Conventional perioperative analgesia regimens do not meet the needs of chronic pain patients.

Unrelieved postoperative pain because of undermedication may provoke withdrawal.

Patients tend to underreport their medication.

With uncontrolled anxiety or fear of pain, patients tend to overestimate the effect of painful stimuli.

Epidural and intravenous opioid (including patient-controlled analgesia) requirements can be two to four times higher in opioid-consuming than in opioid-naive patients.

Prolonged recovery and need for postoperative analgesia should be expected.

Anxiety and insufficient coping result in poor compliance with analgesic strategies.

Individual variations in response to opioids may necessitate selection of the optimal drug and dosing by sequential trials.

Individual titration of doses to find the optimal balance between analgesia and adverse effects is required.

Adjuvant medication may interfere with anesthesia and postoperative analgesia.

Adapted from Kopf A, Banzhaf A, Stein C: Perioperative management of the chronic pain patient. Best Pract Res Clin Anaesthesiol 19:59-76, 2005.

Chronic Use of Analgesics and Adjuvant Drugs

During the past decade, chronic opioid medication has been discussed thoroughly in the literature (see earlier in the section "Opioids"). Together with aggressive marketing, this has gradually led to decreasing reservations by practitioners regarding the use of these drugs. As a result, opioids are used more frequently in patients with both cancer-related and non–cancer-related pain. Although this seems justified in cancer pain and certain chronic destructive diseases, indications for the use of opioids in patients with chronic non–cancer-related pain are less convincing (see "Opioids"). Nevertheless, the anesthesiologist is increasingly confronted with patients receiving long-term opioid treatment. Such pretreatment can result in a several-fold increased and prolonged requirement for systemic and epidural analgesics in the perioperative period when compared with opioid-naïve patients.[63,67,189] Chronic pain patients with prior opioid consumption also exhibit higher postoperative pain scores.[32] The increased postoperative analgesic demands may be due to lower pain thresholds or a need for higher drug concentrations. In addition, opioid requirements can be influenced by gender, genetic predisposition, age, type of surgery, and preoperative pain levels.[64,185] In contrast, opioid-related side effects (e.g., nausea, pruritus) may be less dominant.[32,190] Physicians and nurses may overestimate tolerance, addiction, and sedation but underestimate dependence.[67,191] A paramount concern is maintenance of adequate perioperative opioid dosing to prevent withdrawal.[67]

COX inhibitors are the most commonly used nonopioid analgesics. Unlike opioids, they are not associated with tolerance and physical dependence but produce serious side effects mainly in the gastrointestinal tract, coagulation system, and kidneys (see earlier in the section "Drugs Used for Chronic Pain"). A major concern for the anesthesiologist is coagulation disturbances and the increased risk of hematoma formation associated with spinal and epidural anesthesia. Practice guidelines do not differentiate between selective COX-2 and nonselective COX inhibitors. European and American societies disagree in their recommendations. Before neuraxial anesthesia, a 24- to 72-hour (in case of aspirin) drug-free interval is recommended by the German Society of Anesthesiology and Intensive Care Medicine and by the Spanish Consensus Forum, whereas the American Society of Regional Anesthesia and Pain Medicine does not believe that there is any added significant risk with these drugs. This discrepancy probably arises from the fact that development of a spinal or epidural hematoma is a rare event (about 1 in 220,000 spinal and 1 in 150,000 epidural anesthetics) and that none of the studies to date have a large enough patient population to predict that there is no risk of hematoma formation when COX inhibitors are continued before surgery.[192]

Antiepileptic drugs can interfere with anesthesia in different ways. The sedation produced by anticonvulsant drugs may have additive effects with anesthetics, whereas drug-induced enzyme induction could alter responses to or contribute to the organ toxicity of anesthetics. Gabapentin has a favorable side effect profile, and its relative absence of drug interactions allows continuation and rapid titration in the perioperative period.[193] Phenytoin and carbamazepine accelerate recovery from nondepolarizing muscle relaxants, but the mechanism is unclear. A kinetic rather than a pharmacodynamic cause is suggested.[194] Preoperative exclusion of toxic serum levels of phenytoin is recommended to reduce the risk for atrioventricular conduction block. States of disorientation, nystagmus, ataxia, and diplopia may be manifestations of excessive plasma concentrations. Carbamazepine may produce sedation, ataxia, nausea, and (rarely) bone marrow depression or hepatorenal dysfunction. Plasma sodium levels have to be monitored perioperatively to avoid hyponatremia. Oral valproic acid is commonly used for the prophylaxis of migraine, and intravenous valproic acid may be used to control episodic headaches.[195] It may inhibit the activity of hepatic microsomal enzymes and interfere with platelet aggregation.[196] Antiepileptics should never be discontinued abruptly to avoid central nervous system hyperexcitability. Stable dosages need to be maintained throughout the perioperative period.

Antidepressants are frequently used for neuropathic pain and for associated depression. Adverse effects are numerous and include sedation, anticholinergic effects, and cardiovascular changes. Electrocardiographic changes, such as prolongation of the PR interval and widening of the QRS complex, can occur, but previous suggestions of an increased risk for perioperative cardiac dysrhythmias have not been substantiated in the absence of drug overdose.[197] Therefore, antidepressants need not be discontinued before anesthesia, but increased anesthetic requirements may be expected because of enzyme induction. Postoperatively, the likelihood of delirium and confusion may potentially be increased as a result of additive anticholinergic effects. Selective serotonin reuptake inhibitors and atypical antidepressants such as mirtazapine or venlafaxine are less likely to interfere with anesthesia.

Ketamine is a mixed opioid agonist/NMDA antagonist that can produce analgesia at subanesthetic doses in selected patients with neuropathic pain.[198,199] Very rarely, patients taking oral

ketamine on a chronic basis will be encountered. In these cases, perioperative administration of ketamine should be discontinued because correct conversion from oral to intravenous ketamine is difficult.[200] Within analgesic dose ranges, the risk of a withdrawal syndrome is low.[199,201]

Benzodiazepines are not analgesic and rarely used for chronic pain with the exception of palliative care situations.[202] Nevertheless, chronic pain is a predictor of increased benzodiazepine use.[203] Side effects relevant to anesthesia include sedation and skeletal muscle weakness. Because of their long half-life, delayed withdrawal has to be anticipated and must be avoided by maintaining a stable perioperative dosage. Neuroleptics are also inappropriate but sometimes are used for chronic pain.[88] In the perioperative period it has to be kept in mind that neuroleptic malignant syndrome can develop in patients treated with antipsychotic drugs. Hyperthermia, hypertonicity of skeletal muscles, fluctuating levels of consciousness, and autonomic nervous system instability are typical symptoms.

Dependence, Addiction, and Pseudo-addiction

Physical dependence is defined as a state of adaptation manifested by a drug class–specific withdrawal syndrome that can be elicited by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, or administration of an antagonist (also see Chapter 101).[204] Dependence is not synonymous with tolerance (see earlier in the section "Opioids"). All opioids, benzodiazepines, and anticonvulsants produce clinically relevant physical dependence when administered for a prolonged period, but sometimes physical dependence can develop within hours of agonist exposure.[205,206] Thus, all patients with continuous preoperative opioid intake should be considered at risk for a withdrawal syndrome if adequate substitution of opioids in the perioperative period is withheld. Opioid and benzodiazepine withdrawal syndromes, especially tachycardia and hypertension, may be detrimental in high-risk cardiac patients. Rapid withdrawal from an anticonvulsant drug may trigger seizures, anxiety, and depression.[207]

Addiction is defined as a behavioral syndrome characterized by evidence of psychological dependence (craving), uncontrolled/compulsive drug use despite harmful side effects, and other drug-related aberrant behavior (e.g., altering prescriptions, manipulating health care providers, drug hoarding or sales, unsanctioned dose escalation).[84,204] Reviews indicate that the prevalence of opioid addiction is as high as 50% in patients with chronic nonmalignant pain and up to 7.7% in patients with cancer-related pain.[84,85] Many comments regarding opioid-consuming chronic pain patients also apply to those who abuse or are addicted to opioids. The daily dose of opioids in abusing or addicted patients is typically larger, such patients often have coexisting psychiatric diseases (depression, anxiety, psychosis), and the known history of abuse may lead to tempered use of opioids by health care providers, which makes these patients particularly vulnerable to inadequate postoperative pain control.[67] Additional special considerations in the management of drug-addicted patients are discussed elsewhere (e.g., see Carroll and colleagues and Peng and coworkers[67,208]).

Pseudo-addiction describes a situation in which medical personnel do not provide a sufficient dosage of medication. This provokes repetitive demands from the patient for analgesics and may be interpreted to be an indication of "drug-seeking behavior." Pseudo-addiction can be avoided with adequate algorithms and regular education of health care providers.[62]

Management and Practical Recommendations

Preoperative Evaluation

Preanesthesia evaluation is necessary to educate patients, to organize resources for preoperative improvement of the patient's physical function, to choose optimal anesthetic techniques, and to formulate plans for postoperative recovery, including perioperative pain management.[67] Misconceptions about the surgical procedure, the role of the anesthesiologist in perioperative care, and postoperative pain treatment are common in patients.[209] A thorough history must be obtained to identify all preoperative medications, including opioids, other analgesics, and adjuvants, as well as signs of psychiatric comorbidity and aberrant drug-related behavior. Consultation with a pain specialist should always be considered. Pertinent issues and practical recommendations are summarized in Boxes 58-1 and 58-2.

Perioperative Management

To avoid opioid withdrawal, the preoperative systemic dosage has to be continued throughout the perioperative period, and mixed agonist/antagonists (buprenorphine, nalbuphine) must be avoided. For minor surgery, oral slow-release opioid medication may be continued at its regular intervals. For medium and major surgery, oral opioids should be discontinued and replaced with equivalent doses of intravenous opioids, which have to be maintained for the entire perioperative period. This applies to general as well as regional anesthesia. The anesthesia technique should be selected on an individual basis because no data are available in favor of general, regional, or combined anesthesia for this patient population. The frequency and extent of monitoring techniques should be adapted to the risk of patient instability. Pain should be periodically assessed during emergence and recovery.[210] For thorough evaluation of pain relief, functional criteria (ability to cough, breathe deeply, perform physical therapy, ambulate) should be used in conjunction with patient-generated pain ratings to determine the end points for analgesic therapy.[32] One has to keep in mind that pain acts as an antagonist to central nervous system depressants and in particular to the respiratory depressant effects of opioids. Thus, any surgical procedure that removes a major nociceptive stimulus (e.g., a tumor) may lead to unopposed opioid-mediated respiratory depression or somnolence in the postoperative period. For patients without chronic pain, randomized trials suggest that a multimodal approach to ensuring adequate postoperative analgesia may facilitate return of gastrointestinal function, be cardioprotective, reduce pulmonary complications, and shorten length of stay in the intensive care unit and hospital.[211] Whether these findings are applicable to chronic pain patients is unknown. Individually adapted regimens are usually superior to "conventional" analgesia, regardless of the specific analgesia technique used.[212] In minor and medium-complexity surgery, an opioid/NSAID combination should always be considered to enhance the effects of the opioid. If pain is not sufficiently controlled with opioids and NSAIDs, adjuvant anal-

Box 58-2 Preoperative Considerations and Recommendations for Patients with Chronic Pain

Take a thorough history to identify all analgesic and adjuvant medications, risk factors, and comorbidity.

Educate the patient about the perioperative procedures, the potential for aggravated pain, and increased opioid requirements.

Communicate plans to the designated anesthesiologist in the operating room, the postanesthesia care unit, and the surgical and nursing personnel on the ward.

Differentiate among addiction, pseudo-addiction, and physical dependence in patients maintained on long-term opioid medication.

Expect physical dependence in patients receiving long-term opioid medication.

Continue previous long-acting opioid analgesics for short procedures.

For major surgery, calculate and order a background infusion of an equianalgesic opioid dose for patients held without oral intake for longer than 8 hours to be started in the operating room.

Order regular opioid medication on the morning of surgery.

Maintain anticonvulsant drugs and benzodiazepines at preoperative doses.

Discontinue all other adjuvants if kept without oral intake for longer than 24 hours.

Identify untreated depressive disorders with screening questions for disturbed sleep, depressed mood, reduced concentration, self-confidence, and motivation.

Identify untreated anxiety disorders with screening questions for restlessness, irritability, difficult-to-control anxiousness, and worrying.

Consider referral to a pain specialist for evaluation.

Choose regional or general anesthesia based on individual considerations.

Adapted from Kopf A, Banzhaf A, Stein C: Perioperative management of the chronic pain patient. Best Pract Res Clin Anaesthesiol 19:59-76, 2005.

gesics such as anticonvulsants or alternative routes of opioid administration may be required.[67] Support from a multimodal pain treatment facility should be requested. Apart from the choice of analgesia techniques and exploitation of opioids, optimization of organizational structures is a key factor for improving perioperative analgesia.[213] If addiction is suspected, the patient should be re-evaluated after the acute postoperative pain has resolved.[214] Specific risk factors in chronic pain patients are summarized in Box 58-1.

Postoperative Regional Anesthesia

Despite the lack of strong evidence indicating superiority of particular anesthetic techniques for postoperative analgesia in chronic pain patients, individual considerations may favor regional anesthesia, particularly since these patients are prone to intensified postoperative pain experiences. Chronically opioid-consuming patients need their daily systemic dosage by the intravenous or oral route to prevent withdrawal.[67] In addition, postoperative analgesia via an epidural or plexus catheter may be accomplished with a combination of local anesthetics and opioids, as in patients without chronic pain (see Chapters 51 and 87). However, higher doses of epidural opioids are recommended because cross-tolerance between orally and epidurally administered opioids has been described.[190] Epidural lipophilic opioids (fentanyl, sufentanil) appear to provide better postoperative pain relief than epidural morphine does in chronically opioid-consuming patients,[215,216] an observation that has been attributed to the need for lower receptor occupancy or incomplete cross-tolerance between morphine and sufentanil.[217]

Postoperative Intravenous Opioids

The total opioid dose required consists of the daily dose taken before and the dose made necessary by surgical stimulation. A continuous perioperative intravenous opioid infusion equivalent to the regular daily dosage is recommended if the oral route is unavailable.[67,212] Additional bolus doses of opioid or nonopioid analgesics (or both) have to be titrated to individual needs to achieve adequate pain control in the postanesthesia care unit. Depending on local circumstances, this may be patient, nurse, or physician controlled. The size of the bolus should be equal to the hourly dose of the background infusion. Once the patient demands less than four extra bolus doses per day, the background infusion may be reduced in daily steps of about 20% to 30%. For calculation of opioid dose equivalents, the relative potency, half-life, bioavailability, and route of administration have to be considered.[218] As soon as possible, oral medication should be resumed. Intravenous doses during the first 24 to 48 hours after surgery should be converted to oral dose equivalents. Half the total dosage may be delivered as long-acting and half as short-acting breakthrough medication.[67]

Perioperative Transdermal Opioids

Transdermal fentanyl patches are relatively reliable in administering controlled amounts of the drug to the circulation over long periods. However, during surgery the amount of drug delivered to the patient may shift significantly. Changes in intravascular volume, body temperature, and volatile anesthetics alter skin permeability and perfusion and thereby result in relatively large fluctuations in transdermal fentanyl passage. In addition, forced-air warming blankets and heat packs applied onto the patch itself can lead to several-fold increases in permeation of fentanyl through the skin.[63] Thus, in major surgery, removal of transdermal systems is advisable to avoid unforeseen decreases and increases in systemic opioid uptake. The transdermal opioid dose should be converted to intravenous morphine administered as a continuous background infusion.[218] Pertinent issues and practical recommendations are summarized in Box 58-3.

Acknowledgment

We thank Drs. Britta Oldörp and Halina Machelska for critical comments on the manuscript. This work was supported by the Deutsche Forschungsgemeinschaft (KFO 100, GRK 1258) and the International Anesthesia Research Society.

Box 58-3 Intraoperative and Postoperative Management Issues and Practical Recommendations

Start a background opioid infusion immediately when the patient arrives in the operating room.

Remove the opioid patch when major surgery is planned; with minor surgery, the patch may be continued without a background infusion.

Every chronic pain patient should be seen postoperatively three times daily to evaluate pain at rest, pain with exercise (e.g. coughing), nausea, sedation, mobilization, and sleep quality.

Monitor closely for signs of respiratory depression and withdrawal (e.g., unexplained tachycardia, restlessness, sweating, confusion, hypertension).

Integrate the patient in the acute pain service protocol if available.

Titrate a short-acting opioid for acute pain at two to four times the usual starting dose needed for an opioid-naive patient.

Add cyclooxygenase inhibitors, anticonvulsants, and other adjuvants as needed.

Evaluate the demand-delivery ratio of patient-controlled analgesia frequently; adapt the demand dose to the background infusion (the demand dose equals the hourly dose of the background infusion).

Increase the background infusion in patient-controlled analgesia in proportion to the cumulative daily opioid demand dose (add 50% to 75% of the daily demand dose to the background infusion).

Change the technique of postoperative analgesia if inadequate use persists despite repeated patient education.

If insufficient epidural analgesia is achieved with morphine, use epidural fentanyl or sufentanil.

In the event of escalation of the intravenous opioid dose, consider spinal/epidural opioid application or switch the intravenous agonist.

Reduce daily opioid doses after the second postoperative day stepwise to the preexisting dose.

Switch back to oral or transdermal medication as early as possible; use 50% to 75% of the last daily intravenous opioid dose as slow-release oral or transdermal delivery plus the rest as a demand dose.

When switching back to the transdermal route, consider 12- to 16-hour delayed effects and supply the patient for this period with sufficient on-demand analgesia.

Do not attempt to solve a chronic pain problem in the immediate postoperative period.

Use nonpharmacologic techniques (distraction, relaxation) when appropriate and offer counseling in the pain unit after postoperative recovery.

59 Anesthesia for Thoracic Surgery

Key Points

1. Patients undergoing pulmonary resection should have a preoperative assessment of their respiratory function in three areas: lung mechanical function, pulmonary parenchymal function, and cardiopulmonary reserve (the "three-legged stool" of respiratory assessment).
2. After lung resection surgery, it is usually possible to wean and extubate patients with adequate predicted postoperative respiratory function in the operating room provided they are "AWaC" (alert, warm, and comfortable).
3. Interventions that have been shown to decrease the incidence of respiratory complications in high-risk patients undergoing thoracic surgery include cessation of smoking, physiotherapy, and thoracic epidural analgesia.
4. Geriatric patients are at a high risk for cardiac complications, particularly arrhythmias, after large pulmonary resections. Preoperative exercise capacity is the best predictor of post-thoracotomy outcome in the elderly.
5. The ability to perform fiberoptic bronchoscopy and a detailed knowledge of bronchial anatomy are necessary for anesthesiologists to provide reliable lung isolation.
6. Use of double-lumen endobronchial tubes (DLTs) is the standard method of providing lung isolation in adults. Bronchial blockers are a reasonable alternative for lung isolation in patients with abnormal upper or lower airways.
7. With the use of intravenous anesthetic techniques or volatile anesthetics at less than or equal to 1-MAC doses, hypoxemia during one-lung ventilation (OLV) occurs infrequently. The use of continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP) as treatment for hypoxemia during OLV should be guided by the individual patient's lung mechanics.
8. The use of large tidal volumes during OLV (e.g., 10 mL/kg) can contribute to acute lung injury, particularly in patients at increased respiratory risk, such as after pneumonectomies.
9. Anesthetic management of a patient with an anterior or superior mediastinal mass should be guided by the patient's symptoms and the preoperative CT scan and echocardiography. The fundamental principle of anesthetic management for these patients is *noli ponti ignii consumere* ("don't burn your bridges").
10. Continuous paravertebral local anesthetic blockade combined with multimodal analgesia is a reasonable alternative to epidural analgesia for thoracic surgery with fewer side effects.

Thoracic anesthesia encompasses a wide variety of diagnostic and therapeutic procedures involving the lungs, airways, and other intrathoracic structures. As the patient population presenting for noncardiac thoracic surgery has evolved so have the anesthetic techniques to manage these patients. Thoracic surgery at the beginning of the past century was primarily for infectious indications (e.g., lung abscess, bronchiectasis, empyema). Although these cases still present for surgery in the postantibiotic era, now the most common indications are related to malignancies (pulmonary, esophageal, and mediastinal). In addition, in the past 2 decades we have seen the beginnings of surgical therapy for end-stage lung diseases with procedures such as lung transplantation and lung volume reduction. Fundamental to anesthetic management for the majority of thoracic procedures are two techniques: lung isolation to facilitate surgical access within the thorax and management of one-lung anesthesia. In this chapter we initially discuss preanesthetic assessment for thoracic surgery, then outline intraoperative management principles common to most thoracic surgical procedures, then discuss specific anesthetic considerations in common and less-common surgical operations, and finish with a description of postoperative management issues in thoracic surgical patients.

Preoperative Evaluation of the Thoracic Surgery Patient

Preoperative anesthetic assessment before chest surgery is a continually evolving science and art. Recent advances in anesthetic management, surgical techniques, and perioperative care have expanded the group of patients now considered to be "operable."[1] This discussion focuses primarily on preanesthetic assessment for pulmonary resection surgery in cancer patients. However, the basic principles described will apply to all other types of nonmalignant pulmonary resections and to other chest surgery. The major difference is that in patients with malignancy the risk-benefit ratio of canceling or delaying surgery pending other investigation/therapy is always complicated by the risk of further spread of cancer during any extended interval prior to resection. This is never completely "elective" surgery.

Although 87% of patients with lung cancer will die of their disease, the 13% cure rate represents approximately 26,000 survivors per year in North America. Surgical resection is responsible for essentially all of these cures. A patient with a "resectable" lung cancer has a disease that is still local or locoregional in scope and can be encompassed in a plausible surgical procedure. An "operable" patient is someone who can tolerate the proposed resection with acceptable risk. Several general points should be appreciated in the assessment of pulmonary resection patients.

Currently, the reality of practice patterns in anesthesia has changed such that a patient is commonly assessed initially in an outpatient clinic and often not by the member of the anesthesia staff who will actually administer the anesthesia. The actual contact with the responsible anesthesiologist may be only 10 to 15 minutes before induction. It is necessary to organize and standardize the approach to preoperative evaluation for these patients into two temporally disjoint phases: the initial (clinic) assessment and the final (day-of-admission) assessment. There are elements vital to each assessment that will be described.

There has been a comparatively small volume of research on the short-term (<6 weeks) outcome of these patients. However, this research area is currently very active and there are several studies that can be used to guide anesthetic management in the immediate perioperative period where it has an influence on outcome.

An increasing number of thoracic surgeons are now being trained to perform "lung-sparing" resections such as sleeve-lobectomies or segmentectomies and to perform resections with minimally invasive techniques such as video-assisted thoracoscopic surgery (VATS). The postoperative preservation of respiratory function has been shown to be proportional to the amount of functioning lung parenchyma preserved. To assess patients with limited pulmonary function the anesthesiologist must appreciate these newer surgical options in addition to the conventional open lobectomy or pneumonectomy.

Most commonly it is not the anesthesiologist's function to assess these patients to decide who is or is not an operative candidate. In the majority of situations, the anesthesiologist will be seeing the patient at the end of a referral chain from chest or family physician to surgeon. At each stage there should have been a discussion of the risks and benefits of operation. It is the anesthesiologist's responsibility to use the preoperative assessment to identify those patients at elevated risk and then to use that risk assessment to stratify perioperative management and focus resources on the high-risk patients to improve their outcome. This is the primary function of the preanesthetic assessment. However, there are occasions when the anesthesiologist is asked to contribute an opinion whether a specific high-risk patient will tolerate a specific surgical procedure. This may occur preoperatively but also occurs intraoperatively when the surgical findings suggest that a planned procedure, such as a lobectomy, may require a larger resection, such as a pneumonectomy. For these reasons it is imperative that the anesthesiologist have a complete preoperative knowledge of the patient's medical status and also an appreciation of the pathophysiology of lung resection surgery.

Prethoracotomy assessment naturally involves all of the factors of a complete anesthetic assessment: past history, allergies, medications, upper airway, and so on. This section will concentrate on the additional information, beyond a standard anesthetic assessment, that the anesthesiologist needs to manage a pulmonary resection patient.

Perioperative Complications

The major causes of perioperative morbidity and mortality in the thoracic surgical population are respiratory complications. Major respiratory complications include atelectasis, pneumonia, and respiratory failure, occur in 15% to 20% of patients, and account for the majority of the expected 3% to 4% mortality.[2] For other types of surgery, cardiac and vascular complications are the leading causes of early perioperative morbidity and mortality. Cardiac complications such as arrhythmia and ischemia occur in 10% to 15% of the thoracic population.

Assessment of Respiratory Function

The best assessment of respiratory function comes from a detailed history of the patient's quality of life. All pulmonary resection patients should have baseline simple spirometry preoperatively.[3]

Objective measures of pulmonary function are required to guide anesthetic management and to have this information in a format that can be easily transmitted between members of the health care team. It is useful to think of the respiratory function in three related but somewhat independent areas: respiratory mechanics, gas exchange, and cardiorespiratory interaction (see Chapter 15). These can be remembered as the basic functional units of extracellular respiration that are to get the oxygen: (1) into the alveoli, (2) into the blood, and (3) to the tissues (the process is reversed for carbon dioxide removal).

Respiratory Mechanics

Many tests of respiratory mechanics and volumes show correlation with post-thoracotomy outcome: forced expiratory volume in 1 second (FEV_1), forced vital capacity (FVC), maximal voluntary ventilation (MVV), residual volume/total lung capacity ratio (RV/TLC), and so on (see Chapter 15 on pulmonary function testing). It is useful to express these as a percent of predicted volumes corrected for age, sex, and height (e.g., FEV_1%). Of these the most valid single test for post-thoracotomy respiratory complications is the predicted postoperative FEV_1 ($ppoFEV_1$%),[4] which is calculated as follows:

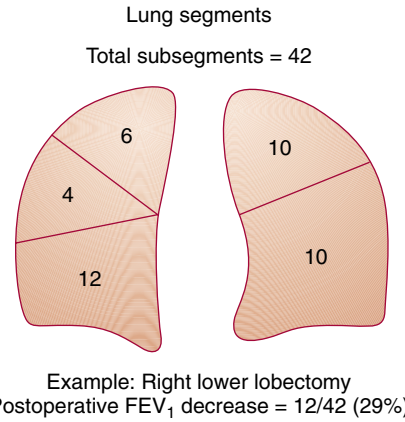

Figure 59-1 The number of subsegments of each lobe is used to calculate the predicted postoperative pulmonary function. For example, after a right lower lobectomy a patient with a preoperative FEV_1 (or DLco) 70% of normal would be expected to have a postoperative $FEV_1 = 70\% \times (1 - 29/100) = 50\%$. (*Reproduced with permission from Slinger PD, Johnston MR: Preoperative assessment: an anesthesiologist's perspective. Thorac Surg Clin 15:11, 2005.*)

$$\text{ppoFEV}_1\% = \text{preoperative FEV}_1\% \times \left(1 - \%\ \text{functional lung tissue removed}/100\right)$$

One method of estimating the percent of functional lung tissue is based on a calculation of the number of functioning subsegments of the lung removed (Fig. 59-1). Patients with a $ppoFEV_1$ greater than 40% are at low risk for postresection respiratory complications. The risk of major respiratory complications is increased in the subgroup with a $ppoFEV_1$ less than 40% (although not all patients in this subgroup develop respiratory complications), and patients with a $ppoFEV_1$ less than 30% are at high risk.

Lung Parenchymal Function

As important to the process of respiration as the mechanical delivery of air to the distal airways is the subsequent ability of the lung to exchange oxygen and carbon dioxide between the pulmonary vascular bed and the alveoli. Traditionally, arterial blood gas data such as Pao_2 less than 60 mm Hg or $Paco_2$ greater than 45 mm Hg have been used as cutoff values for pulmonary resection. Cancer resections have now been successfully done or even combined with volume reduction in patients who do not meet these criteria, although they remain useful as warning indicators of increased risk. The most useful test of the gas exchange capacity of the lung is the diffusing capacity for carbon monoxide (DLco). The DLco correlates with the total functioning surface area of the alveolar-capillary interface. This simple noninvasive test, which is included with spirometry and plethysmography by most pulmonary function laboratories, is a useful predictor of perioperative mortality but not long-term survival.[5] The corrected DLco can be used to calculate a postresection (ppo) value using the same calculation as for the FEV_1 (see Fig. 59-1). A ppoDLco less than 40% predicted correlates with both increased respiratory and cardiac complications and is, to a large degree, independent of the FEV_1. The National Emphysema Treatment Trial has shown that patients with a preoperative FEV_1 or DLco less than 20% had an unacceptably high perioperative mortality rate.[6] These can be considered as the absolute minimal values compatible with successful outcome.

Cardiopulmonary Interaction

The final and perhaps most important assessment of respiratory function is an assessment of the cardiopulmonary interaction. Formal laboratory exercise testing is currently the "gold standard" for assessment of cardiopulmonary function,[7] and the maximal oxygen consumption (Vo_{2max}) is the most useful predictor of postthoracotomy outcome. The risk of morbidity and mortality is unacceptably high if the preoperative Vo_{2max} is less than 15 mL/kg/min.[8] Few patients with a Vo_{2max} greater than 20 mL/kg/min have respiratory complications (for comparison, the highest Vo_{2max} recorded is 85 mL/kg/min by the American cyclist Lance Armstrong in 2005[8]). Complete laboratory exercise testing is expensive. Several alternatives have been demonstrated to be valid surrogate tests for prethoracotomy assessment. The traditional, and still extremely useful, test in ambulatory patients is stair climbing.[9] Stair climbing is done at the patient's own pace but without stopping and is usually documented as a certain number of flights. There is no exact definition for a "flight," but 20 steps at 6 in/step is a frequent value. The ability to climb five flights correlates with a Vo_{2max} greater than 20 mL/kg/min, and climbing two flights corresponds to a Vo_{2max} of 12 mL/kg/min. A patient unable to climb two flights is at extremely high risk.[10]

The distance that a patient can walk during a 6-minute test (6MWT) also shows an excellent correlation with Vo_{2max} and requires little or no laboratory equipment. A 6MWT distance of less than 2000 ft (610 m) correlates to a Vo_{2max} less than 15 mL/kg/min and also correlates with a fall in oximetry (Spo_2) during exercise. Patients with a decrease of Spo_2 greater than 4% during exercise (stair climbing two or three flights or equivalent)[11] are at increased risk for morbidity and mortality. Postresection exercise capacity can be estimated based on the amount of functioning lung tissue removed (see Fig. 59-1). An estimated $ppoVo_{2max}$ less than 10 mL/kg/min may be an absolute contraindication to pulmonary resection. In a small series,[12] the mortality rate was 100% (3/3) patients with a $ppoVo_{2max}$ less than 10 mL/kg/min.

After pulmonary resection there is a degree of right ventricular dysfunction that seems to be in proportion to the amount of functioning pulmonary vascular bed removed. The exact etiology and duration of this dysfunction remains unknown. Clinical evidence of this hemodynamic problem is minimal when the patient is at rest but is dramatic when the patient exercises, leading to elevation of pulmonary vascular pressures, limitation of cardiac output, and absence of the normal decrease in pulmonary vascular resistance usually seen with exertion.[13]

Ventilation-Perfusion Scintigraphy

Prediction of postresection pulmonary function can be further refined by assessment of the preoperative contribution of the lung or lobe to be resected using ventilation-perfusion $\left(\dot{V}/\dot{Q}\right)$ lung scanning. If the lung region to be resected is nonfunctioning or minimally functioning, the prediction of postoperative function can be modified accordingly. This is particularly useful in pneumonectomy patients,[14] and $\dot{V}/\dot{Q}$ scanning should be considered for any pneumonectomy patient who has a preoperative FEV_1 and/or DLco less than 80%. Because the $\dot{V}/\dot{Q}$ scanning is performed at rest while the FEV_1 is a forced maneuver, there is always some error in estimating the true eventual lung mechanics after a pulmonary resection.

Split-Lung Function Studies

A variety of methods have been described to try and simulate the postoperative respiratory situation by unilateral exclusion of a lung or lobe with an endobronchial tube/blocker or by pulmonary artery balloon occlusion of a lung or lobe artery, or by both. These tests have not shown sufficient predictive validity for universal adoption in lung resection patients. Lewis and colleagues[15] have shown that in a group of patients with chronic obstructive pulmonary disease (COPD) (ppoFEV_1 < 40%) undergoing pneumonectomy there were no significant changes in the pulmonary vascular pressures intraoperatively when the pulmonary artery was clamped but the right ventricular ejection fraction and cardiac output decreased. Echocardiography may offer more useful information than vascular pressure monitoring in these patients.[16] For the present, split-lung function studies have been replaced in most centers by a combination assessment involving, spirometry, DLco, exercise tolerance, and $\dot{V}/\dot{Q}$ scanning.

Combination of Tests

No single test of respiratory function has shown adequate validity as a sole preoperative assessment. Before surgery, an estimate of respiratory function in all three areas—lung mechanics, parenchymal function, and cardiopulmonary interaction—should be made for each patient. These three aspects of pulmonary function form the "three-legged stool" that is the foundation of prethoracotomy respiratory assessment (Fig. 59-2). These data can then be used to plan intraoperative and postoperative management (Fig. 59-3) and also to alter these plans when intraoperative surgical factors necessitate that a resection becomes more extensive than foreseen. If a patient has a ppoFEV_1 less than 40%, it should be possible for that patient to be extubated in the operating room at the conclusion of surgery, assuming the patient is alert, warm, and comfortable ("AWaC"). Patients with a ppoFEV_1 less than 40% will usually comprise about a fourth of an average thoracic surgical population. If the ppoFEV_1 is more than 30% and exercise tolerance and lung parenchymal function exceed the increased risk thresholds, then extubation in the operating room should be possible, depending on the status of associated medical conditions. Those patients in this subgroup who do not meet the minimal criteria for cardiopulmonary and parenchymal function should be considered for staged weaning from mechanical ventilation postoperatively so that the effect of the increased oxygen consumption of spontaneous ventilation can be assessed. Patients with a ppoFEV_1 of 20% to 30% and favorable predicted cardiorespiratory and parenchymal function can be considered for early extubation if thoracic epidural analgesia if used or if the resection is performed with VATS. Otherwise, these patients should have a postoperative staged weaning from mechanical ventilation. In the borderline group (ppoFEV_1 30%-40%) the presence of several associated factors and diseases that should be documented during the preoperative assessment will enter into the considerations for postoperative management (see later).

Concomitant Medical Conditions

Cardiovascular Disease

Cardiac complications represent the second most common cause of perioperative morbidity and mortality in the thoracic surgical population.

Ischemia

Because the majority of pulmonary resection patients have a smoking history, they already have one risk factor for coronary artery disease. Elective pulmonary resection surgery is regarded as an "intermediate risk" procedure in terms of perioperative cardiac ischemia.[17] The overall documented incidence of postthoracotomy ischemia is 5% and peaks on days 2 to 3 postoperatively. Beyond the standard history, physical examination, and electrocardiogram, routine screening testing for cardiac disease does not appear to be cost effective for all prethoracotomy patients. Noninvasive testing is indicated in patients with major (unstable ischemia, recent infarction, severe valvular disease, significant arrhythmia) or intermediate (stable angina, remote infarction, previous congestive failure, or diabetes) clinical predictors of myocardial risk (see Chapter 35). Therapeutic options to be considered in patients with significant coronary artery disease are optimization of medical therapy, coronary angioplasty, or coronary artery bypass, either before or at the time of lung resection. Timing of lung resection surgery after a myocardial infarction is always a difficult decision. Limiting the delay to 4 to 6 weeks in a medically stable and fully investigated and optimized patient seems acceptable after myocardial infarction. The appropriate

delay after coronary stenting is controversial. Surgery needs to be delayed until it is safe to temporarily discontinue major antiplatelet drugs (except aspirin). This represents a delay of 3 months for bare metal stents and of more than 6 months for drug-eluting stents.[18] The use of prophylactic β-blockers to reduce the risk of perioperative ischemia in thoracic surgical patients with known or suspected coronary artery disease in the absence of contraindications seems justified based on the recent literature.[17]

Arrhythmia

Dysrhythmias (see Chapter 42) are a common complication of pulmonary resection surgery, and the incidence is 30% to 50% of patients in the first week postoperatively when Holter monitoring is used.[19] Of these arrhythmias, 60% to 70% are atrial fibrillation. Several factors correlate with an increased incidence of arrhythmias: extent of lung resection (pneumonectomy, 60%, versus lobectomy, 40%, versus nonresection thoracotomy, 30%) intrapericardial dissection, intraoperative blood loss, and age of the patient. Extrapleural pneumonectomy patients are a particularly high-risk group.[20]

Two factors in the early post-thoracotomy period interact to produce atrial arrhythmias: (1) increased flow resistance through the pulmonary vascular bed due to permanent (lung resection) or transient (atelectasis, hypoxemia) causes, with attendant strain on the right side of the heart; and (2) increased sympathetic stimuli and oxygen requirements, which are maximal on the second postoperative day as patients become more mobile.

In pneumonectomy patients, versus lobectomy patients, followed for 24 hours with right ventricular ejection fraction (RVEF) catheters there was a significant fall of RVEF on the first postoperative day. This was accompanied by an increase in right ventricular size and in pulmonary artery pressures. Pneumonectomy patients did not demonstrate the early postoperative increase in oxygen delivery, oxygen consumption, or cardiac index seen in lobectomy patients.[21] This suggests that in some pneumonectomy patients the right side of the heart may not be able to increase its output adequately to meet the usual postoperative stress. Transthoracic echocardiographic studies have shown that pneumonectomy patients develop an increase in right ventricular systolic pressure as measured by the tricuspid regurgitation jet on postoperative day 2 but not on day 1. An increase in tricuspid regurgitation jet velocity has been associated with post-thoracotomy supraventricular tachyarrhythmias.[20] Preoperative exercise testing, which assesses the cardiopulmonary interaction, can predict post-thoracotomy arrhythmias. Patients with COPD are more resistant to pharmacologic rate control when they develop post-thoracotomy atrial fibrillation and often require multiple drugs.[22]

Many antiarrhythmic agents have been tried to decrease the incidence of atrial arrhythmias after lung surgery, especially digoxin preparations. Yet, digoxin does not prevent arrhythmias after pneumonectomy or other intrathoracic procedures. Other antiarrhythmics that have been tried to prevent post-thoracotomy arrhythmias, include β-blockers, verapamil, and amiodarone. All of these drugs decrease arrhythmias in thoracic patients. However, they are all associated with side effects that preclude their widespread application in this surgical population. At present, diltiazem is the most useful drug for post-thoracotomy arrhythmia prophylaxis.[1] It seems that atrial arrhythmias are only a symptom of the dysfunctional right side of the heart and preventing the symptom does not solve the underlying problem. In one study,[23] patients who subsequently developed atrial tachyarrhythmias could be identified in the early postoperative period by their right ventricular response to the withdrawal of supplemental oxygen. On the first postoperative day, a decrease of F_{IO_2} from 0.35 to 0.21 caused a significant rise of right ventricular end-diastolic pressure (RVEDP) in the patients who subsequently developed arrhythmias. Thoracic epidural analgesia with local anesthetics may decrease the incidence and severity of arrhythmias. This effect is due to increasing myocardial refractory period, decreasing ventricular diastolic pressures, and improving endocardial/epicardial blood flow ratios.[24]

Age

There is no maximum age that is a cutoff for pulmonary resection.[4] The operative mortality in a group of patients 80 to 92 years of age was 3%, a very respectable figure, in one series.[25] However, the rate of respiratory complications (40%) was double that expected in a younger population and the rate of cardiac complications (40%), particularly arrhythmias, was nearly triple that which would be seen in younger patients. In the elderly, thoracotomy should be considered a high-risk procedure for cardiac complications and cardiopulmonary function is the most important part of the preoperative assessment. An algorithm for the cardiac assessment of the elderly for thoracic surgery is presented in Figure 59-4. Although the mortality resulting from lobectomy among the elderly is acceptable, the mortality from pneumonectomy, particularly right pneumonectomy, is excessive.[26] Exercise tolerance seems to the primary determinant of outcome in the elderly.[27] The American College of Cardiology/American Heart Association guidelines[17] suggest that with "adequate functional capacity" (i.e., 4 Mets or one-flight stair climbing) patients with "intermediate" predictors of coronary artery disease do not need further cardiac assessment. However, this recommendation should not be extrapolated to elderly patients. The elderly should also have, as a minimum cardiac investigation, a transthoracic echocardiogram, to rule out pulmonary hypertension.

Renal Dysfunction

Renal dysfunction after pulmonary resection surgery is associated with a high mortality. Golledge and Goldstraw[28] reported a perioperative mortality of 19% (6/31) in patients who developed a significant elevation of serum creatinine concentration in the post-thoracotomy period, compared with 0% (0/99) in those who did not show any renal dysfunction. The factors, which were associated with an increased risk of renal impairment, were history of previous renal impairment, diuretic therapy, pneumonectomy, postoperative infection, and blood transfusion. Nonsteroidal anti-inflammatory drugs (NSAIDs) were not associated with renal impairment in this series but are clearly a concern in any thoracotomy patient with an increased risk of renal dysfunction. The high mortality in pneumonectomy patients from either renal failure or postoperative pulmonary edema emphasizes the importance of fluid management in these patients[29] and the need for close and intensive perioperative monitoring, particularly in those patients on diuretics or with a history of renal dysfunction.

Chronic Obstructive Pulmonary Disease

The most common concurrent illness in the thoracic surgical population is COPD, which incorporates three disorders: emphy-

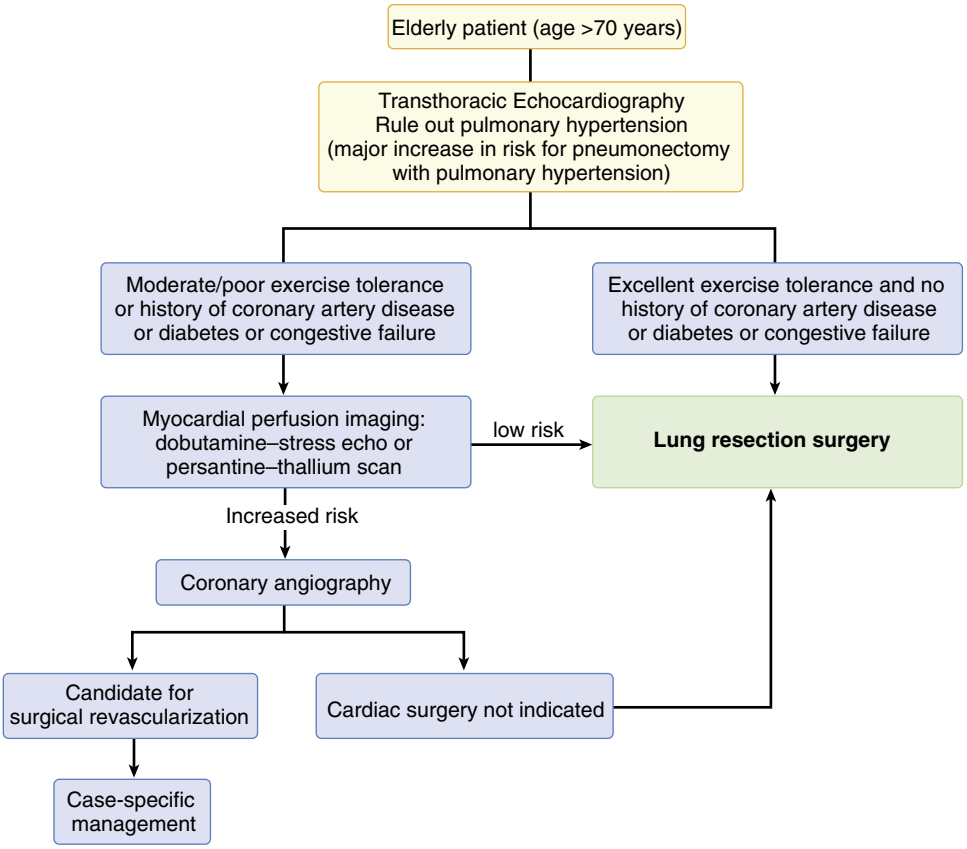

Figure 59-4 Algorithm for the preoperative cardiac assessment of elderly patients for thoracic (noncardiac) surgery.

sema, peripheral airways disease, and chronic bronchitis (see Chapter 35). Any individual patient may have one or all of these conditions, but the dominant clinical feature is impairment of expiratory airflow.[30] Assessment of the severity of COPD has traditionally been on the basis of the FEV_1% of predicted values. The American Thoracic Society currently categorizes stage I as greater than 50% predicted (this category previously included both "mild" and "moderate" COPD), stage II as 35% 50%, and stage III as less than 35%. Life expectancy may be less than 3 years in stage III patients older than age 60 years. Stage I patients should not have significant dyspnea, hypoxemia, or hypercarbia, and other causes should be considered if these are present. Recent advances in the understanding of COPD that are relevant to anesthetic management are discussed next.

Respiratory Drive

Many stage II or III COPD patients have an elevated P_{ACO_2} at rest. It is not possible to differentiate these "CO_2 retainers" from nonretainers on the basis of history, physical examination, or spirometric pulmonary function testing. This CO_2 retention seems to be more related to an inability to maintain the increased work of respiration (W_{Resp}) required to keep the P_{ACO_2} normal in patients with mechanically inefficient pulmonary function and not primarily due to an alteration of respiratory control mechanisms. It was previously thought that chronically hypoxemic/hypercapnic patients relied on a hypoxic stimulus for ventilatory drive and became insensitive to P_{ACO_2}. This explained the clinical observation that COPD patients in incipient respiratory failure could be put into a hypercapnic coma by the administration of a high concentration of oxygen (F_{IO_2}). Actually, only a minor fraction of the increase in P_{ACO_2} in such patients is due to a diminished respiratory drive, because minute ventilation is basically unchanged. The P_{ACO_2} rises because a high F_{IO_2} causes a relative decrease in alveolar ventilation and an increase in alveolar dead space and shunt by the redistribution of perfusion away from lung areas of relatively normal $\dot{V}/\dot{Q}$ matching to areas of very low $\dot{V}/\dot{Q}$ ratio because regional hypoxic pulmonary vasoconstriction (HPV) is decreased[31] and also due to the Haldane effect.[32] However, supplemental oxygen must be administered to these patients postoperatively to prevent the hypoxemia associated with the unavoidable fall in functional residual capacity (FRC). The attendant rise in P_{ACO_2} should be anticipated and monitored. To identify these patients preoperatively, all stage II or III COPD patients need arterial blood gas analysis.

Nocturnal Hypoxemia

COPD patients desaturate more frequently and severely than normal patients during sleep. This is due to the rapid/shallow breathing pattern that occurs in all patients during rapid-eye-movement (REM) sleep. In COPD patients breathing air, this causes a significant increase in the respiratory dead space/tidal volume (V_{DS}/V_T) ratio and a fall in alveolar oxygen tension (P_{AO_2}) and P_{aO_2}. This is not the sleep apnea/hypoventilation syndrome (SAHS). There is no increased incidence of SAHS in COPD. In 8 of 10 COPD patients studied, the oxygen saturation fell to less than 50% at some time during normal sleep, and this

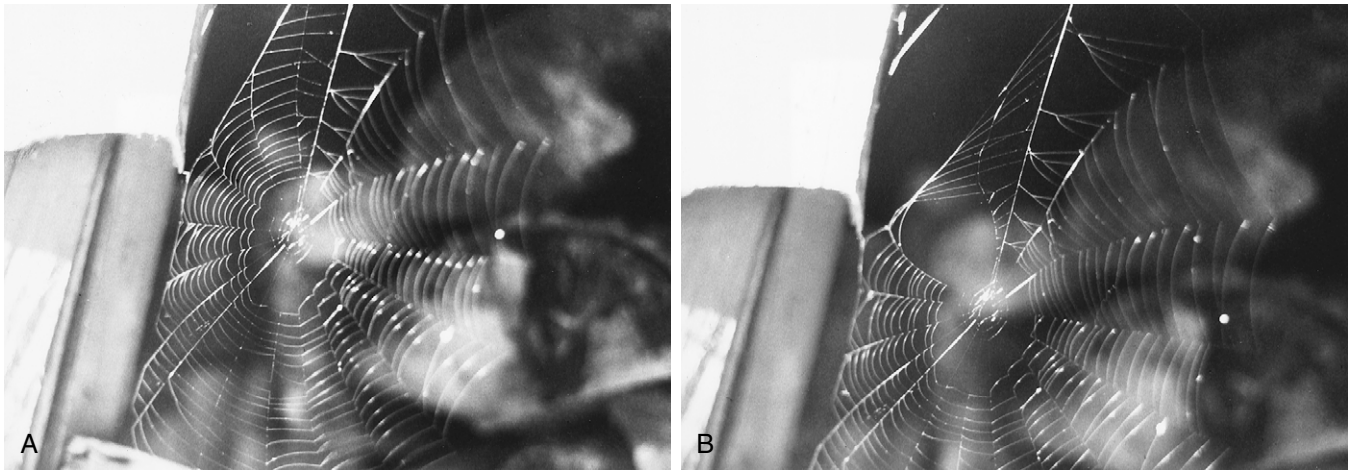

Figure 59-5 A, A spider's web as a lung model to demonstrate the pathophysiology of bullae. **B,** Breaking one septum of the spider's web causes a bulla to appear as elastic recoil pulls the web away from the area where structural support has been lost. Although the cells surrounding the bulla appear compressed, this is due only to redistribution of elastic forces. It is not positive pressure inside the bulla that causes this appearance of surrounding compression. (*Reproduced with permission from Slinger P: Anesthesia for lung resection surgery. In Thys D [ed]: Textbook of Cardiothoracic Anesthesia. New York, McGraw-Hill, 2001.*)

was associated with an increase in pulmonary artery pressure. This tendency to desaturate, combined with the postoperative fall in FRC and opioid analgesia, places these patients at high risk for severe hypoxemia postoperatively during sleep.

Right Ventricular Dysfunction

Right ventricular (RV) dysfunction occurs in up to 50% of COPD patients. The dysfunctional right ventricle is poorly tolerant of sudden increases in afterload,[33] such as the change from spontaneous to controlled ventilation.[34] RV function becomes critical in maintaining cardiac output as the pulmonary artery pressure rises. The RV ejection fraction does not increase with exercise in COPD patients as it does in normal patients. Chronic recurrent hypoxemia is the cause of the RV dysfunction and the subsequent progression to cor pulmonale. Patients who have episodic hypoxemia in spite of normal lungs (e.g., central alveolar hypoventilation, SAHS)[35] develop the same secondary cardiac problems as in COPD patients. Cor pulmonale occurs in 40% of adult COPD patients with an FEV_1 less than 1 L and in 70% with an FEV_1 less than 0.6 L. Mortality in COPD patients is primarily related to chronic hypoxemia. The only therapy that has been shown to improve long-term survival and decrease right-sided heart strain in COPD is oxygen. COPD patients who have resting Pao_2 less than 55 mm Hg should receive supplemental home oxygen; this includes those who desaturate to less than 44 mm Hg with usual exercise. The goal of supplemental oxygen is to maintain a Pao_2 of 60 to 65 mm Hg. Compared with patients with chronic bronchitis, emphysematous COPD patients tend to have a decreased cardiac output and mixed venous oxygen tension while maintaining lower pulmonary artery pressures. Pneumonectomy candidates with a $ppoFEV_1$ less than 40% should have transthoracic echocardiography to assess right-sided heart function. Elevation of right-sided heart pressures places these patients in a very high-risk group.

Bullae

Many patients with moderate or severe COPD will develop cystic air spaces in the lung parenchyma known as bullae. These bullae will often be asymptomatic unless they occupy more than 50% of the hemithorax, in which case the patient will present with findings of restrictive respiratory disease in addition to their obstructive disease. Previously, it was thought that bullae represented positive-pressure areas with in the lung that compressed surrounding lung tissue. It is now appreciated that a bulla is actually a localized area of loss of structural support tissue in the lung with elastic recoil of surrounding parenchyma (Fig. 59-5). The pressure in a bulla is actually the mean pressure in the surrounding alveoli averaged over the respiratory cycle. This means that during normal spontaneous ventilation the intra-bulla pressure is actually slightly negative in comparison with the surrounding parenchyma.[36] However, whenever positive-pressure ventilation is used the pressure in a bulla will become positive in relation to the adjacent lung tissue and the bulla will expand with the attendant risk of rupture, tension pneumothorax, and bronchopleural fistula. Positive-pressure ventilation can be used safely in patients with bullae provided the airway pressures are kept low and there is adequate expertise and equipment immediately available to insert a chest drain and obtain lung isolation if necessary. Management of patients for bullectomy is discussed later in this chapter.

Flow Limitation

Severe COPD patients are often "flow limited" even during tidal volume expiration at rest.[37] Flow limitation is present in normal patients only during a forced expiratory maneuver. Flow limitation occurs when an equal pressure point develops in the intrathoracic airways during expiration. During quiet expiration in the normal patient the pressure in the lumen of the airways always exceeds the intrapleural pressure because of the upstream elastic recoil pressure that is transmitted from the alveoli. The effect of this elastic recoil pressure diminishes as air flows downstream in the airway. With a forced expiration the intrapleural pressure may equal the intraluminal pressure at a certain point, the equal pressure point, which then limits the expiratory flow. Then, any increase in expiratory effort will not produce an increase in flow at that given lung volume.[38]

Flow limitation occurs particularly in emphysematous patients, who primarily have a problem with loss of lung elastic recoil and have marked dyspnea on exertion. Flow limitation causes dyspnea because of stimulation of mechanoreceptors in the muscles of respiration, thoracic cage, and airway distal to the equal pressure point. Any increase in the work of respiration will lead to increased dyspnea. This variable mechanical compression of airways by overinflated alveoli is the primary cause of the airflow obstruction in emphysema.

Severely flow-limited patients are at risk for hemodynamic collapse with the application of positive-pressure ventilation owing to dynamic hyperinflation of the lungs.[34] Even the modest positive airway pressures associated with manual ventilation with a bag/mask at induction can lead to hypotension because these patients have no increased resistance to inspiration but a marked obstruction of expiration. In some of these patients this has contributed to the "Lazarus" syndrome, in which patients have recovered from a cardiac arrest only after resuscitation and positive-pressure ventilation were discontinued.[39]

Auto-PEEP

Patients with severe COPD often breathe in a pattern that interrupts expiration before the alveolar pressure has fallen to atmospheric pressure. This incomplete expiration is due to a combination of factors, which include flow limitation, increased work of respiration, and increased airway resistance. This interruption leads to an elevation of the end-expiratory lung volume above the FRC. This positive end-expiratory pressure (PEEP) in the alveoli at rest has been termed *auto-PEEP* or *intrinsic-PEEP.* During spontaneous respiration the intrapleural pressure will have to be decreased to a level that counteracts auto-PEEP before inspiratory flow can begin. Thus, COPD patients can have an increased inspiratory load added to their already increased expiratory load.

Auto-PEEP becomes even more important during mechanical ventilation. It is directly proportional to tidal volume and inversely proportional to expiratory time. The presence of auto-PEEP is not detected by the manometer of standard anesthesia ventilators. It can be measured by end-expiratory flow interruption, a feature available on the newer generation of intensive care ventilators. Auto-PEEP has been found to develop in most COPD patients during one-lung anesthesia.[40]

Combined Cancer and Emphysema Surgery

Although the predicted values for $ppoFEV_1$ are very useful for the anesthesiologist to stratify a patient's perioperative risk, the actual postoperative FEV_1 that the patient will reach by 3 months after recovery from surgery will usually exceed the $ppoFEV_1$ owing to compensatory hyperinflation of the residual lung. For lobectomies the eventual FEV_1 will usually exceed the $ppoFEV_1$ by approximately 250 mL and for pneumonectomies by 500 mL.[41] This improvement can be particularly noticed in some emphysema patients who experience a "volume reduction" effect from their pulmonary resection for cancer. The combination of volume reduction surgery and/or bullectomy in addition to lung cancer surgery has been reported in emphysematous patients who would previously not have met minimal criteria for pulmonary resection due to their concurrent lung disease.[42]

Preoperative Therapy for COPD

There are four treatable complications of COPD that must be actively sought and therapy begun at the time of the initial preoperative assessment. These are atelectasis, bronchospasm, respiratory tract infections, and pulmonary edema (Table 59-1). Atelectasis impairs local lung lymphocyte and macrophage function, predisposing to infection. Pulmonary edema can be very difficult to diagnose by auscultation in the presence of COPD and may present in very abnormal radiologic distributions (e.g., unilateral, upper lobes). Bronchial hyperreactivity may be a symptom of congestive failure or may represent an exacerbation of reversible airways obstruction. All COPD patients should receive maximal bronchodilator therapy as guided by their symptoms. Only 20% to 25% of COPD patients will respond to corticosteroids. In a patient who is poorly controlled on sympathomimetic and anticholinergic bronchodilators, a trial of corticosteroids may be beneficial.

Table 59-1 Concurrent Problems That Should Be Treated before Anesthesia in COPD Patients

Problem	Method of Diagnosis
Bronchospasm	Auscultation
Atelectasis	Chest radiography
Infection	History, sputum analysis
Pulmonary edema	Auscultation, chest radiography

Physiotherapy

Patients with COPD have fewer postoperative pulmonary complications when a perioperative program of intensive chest physiotherapy is initiated preoperatively (see Chapter 93).[43] Among the different modalities available (e.g., cough and deep breathing, incentive spirometry, PEEP, continuous positive airway pressure [CPAP]), there is no clearly proven superior method. The important variable is the quantity of time spent with the patient and devoted to chest physiotherapy. Family members or nonphysiotherapy hospital staff can easily be trained to perform effective preoperative chest physiotherapy, and this should be arranged at the time of the initial preoperative assessment. Even in the most severe COPD patient, it is possible to improve exercise tolerance with a physiotherapy program. Little improvement is seen before 1 month. Among COPD patients, those with excessive sputum benefit the most from chest physiotherapy.

A comprehensive program of pulmonary rehabilitation involving physiotherapy, exercise, nutrition, and education can improve functional capacity for patients with severe COPD.[44] These programs are usually of several months' duration and are generally not an option in resections for malignancy, although rehabilitation should be considered for nonmalignant resections in patients with severe COPD. The benefits of short-duration rehabilitation programs before malignancy resection have not been fully assessed.

Smoking

Pulmonary complications are decreased in thoracic surgical patients who cease smoking for more than 4 weeks before surgery.[45] Carboxyhemoglobin concentrations decrease if smoking is stopped more than 12 hours.[46] It is extremely important for patients to avoid smoking postoperatively. Smoking leads to a prolonged period of tissue hypoxemia. Wound tissue oxygen tension correlates with wound healing and resistance to infection.

There is no rebound increase in pulmonary complications if patients stop for shorter (<8 wk) periods before surgery.[47] The balance of evidence suggests that thoracic surgical patients should be counseled to stop smoking and advised that the longer the period of cessation the greater the risk reduction for postoperative pulmonary complications.

Primary Thoracic Tumors

The majority of patients presenting for major pulmonary surgery will have some type of malignancy. Because the different types of thoracic malignancies have varying implications for both surgery and anesthesia, it is important for the anesthesiologist to have some knowledge of the presentation and biology of these cancers. By far the most common tumor is lung cancer. There are over 200,000 new cases of lung cancer diagnosed per year in North America and more than 1.2 million in the world. Lung cancer is currently the leading cause of cancer deaths in both sexes in North America subsequent to the peak incidence of smoking in the period 1940 to 1970.[48]

Lung cancer is broadly divided into small cell lung cancer (SCLC) and non–small cell lung cancer (NSCLC), with 75% to 80% of these tumors being NSCLC. Other less common and less aggressive tumors of the lung include the carcinoid tumors (typical and atypical) and adenoid cystic carcinoma. In comparison to lung cancer, primary pleural tumors are rare. They include the localized fibrous tumors of pleura (previously referred to as benign mesotheliomas) and malignant pleural mesothelioma. Asbestos exposure is implicated as a causative effect in up to 80% of malignant pleural mesotheliomas. A dose-response relationship is not always apparent, and even brief exposures can lead to the disease. An exposure history is often difficult to obtain because the latent period before clinical manifestation of the tumor may be as long as 40 to 50 years.

Tobacco smoke is responsible for approximately 90% of all lung cancers, and the epidemiology of lung cancer follows the epidemiology of cigarette smoking, with approximately a 3-decade lag time.[49] Other environmental causes include asbestos and radon gas (a decay product of naturally occurring uranium), which act as co-carcinogens with tobacco smoke. For a pack-a-day cigarette smoker the lifetime risk of lung cancer is approximately 1 in 14. Assuming current mortality patterns continue, cancer will pass heart disease as the leading cause of death in North America in this decade.

Non–Small Cell Lung Cancer

This pathologically heterogeneous group of tumors includes squamous cell, adenocarcinoma, and large-cell carcinoma. Overall 5-year survival with surgery approaches 40%. This seemingly low figure must be viewed in the light of an estimated 5-year survival without surgery of less than 10%. Although it is not always possible to be certain of the pathology of a given lung tumor preoperatively, many patients will have a known tissue diagnosis at the time of preanesthetic assessment on the basis of prior cytology, bronchoscopy, mediastinoscopy, or transthoracic needle aspiration. This is useful information for the anesthesiologist to obtain preoperatively. Specific anesthetic implications of the different types of lung cancer are listed in Table 59-2.

Table 59-2 Anesthetic Considerations for Different Types of Lung Cancer

Type	Considerations
Squamous cell	Central lesions (predominantly) Often with endobronchial tumor Mass effects: obstruction, cavitation Hypercalcemia
Adenocarcinoma	Peripheral lesions Extrapulmonary invasion common Most Pancoast tumors Growth hormone, corticotropin Hypertrophic osteoarthropathy
Large cell	Large, cavitating peripheral tumors Similar to adenocarcinoma
Small cell	Central lesions (predominantly) Surgery usually not indicated Paraneoplastic syndromes Lambert-Eaton syndrome Fast growth rate Early metastases
Carcinoid	Proximal, endobronchial Bronchial obstruction with distal pneumonia Highly vascular Benign (predominantly) No association with smoking 5 year survival > 90% Carcinoid syndrome (rarely)

Squamous Cell Carcinoma. This subgroup of NSCLC is strongly linked to cigarette smoking. The tumors tend to grow to a large size and metastasize later than others. They tend to cause symptoms and signs related to local effects of a large tumor mass with a dominant endobronchial component, such as cavitation, hemoptysis, obstructive pneumonia, superior vena cava syndrome, and involvement of mainstem bronchus, trachea, carina, and main pulmonary arteries. Hypercalcemia is specifically associated with this cell type due to elaboration of a parathyroid-like factor and not due to bone metastases.

Adenocarcinoma. Adenocarcinoma is currently the most common NSCLC in both sexes. These tumors tend to be peripheral and often metastasize early in their course, particularly to brain, bone, liver, and adrenal. They often invade extrapulmonary structures, including chest wall, diaphragm, and pericardium. Almost all Pancoast tumors are adenocarcinomas. A variety of paraneoplastic metabolic factors can be secreted by adenocarcinomas, such as growth hormone and corticotropin. Hypertrophic pulmonary osteoarthropathy (HPOE) is particularly associated with adenocarcinoma.

Bronchioloalveolar carcinoma (BAC) is a subtype of adenocarcinoma that is not related to cigarette smoking. In its early stages it lines the alveolar membrane with a thin layer of tumor cells without destroying the alveolar architecture. Because of its low potential to spread outside of the lungs, multifocal BAC can be treated by lung transplantation.[50]

Large Cell Undifferentiated Carcinoma. This is the least common of the NSCLCs. It tends to present as a large, often cavitating peripheral tumor. The rapid growth rate may lead to widespread metastases, similar to adenocarcinoma.

Small Cell Lung Cancer

This tumor of neuroendocrine origin is considered metastatic on presentation and is usually regarded as a medical, not a surgical,

disease. The staging system differs from NSCLC and is divided simply into limited stage and extensive stage. Treatment of limited-stage SCLC with combination chemotherapy (etoposide/cisplatin or cyclophosphamide/doxorubicin/vincristine) gives objective response rates in over 80% of patients. In addition, these patients typically receive aggressive radiotherapy to the primary lung tumor and prophylactic cranial irradiation. Despite this initial response, the tumor invariably recurs and is quite resistant to further treatment. The overall survival rate is no better than 10%. Extensive-stage disease is treated with chemotherapy and palliative radiation as needed.

There are two situations in which surgery for SCLC might be considered. The rare instance in which a solitary pulmonary nodule is diagnosed as SCLC should be treated with surgical resection followed by chemotherapy. Salvage resection of a residual mass after chemotherapy for limited-stage disease may offer some long-term survival in selected cases. Many of these patients will have mixed SCLC/NSCLC in which the small cell component has responded to chemotherapy and the non–small cell component is then resected.

SCLC causes a variety of paraneoplastic syndromes owing to the production of peptide hormones and antibodies. The most common of these is hyponatremia usually due to an inappropriate production of antidiuretic hormone (SIADH). Cushing's syndrome and hypercortisolism through ectopic production of adrenocorticotropic hormone (ACTH) are also commonly seen.

A well-known but rare neurologic paraneoplastic syndrome associated with small cell lung tumors is the Lambert-Eaton (also called Eaton-Lambert) myasthenic syndrome due to impaired release of acetylcholine from nerve terminals. This typically presents as proximal lower limb weakness and fatigability that may temporarily improve with exercise. The diagnosis is confirmed by electromyography (EMG) showing increasing amplitude of unusual action potentials with high-frequency stimulation. Similar to patients with true myasthenia gravis, patients with myasthenic syndrome are extremely sensitive to nondepolarizing muscle relaxants (see Chapter 29). However, they respond poorly to anticholinesterase reversal agents.[51] Subclinical involvement of the diaphragm and muscles of respiration may be involved. Thoracic epidural analgesia has been used after thoracotomy in these patients without complication. Also, neuromuscular function may improve after resection of the lung cancer.

Carcinoid Tumors

Carcinoid tumors are part of a continuum of neuroendocrine tumors that form a spectrum of diseases from SCLC as the most malignant to a typical carcinoid as the most benign. Five-year survival after resection for a typical carcinoid tumor exceeds 90%. Lymph node metastasis is not uncommon and does not impact survival. Systemic metastasis is rare, as is the carcinoid syndrome, which is caused by the ectopic synthesis of vasoactive mediators and is usually seen with carcinoid tumors of gut origin that have metastasized to the liver. Atypical carcinoid tumors are more aggressive. They often metastasize both regionally and systemically.

Carcinoid tumors can precipitate an intraoperative hemodynamic crisis or coronary artery spasm even during bronchoscopic resection.[52] The anesthesiologist should be prepared to deal with severe hypotension that may not respond to the usual vasoconstrictors and will require the use of the specific antagonists octreotide or somatostatin.[53]

Pleural Tumors

Localized fibrous tumors of pleura are usually large, space-occupying masses that are attached to visceral or parietal pleura. They can be either benign or malignant, but most are easily resected with good results.

Malignant pleural mesotheliomas are strongly associated with exposure to asbestos fibers. Their incidence in Canada has almost doubled in the past 15 years. With the phasing out of asbestos-containing products and the long latent period between exposure and diagnosis, the peak incidence is not predicted for another 10 to 20 years. The tumor initially proliferates within the visceral and parietal pleura, typically forming a bloody effusion. Most patients present with shortness of breath or dyspnea on exertion from this pleural effusion. Thoracentesis often relieves the symptoms but rarely provides a diagnosis. Pleural biopsy by VATS is most efficient to secure a diagnosis, and talc poudrage is performed under the same anesthetic to treat the effusion.

Malignant pleural mesotheliomas respond poorly to therapy, and the median survival is less than 1 year. In patients with very early disease extrapleural pneumonectomy may be considered but it is difficult to know whether survival is improved. Recently, several groups have reported improved results with combinations of radiation therapy, chemotherapy, and surgery. Extrapleural pneumonectomy is an extensive procedure that is rife with potential complications, both intraoperative and postoperative.[54] Blood loss from the denuded chest wall or major vascular structures is always a risk. Complications related to resection of diaphragm and pericardium are additional risks to that of pneumonectomy.

Assessment of the Patient with Lung Cancer

At the time of initial assessment cancer patients should be assessed for the "4 Ms" associated with malignancy (Table 59-3): *m*ass effects, *m*etabolic abnormalities, *m*etastases, and *m*edications. The prior use of medications that can exacerbate oxygen-induced pulmonary toxicity such as bleomycin should be considered.[55] Bleomycin is not used to treat primary lung cancers, but patients presenting for excision of lung metastases from germ cell tumors will often have received prior bleomycin therapy. Although the association between previous bleomycin therapy and pulmonary toxicity from high-inspired oxygen concentrations is well documented, none of the details of the association are understood (i.e., safe doses of oxygen or safe period after bleomycin exposure). The safest anesthetic management is to use the lowest F_{IO_2} consistent with patient safety and closely monitor oximetry in any patient who has received bleomycin. We have seen lung cancer patients who received preoperative chemotherapy with cisplatin and then developed an elevation of serum creatinine when they

Table 59-3 Anesthetic Considerations in Lung Cancer Patients (the "4 Ms")

Mass effects: Obstructive pneumonia, lung abscess, superior vena cava syndrome, tracheobronchial distortion, Pancoast's syndrome, recurrent laryngeal nerve or phrenic nerve paresis, chest wall or mediastinal extension
Metabolic effects: Lambert-Eaton syndrome, hypercalcemia, hyponatremia, Cushing's syndrome
Metastases: particularly to brain, bone, liver, and adrenal
Medications: chemotherapy agents, pulmonary toxicity (bleomycin, mitomycin C), cardiac toxicity (doxorubicin), renal toxicity (cisplatin)

received nonsteroidal anti-inflammatory analgesics (NSAIDs) postoperatively. For this reason, we do not routinely administer NSAIDs to patients who have been treated recently with cisplatin.

Postoperative Analgesia

The strategy for postoperative analgesia (see Chapter 87) should be developed and discussed with the patient during the initial preoperative assessment. A discussion of postoperative analgesia is presented at the end of this chapter. Many techniques have been shown to be superior to the use of on-demand parenteral (intramuscular or intravenous) opioids alone in terms of pain control. These include the addition of neuraxial blockade, paravertebral blocks, and anti-inflammatory agents to narcotic-based analgesia. Only epidural techniques have been shown to consistently have the capability to decrease post-thoracotomy respiratory complications in high-risk patients.[2] However, continuous paravertebral blockade may offer comparable analgesia with a lower rate of block failure and fewer side effects.[56]

At the time of initial preanesthetic assessment the risks and benefits of the various forms of post-thoracotomy analgesia should be explained to the patient. Potential contraindications to specific methods of analgesia should be determined, such as coagulation problems, sepsis, or neurologic disorders. If the patient is to receive prophylactic anticoagulants and it is elected to use epidural analgesia, appropriate timing of anticoagulant administration and neuraxial catheter placement needs to be arranged. American Society of Regional Anesthesia (ASRA) guidelines suggest an interval of 2 to 4 hours before or 1 hour after catheter placement for prophylactic heparin administration.[57] Low-molecular-weight heparin (LMWH) precautions are less clear: an interval of 12 to 24 hours before and 24 hours after catheter placement is recommended.

Premedication

Premedication should be discussed and ordered at the time of the initial preoperative visit (see Chapter 34). The most important aspect of preoperative medication is to avoid inadvertent withdrawal of those drugs that are taken for concurrent medical conditions (e.g., bronchodilators, antihypertensives, β-blockers). For some types of thoracic surgery, such as esophageal reflux surgery, oral antacid and H_2-blockers or proton-pump inhibitors are routinely ordered preoperatively. We do not routinely order preoperative sedation or analgesia for pulmonary resection patients. Mild sedation such as an intravenous short-acting benzodiazepine is often given immediately before placement of invasive monitoring lines and catheters. In patients with copious secretions, an antisialagogue (e.g., glycopyrrolate) is useful to facilitate fiberoptic bronchoscopy for positioning of a double-lumen tube (DLT) or bronchial blocker. It is a common practice to use short-term intravenous antibacterial prophylaxis such as a cephalosporin in thoracic surgical patients. If it is the local practice to administer these drugs before admission to the operating room they will have to be ordered preoperatively. Consideration for those patients allergic to cephalosporins or penicillin will have to be made at the time of the initial preoperative visit.

Summary of the Initial Preoperative Assessment

The anesthetic considerations that should be addressed at the time of the initial preoperative assessment are summarized in Table 59-4. Patients need to be specifically assessed for risk factors associated with respiratory complications, which are the major cause of morbidity and mortality after thoracic surgery.

Table 59-4 Initial Preanesthetic Assessment for Thoracic Surgery

1. All patients: Assess exercise tolerance, estimate predicted postoperative FEV_1%, discuss postoperative analgesia, discontinue smoking
2. Patients with predicted postoperative FEV_1< 40%: DLco, $\dot{V}/\dot{Q}$ scan, Vo_2 max
3. Cancer patients: consider the "4 Ms": mass effects, metabolic effects, metastases, medications
4. COPD patients: Arterial blood gas analysis, physiotherapy, bronchodilators
5. Increased renal risk: Measure creatinine and blood urea nitrogen

Final Preoperative Assessment

The final preoperative anesthetic assessment for the majority of thoracic surgical patients is carried out immediately before admission of the patient to the operating room (see Chapter 34). At this time it is important to review the data from the initial prethoracotomy assessment and the results of tests ordered at that time. In addition, two other specific areas affecting thoracic anesthesia need to be assessed: the potential for difficult lung isolation and the risk of desaturation during one-lung ventilation (OLV) (Table 59-5).

Difficult Endobronchial Intubation

Anesthesiologists are familiar with the clinical assessment of the upper airway for ease of endotracheal intubation. In a similar fashion, each thoracic surgical patient must be assessed for the ease of endobronchial intubation. At the time of the preoperative visit, there may be historical factors or physical findings that lead to suspicion of difficult endobronchial intubation (previous radiotherapy, infection, prior pulmonary or airway surgery) (see Chapter 50). In addition, there may be a written bronchoscopy report with detailed description of anatomic features. The most useful predictor of difficult endobronchial intubation is the plain chest radiograph (Fig. 59-6).

The anesthesiologist should personally view the chest radiograph before induction of anesthesia because neither the radiologist's nor the surgeon's report of the radiograph is made with the specific consideration of lung isolation in mind. A large portion of thoracic surgical patients will also have had a chest CT scan done preoperatively. As anesthesiologists have learned to assess x-rays for potential lung-isolation difficulties, it is also worthwhile to learn to examine the CT scan. Distal airway problems not detectable on the plain chest film can sometimes be visualized on the CT scan: a side-to-side compression of the distal trachea, the so-called saber-sheath trachea, can cause obstruction of the tracheal lumen of a left-sided DLT during ventilation of the dependent lung for a left thoracotomy.[58] Similarly, extrinsic

Table 59-5 Final Preanesthetic Assessment for Thoracic Surgery

1. Review initial assessment and test results.
2. Assess difficulty of lung isolation: examine chest radiograph and computed tornography scan.
3. Assess risk of hypoxemia during one-lung ventilation.

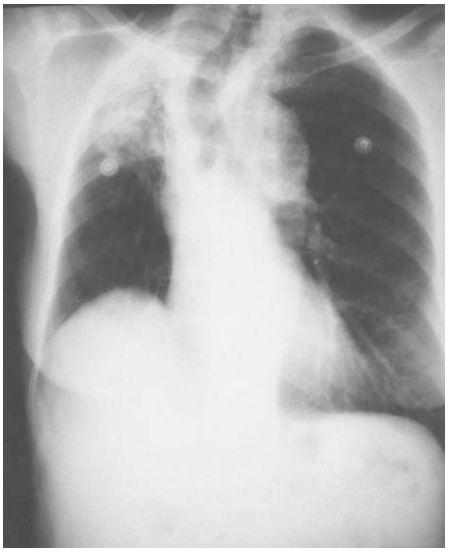

Figure 59-6 Preoperative chest radiograph of a 50-year-old woman with a history of previous tuberculosis, right upper lobectomy, and recent hemoptysis presenting for right thoracotomy for a possible complete pneumonectomy. The potential problems of positioning a left-sided double-lumen tube in this patient are easily appreciated by viewing the radiograph but are not mentioned in the radiologist's report. The anesthesiologist must examine the chest images preoperatively to anticipate problems in lung isolation. (*Reproduced with permission from Slinger PD, Johnston MR: Preoperative assessment: An anesthesiologist's perspective. Thorac Surg Clin 15:11, 2005.*)

compression or intraluminal obstruction of a mainstem bronchus that can interfere with endobronchial tube placement may be evident only on CT (Fig. 59-7). The major factors in successful lower airway management are anticipation and preparation based on the preoperative assessment. Management of lung isolation in patients with difficult upper and lower airways is discussed later in this chapter.

Prediction of Desaturation during One-Lung Ventilation

In the vast majority of cases it is possible to determine those patients who are most at risk of desaturation during OLV for thoracic surgery. The factors that correlate with desaturation during OLV are listed in Table 59-6. In patients at high risk of desaturation, prophylactic measures can be used during OLV to decrease this risk. The most useful prophylactic measures are the use of CPAP of 2 to 5 cm H_2O of oxygen to the nonventilated lung or PEEP to the dependent lung or both (see Chapter 15).

Table 59-6 Factors That Correlate with an Increased Risk of Desaturation during One-Lung Ventilation

- High percentage of ventilation or perfusion to the operative lung on preoperative $\dot{V}/\dot{Q}$ scan
- Poor Pao_2 during two-lung ventilation, particularly in the lateral position intraoperatively
- Right-sided thoracotomy
- Normal preoperative spirometry (FEV_1 or FVC) or restrictive lung disease
- Supine position during one-lung ventilation

The most important predictor of Pao_2 during OLV is the Pao_2 during two-lung ventilation, specifically the intraoperative Pao_2 during two-lung ventilation in the lateral position before OLV.[59] The proportion of perfusion or ventilation to the nonoperated lung on preoperative $\dot{V}/\dot{Q}$ scans also correlates with the Pao_2 during OLV.[60] If the operative lung has little perfusion preoperatively due to unilateral disease, the patient is unlikely to desaturate during OLV. The side of the thoracotomy has an effect on Pao_2 during OLV. Because the left lung is 10% smaller than the right there is less shunt when the left lung is collapsed. In a series of patients the mean Pao_2 during left thoracotomy was approximately 70 mm Hg higher than during right thoracotomy.[61] Finally, the degree of obstructive lung disease correlates in an inverse fashion with Pao_2 during OLV. Other factors being equal, patients with more severe airflow limitation on their preoperative spirometry will tend to have a better Pao_2 during OLV than patients with normal spirometry (this will be discussed below under "Anesthetic Management"; see Chapter 15).

Assessment for Repeat Thoracic Surgery

Patients who survive lung cancer surgery form a high-risk cohort to have a recurrence of the original tumor or to develop a second primary tumor. The incidence of developing a second primary

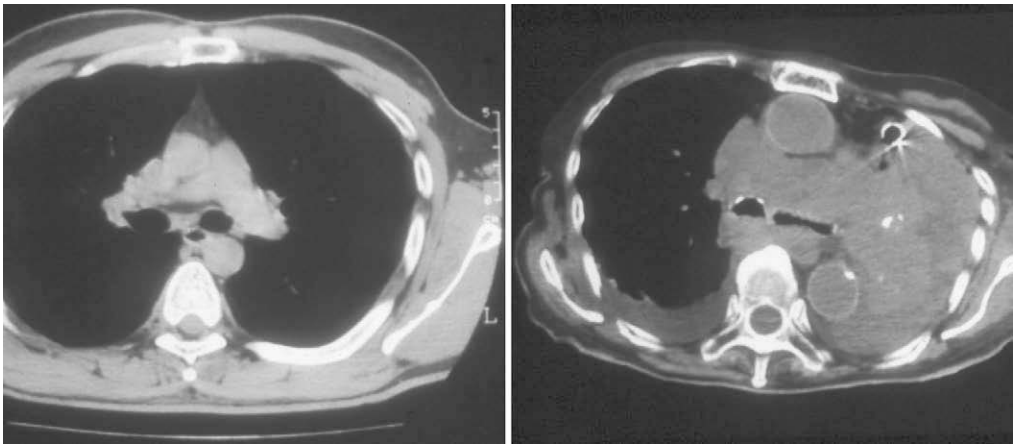

Figure 59-7 CT scans from just below the level of the carinal bifurcation. A normal scan is shown on the left. On the right is a scan from a 70-year-old woman scheduled for thoracoscopic left lung biopsy. The patient has a left-sided lung tumor and effusion that compresses the left mainstem bronchus. This bronchial compression was not evident on the chest radiograph. It may be difficult to place a left-sided double-lumen tube in this patient. (*Reproduced with permission from Slinger P: Anesthesia for lung resection surgery. In Thys D [ed]: Textbook of Cardiothoracic Anesthesia. New York, McGraw-Hill, 2001.*)

lung tumors is estimated at 2% per year. The use of routine screening low-dose spiral CT scans will probably increase the rate of early detection.[62] Patients who present for repeat thoracotomy should be assessed using the same framework as those who present for surgery the first time. Predicted values for postoperative respiratory function based on the preoperative lung mechanics, parenchymal function, exercise tolerance, and the amount of functioning lung tissue resected should be calculated and used to identify patients at increased risk.

Intraoperative Monitoring

General principles of monitoring are discussed in Chapters 38 and 44. A few points specific to intraoperative monitoring of the thoracic surgical patient need to be emphasized.

A majority of these operations are major procedures of moderate duration (2-4 hours) and performed in the lateral position with the hemithorax open. Thus, consideration for monitoring and maintenance of body temperature and fluid volume should be given to all of these cases. Because surgery is usually performed in the lateral position, monitors will initially be placed with the patient in the supine position and have to be rechecked and often repositioned after the patient is turned. It is often difficult to add additional monitoring, particularly invasive vascular monitoring, after the case is started if complications arise. Thus, the risk-benefit ratio often tends to favor being overly invasive at the outset. Several intraoperative complications that can occur during all types of surgery are more prone to occur during thoracotomy. Choice of monitoring should be guided by a knowledge of which complications are likely to occur (Table 59-7).

There are also complications that are more prone to occur with certain procedures, for example, hemorrhage from an extrapleural pneumonectomy, contralateral lung soiling with resection of an abscess or bronchiectasis, and air leak, hypoventilation, or tension pneumothorax with a bronchopleural fistula. Monitoring for these specific types of surgery will be directed in part by the intraoperative complications associated with the underlying disease.

Table 59-7 Intraoperative Complications That Occur with Increased Frequency during Thoracotomy

Complication	Etiology
Hypoxemia	Intrapulmonary shunt during one-lung ventilation
Sudden severe hypotension	Surgical compression of the heart or great vessels
Sudden changes in ventilating pressure or volume	Movement of endobronchial tube/blocker, air leak
Arrhythmias	Direct mechanical irritation of the heart
Bronchospasm	Direct airway stimulation, increased frequency of reactive airways disease
Massive hemorrhage	Surgical blood loss from great vessels or inflamed pleura
Hypothermia	Heat loss from the open hemithorax

Oxygenation

Significant desaturation (Spo_2 < 90%) during OLV occurs in 1% to 10% of the surgical population in spite of a high Fio_2 (1.0) (see "Management of One-lung Ventilation" later). For several reasons, pulse oximetry (Spo_2) has not negated the need for direct measurement of Pao_2 via intermittent blood gas analysis in the majority of thoracotomy patients. First, the Pao_2 value offers a more useful estimate of the margin of safety above desaturation than the SpO_2. A patient with a two-lung ventilation Pao_2 greater than 400 mm Hg with an Fio_2 of 1.0 (or an equivalent Pao_2/Fio_2 ratio) is unlikely to desaturate during OLV whereas a patient with a Pao_2 of 200 mm Hg is prone to desaturate during OLV, although both may have SpO_2 values of 99% to 100%. Second, the rapidity of the fall in Pao_2 after the onset of OLV is an indicator of the risk of subsequent desaturation. For this reason it is useful to measure Pao_2 by arterial blood gas analysis before OLV and 20 minutes after the start of OLV. Third, there are significant intermanufacturer differences in the accuracy of SpO_2 monitors. Although the trends are reliable, to use a specific cutoff of SpO_2 value as a guideline for treatment of hypoxemia the accuracy of the oximeter should be verified intraoperatively with arterial blood gas measurement. Also, during hypoxemia, SpO_2 sensor malpositioning can cause significant underestimation of saturation.

Capnometry

The end-tidal CO_2 ($Petco_2$) is a less reliable indicator of the $Paco_2$ during OLV than during two-lung ventilation, and the $Paco_2$- $Petco_2$ gradient tends to increase during OLV. Although the $Petco_2$ is less directly correlated with alveolar minute ventilation during OLV, because the $Petco_2$ also reflects lung perfusion and cardiac output it gives an indication of the relative changes in perfusion of the two lungs independently during position changes and during OLV.[63] As the patient is turned to the lateral position the $Petco_2$ of the nondependent lung will fall relative to the dependent lung, reflecting increased perfusion of the dependent lung and increased dead space of the nondependent lung. However, the fractional excretion of CO_2 will be higher from the nondependent lung in most patients owing to the increased fractional ventilation of this lung. Patients with higher fractional excretion of CO_2 from the dependent lung (i.e., better perfusion) during two-lung ventilation tend to have better Pao_2 values during OLV.[64]

At the onset of OLV the $Petco_2$ of the dependent lung will usually fall transiently as all the minute ventilation is transferred to this lung. The $Petco_2$ will then rise as the fractional perfusion is increased to this dependent lung by collapse and pulmonary vasoconstriction of the nonventilated lung. If there is no correction of minute ventilation, the net result will be both an increased baseline $Paco_2$ and $Petco_2$ with an increased gradient. However, severe (>5 mm Hg) or prolonged falls in $Petco_2$ can indicate an maldistribution of perfusion between ventilated and nonventilated lungs and may be an early warning of a patient who will subsequently experience desaturation during OLV (see Chapter 15).

Invasive Hemodynamic Monitoring

Arterial Line

There is a significant incidence of transient severe hypotension from surgical compression of the heart or great vessels during intrathoracic procedures. For this reason, plus the utility of intermittent arterial blood gas sampling, it is useful to have beat-to-beat assessment of systemic blood pressure during a majority of thoracic surgery cases. Naturally, exceptions occur during limited procedures such as thoracoscopic resections in younger and healthier patients. For most thoracotomies placement of a radial artery catheter can be in either the dependent or the nondependent arm.

Central Venous Pressures

Central venous pressure (CVP) monitoring and access is a routine for thoracic surgery in some centers. However, it is a common impression that CVP readings in the lateral position with the chest open are not reliable. The CVP is a useful monitor postoperatively, particularly for cases in which fluid management is critical (e.g., pneumonectomies). It is our practice to routinely place CVP lines in pneumonectomy patients but not for lesser resections unless there is significant other concurrent illness. For lobectomies that unforeseeably become pneumonectomies during the course of the surgery, a CVP catheter is placed at the end of the operation. Our choice is to use the right internal jugular vein to minimize the risk of pneumothorax for CVP access unless there is a contraindication. Internal jugular CVP data are not reliable in patients with superior vena cava obstruction.

Pulmonary Artery Catheters

Similar to CVP data, intraoperative pulmonary artery pressure may be a less accurate indicator of true left heart preload in the lateral position with the chest open than in other clinical situations. This is partly because it is often initially not known if the catheter tip lies in the dependent or nondependent lung. Also, it is possible that thermodilution cardiac output data may be unreliable if there are significant transient unilateral differences in perfusion between the lungs, as can occur during OLV and positive pressure. There is no consensus on the reliability of thermodilution cardiac output data during OLV.

When left-sided pulmonary artery catheter placement is required it can be achieved in 50% of patients (versus the usual 10%) by floating the catheter into the pulmonary artery when the patient is in the right lateral position.[65] It is usually possible for the surgeon to confirm the placement of the pulmonary artery catheter once the chest is open. It is extremely important to remember that a pulmonary artery catheter ipsilateral to the side of surgery must be withdrawn before vascular clamping or it could be transected. Complications from the use of pulmonary artery catheters including arrhythmias, hemorrhage, pulmonary infarction, and so on are well documented.[66] Also, if a pulmonary artery catheter is in the nonventilated lung it frequently becomes accidentally wedged without balloon inflation as the lung collapses. The risk-benefit ratio for the routine use of pulmonary artery catheters for pulmonary resection surgery favors their use only in certain specific cases, such as patients with major coexisting disease (e.g., cardiac, renal) or having particularly extensive procedures (e.g., extrapleural pneumonectomy).

Fiberoptic Bronchoscopy

Placement of DLTs and bronchial blockers is discussed later in the section on "Lung Isolation." Significant malpositions of DLTs and blockers that can lead to desaturation during OLV are often not detected by auscultation or other traditional methods of confirming placement.[67] Placement of DLTs or blockers should be performed with fiberoptic bronchoscopic guidance and should be reconfirmed after placing the patient in the surgical position because a large number of these tubes/blockers migrate during repositioning of the patient.[68]

Continuous Spirometry

The development of side-stream spirometry has made it possible to continuously monitor inspiratory and expiratory volumes, pressures, and flow interactions during one-lung anesthesia. This monitoring is particularly useful during pulmonary resection surgery. The breath-by-breath monitoring of inspired and expired tidal volumes gives early warning of accidental changes in the intraoperative position of a DLT, with loss of lung isolation if the expired volume suddenly decreases (there is normally a 20- to 30-mL/breath difference owing in part to the uptake of inspired oxygen). The development of a persistent end-expiratory flow during OLV, which correlates with the development of auto-PEEP, can be seen on the flow-volume loop. Also, the ability to accurately measure differences in inspiratory and expiratory tidal volumes is extremely useful to aid the surgeon in assessing and managing pulmonary air leaks during pulmonary resections.

Transesophageal Echocardiography

Transesophageal echocardiography (TEE) allows the anesthesiologist to have a continuous real-time monitor of myocardial function and cardiac preload (see Chapter 41). This information is difficult to estimate intraoperatively in the lateral position from other hemodynamic monitors. However, there are also disincentives to the routine use of TEE in thoracic surgery. The equipment is cumbersome and expensive, and there is a specific expertise required to obtain and interpret the images.[69] Also, many thoracic surgical patients have esophageal pathology precluding TEE and there is the potential for laryngopharyngeal trauma when both a DLT and a TEE probe are placed in smaller patients. The American Society of Anesthesiologists and Society of Cardiovascular Anesthesiologists have published indications for the use of perioperative TEE.[70] Potential indications for the intraoperative TEE that apply to thoracic surgery include hemodynamic instability (Fig. 59-8), pericardial effusions, cardiac involvement by tumor, air emboli, pulmonary thromboendarterectomy, thoracic trauma, lung transplantation, and pleuropulmonary disease (Table 59-8).

Assessment of right ventricular function is a very appealing potential use for TEE, particularly in patients with limited cardiac reserves who are having major pulmonary resections. Right ventricular ejection fraction catheters have been tried for this purpose but have not gained wide acceptance, probably owing to the errors in the measurements. Quantitative assessment of right ventricular function is a valid procedure when performed by transthoracic echocardiography.[71] However, owing to imaging difficulties, at present TEE is commonly used only for qualitative assessment of the right ventricle.

A rare cause of hypoxemia associated with thoracic surgery is reversal of shunt flow through an undiagnosed patient foramen

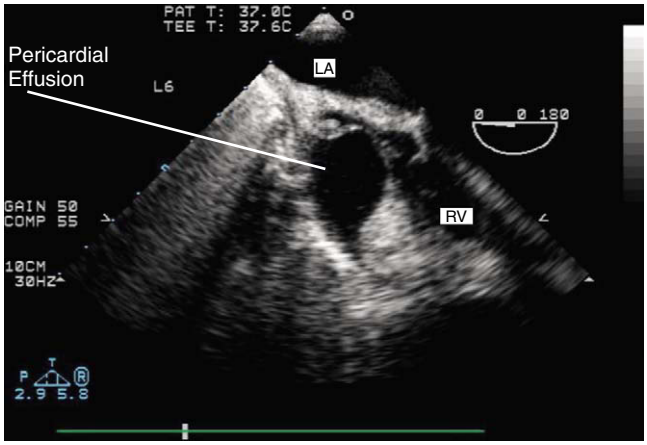

Figure 59-8 Transesophageal echocardiography (TEE), midesophageal view, in patient with metastatic breast cancer who had a hemodynamic collapse after induction of general anesthesia for a VATS drainage of a left pleural effusion. TEE was performed for diagnosis of hemodynamic instability. TEE revealed a previously undiagnosed large pericardial effusion. The "Pericardial Effusion" label shows complete collapse of the right atrium during systole due to the effusion, consistent with tamponade. The VATS procedure was modified to include creation of a pericardial window. LA, left atrium; RV, right ventricle. VATS, video-assisted thoracoscopic surgery.

ovale. When PEEP (to 15 cm H_2O) was applied during controlled ventilation for nonthoracic surgery 9% of patients developed a right-to-left intracardiac shunt.[72] TEE should be capable of detecting patients who might intraoperatively develop a right-to-left interatrial shunt during or after thoracic surgery.

Lung-Isolation Techniques

Lung-isolation techniques are primarily designed to facilitate OLV in patients undergoing cardiac, thoracic, mediastinal, vascular, esophageal, or orthopedic procedures involving the chest cavity.[73] Lung isolation is also used to protect the lung from soiling by the contralateral lung in such cases as bronchopleural fistula, pulmonary hemorrhage, and whole-lung lavage. And, lung isolation can be used to provide differential patterns of ventilation in cases of unilateral reperfusion injury (after lung transplantation or pulmonary thromboendarterectomy) or in unilateral lung trauma.

Lung isolation can be achieved by three different methods: DLTs, bronchial blockers, or single-lumen endobronchial tubes (SLTs) (Table 59-9). The most common technique is with a DLT. The DLT is a bifurcated tube with both an endotracheal and an endobronchial lumen and can be used to achieve isolation of either the right or the left lung. The second method involves blockade of a mainstem bronchus to allow lung collapse distal to the occlusion. These bronchial blockers can be used with an standard endotracheal tube or contained within a separate channel inside a modified SLT such as the Univent tube. The final option for lung isolation is to use either an SLT or endobronchial tube that is advanced into the contralateral mainstem bronchus, protecting this lung while allowing collapse of the lung on the side of surgery (Fig. 59-9). This technique is rarely used today in adult practice (except in some cases of difficult airways, emergencies, or after a pneumonectomy), owing to the limited access to the nonventilated lung and the difficulty in positioning a standard SLT in the bronchus. This technique is still used when needed in infants and small children: an uncuffed uncut pediatric size endotracheal is advanced into the mainstem bronchus under direct guidance with an infant bronchoscope.

Double-Lumen Endotracheal Tubes

The use of the Carlens design of DLT (Fig. 59-10) for lung surgery in 1950 was a landmark in the development of thoracic anesthesia because it allowed anesthesiologists to obtain reliable lung isolation in a majority of patients using only laryngoscopy and auscultation. However, the Carlens tube had a high flow resistance owing to the narrow lumens and also the carinal hook was difficult to pass through the glottis in some patients. In the 1960s, Robertshaw introduced design modifications for separate left- and right-sided DLTs, removing the carinal hook and using larger lumens. In the 1980s, manufacturers introduced disposable DLTs made of polyvinyl chloride based on the design of the Robertshaw DLT. Among other subsequent improvements is the inclusion of radiographic markers near the endotracheal and endobronchial cuffs and a radiographic marker surrounding the ventilation slot for the right upper lobe bronchus for the right-sided DLT version. Bright blue, low-volume, low-pressure endobronchial cuffs are incorporated for easier visualization during fiberoptic bronchoscopy. Table 59-10 lists the different sizes of DLT, the appropriate fiberoptic bronchoscope sizes to be used, and the comparable diameters of SLTs.

Size Selection

A properly sized, left-sided DLT should have a bronchial tip 1 to 2 mm smaller than the patient's left bronchus diameter to allow

Table 59-9 Options for Lung Isolation

Options	Advantages	Disadvantages
Double-lumen tube 1. Direct laryngoscopy 2. Via tube exchanger 3. Fiberoptically	Quickest to place successfully Repositioning rarely required Bronchoscopy to isolated lung Suction to isolated lung CPAP easily added Can alternate OLV to either lung easily Placement still possible if bronchoscopy not available	Size selection more difficult Difficult to place in patients with difficult airways or abnormal tracheas Not optimal for postoperative ventilation Potential laryngeal trauma Potential bronchial trauma
Bronchial blockers (BB) Arndt Cohen Fuji	Size selection rarely an issue Easily added to regular ETT Allows ventilation during placement Easier placement in patients with difficult airways and in children Postoperative two-lung ventilation by withdrawing blocker Selective lobar lung isolation possible CPAP to isolated lung possible	More time needed for positioning Repositioning needed more often Bronchoscope essential for positioning Nonoptimal right lung isolation due to RUL anatomy Bronchoscopy to isolated lung impossible Minimal suction to isolated lung Difficult to alternate OLV to either lung
Univent tube	Same as BBs Less repositioning compared with BBs	Same as for BBs ETT portion has higher air flow resistance than regular ETT ETT portion has larger diameter than regular ETT
Endobronchial tube	Like regular ETTs, easier placement in patients with difficult airways Longer than regular ETT Short cuff designed for lung isolation	Bronchoscopy necessary for placement Does not allow for bronchoscopy, suctioning or CPAP to isolated lung Difficult right lung OLV
Endotracheal tube (ETT) advanced into bronchus	Easier placement in patients with difficult airways	Does not allow for bronchoscopy, suctioning or CPAP to isolated lung Cuff not designed for lung isolation Extremely difficult right OLV

CPAP, continuous positive airway pressure; ETT, endotracheal tube; OLV, one-lung ventilation; RUL, right upper lobe.

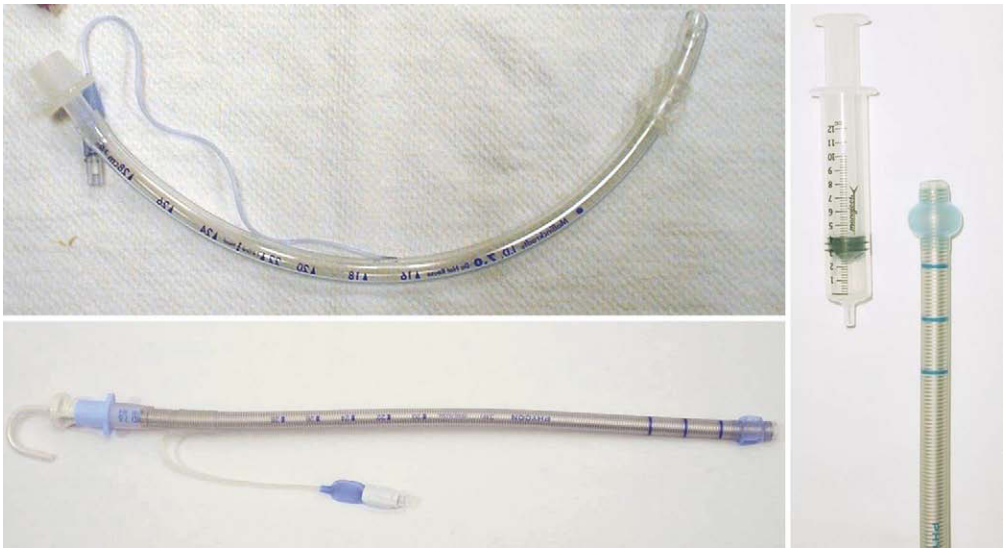

Figure 59-9 Photographs of a standard single-lumen endotracheal tube (*upper left*) and a specifically designed single-lumen endobronchial tube (*lower left and right*). The endobronchial tube is longer and has a shorter cuff. It can be used as an endotracheal tube and advanced into a mainstem bronchus with fiberoptic guidance when needed for lung isolation. for the space occupied by the deflated bronchial cuff. A study by Eberle and associates[74] used a three-dimensional image reconstruction of tracheobronchial anatomy from the spiral CT scans combined with superimposed transparencies of DLTs to predict proper size for a right- or left-sided DLT. Chest radiographs and CT scans are valuable tools for selection of proper DLT size in addition to their proven value in assessment of abnormal tracheobronchial anatomy and should be reviewed before the placement of the DLT. A simplified method of selection of DLT size is given in Table 59-11. It is important to appreciate that, compared with

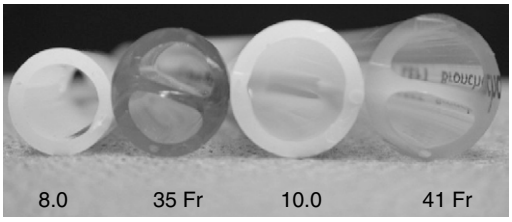

Figure 59-11 Photograph of the cut cross-sections of several single- and double-lumen tubes (DLTs). Note that the external diameter of a 35-Fr DLT is larger than that of an 8.0 mm (ID) single-lumen tube and a 41-Fr DLT is larger than a 10-mm single-lumen tube. (*Photograph courtesy of Dr. J. Klafta.*)

SLTs, DLTs have a large external diameter (Fig. 59-11) and they should not be advanced against significant resistance.

Methods of Insertion

Two techniques are used commonly when inserting and placing a DLT. One is the blind technique: the DLT is passed with direct laryngoscopy and then turned 90 degrees counterclockwise (for a left-sided DLT placement) after the endobronchial cuff has passed beyond the vocal cords. The DLT should pass the glottis without any resistance. Seymour[75] showed that the mean diameter of the cricoid ring is approximately the same as that of the left mainstem bronchus. The optimal depth of insertion for a left-sided DLT is strongly correlated with the patient's height in average-sized adults. In adults, depth, measured at the teeth, for a properly positioned DLT will be approximately 12 + (patient

height/10) cm.[76] In patients of Asian descent, which comprises many individuals of shorter stature (<155 cm), patient height is not a good predictor of depth of insertion of a DLT.[77] An inadvertently deep insertion of a DLT can lead to serious complications, including rupture of the left mainstem bronchus. Figure 59-12 depicts the blind method technique for insertion of a left-sided DLT.

The direct vision technique uses bronchoscopic guidance, in which the tip of the endobronchial lumen is guided into the correct bronchus after the DLT passes the vocal cords using direct vision with a flexible fiberoptic bronchoscope. A study by Boucek and associates[78] comparing the blind technique versus fiberoptic bronchoscopy-guided technique showed that of the 32 patients who underwent the blind technique approach, primary success occurred in 27 patients and eventual success occurred in 30 patients. In contrast, in the 27 patients using the bronchoscopy-guided technique, primary success was achieved only in 21 patients and eventual success in 25 patients. Although both methods resulted in successful left mainstem bronchus placement in all patients, more time was required when fiberoptic bronchoscopy guidance technique was used (88 versus 181 seconds).

Right-Sided Double-Lumen Endobronchial Tubes

Although a left-sided DLT is used more commonly for most elective thoracic procedures,[79] there are specific clinical situations in which the use of a right-sided DLT is indicated (Table 59-12). The anatomic differences between the right and the left mainstem bronchus are reflected in the fundamentally different designs of the right-sided and left-sided DLTs. Because the right mainstem bronchus is shorter than the left bronchus and because the right upper lobe bronchus originates at a distance of 1.5 to 2 cm from the carina, techniques using right endobronchial intubation must take into account the location and potential for obstruction of the orifice of the right upper lobe bronchus. The right-sided DLT incorporates a modified cuff, or slot, on the endobronchial side that allows ventilation for the right upper lobe (Fig. 59-13).[80]

Table 59-12 Indications for a Right-Sided Double-Lumen Tube*

Distorted Anatomy of the Entrance of Left Mainstem Bronchus

Left lung transplantation
Left-sided tracheobronchial disruption
Left-sided pneumonectomy†
Left-sided sleeve resection

*This is a common clinical practice pattern for using right-sided DLTs and assumes normal tracheobronchial anatomy—specifically, a normal position of the orifice of the right upper lobe. However, some clinicians prefer to use right DLTs for all left-sided surgery.

†It is possible to manage a left pneumonectomy with a left-sided DLT or bronchial blocker. However, the tube or blocker will have to be withdrawn before stapling the left mainstem bronchus.

Positioning of Double-Lumen Tubes

Auscultation alone is unreliable for confirmation of proper DLT placement. Auscultation (Fig. 59-14) and bronchoscopy should both be used each time a DLT is placed and again when the patient is repositioned. Fiberoptic bronchoscopy is performed first through the tracheal lumen to ensure that the endobronchial portion of the DLT is in the left bronchus and that there is no bronchial cuff herniation over the carina after inflation. Through the tracheal view, the blue endobronchial cuff ideally should be seen approximately 5 mm below the tracheal carina in the left bronchus. It is crucial to identify the takeoff of the right upper lobe bronchus through the tracheal view. Going inside this right upper lobe with the bronchoscope should reveal three orifices (apical, anterior, and posterior). This is the only structure in the tracheobronchial tree that has three orifices. In the supine patient the takeoff of the right upper lobe is normally on the lateral wall of the right mainstem bronchus at the 3- to 4-o'clock position in relation to the main carina (Fig. 59-15). Broncho-Cath tubes from Mallinckrodt have a radiopaque line encircling the tube. This line is proximal to the bronchial cuff and can be useful while positioning a left-sided DLT. The radiopaque marker is 4 cm from the distal tip of the endobronchial lumen. This marker reflects white during fiberoptic visualization and, when positioned slightly above the tracheal carina, should provide the necessary margin of safety for positioning into the left mainstem bronchus.[81] The next observation with the fiberoptic bronchoscope is made through the endobronchial lumen to check for patency of the tube and determination of margin of safety. The orifices of both the left upper and lower lobes must be identified to avoid distal impaction in the left lower lobe and occlusion of the left-upper lobe (Fig. 59-16). Figure 59-17 displays the

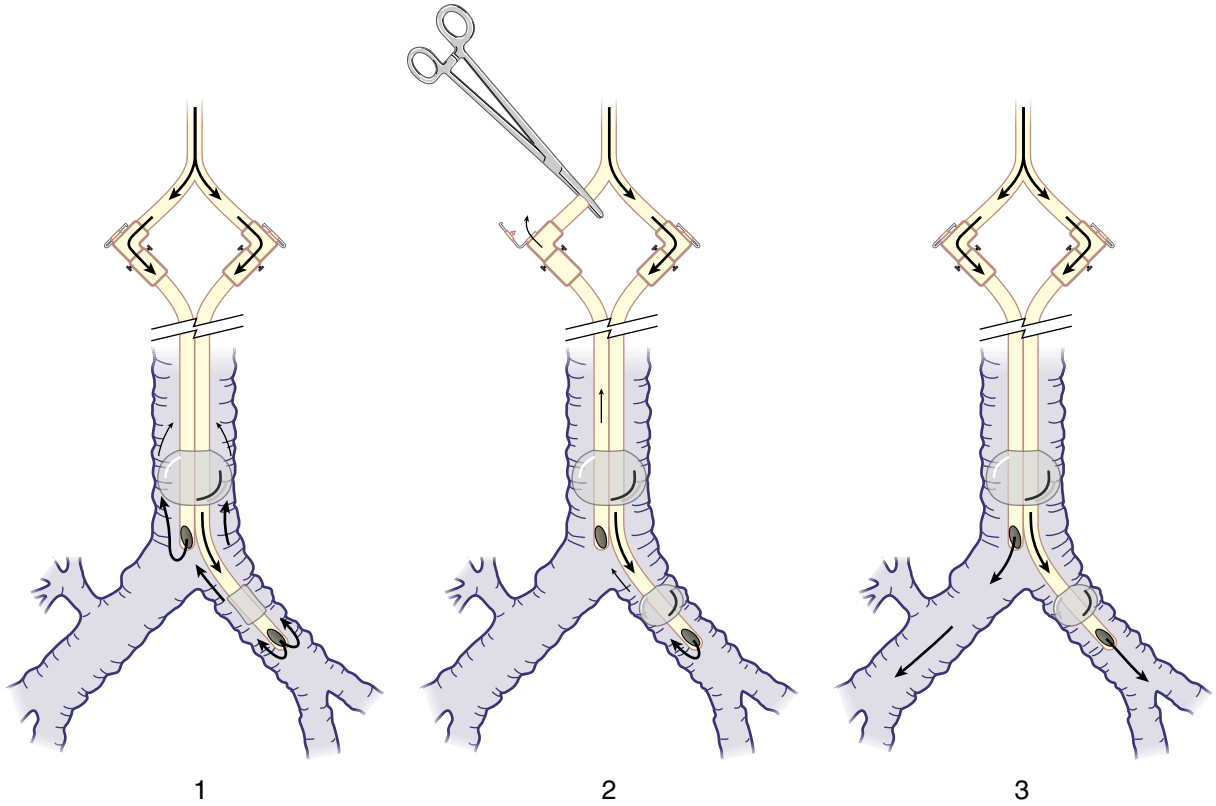

Figure 59-14 A "three-step" method to confirm position of a left DLT by auscultation: *Step 1.* During bilateral ventilation, the tracheal cuff is inflated to the minimal volume that seals the air leak at the glottis. Auscultate to confirm bilateral ventilation. *Step 2.* The tracheal lumen of the DLT is clamped proximally ("clamp the short side short") and the port distal to the clamp opened. During ventilation via the bronchial lumen the bronchial cuff is inflated to the minimal volume that seals the air leak from the open tracheal lumen port. Auscultate to confirm correct unilateral ventilation. *Step 3.* The tracheal lumen clamp is released and the port closed. Auscultate to confirm resumption of bilateral breath sounds. tracheobronchial anatomy along with fiberoptic bronchoscopy findings from the endotracheal or endobronchial lumen for a left-sided DLT.

Problems Related to Double-Lumen Tubes

The most common problems and complications associated with the use of a DLT are malposition and airway trauma. A malpositioned DLT will fail to allow collapse of the lung, causing gas trapping during positive-pressure ventilation, or it may partially collapse the ventilated or dependent lung, producing hypoxemia. A common cause of malposition is dislodgment of the endobronchial cuff because of overinflation, surgical manipulation of the bronchus, or extension of the head and neck during or after patient positioning. Fiberoptic bronchoscopy is the recommended method to diagnose and correct intraoperative malposition of DLTs. If a DLT is malpositioned in the supine or lateral decubitus position, there is a greater likelihood of hypoxemia during OLV.[82] If a DLT is in the optimal position, but lung deflation is not completely achieved, a suction catheter should be passed to the side where lung collapse is supposed to occur. This suction will expedite lung deflation. The suction catheter must then be removed to avoid including it in a suture line.

Airway trauma and rupture of the membranous part of the trachea or the bronchus is a potential complication with the use

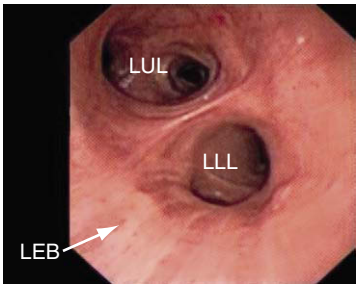

Figure 59-16 The view from the distal bronchial lumen of a well-positioned left-sided double-lumen tube. Both the orifices of the left upper lobe (LUL) and left lower lobe (LLL) can be identified. Note the longitudinal elastic bundles (LEB, *arrow*). These extend down the posterior membranous walls of the trachea and mainstem bronchi. They are useful landmarks to orient the bronchoscopist to anteroposterior directions. In the left mainstem bronchus they extend into the left lower lobe and are a useful landmark to distinguish the lower from the upper lobe.

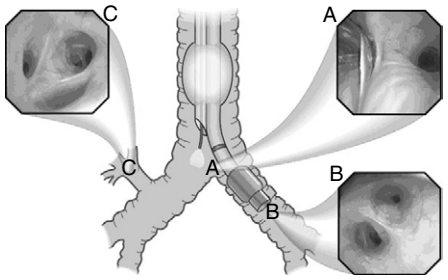

Figure 59-17 Fiberoptic bronchoscopic examination of a Mallinckrodt left-sided double-lumen tube. **A,** The edge of the endobronchial cuff around the entrance of the left mainstem bronchus when the bronchoscope is passed through the tracheal lumen. A white line marker is seen above the tracheal carina. **B,** Clear view of the bronchial bifurcation (left upper and left lower bronchi) when the left-sided DLT is in the optimal position and the fiberoptic bronchoscope is being advanced through the endobronchial lumen. **C,** Clear view of the right upper lobe bronchus and its three orifices: apical, anterior, and posterior segments. (*Reproduced with permission from Campos JH: Progress in lung separation. Thorac Surg Clin 15:71, 2005.*)

of DLTs.[83] Airway trauma can occur from an oversized DLT or when an undersized DLT migrates distally into the bronchus and the main (i.e., tracheal) body of the DLT comes into the bronchus, producing lacerations or rupture of the airway. Airway damage during the use of DLTs can present an unexpected air leak, subcutaneous emphysema, massive airway bleeding into the lumen of the DLT, or protrusion of the endotracheal or endobronchial cuffs into the surgical field, with visualization of this by the surgeon. If any of the above-mentioned problems occur, a bronchoscopic examination and surgical repair should be performed. Another potential problem is the development of a tension pneumothorax in the dependent, ventilated, lung during OLV.[84]

Bronchial Blockers

An alternative method to achieve lung separation involves blockade of a mainstem bronchus to allow lung collapse distal to the occlusion. Bronchial blockers also can be used selectively to achieve lobar collapse if necessary.[73] Currently, there are several different bronchial blockers available to facilitate lung separation. These devices are either within a modified SLT as an enclosed bronchial blocker (Torque Control Blocker Univent; Vitaid, Lewinston, NY) or are used independently with a conventional SLT, the Arndt wire-guided endobronchial blocker (Cook Critical Care, Bloomington, IN), the Cohen tip-deflecting endobronchial blocker (Cook Critical Care, Bloomington, IN), and the Fuji Uniblocker (Vitaid, Lewinston, NY).

There are specific conditions in which a bronchial blocker may be preferred to a DLT, such as patients with previous oral or neck surgery who present with a challenging airway and require lung separation for intrathoracic surgery. In these cases the use of an SLT during an awake nasotracheal, or orotracheal, intubation or via tracheostomy secures the airway and thereafter an independent bronchial blocker can be placed to achieve lung separation. Another group of patients who may benefit from the use of bronchial blockers are those cancer patients who have undergone a previous contralateral pulmonary resection. In such cases selective lobar blockade with a bronchial blocker in the ipsilateral side improves oxygenation and facilitates surgical

Table 59-13 Characteristics of the Cohen, Arndt, and Fuji Bronchial Blockers

	Cohen Blocker	Arndt Blocker	Fuji Uniblocker
Size	9 Fr	5 Fr, 7 Fr, and 9 Fr	5 Fr, 9 Fr
Balloon shape	Spherical	Spherical or elliptical	Spherical

exposure. Bronchial blockers are most commonly used intraluminal (coaxial) with an SLT. They can also be placed separately thorough the glottis or tracheostomy exterior to an SLT. This allows the use of a smaller SLT and is often an option in pediatrics. Another advantage of the bronchial blockers is when postoperative mechanical ventilation is being considered after prolonged thoracic or esophageal surgery. In many instances these patients have an edematous upper airway at the end of the procedure. If a bronchial blocker is used there is no need to change the SLT and there is no compromise of the airway if mechanical ventilation is needed in the postoperative period. Table 59-13 describes the characteristics of current bronchial blockers. The smallest internal diameter (ID) of an endotracheal tube that will allow passage of both a bronchial blocker and a fiberoptic bronchoscope depends on the diameters of the bronchoscope and blocker. For standard adult 9-Fr blockers, an endotracheal tube greater than or equal to 7.0 mm ID can be used with a bronchoscope less than 4.0 mm in diameter. Larger bronchoscopes will require an endotracheal tube greater than 7.5 mm ID. All blockers need to be well lubricated before placement.

Torque Control Blocker (Univent)

Placement of the Univent is straightforward (Fig. 59-18). The enclosed bronchial blocker is fully retracted into the standard lumen of the tube. Conventional endotracheal tube intubation technique is used. Then a fiberoptic bronchoscope is passed into the main lumen through a bronchoscopy adaptor. Under direct vision the enclosed bronchial blocker is advanced into the targeted bronchus of the surgical side, where lung collapse is to occur.

The Wire-Guided Endobronchial Blocker (Arndt Blocker)

Figure 59-19 displays the placement of the Arndt blocker by placing the endobronchial blocker through the endotracheal tube and using the fiberoptic bronchoscope and wire-guided loop to direct the blocker into a mainstem bronchus. The fiberoptic bronchoscope has to be advanced distally enough so that the Arndt blocker enters the bronchus while it is being advanced. When the deflated cuff is beyond the entrance of the bronchus approximately 2 cm inside the bronchus, then the fiberoptic bronchoscope is withdrawn. Once the patient is turned into a lateral decubitus position then the cuff of the endobronchial blocker is fully inflated with fiberoptic visualization with 4 to 6 mL of air to obtain total bronchial blockade. For a right mainstem bronchus blockade, the Arndt blocker can be advanced independently of the wire loop by observing its entrance into the right mainstem bronchus under fiberoptic visualization. The optimal position of the Arndt blocker in the left or in the right bronchus is achieved when the blocker balloon's outer surface is seen with the fiberop-

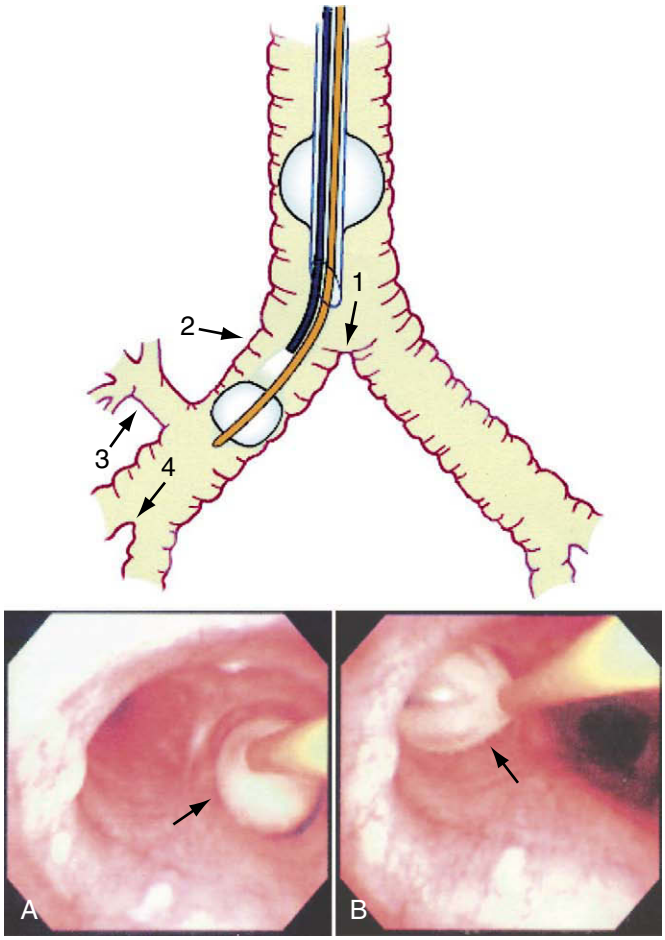

Figure 59-18 Univent torque control blocker. The optimal position of the Univent torque control blocker in the right (**A**) and left (**B**) mainstem bronchus. Figure 59-19 Placement of the Arndt wire-guided endobronchial blocker. **A,** Coupling of the nylon wire loop and the fiberoptic bronchoscope through a single-lumen endotracheal tube. **B,** The Arndt blocker along with the fiberoptic bronchoscope is advanced together inside the left mainstem bronchus. **C,** Disengagement of the blocker by withdrawing the fiberoptic bronchoscope.

tic bronchoscope at least 5 mm below the tracheal carina in the target bronchus and the proper seal is obtained.

Cohen Endobronchial Blocker

The Cohen blocker uses a wheel located in the most proximal part of the unit that deflects the tip of the distal part of the blocker into the desired bronchus. This blocker has been pre-angled at the distal tip to facilitate insertion into a target bronchus. On the distal shaft above the balloon, there is an arrow that, when seen with the fiberoptic bronchoscope, indicates in which direction the tip deflects. To position the Cohen blocker, the arrow is aligned with the bronchus to be intubated, the proximal wheel is turned to deflect the tip toward the desired side and then the blocker is advanced with fiberoptic guidance.

Fuji Uniblocker

The Fuji Uniblocker is an independent blocker that is made of silicone material and has a fixed distal angulation to facilitate insertion. Methods of placement and insertion are similar to the ones described for the Cohen blocker but without the wheel device. The optimal position of this device is achieved after the patient is turned into the lateral decubitus position. The characteristics of the independent bronchial blockers are presented in Table 59-13.

Complications Related to the Bronchial Blockers

A complication seen with early versions of the Univent occurred when a fracture of the blocker cap connector was found.[73] Failure to achieve lung separation because of abnormal anatomy or lack of a seal within the bronchus also has been reported.[85] Inclusion of the bronchial blocker or the distal wire loop of an Arndt blocker into the stapling line has been reported during a right upper lobectomy[86] and required surgical reexploration after unsuccessful removal of the bronchial blocker after extubation. To avoid these mishaps communication with the surgical team regarding the presence of a bronchial blocker in the surgical side is crucial and if the blocker is near the staple line. Clearly, the bronchial blocker needs to be withdrawn a few centimeters before stapling.

Another potentially dangerous complication with all bronchial blockers is that the inflated balloon may move and lodge above the carina or be accidentally inflated in the trachea. This leads to inability to ventilate, hypoxia, and potentially cardiorespiratory arrest unless quickly recognized and the blocker deflated.[87] There is a report of a sheared balloon of the Arndt blocker that occurred when the blocker was removed through the multiport blocker side port.[88] It is advised that when an independent bronchial blocker is not in use it needs to be removed with the multiport connector in place rather than through the connector.

Difficult Airways and One-Lung Ventilation

A number of patients requiring OLV are identified during preoperative evaluation to have a potentially difficult airway. Others present with unexpected difficulty to intubate after induction of anesthesia. Between 5% and 8% of patients with primary lung carcinoma also have a carcinoma of the pharynx, usually in the epiglottic area.[89] Many of these patients have had previous radiation therapy on the neck or previous airway surgery, such as hemi-mandibulectomy or hemiglossectomy, making intubation and achievement of OLV difficult due to distorted upper airway anatomy. Also, a patient who requires OLV might have distorted anatomy at or beyond the tracheal carina, such as descending thoracic aortic aneurysm compressing the entrance of the left mainstem bronchus or an intraluminal or extraluminal tumor near the tracheobronchial bifurcation that makes the insertion of

a left-sided DLT relatively difficult or impossible. Such anomalies can be detected by reviewing the chest radiographs and CT scans of the chest (see Fig. 59-7). A flexible fiberoptic bronchoscopic examination is necessary to assess a distorted area of the airway before selection of a specific tube or blocker to achieve OLV.

In patients who require OLV and present with a difficult airway, the primary goal is to establish an airway with an SLT placed orally with the aid of a flexible fiberoptic bronchoscope, after appropriate airway anesthesia is achieved. In selected patients who seem easy to ventilate, this may be performed after induction of anesthesia with a bronchoscope or with a videolaryngoscope.[90] Once the SLT is in place, an independent bronchial blocker can be passed. If the patient requires OLV and cannot be intubated orally, an awake nasotracheal intubation can be performed with an SLT and, once the airway is established, then a bronchial blocker can be passed.

An alternative to achieve OLV in a patient with a difficult airway is to intubate the patient's trachea with an SLT; then a tube-exchange technique can be used to replace the existing SLT for a DLT after general anesthesia is induced. A tube-exchange catheter should have a hollow center channel and universal adapters to insufflate oxygen or be connected to a jet ventilator if necessary. The exchange catheter must be flexible, be long, and have markings on the outer surface to control the depth of insertion while in use. For a DLT the exchange catheter should be at least 83 cm. A 14-Fr exchange catheter can be used for 41-Fr and 39-Fr DLTs; for 37-Fr or 35-Fr DLTs an 11-Fr exchange catheter is used. Specially designed exchange catheters for DLTs are available with a softer distal tip to try to decrease the risk of distal airway trauma (e.g., Cook Exchange Catheter, Cook Critical Care, Bloomington, IN).

The exchange catheter, SLT, and the DLT combination should be tested in vitro before the exchange. A sniffing position facilitates tube exchange. After the exchange catheter is lubricated, it is advanced through an SLT. The catheter should not be inserted deeper than 24 cm at the lips to avoid accidental rupture or laceration of the trachea or bronchi. After cuff deflation, the SLT is withdrawn. Then the endobronchial lumen of the DLT is advanced over the exchange catheter. It is optimal to use a videolaryngoscope during the tube exchange to guide the DLT thorough the glottis under direct vision. If a videolaryngoscope is not available, having an assistant perform standard laryngoscopy during tube exchange partially straightens out the alignment of the oropharynx and glottis and facilitates the exchange. Proper final position of the DLT is then achieved with auscultation and bronchoscopy.

Lung-Isolation Techniques in Patients with a Tracheostomy in Place

Placement of a DLT through a tracheostomy stoma may be prone to malposition because the upper airway has been shortened and the conventional DLT may be too long. Before placing any lung-isolation devices through a tracheostomy stoma it is important to consider whether it is a fresh stoma (i.e., a few days old, when the airway can be lost immediately on decannulation) versus a chronic tracheostomy. The alternatives to achieve OLV in a tracheostomized patients include (1) insertion of an SLT followed by an independent bronchial blocker[91]; (2) the use of a disposable cuffed tracheostomy cannula with an independent bronchial blocker passed coaxially; (3) replacement of the tracheostomy cannula with a specially designed short DLT such as the Naruke DLT, which is made for use in tracheostomized patients[92]; (4) placement of a small DLT through the tracheostomy stoma; or (5) if possible, oral access to the airway for standard placement of a DLT or blocker (this is occasionally an option in patients on prolonged mechanical ventilation for respiratory failure or postoperative complications).

In summary, the optimal method of lung isolation will depend on a number of factors, including the patient's airway anatomy, the indication for lung isolation, the available equipment, and the training of the anesthesiologist. Suggested methods for lung isolation in specific clinical situations are listed in Table 59-14. Whatever method of lung isolation is used, the "ABCs" of lung isolation are:

*A*natomy. Know the tracheobronchial anatomy. One of the major problems that many anesthesiologists have in achieving satisfactory lung isolation is due to lack of familiarity with distal airway anatomy (Fig. 59-20).

*B*ronchoscopy. Whenever possible use a fiberoptic bronchoscope to position endobronchial tubes and blockers. The ability to perform fiberoptic bronchoscopy is now a fundamental skill needed by all anesthesiologists providing anesthesia for thoracic surgery. An online bronchoscopy simulator has been developed to help train anesthesiologists in positioning DLTs and blockers. This simulator, which uses real-time video, is available without cost at www.thoracicanesthesia.com.

*C*hest imaging. The anesthesiologist should always look at the chest imaging before placement of a DLT or blocker. Abnormalities of the lower airway can often be identified in advance, and this will have an impact on the selection of the optimal method of lung isolation for a specific case (see Figs. 59-6 and 59-7).

Positioning

The majority of thoracic procedures are performed with the patient in the lateral position, most often the lateral decubitus position, but, depending on the surgical technique, a supine, semisupine, or semiprone lateral position may be used (see Chapter 36). These lateral positions have specific implications for the anesthesiologist.

Position Change

It is awkward to induce anesthesia with the patient in the lateral position. Thus, monitors will be placed and anesthesia will usually be induced with the patient in the supine position and the anesthetized patient will then be repositioned for surgery. It is possible to induce anesthesia in the lateral position, and this may rarely be indicated with unilateral lung diseases such as bronchiectasis or hemoptysis until lung isolation can be achieved. However, even these patients will then have to be repositioned and the diseased lung turned to the nondependent side.

Because of the loss of venous vascular tone in the anesthetized patient it is not uncommon to see hypotension on turning the patient to or from the lateral position. All lines and monitors will have to be secured during position change and their function

Table 59-14 Suggested Methods of Lung Isolation for Specific Indications

Indication for Lung Isolation	Preferred Method(s)	Possible Alternative(s)
Pulmonary resection right side	Left DLT	BB/Left EBT
Pulmonary resection left side:		
Pneumonectomy unlikely	Left DLT	BB/Right DLT
Pneumonectomy	Right DLT	Left DLT/BB
Thoracoscopy (either side)	Left DLT	BB/Right DLT
Pulmonary hemorrhage	Left DLT	BB/contra-lateral EBT
Bronchopleural fistula		
Left mainstem bronchus	Right DLT	EBT
All other sites	Left DLT	Right DLT/BB/EBT
Purulent secretions (e.g., abscess, cyst, etc.)	Left DLT	Right DLT/BB/EBT
Bullae, blebs	Left DLT	Right DLT/BB
Nonpulmonary surgery (e.g., thoracic aorta, esophagus)	Left DLT/BB	Right DLT/EBT
Bronchial surgery (tumor, trauma)		
Left side	Right DLT	EBT
Right side	Left DLT	EBT
Upper airway abnormalities	BB	Left DLT/EBT
Lung transplantation:		
Bilateral	Left DLT	BB/EBT
Single right lung	Left DLT	BB/EBT
Single left lung	Right DLT	BB/Left DLT/EBT
Whole lung lavage	Left DLT	
Independent lung ventilation	Left DLT	Right DLT

BB, ipsilateral bronchial blocker; DLT, Double-lumen tube; EBT, contralateral single-lumen endobronchial tube.

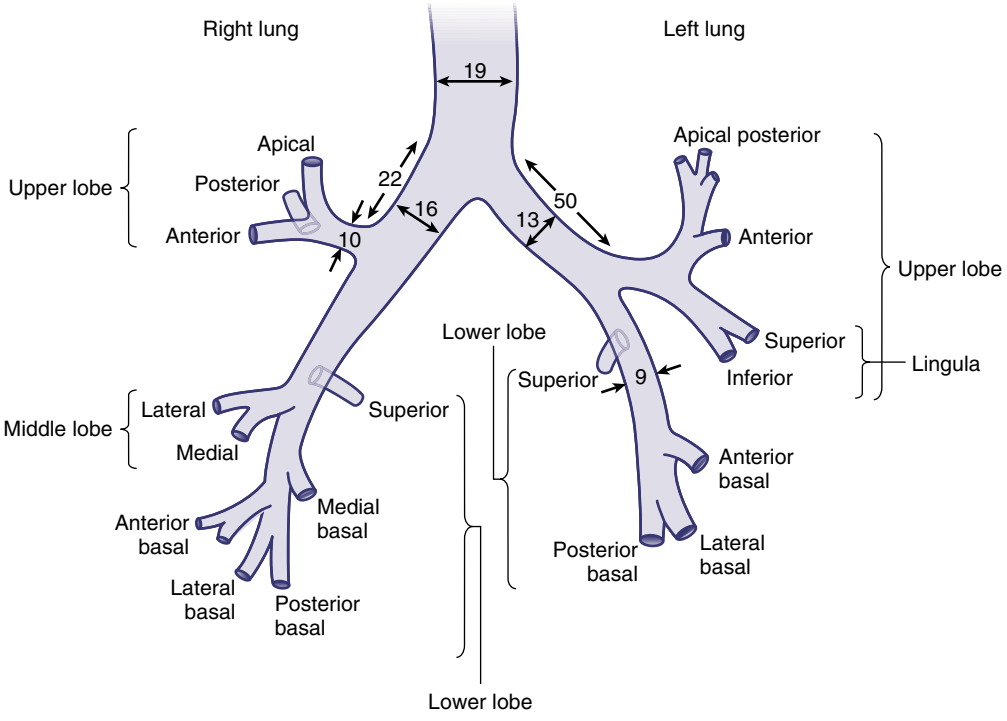

Figure 59-20 Diagram of the tracheobronchial tree. Mean lengths and diameters are shown in millimeters. Note that the right middle lobe bronchus exits directly anteriorly while the superior segments (some authors refer to these as the "apical" segments) of the lower lobes exit directly posteriorly. Using the apical designation on the right side the segmental bronchi in a rostral to caudal sequence give the mnemonic "A PALM A MAPL." (*From Youngberg JA: Cardiac, Vascular and Thoracic Anesthesia. Philadelphia, Churchill Livingstone, 2000.*)

reassessed after repositioning. The anesthesiologist should take responsibility for the head, neck, and airway during position change and must be in charge of the operating team to direct repositioning. It is useful to make an initial "head-to-toe" survey of the patient after induction and intubation, checking oxygenation, ventilation, hemodynamics, lines, monitors, and potential nerve injuries. This survey then must be repeated after repositioning. It is nearly impossible to avoid some movement of a DLT or bronchial blocker during repositioning.[68] Certainly the patient's head, neck, and endobronchial tube should be turned "en bloc" with the patient's thoracolumbar spine. However, the margin of error in positioning endobronchial tubes or blockers is often so narrow that even very small movements can have significant clinical implications.[81] The carina and mediastinum may shift independently with repositioning, and this can lead to proximal misplacement of a previously well-positioned tube. Endobronchial tube/blocker position and the adequacy of ventilation must be rechecked by auscultation and fiberoptic bronchoscopy after patient repositioning.

Neurovascular Complications

There are a specific set of nerve and vascular injuries related to the lateral position that must be appreciated. The brachial plexus is the site of a majority of intraoperative nerve injuries related to the lateral position. These are basically of two varieties: the majority are compression injuries of the brachial plexus of the dependent arm, but there is also significant risk of stretch injuries to the brachial plexus of the nondependent arm. The brachial plexus is fixed at two points: proximally by the transverse process of the cervical vertebrae and distally by the axillary fascia. This two-point fixation plus the extreme mobility of neighboring skeletal and muscular structures makes the brachial plexus extremely liable to injury (Table 59-15). The patient should be positioned with padding under the dependent thorax (Fig. 59-21) to keep the weight of the upper body off the dependent arm brachial plexus. However, this padding will exacerbate the pressure on the brachial plexus if it migrates superiorly into the axilla.

The brachial plexus of the nondependent arm is most at risk if it is suspended from an independently fixed arm support or "ether screen." Traction on the brachial plexus in these situations is particularly likely to occur if the patient's trunk accidentally slips toward a semiprone or semisupine position after fixation of the nondependent arm. Vascular compression of the nondependent arm in this situation is also possible, and it is useful to monitor pulse oximetry in the nondependent hand to observe

Table 59-15 Factors Contributing to Brachial Plexus Injury in the Lateral Position

Dependent Arm (Compression Injuries)
Arm directly under thorax
Pressure on clavicle into retroclavicular space
Cervical rib
Caudal migration of thorax padding into the axilla*
Nondependent Arm (Stretch Injuries)
Lateral flexion of cervical spine
Excessive abduction of arm (>90%)
Semiprone or semisupine repositioning after arm fixed to a support

*Unfortunately this padding under the thorax is misnamed an "axillary roll" in some institutions. This padding absolutely should NOT be placed in the axilla.

this. The arm should not be abducted beyond 90 degrees and should not be extended posteriorly beyond the neutral position nor flexed anteriorly greater than 90 degrees. Fortunately, the majority of these nerve injuries resolve spontaneously over a period of months.

Anterior flexion of the arm at the shoulder (circumduction) across the chest or lateral flexion of the neck toward the opposite side can cause a traction injury of the suprascapular nerve. This causes a deep, poorly circumscribed pain of posterior and lateral aspects of the shoulder and may be responsible for some cases of post-thoracotomy shoulder pain.

Repositioning the patient in the lateral decubitus position can easily cause excessive lateral flexion of the cervical spine because of improper positioning of the patient's head. This malpositioning that exacerbates brachial plexus traction can cause a "whiplash" syndrome and can be difficult to appreciate from the head of the operating table, particularly after the surgical drapes have been placed. It is useful for the anesthesiologist to survey the patient from the side of the table immediately after turning to ensure that the entire vertebral column is aligned properly.

The dependent leg should be slightly flexed with padding under the knee to protect the peroneal nerve lateral to the proximal head of the fibula. The nondependent leg is placed in a neutral extended position and padding placed between it and the dependent leg. The dependent leg must be observed for vascular compression. Excessively tight strapping at the hip level can compress the sciatic nerve of the nondependent leg. Other sites particularly liable for neurovascular injury in the lateral position are the dependent ear pinna and eye. A "head-to-toe" protocol to monitor for possible neurovascular injuries related to the lateral decubitus position is presented in Table 59-16.

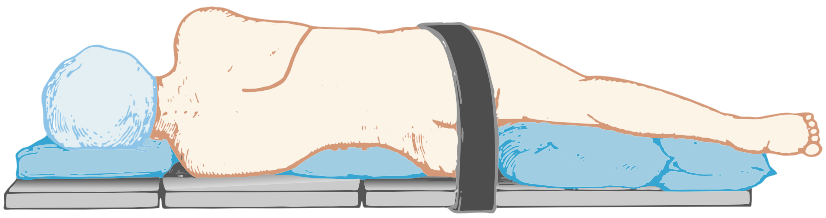

Figure 59-21 Typical positioning of a patient in the lateral decubitus position for thoracotomy seen from behind. It is useful for the anesthesiologist to survey the anesthetized patient from this perspective before draping to ensure that there is no lateral flexion of the cervical spine, which can be very difficult to appreciate from the head of the operating table. Note also padding of the dependent thorax and the nondependent leg. (*From Kaplan J, Slinger P [eds]: Thoracic Anesthesia, 3rd ed. Philadelphia, Churchill Livingstone, 2003.*)

Table 59-16 Neurovascular Injuries Specific to the Lateral Position: Routine "Head-to-Toe" Survey

1. Dependent eye
2. Dependent ear pinna
3. Cervical spine in line with thoracic spine
4. Dependent arm:
   a. Brachial plexus
   b. Circulation
5. Nondependent arm*:
   a. Brachial plexus
   b. Circulation
6. Dependent and nondependent suprascapular nerves
7. Nondependent leg: sciatic nerve
8. Dependent leg:
   a. Peroneal nerve
   b. Circulation

*Neurovascular injuries of the nondependent arm are more likely to occur if the arm is suspended or held in an independently positioned armrest.

Physiologic Changes in the Lateral Position

Ventilation

Significant changes in ventilation develop between the lungs when the patient is placed in the lateral position. Originally this was explained by the theory that the lungs move up and down a common compliance curve with the dependent lung becoming less compliant and the nondependent lung more compliant. However, subsequent studies suggest that the reality is more complex.[93] The compliance curves of the two lungs are different because of their difference in sizes. The lateral position, anesthesia, paralysis, and opening of the thorax all combine to magnify these differences between the lungs (Fig. 59-22). The compliance curve (change in volume versus change in pressure) of a lung depends on the balance of two "springs": the chest wall (normally distending the lung) and the elastic recoil of the lung itself. Any factor that changes the mechanics of either of these springs places the lung on a different compliance curve.[94]

In a healthy, conscious, spontaneously breathing patient, the ventilation of the dependent lung will increase approximately 10% when the patient is turned to the lateral position. Once the patient is anesthetized and paralyzed, the ventilation of the dependent lung will then decrease 15%. Although the ventilation will not change significantly once the nondependent hemithorax is open, the FRC of this nondependent lung will tend to increase approximately 10%. These changes will depend on the method used for ventilation in the individual patient. When the chest is open, due to disruption of the chest wall, both lungs will tend to collapse to a minimal lung volume if expiration is prolonged. Thus the end-expiratory volume of each lung is directly a function of the time allowed for expiration. The compliance of the entire respiratory system will increase significantly once the nondependent hemithorax is open (see Chapter 15).

Because of the fall in FRC and compliance of the nondependent lung in the lateral position, application of PEEP selectively to this lung only (using a DLT and two anesthetic circuits) will improve gas exchange.[95] This is different than the effect of nonselectively applying PEEP to both lungs in the lateral position where PEEP tends to preferentially distribute to the most compliant lung regions and will tend to hyperinflate the nondependent lung without causing any improvement in gas exchange.

Atelectasis will develop in an average of 6% of the lung parenchyma after induction of anesthesia in the supine position. This atelectasis will be evenly distributed in the dependent portions of both lungs.[96] After turning the patient to the lateral position there will be a slight decrease of total atelectasis to 5% of lung volume, but this will now be concentrated totally in the dependent lung (Fig. 59-23). Further complicating our understanding of this physiology in clinical thoracic anesthesia is the fact that most studies of the effects of position on ventilation were done in healthy subjects and the majority of thoracic surgery patients have underlying lung disease with altered respiratory resistance and compliance, so the intraoperative distribution of ventilation becomes even less predictable.

Perfusion

Traditional teaching has been that turning the patient from the supine to the lateral position will decrease the blood flow of the nondependent lung due to gravity. This decrease has been assumed to be approximately 10% of the total pulmonary blood flow. Subsequent animal research has led to some question about the effects of gravity on pulmonary blood flow distribution.[97] The distribution of pulmonary blood flow in various positions may be more related to inherent pulmonary vascular anatomic factors than to gravity (see Chapter 15). The matching of ventilation and perfusion will usually be decreased in the lateral position compared with the supine position during anesthesia. Pulmonary arteriovenous shunt during general anesthesia will usually increase from approximately 5% in the supine position to 10% to 15% in the lateral position.[98]

Anesthetic Management

The development of thoracic anesthesia and thoracic surgery was delayed more than 50 years after the introduction of ether because anesthesiologists could not manage patients during mask anesthesia with spontaneous ventilation and an open chest. These patients developed what was originally called the "pneumothorax syndrome." The respiratory systems of mammals do not function

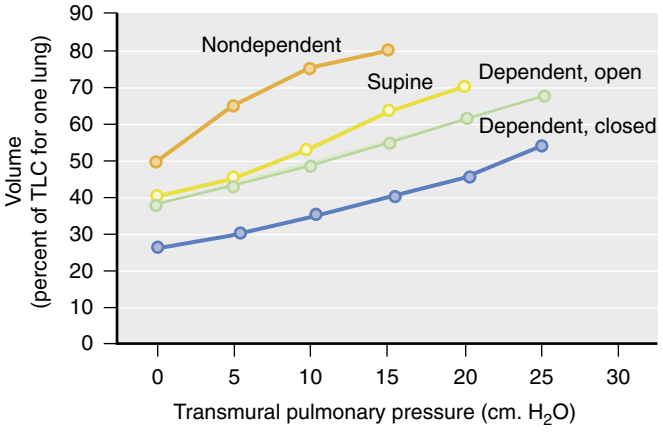

Figure 59-22 Changes in the compliance of a single lung during position changes in an anesthetized, paralyzed patient during controlled mechanical ventilation. These compliance changes are responsible for the resulting differences in ventilation between the lungs that occur in the lateral position. TLC, total lung capacity.

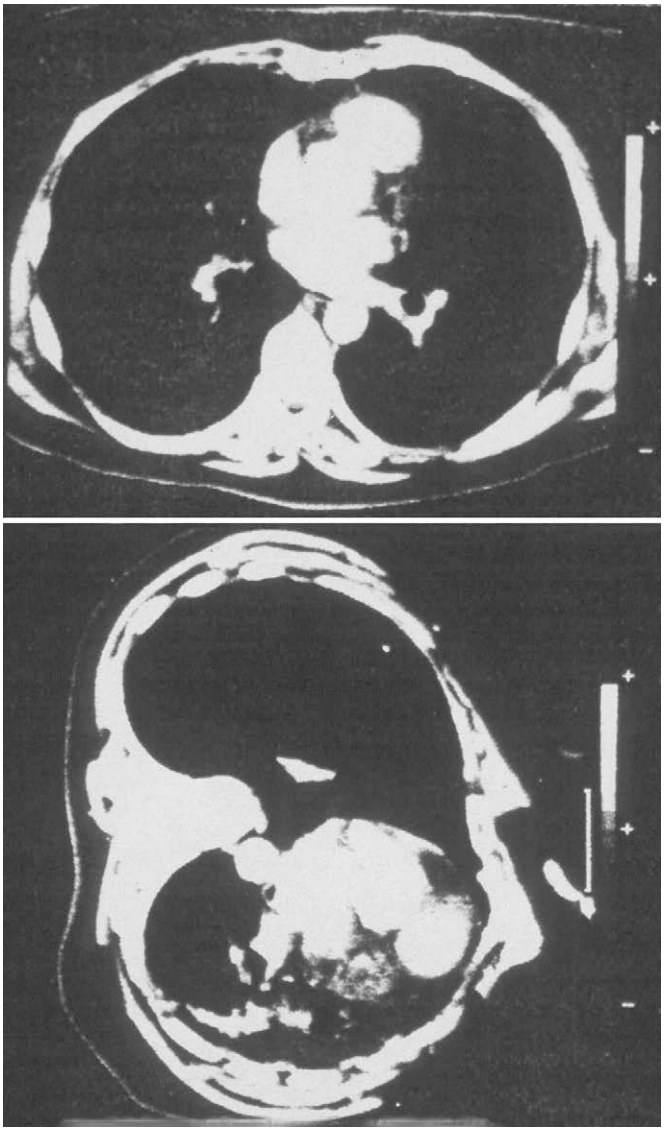

Figure 59-23 Atelectasis develops in the dependent portions of both lungs after induction of anesthesia, as seen in this chest CT scan (*top*). This atelectasis disappears in the nondependent lung after turning the patient to the lateral position but increases in the dependent lung (*bottom*). This is the lung that will subsequently be used for gas exchange during one-lung ventilation. (*From Kaplan J, Slinger P [eds]: Thoracic Anesthesia, 3rd ed. Philadelphia, Churchill Livingstone, 2003.*)

adequately with open hemithoraces because of two physiologic problems. First, paradoxical ventilation (also called "pendelluft") occurs in which gas moves into the lung in the open hemithorax from the lung in the closed hemithorax during expiration. Flow reverses during inspiration. This leads to hypercapnia and hypoxemia. Second, there is swinging motion of the mediastinum between the hemithoraces during the respiratory cycle that interferes with cardiac preload and causes hemodynamic instability. In the early 1900s, several pioneers, such as the New Orleans surgeon Matas, advocated positive-pressure ventilation and a primitive form of endotracheal ventilation, which had been demonstrated to be safe in animal experiments, for thoracic anesthesia. Modern methods, incorporating OLV, have evolved from these experiments. Essentially, any anesthetic technique that provides safe and stable general anesthesia for major surgery can and has been used for lung resection. There is currently a major trend to the use of combined thoracic epidural and general anesthesia for thoracic surgery.

Fluid Management

Because of hydrostatic effects, excessive administration of intravenous fluids can cause increased shunting and subsequently lead to pulmonary edema of the dependent lung, particularly during prolonged surgery. Because the dependent lung is the lung that must carry on gas exchange during OLV it is best to be as judicious as possible with fluid administration. Intravenous fluids are administered to replace volume deficits and for maintenance only during lung resection anesthesia. No volume is given for theoretical "third space" losses during thoracotomy; there is no good evidence that such third space losses occur during lung resection as they do during abdominal or other types of surgery (Table 59-17). The commonly accepted dictum is "don't drown the down lung."

Nitrous Oxide

Nitrous oxide/oxygen (N_2O/O_2) mixtures are more prone to cause atelectasis in poorly ventilated lung regions than oxygen by itself. Although N_2O is relatively insoluble compared with other volatile anesthetics, it is more soluble than atmospheric gases (nitrogen, oxygen, argon). The rate of uptake of an N_2O/O_2 mixture from an unventilated lung exceeds that of pure oxygen. The maximal uptake is with a mixture of N_2O/O_2 with an F_{IO_2} of 0.4 to 0.5.[99] The use of N_2O/O_2 mixtures is associated with a higher incidence of post-thoracotomy radiographic atelectasis (51%) in the dependent lung than when air/oxygen mixtures are used (24%). Nitrous oxide also tends to increase pulmonary artery pressures in patients who have pulmonary hypertension,[100] N_2O inhibits HPV,[101] and N_2O is contraindicated in patients with blebs or bullae. For these reasons N_2O is usually avoided during thoracic anesthesia.

Temperature

Maintenance of body temperature can be a problem during thoracic surgery because of heat loss from the open hemithorax. This is particularly a problem at the extremes of the age spectrum. Most of the body's physiologic functions, including HPV, are inhibited during hypothermia. Increasing the ambient room tem-

Table 59-17 Fluid Management for Pulmonary Resection Surgery

1. Total positive fluid balance in the first 24-hour perioperative period should not exceed 20 mL/kg.
2. For an average adult patient, crystalloid administration should be limited to < 3 L in the first 24 hours.
3. There should be no fluid administration for third space fluid losses during pulmonary resection.
4. Urine output > 0.5 mL/kg/hr is unnecessary.
5. If increased tissue perfusion is needed postoperatively, it is preferable to use invasive monitoring and inotropes rather than to cause fluid overload.

perature, fluid warmers, and the use of lower- or upper-body forced-air patient warmers (or both) are the best methods to prevent inadvertent intraoperative hypothermia.

Prevention of Bronchospasm

Because of the high incidence of coexisting reactive airways disease in the thoracic surgical population it is generally advisable to use an anesthetic technique that decreases bronchial irritability. This is particularly important because the added airway manipulation caused by placement of a DLT or bronchial blocker is a potent trigger for bronchoconstriction. The principles of anesthetic management are the same as for any asthmatic patient: avoid manipulation of the airway in a lightly anesthetized patient, use bronchodilating anesthetics, and avoid drugs that release histamine. For intravenous induction of anesthesia either propofol or ketamine can be expected to diminish bronchospasm. This benefit will not be seen with barbiturate, opioid, benzodiazepine, or etomidate intravenous induction. For maintenance of anesthesia, propofol and/or any of the volatile anesthetics will diminish bronchial reactivity. Sevoflurane may be the most potent bronchodilator of the volatile anesthetics.[102]

Coronary Artery Disease

Because the lung resection population is largely elderly and smokers there is a high coincidence of coronary artery disease. This consideration will be a major factor in the choice of the anesthetic technique for most thoracic patients. The anesthetic technique should optimize the myocardial oxygen supply/demand ratio by maintaining arterial oxygenation and diastolic blood pressure while avoiding unnecessary increases in cardiac output and heart rate. Thoracic epidural anesthesia/analgesia may aid in this (see "Postoperative Analgesia" later).

The ability to provide effective regional anesthesia with thoracic epidural blockade has opened the possibility of performing some thoracic surgical procedures in awake patients. A wide variety of thoracic operations have been reported using this technique, including thoracoscopy, thoracotomy, and sternotomy.[103] Epidural block is often combined with ipsilateral stellate ganglion block to decrease the cough reflex from stimulation of the hilum. The specific indications to use these techniques do not arise commonly but may occur in severely compromised patients with airway management issues.[104] Obviously the original concerns with the "pneumothorax syndrome" apply to prolonged surgery with these techniques. However, during VATS the operative hemithorax is effectively closed, and gas exchange is usually adequate during spontaneous ventilation with supplemental oxygen.

Management of One-Lung Ventilation

During OLV the anesthesiologist has the unique and often conflicting goals of trying to maximize atelectasis in the nonventilated lung to improve surgical access while trying to avoid atelectasis in the ventilated lung (usually the dependent lung) to optimize gas exchange. The gas mixture in the nonventilated lung immediately before OLV has a significant effect of the speed of collapse of this lung. Because of its low blood gas solubility, nitrogen (or an air-oxygen mixture) will delay collapse of this lung (Fig. 59-24).[105] This is particularly a problem at the start of VATS surgery, when surgical visualization in the operative hemithorax is limited and in patients with emphysema who have delayed collapse of the nonventilated lung due to decreased lung elastic recoil. It is important to thoroughly de-nitrogenate the operative lung, by ventilating with oxygen, immediately before it is allowed to collapse. Although nitrous oxide is even more effective than oxygen in speeding lung collapse, for the reasons cited earlier it is not commonly used in thoracic anesthesia.

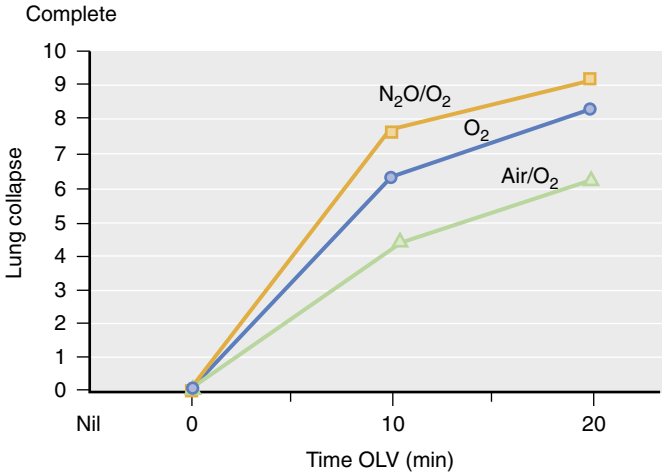

Figure 59-24 The effects of the gas mixture used during two-lung ventilation, immediately before one-lung ventilation (OLV), on the speed of collapse of the nonventilated lung during OLV. O_2 = F_{IO_2} 1.0; N_2O/O_2 = nitrous oxide/oxygen 60/40; Air/O_2 = air/oxygen F_{IO_2} 0.4. All patients were ventilated with an F_{IO_2} of 1.0 during OLV. The poorly soluble nitrogen in the air/oxygen mixture delays collapse of the nonventilated lung. (*Based on data from Ko R, Kruger M, McRae K, et al: Impact of inspired gas mixtures on oxygenation and surgical conditions during one-lung ventilation. Can J Anesth 50:A13, 2003.*)

Also during the period of two-lung anesthesia before the start of OLV, atelectasis will develop in the dependent lung (see Fig. 59-23). It is useful to perform a recruitment maneuver (similar to a Valsalva maneuver, holding the lung at an end-inspiratory pressure of 20 cm H_2O for 15 to 20 sec) immediately after the start of OLV to decrease this atelectasis. This recruitment has been shown to increase the mean Pao_2 levels during subsequent OLV (see Chapter 15).[106]

Hypoxemia

A major concern that influences anesthetic management for thoracic surgery is the occurrence of hypoxemia during OLV. There is no universally acceptable figure for the safest lower limit of oxygen saturation during OLV. A saturation greater than or equal to 90% (Pao_2 > 60 mm Hg) is commonly accepted, and for brief periods a saturation in the high 80s may be acceptable in patients without significant comorbidity. However, the lowest acceptable saturation will be higher in patients with organs at risk of hypoxia

due to limited regional blood flow (e.g., coronary or cerebrovascular disease) and in patients with limited oxygen transport (e.g., anemia or decreased cardiopulmonary reserve). It has been shown that during OLV patients with COPD desaturate more quickly during isovolemic hemodilution than normal patients.[107]

Previously, hypoxemia occurred frequently during OLV. Reports for the period 1950-1980 describe an incidence of hypoxemia (arterial saturation < 90%) of 20% to 25%. During the 1990s reports described an incidence of less than 10%,[108] and more recently the incidence of hypoxemia during OLV for thoracic surgery has been reported at less than 1%.[109] This improvement is most likely due to several factors: improved lung-isolation techniques such as routine fiberoscopy to prevent lobar obstruction from DLTs, improved anesthetic techniques that cause less inhibition of HPV, and better understanding of the pathophysiology of OLV. The pathophysiology of OLV involves the body's ability to redistribute pulmonary blood flow to the ventilated lung. Several factors aid and impede this redistribution, and these are under the control of the anesthesiologist to a variable degree. These factors are illustrated in Figure 59-25. The anesthesiologist's goal during OLV is to maximize pulmonary vascular resistance (PVR) in the nonventilated lung while minimizing PVR in the ventilated lung. Key to understanding this physiology is the appreciation that PVR is correlated with lung volume in a hyperbolic fashion (Fig. 59-26). PVR is lowest at FRC and increases as lung volume rises or falls above or below FRC (see Chapter 15).[110] The anesthesiologist's aim, to optimize pulmonary blood flow redistribution during OLV, is to maintain the ventilated lung as close as possible to its FRC while facilitating collapse of the nonventilated lung to increase its PVR.

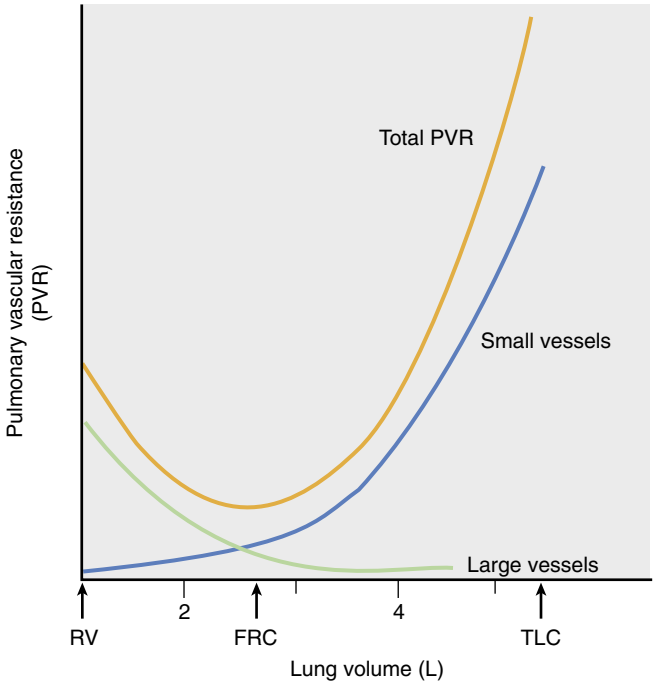

Figure 59-26 The relationship between pulmonary vascular resistance (PVR) and lung volume. PVR is lowest at functional residual capacity (FRC) and increases as the lung volume decreases toward residual volume (RV), owing primarily to increase in resistance of large pulmonary vessels. PVR also increases as lung volume increases above FRC toward total lung capacity (TLC) because of an increase in the resistance of small interalveolar lung vessels.

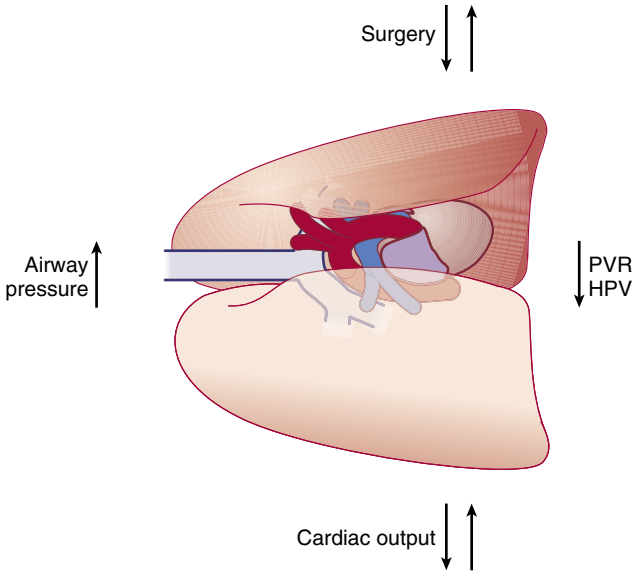

Figure 59-25 Factors affecting the distribution of pulmonary blood flow during one-lung ventilation. Hypoxic pulmonary vasoconstriction (HPV) and the collapse of the nonventilated lung, which increases pulmonary vascular resistance (PVR), tend to distribute blood flow toward the ventilated lung. The airway pressure gradient between the ventilated and nonventilated thoraces tends to encourage blood flow to the nonventilated lung. Surgery and cardiac output can have variable effects, either increasing or decreasing the proportional flow to the ventilated lung (see text).

Intraoperative Position

Most thoracic surgery is performed in the lateral position. Patients having OLV in the lateral position have significantly better Pa_{O_2} levels than patients during OLV in the supine position.[111] This applies both to patients with normal lung function and to those with COPD (Fig. 59-27).[112]

Hypoxic Pulmonary Vasoconstriction

HPV is generally considered to be a factor governing the redistribution of blood flow during OLV. It is thought to be able to decrease the blood flow to the nonventilated lung by 50%. The stimulus for HPV is primarily the alveolar oxygen tension ($P_{A_{O_2}}$), which stimulates precapillary vasoconstriction redistributing pulmonary blood flow away from hypoxemic lung regions via a pathway involving NO and/or cyclooxygenase synthesis inhibition.[113] The mixed venous P_{O_2} ($P\bar{v}_{O_2}$) is also a stimulus, although considerably weaker than $P_{A_{O_2}}$, and the Pa_{O_2} has a biphasic effect on HPV. HPV in humans has a rapid onset over the first 30 minutes and then a slower increase to a maximal response at approximately 2 hours. HPV is a reflex that has a preconditioning effect, and the response to a second hypoxic challenge will be greater than to the first challenge.[114]

The surgical trauma to the lung can affect pulmonary blood flow redistribution. Surgery may oppose HPV by release of vasoactive metabolites locally in the lung or may cause autonomic effects by trauma to the perihilar plexus. Conversely, surgery can

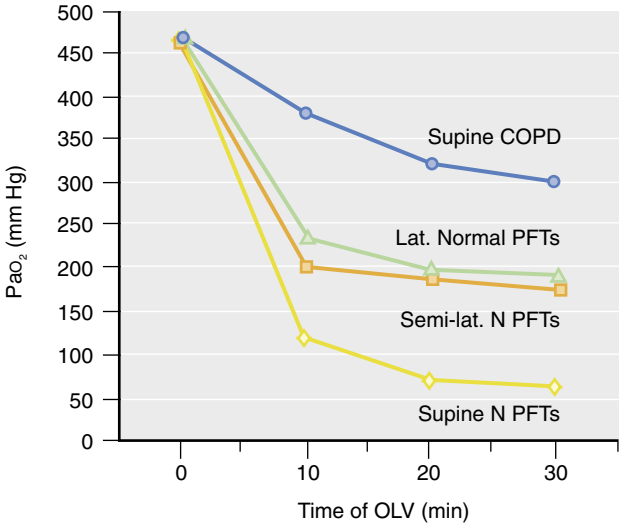

Figure 59-27 Mean Pao_2 in groups of patients vs. time of one-lung ventilation (OLV). Supine COPD, patients with COPD having OLV in the supine position; Lat. PFTs, patients with normal pulmonary function having OLV in the lateral position; Semi-lat. N PFTs, patients with normal pulmonary function having OLV in the semi-lateral position; Supine N PFTs, patients with normal pulmonary function having OLV in the supine position. Patients with normal pulmonary function having OLV in the supine position are the most likely to desaturate. (*Based on data from Watanabe S, Noguchi E, Yamada S, et al: Sequential changes in arterial oxygen tension in the supine position during one-lung ventilation. Anesth Analg 90:28, 2000; and Bardoczky GI, Szegedi LL, d'Hollander AA, et al: Two-lung and one-lung ventilation in patients with chronic lung disease: The effects of position and Fio_2. Anesth Analg 90:35, 2000.*)

dramatically decrease blood flow to the nonventilated lung by deliberately or accidentally mechanically interfering with either the unilateral pulmonary arterial or venous blood flow.[115] Ventilation increases blood flow through a hypoxic lung more than in a normoxic lung, which is generally not of clinical relevance but does complicate studies of HPV. HPV is decreased by vasodilators such as nitroglycerin and nitroprusside. In general, vasodilators can be expected to cause a deterioration in Pao_2 during OLV. Thoracic epidural sympathetic blockade probably has little or no direct effect on HPV, which is a localized chemical response in the lung.[116] However, thoracic epidural anesthesia can have an indirect effect on oxygenation during OLV if it is allowed to cause hypotension and a fall in cardiac output (see "Cardiac Output" later).

Choice of Anesthetic

All of the volatile anesthetics inhibit HPV in a dose-dependent fashion. Animal studies suggest that this inhibition is dependent on the agent: halothane > enflurane > isoflurane. The older agents were potent inhibitors of HPV, and this may have contributed to the high incidence of hypoxemia reported during OLV in the 1960s and 1970s (see earlier); many of these studies used 2- to 3-MAC doses of halothane.

In doses less than or equal to 1 MAC, the modern volatile anesthetics (isoflurane, sevoflurane,[117] and desflurane[118]) are weak, and equipotent, inhibitors of HPV. The inhibition of the HPV response by 1 MAC of a volatile agent such as isoflurane is approximately 20% of the total HPV response, and this could account for only a net 4% increase in total arteriovenous shunt during OLV, which is a difference too small to be detected in most clinical studies.[119] In addition, volatile anesthetics cause less inhibition of HPV when delivered to the active site of vasoconstriction via the pulmonary arterial blood than via the alveolus. This pattern is similar to the HPV stimulus characteristics of oxygen. During established OLV, the volatile agent only reaches the hypoxic lung pulmonary capillaries via the mixed venous blood. No clinical benefit in oxygenation during OLV has been shown for total intravenous anesthesia above that seen with 1 MAC of the modern volatile anesthetics.[120]

Cardiac Output

The effects of alterations of cardiac output during OLV are complex (Fig. 59-28). Increasing cardiac output tends to cause increased pulmonary artery pressures and passive dilation of the pulmonary vascular bed, which in turn opposes HPV and has been shown to be associated with increased arteriovenous shunt $\left(\dot{Q}s/\dot{Q}t\right)$ during OLV.[121] However, in patients with a relatively fixed oxygen consumption, as is seen during stable anesthesia, the effect of an increase in cardiac output is to increase the mixed venous oxygen saturation $(S\bar{v}O_2)$. Thus, increasing cardiac output during OLV tends to increase both shunt and $S\bar{v}O_2$, which have opposing effects on Pao_2. There is a ceiling effect to the amount that $S\bar{v}O_2$ can be increased. Increasing the cardiac output to supranormal levels by administering inotropes such as dopamine tends to have an overall negative effect on Pao_2.[122] Conversely, allowing the cardiac output to fall will lead to falls in both shunt and $S\bar{v}O_2$ with a net effect of decreasing Pao_2. Because even with optimal anesthetic management there is usually a shunt of 20% to 30% during OLV, it is very important to maintain cardiac output.

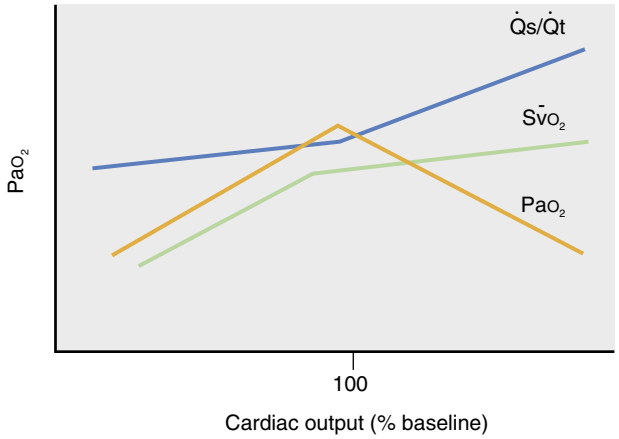

Figure 59-28 The relationship between Pao_2 and cardiac output during one-lung ventilation (OLV). As cardiac output falls below baseline, arteriovenous shunt $\left(\dot{Q}s/\dot{Q}t\right)$ falls but the mixed venous oxygen saturation ($S\bar{v}O_2$) also decreases, resulting in a net fall in Pao_2. Conversely, raising cardiac output above baseline tends to increase $S\bar{v}O_2$ but also to increase $\dot{Q}s/\dot{Q}t$, and the net result again is a decrease in Pao_2. (*Based on data from Slinger P, Scott WAC: Arterial oxygenation during one-lung anesthesia: A comparison of enflurane and isoflurane. Anesthesiology 82:940, 1995; and Russell WJ, James MF: The effects on arterial haemoglobin oxygen saturation and on shunt of increasing cardiac output with dopamine or dobutamine during one-lung ventilation. Anaesth Intens Care 32:644, 2004.*)

Ventilation Strategies

The strategy used to manage the ventilated lung during OLV plays an important part in the distribution of pulmonary blood flow between the lungs. It has been the practice of many anesthesiologists to use the same large tidal volume (e.g., 10 mL/kg ideal body weight) during OLV as during two-lung ventilation. This strategy decreases hypoxemia probably by recurrently recruiting atelectatic regions in the dependent lung. There is a trend to use smaller tidal volumes with PEEP during OLV for several reasons. First, the incidence of hypoxemia during OLV is much lower than 20 to 30 years ago. Second, there is a risk of causing acute injury to the ventilated lung with prolonged use of large tidal volumes. And third, a ventilation pattern that allows recurrent atelectasis followed by recruitment of lung parenchyma seems to be injurious.[29] The ventilation technique needs to be individualized depending on the patient's underlying lung mechanics.

Respiratory Acid-Base Status

The efficacy of HPV in a hypoxic lung region is increased in the presence of respiratory acidosis and is inhibited by respiratory alkalosis. However, there is no net benefit to gas exchange during OLV from hypoventilation because the respiratory acidosis preferentially increases the pulmonary vascular tone of the well-oxygenated lung and this opposes any clinically useful pulmonary blood flow redistribution.[123] Overall, the effects of hyperventilation will usually tend to decrease pulmonary vascular pressures.

Positive End-expiratory Pressure

Resistance to blood flow through the lung is related to lung volume in a biphasic pattern and is lowest when the lung is at its FRC (see Fig. 59-26 and Chapter 15). Keeping the ventilated lung as close as possible to its normal FRC favorably encourages pulmonary blood flow to this lung. Several intraoperative factors that are known to alter FRC tend to cause the FRC of the ventilated lung to fall below its normal level; these include lateral position, paralysis, and opening the nondependent hemithorax, which allows the weight of the mediastinum to compress the dependent lung. Attempts to measure FRC in human patients during OLV have been complicated by the presence of a persistent end-expiratory airflow in COPD patients.[124] Many patients do not actually reach their end-expiratory equilibrium FRC lung volume as they try to exhale a relatively large tidal volume through one lumen of a DLT. These patients develop dynamic hyperinflation and an occult positive end-expiratory pressure (auto-PEEP).[40]

Auto-PEEP

Auto-PEEP is most prone to occur in patients with decreased lung elastic recoil such as the elderly or those with emphysema.[125] Auto-PEEP increases as the inspiratory/expiratory (I:E) ratio increases (i.e., as the time of expiration decreases). This auto-PEEP, which averages 4 to 6 cm H_2O in most series of lung cancer patients studied, opposes the previously mentioned factors, which tend to diminish dependent-lung FRC during OLV. The effects of applying external PEEP through the ventilator circuit to the lung in the presence of auto-PEEP are complex (Fig. 59-29). Patients with a very low auto-PEEP (<2 cm H_2O) will experience a greater increase in total PEEP from a moderate (5 cm H_2O) external PEEP than those with a high level of auto-PEEP (>10 cm H_2O). Whether the application of PEEP during OLV will improve a patient's gas exchange depends on the individual's lung mechanics. If the application of PEEP tends to shift the expiratory equilibration position on the compliance curve toward the lower inflection point (LIP) of the curve (i.e., toward the FRC), then external PEEP is of benefit (Fig. 59-30). However, if the application of PEEP raises the equilibration point such that it is farther from the LIP, then gas exchange deteriorates.

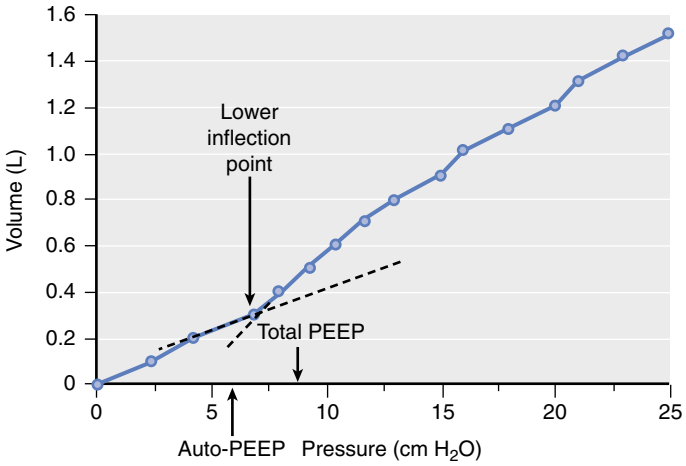

Figure 59-29 The static compliance curve of the ventilated (dependent) lung in a typical lung cancer patient with mild chronic obstructive pulmonary disease. The lower inflection point is thought to represent functional residual capacity (FRC). This patient had 6 cm H_2O of auto-PEEP during OLV. Adding 5 cm H_2O PEEP to the ventilator resulted in a total-PEEP in the circuit of 9 cm H_2O. This patient had a decrease in Pao_2 with the addition of PEEP (positive end-expiratory pressure). (*Based on data from Slinger P, et al: Relation of the static compliance curve and positive end-expiratory pressure to oxygenation during one-lung ventilation. Anesthesiology 95:1096, 2001.*)

Auto-PEEP is difficult to detect and measure using currently available anesthetic ventilators. To detect auto-PEEP the respiratory circuit must be held closed at the end of a normal expiration until an equilibrium appears in the airway pressure. Most current intensive-care unit ventilators can be used to measure auto-PEEP.

Tidal Volume

There will be an optimal combination of tidal volume, respiratory rate, I:E ratio, and pressure- or volume-control ventilation for each individual patient during OLV. However, to try to assess each of these parameters while still providing anesthesia with the available anesthetic ventilators is not practical and the clinician must initially rely on a simplified strategy (Table 59-18). The results of alterations in tidal volume are unpredictable. This may be due in part to the interaction of tidal volume with auto-PEEP. The use of 5 to 6 mL/kg ideal body weight tidal volumes plus 5 cm H_2O PEEP initially for most patients (except those with COPD) seems a logical starting point during OLV. Tidal volume should be managed so that peak airway pressures do not exceed 35 cm H_2O. This will correspond to a plateau airway pressure of approximately 25 cm H_2O.[126] Peak airway pressures exceeding 40 cm H_2O may contribute to hyperinflation injury of the ventilated lung during OLV.[127]

Turning the patient to the lateral position will increase respiratory dead space and the arterial to end-tidal CO_2 tension gradient (Pa-$ETco_2$). This will usually require a 20% increase in minute ventilation to maintain the same $Paco_2$. Individual

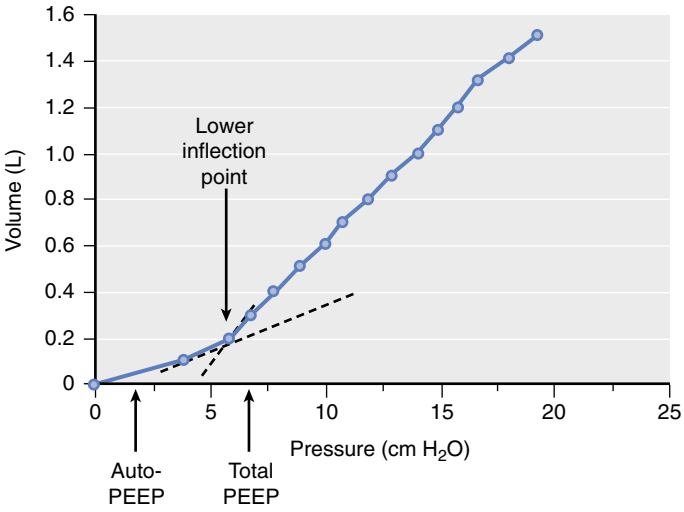

Figure 59-30 Static compliance curve of a young patient with normal pulmonary function during one-lung ventilation (OLV) (in this case, for removal of a mediastinal tumor). The lower inflection point of the curve (FRC) was at 6 cm H_2O. The patient had 2 cm H_2O auto-PEEP during OLV. Adding 5 cm H_2O PEEP to the ventilator raised the total PEEP to 7 cm H_2O and improved Pa_{O_2}. Young patients, and patients with increased lung elastic recoil (such as due to restrictive lung diseases), have an increase in Pa_{O_2} from PEEP during OLV. (*Based on data from Slinger P, et al: Relation of the static compliance curve and positive end-expiratory pressure to oxygenation during one-lung ventilation. Anesthesiology 95:1096, 2001.*)

variations in Pa-ET_{CO_2} gradient become much larger and P_{ETCO_2} is less reliable as a monitor of Pa_{CO_2} during OLV. This effect is possibly because there are individual differences in the excretion of CO_2 between the dependent and nondependent lungs.

Volume-Controlled Versus Pressure-Controlled Ventilation

Traditionally, volume-controlled ventilation has been used in the operating room for all types of surgery. The recent availability of anesthesia ventilators with pressure-control modes has made it possible to study and use this form of ventilation during thoracic surgery. Pressure-controlled ventilation has not been shown to improve oxygenation versus volume-controlled ventilation for most patients, although the peak airway pressures are lower.[128] There is a report suggesting that pressure-controlled ventilation may lead to improved oxygenation in COPD patients.[129] Pressure-controlled ventilation will avoid sudden increases in peak airway pressures that may result from surgical manipulation in the chest. This will be of benefit in patients at increased risk for lung injury from high volumes or pressures such as after lung transplantation or during a pneumonectomy.[130] Because of the rapid changes of lung compliance that occur during pulmonary surgery when pressure-controlled ventilation is used, the delivered tidal volume needs to be closely monitored because this may change suddenly.

Prediction of Hypoxemia

The problem of hypoxemia during OLV has prompted much research in thoracic anesthesia. Hypoxemia during OLV is predictable (see Table 59-6), preventable, and treatable in the vast majority of cases.[131]

Preoperative Ventilation-Perfusion Scan

The shunt and Pa_{O_2} during intraoperative OLV are highly correlated with the fractional perfusion of the ventilated lung, as determined by a preoperative $\dot{V}/\dot{Q}$ scan.[132] Patients with long-standing unilateral disease on the operative side develop a unilateral decrease of ventilation and perfusion and tolerate OLV very well. Similarly, patients who intraoperatively have a higher proportion of gas exchange in the dependent lung during OLV tend to have better oxygenation during OLV.

Side of Operation

Patients having right-sided thoracotomies tend to have a larger shunt and lower Pa_{O_2} during OLV because the right lung is larger and normally 10% better perused than the left. The overall mean Pa_{O_2} difference between left and right thoracotomies during stable OLV is approximately 100 mm Hg.[133]

Two-Lung Oxygenation

Patients who have better Pa_{O_2} levels during two-lung ventilation in the lateral position tend to have better oxygenation during OLV. These patients may have better abilities to match ventilation and perfusion (individual variability of HPV response) and/or they may have less atelectasis in the dependent lung. This is a particularly relevant consideration in trauma patients who may require a thoracotomy but have a contusion of the dependent lung.

Preoperative Spirometry

Studies consistently show that when the previous factors are controlled, patients with better spirometric lung function preoperatively are more likely to desaturate and have lower Pa_{O_2} values

Table 59-18 Suggested Ventilation Parameters for One-Lung Ventilation

Parameter	Suggested	Guidelines/ Exceptions
Tidal volume	5-6 mL/kg	Maintain: Peak airway pressure < 35 cm H_2O Plateau airway pressure < 25 cm H_2O
Positive end-expiratory pressure	5 cm H_2O	Patients with COPD: no added PEEP
Respiratory rate	12 breaths/min	Maintain normal Pa_{CO_2}; Pa-ET_{CO_2} will usually increase 1-3 mm Hg during OLV
Mode	Volume or pressure controlled	Pressure control for patients at risk of lung injury (e.g., bullae, pneumonectomy, post lung transplantation)

Table 59-19 Therapies for Desaturation during One-Lung Ventilation

Severe or precipitous desaturation: Resume two-lung ventilation (if possible).

Gradual desaturation:

1. Ensure that delivered F_{IO_2} is 1.0.
2. Check position of double-lumen tube or blocker with fiberoptic bronchoscopy.
3. Ensure that cardiac output is optimal; decrease volatile anesthetics to < 1 MAC.
4. Apply a recruitment maneuver to the ventilated lung (this will transiently make the hypoxemia worse).
5. Apply PEEP 5 cm H_2O to the ventilated lung (except in patients with emphysema).
6. Apply CPAP 1-2 cm H_2O to the nonventilated lung (apply a recruitment maneuver to this lung immediately before CPAP).
7. Intermittent reinflation of the nonventilated lung
8. Partial ventilation techniques of the nonventilated lung:
   a. Oxygen insufflation
   b. High-frequency ventilation
   c. Lobar collapse (using a bronchial blocker)
9. Mechanical restriction of the blood flow to the nonventilated lung

during OLV. Clinically this is evident because emphysematous lung volume reduction patients generally tolerate OLV very well. The explanation is not clear but may be related to maintenance of a more favorable FRC in patients with obstructive airways disease during OLV with an open hemithorax due to the development of auto-PEEP.[40]

Treatment of Hypoxemia

During OLV there will be a fall in arterial oxygenation that usually reaches its nadir 20 to 30 minutes after the initiation of OLV; then the saturation will stabilize or may rise slightly as HPV increases over the next 2 hours. A majority of patients who desaturate do so quickly and within the first 10 minutes of OLV. Hypoxemia during OLV responds readily to treatment in the vast majority of cases. Potential therapies are outlined in Table 59-19.

1. Resume two-lung ventilation. Reinflate the nonventilated lung and deflate the bronchial cuff of the double lumen tube or the bronchial blocker. This will necessitate interruption of surgery but is necessary in case of severe or precipitate desaturation. After an adequate level of oxygenation is obtained, the diagnosis of the cause of desaturation can be made and prophylactic measures instituted (see later) before another trial of OLV is attempted.
2. Increase F_{IO_2}. Ensure that the delivered F_{IO_2} is 1.0. This is an option in essentially all patients except those who have received bleomycin or similar therapies that potentiate pulmonary oxygen toxicity.
3. Recheck the position of the DLT or bronchial blocker. Ensure that there is no lobar obstruction in the ventilated lung.
4. Check the patient's hemodynamics to ensure that there has been no decrease in cardiac output. It is very common for the surgeon to accidentally compress the inferior vena cava during pulmonary resections, and the fall in blood pressure and cardiac output that this causes leads to rapid desaturation during OLV. Treat the fall in cardiac output as indicated (e.g., inotropes/vasopressors if due to thoracic epidural sympathetic blockade). Stop administration of vasodilators, and decrease MAC of volatile anesthetics to less than or equal to 1 MAC.
5. Perform a recruitment maneuver of the ventilated lung. To eliminate any atelectasis, inflate the lung to 20 cm H_2O or more for 15 to 20 seconds. This may cause transient hypotension and will also cause a transient further fall in the Pao_2 as the blood flow is temporarily redistributed to the nonventilated lung.
6. Apply PEEP to the ventilated lung. It is necessary to perform a recruitment maneuver before applying PEEP to get the maximal benefit (see Chapter 15). PEEP will raise the end-expiratory volume of the ventilated lung toward the FRC in patients with normal lung mechanics and in those with increased elastic recoil due to restrictive disease. It is not possible to predict the optimal PEEP for individual patients; a level of 5 cm H_2O is a useful starting point. PEEP will increase the end-expiratory lung volume of patients with significant levels of auto-PEEP (e.g., emphysema patients). Unlike CPAP, application of PEEP does not require reinflation of the nonventilated lung and interruption of surgery. PEEP has been shown to be as effective for increasing Pao_2 levels during OLV in patients with normal lung function as CPAP (Fig. 59-31).[134] For patients with normal pulmonary function it is logical to routinely apply a recruitment maneuver and PEEP from the start of OLV.

CPAP with oxygen to the nonventilated lung is a most useful ventilatory manipulation in patients with COPD and the next line of therapy after application of PEEP in patients with normal pulmonary function. There is an important caveat to be observed when CPAP is applied to the nonventilated lung, and

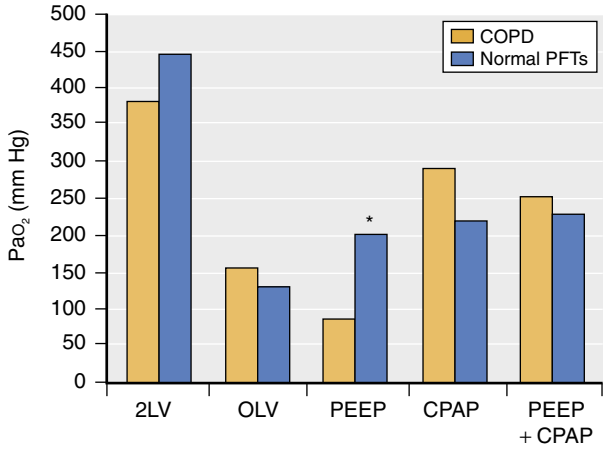

Figure 59-31 A comparison of the effects of positive end-expiratory pressure (PEEP) to the ventilated lung and continuous positive airway pressure (CPAP) to the nonventilated lung on mean Pao_2 levels during one-lung ventilation (OLV). 2LV, two-lung ventilation; COPD, a group of lung cancer surgery patients; Normal PFTs, a group of esophageal surgery patients with normal preoperative pulmonary function tests. Asterisk indicates significant $P < .05$ vs. OLV. (*Based on data from Fujiwara M, Abe K, Mashimo T: The effect of positive end-expiratory pressure and continuous positive airway pressure on the oxygenation and shunt fraction during one-lung ventilation with propofol anesthesia. J Clin Anesth 13:473, 2001; and Capan LM, Turndorf H, Patel C, et al: Optimization of arterial oxygenation during one-lung anesthesia. Anesth Analg 59:847, 1980.*)

Figure 59-32 Photograph of a commercial disposable CPAP circuit applied to the nonventilated lung during a left thoracotomy (in this case applied to the tracheal lumen of a right-sided double-lumen tube). This circuit has an adjustable exhaust valve that allows titration of CPAP between 1 and 10 cm H_2O. (*Courtesy of Mallinckrodt, St. Louis, MO.*)

that is that CPAP must be applied to a fully inflated (recruited) lung to be effective. The opening pressure of atelectatic lung regions is greater than 20 cm H_2O,[135] and these units will not be recruited by simple application of CPAP levels of 5 to 10 cm H_2O. Even a period as short as 5 minutes of collapse before CPAP application can have deleterious effects on oxygenation during OLV.[136] When CPAP is applied to a fully inflated lung, levels of CPAP as low as 1 to 2 cm H_2O can be used.[137] Because the normal transpulmonary pressure of the lung at FRC is approximately 5 cm H_2O, levels of 5 to 10 cm H_2O CPAP applied to a fully recruited lung result in a large-volume lung that impedes surgery. Because surgical exposure is the most common indication for OLV, it is preferable to use lower levels of CPAP that, owing to lung elastic recoil, result in a nonventilated lung that is one third to one half of its resting FRC volume and during open thoracotomy does not interfere with surgical access into the operative hemithorax.

CPAP levels less than 10 cm H_2O do not interfere with hemodynamics. The beneficial effects of low levels of CPAP are primarily due to oxygen uptake from the nonventilated lung and not due to blood flow diversion to the ventilated lung. CPAP is most effective when oxygen (F_{IO_2} 1.0) is applied to the nonventilated lung. Lower F_{IO_2} levels of CPAP are of clinical benefit and can be used along with decreased F_{IO_2} to the ventilated lung in patients at risk of oxygen toxicity.

Numerous anesthetic systems to apply CPAP to the nonventilated lung have been described. Essentially all that is required is a CPAP (or PEEP) valve and an oxygen source. Ideally, the circuit should permit variation of the CPAP level and include a reservoir bag to allow easy reinflation of the nonventilated lung and a manometer to measure the actual CPAP supplied. Such circuits are commercially available (Fig. 59-32) or can be readily constructed from standard anesthetic equipment.[138] CPAP can be applied with either a DLT or through the suction channel of a bronchial blocker.

CPAP, even when properly administered, is not completely reliable to improve oxygenation during OLV. When the bronchus of the operative lung is obstructed, or open to atmosphere (as in a bronchopleural fistula or during endobronchial surgery), CPAP will not improve oxygenation. Also in certain situations, particularly during thoracoscopic surgery where access to the operative hemithorax is limited, CPAP can significantly interfere with surgery.[139]

Pharmacologic Manipulations

Eliminating known potent vasodilators such as nitroglycerin, halothane, and large doses of other volatile anesthetics will improve oxygenation during OLV.[140] The selective administration of the vasodilator prostaglandin E_1 to the ventilated lung[141] or a nitric oxide synthase inhibitor (L-NAME)[142] to a hypoxic lobe results in improved redistribution of pulmonary blood flow in animal models. This is not applicable in humans at present. Selective administration of nitric oxide (NO) alone to the ventilated lung was not shown to be of benefit in humans.[143] The combination of NO (20 ppm) to the nonventilated lung and an intravenous infusion of almitrene, which enhances HPV, restores Pa_{O_2} values during OLV in humans to essentially the same levels as during two-lung ventilation. However, this may have been due primarily to the augmentation of HPV by almitrene.[144] It is unlikely that almitrene, which was previously available in North America as a respiratory stimulant, will be reintroduced to this market owing to side effects such as hepatic enzyme changes and lactic acidosis. However, the combination of nitric oxide and other pulmonary vasoconstrictors such as phenylephrine has been shown to improve oxygenation in ventilated intensive care unit patients with adult respiratory distress syndrome,[145] and this may have applications in OLV (see Chapter 31).

Intermittent Reinflation of the Nonventilated Lung

HPV becomes more effective during repeated hypoxic exposure.[118] Often after reinflation, the oxygen saturation will be more acceptable during a second period of lung collapse. Re-expansion can be performed by regular re-expansion of the operative lung via an attached CPAP circuit.

Partial Ventilation Methods

Several alternative methods of OLV, all involving partial ventilation of the nonventilated lung, have been described and improve oxygenation during OLV. These techniques are useful in patients who are particularly at risk of desaturation, such as those who have had previous pulmonary resections of the contralateral lung. These alternatives include the following:

1. Selective lobar collapse of only the operative lobe in the open hemithorax.[146] This is accomplished by placement of a blocker in the appropriate lobar bronchus of the ipsilateral operative lung.
2. Differential lung ventilation can be done by only partially occluding the lumen of the DLT to the operative lung or by insufflating oxygen with a cannula in the lumen of the DLT to the nonventilated lung.
3. High-frequency positive-pressure ventilation (HFPPV)[147] of the nonoperative lung tends to increase the diameters of the central airways in the operative lung and make pulmonary resections surgically more difficult. These methods are most useful to improve oxygenation for intrathoracic nonpulmonary surgery, such as thoracic esophageal or aortic surgery. High-frequency ventilation techniques are also useful because they can be delivered through a catheter in

cases involving surgery on the main bronchi, such as sleeve resection.

Mechanical Restriction of Pulmonary Blood Flow

It is possible for the surgeon to directly compress or clamp the blood flow to the nonventilated lung.[148] This can be done temporarily in emergency desaturation situations or definitively in cases of pneumonectomy or lung transplantation. Another technique of mechanical limitation of blood flow to the nonventilated lung is the inflation of a pulmonary artery catheter balloon in the main pulmonary artery of the operative lung. The pulmonary artery catheter can be positioned at induction with fluoroscopic guidance and inflated as needed intraoperatively. This has been shown to be a useful technique for resection of large pulmonary arteriovenous fistulas.[149]

Prophylaxis for Hypoxemia

The majority of the treatments outlined as therapies for hypoxemia can be used prophylactically to prevent hypoxemia in patients who are at high risk of desaturation during OLV. The advantage of prophylactic therapy of hypoxemia, in addition to the obvious patient safety benefit, is that maneuvers involving CPAP or alternative ventilation patterns of the operative lung can be instituted at the onset of OLV in a controlled fashion and will not require interruption of surgery and emergent reinflation of the nonventilated lung at a time that may be extremely disadvantageous.

Bilateral Pulmonary Surgery

Because of mechanical trauma to the operative lung, the gas exchange in this lung will always be temporarily impaired after OLV. Desaturation during bilateral lung procedures is particularly a problem during the second period of OLV (i.e., during OLV of the lung that has already had surgery).[150] Thus, for bilateral procedures it is advisable to operate first on the lung that has better gas exchange and less propensity to desaturate during OLV. For the majority of patients this means operating on the right side first.

Anesthetic Management for Common Surgical Procedures

Flexible Fiberoptic Bronchoscopy

Flexible fiberoptic bronchoscopy is a diagnostic and therapeutic procedure of great value in the clinical practice of thoracic surgery and anesthesia. In many centers, it is common practice to perform flexible fiberoptic bronchoscopy before lung resections, to reconfirm the diagnosis (if a tumor compresses the airway), or to determine the invasion and obstruction of the distal airway (in relation to the extension of the bronchial resection).

There are multiple techniques for flexible fiberoptic bronchoscopy. Options include awake versus general anesthesia and oral versus nasal approaches. Options for local anesthesia include topical anesthesia via a nebulizer, handheld aerosol, or soaked pledgets; nerve blocks (laryngeal and/or glossopharyngeal nerves); direct administration of local anesthetic through the bronchoscope (spray-as-you-go technique),[151] with/without sedation/opioid or antisialagogues. Options during general anesthesia include spontaneous versus positive-pressure ventilation with/without muscle relaxation. Airway management during general anesthesia can be with an endotracheal tube or a laryngeal mask airway (LMA). The most common method is with the use of a large SLT (e.g., 8.0 mm ID) placed under direct laryngoscopy. Once the tube is advanced, the tip of the endotracheal tube should come to rest 3 to 4 cm above the tracheal carina. A Portex swivel connector with a self-sealing valve is used to facilitate the ventilation and manipulation of the bronchoscope at the same time (Fig. 59-33). Inhalation and/or intravenous anesthetics can be used for anesthesia. Patients who have copious secretions in the preoperative period should receive anticholinergic medication to ensure a dry field, which provides optimal visualization with the flexible bronchoscope. When using a large SLT, an adult fiberoptic bronchoscope should be used (5.2 mm ID). For smaller tubes (i.e., 7.0-7.5 mm ID), a 3.2- or 4.2-mm ID flexible fiberoptic bronchoscope is used.

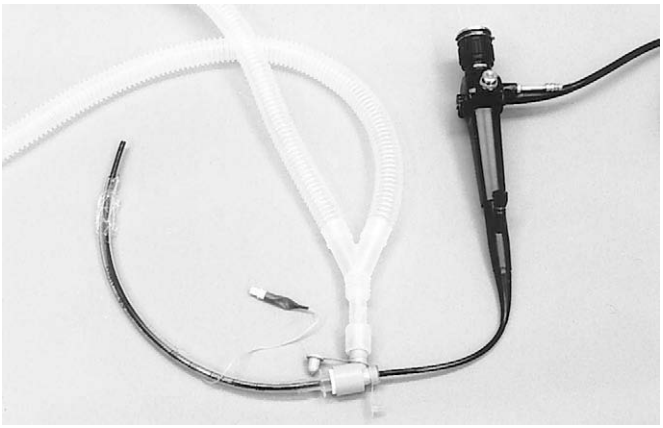

Figure 59-33 Photograph of a fiberoptic bronchoscope inserted through a bronchoscopy adapter on the proximal end of an endotracheal tube with the anesthetic circuit attached. With this technique, when the endotracheal tube cuff is inflated in the trachea, the airway is reasonably protected from aspiration during bronchoscopy and expired CO_2 and anesthetic gases can be monitored. (*From Kaplan J, Slinger P [eds]: Thoracic Anesthesia, 3rd ed. Philadelphia, Churchill Livingstone, 2003.*)

The advantages of an LMA technique include that it allows visualization of the vocal cords and subglottic structures and there is a lower airway resistance versus an endotracheal tube when the bronchoscope is inserted (Fig. 59-34). This is particularly useful in the patient with a difficult airway when maintaining spontaneous respiration may be the safest method of anesthetic management.[152]

Rigid Bronchoscopy

Rigid bronchoscopy has traditionally been considered the technique of choice for the preoperative diagnostic assessment of an airway obstruction involving the trachea and in the therapy of massive hemoptysis and foreign bodies in the airway. The role of interventional bronchoscopy with laser, bronchial dilation, or stent insertion is well established for the palliative treatment of malignant endobronchial lesions as well as for the management of benign central airway lesions (Fig. 59-35).[153] Because rigid

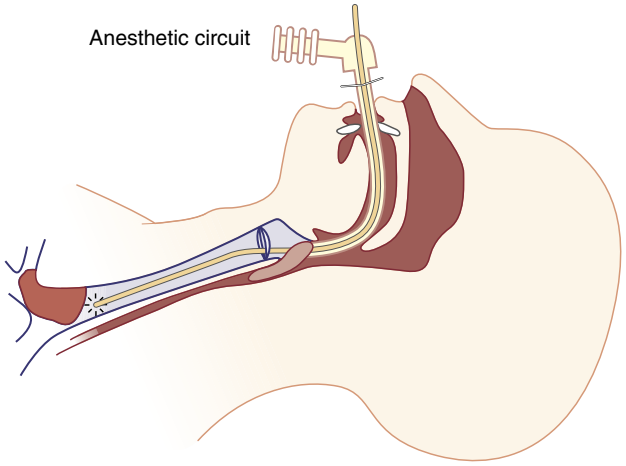

Figure 59-34 Diagram of fiberoptic bronchoscopy performed via a laryngeal mask airway (LMA) during general anesthesia in a spontaneously breathing patient with a carinal tumor, in this case for diagnosis and Nd:YAG laser tumor excision. The LMA permits visualization of the vocal cords and subglottic structures with the bronchoscope, which is not possible when fiberoptic bronchoscopy is performed via an endotracheal tube.

bronchoscopy is performed with ventilating instrumentation, it is the procedure of choice for operative procedures such as dilation of tracheal stenosis.

Central airway obstruction produces symptoms of dyspnea, stridor, or obstructive pneumonia and is often misdiagnosed as asthma. In most cases, resection and surgical reconstruction provides the best opportunity for definitive management. Bronchoscopic management is the first step in providing a diagnosis, stabilizing the obstructed airway, and evaluating the resection. Interventions commonly used for these patients include dilatation, laser ablation, stenting, and palliative creation of an air passage through an obstructing tumor.

Patients undergoing rigid bronchoscopy should have a complete preoperative evaluation, including radiologic studies. Chest radiographs and chest CT scans should be reviewed in the preoperative evaluation. If time permits, it is recommended that patients with severe stridor receive pharmacologic interventions for temporary stabilization of the condition. Treatments may include inspired cool saline mist, nebulized racemic epinephrine, and the use of systemic corticosteroids.[154]

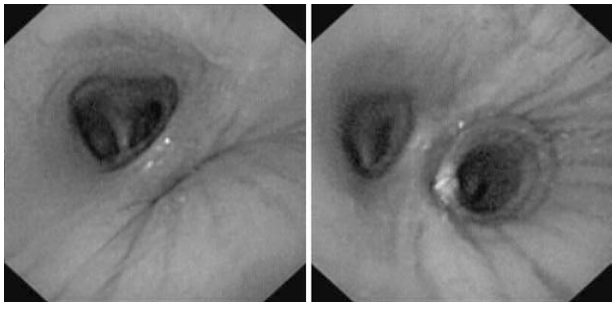

Figure 59-35 Left, Photograph of the airways in a patient with a collapse of the left lower lobe bronchus after lung transplantation. **Right,** A Silastic stent has been placed in the left lower lobe bronchus with rigid bronchoscopy.

There are four basic methods of ventilation management for rigid bronchoscopy:

1. Spontaneous ventilation. The addition of topical anesthesia or nerve blocks to the airway decreases the tendency to breath hold and cough when volatile anesthetics are used.
2. Apneic oxygenation (with/without insufflation of oxygen). This requires thorough preoxygenation, and the anesthesiologist will have to interrupt surgery to ventilate the patient before desaturation occurs. This should allow the surgeon working intervals of 3 minutes or longer depending on the underlying condition of the patient.
3. Positive-pressure ventilation via a ventilating bronchoscope (Fig. 59-36). This allows the use of a standard anesthetic circuit but may cause significant air leaks if there is a discrepancy between the size of a smaller bronchoscope and a larger airway.
4. Jet ventilation. This can be performed with a handheld injector such as the Sanders injector or with a high-frequency ventilator. These techniques are most useful with intravenous anesthesia because they entrain gas from either the room air or an attached anesthetic circuit and the dose of any volatile agent delivered will be very uncertain.

The use of anticholinergic agents (e.g., glycopyrrolate 0.2 mg IV) before manipulation of the airway will decrease secretions during the bronchoscopic examination. For a patient undergoing rigid bronchoscopy, the surgeon must be at the bedside for the induction of anesthesia and be prepared to establish airway control with the rigid bronchoscope. Anesthetic induction, maintained by spontaneous ventilation, with the use of a combined inhalation anesthetic such as sevoflurane, with/without a short-acting intravenous agent (e.g., propofol), may be used until the airway is secured. This is the ideal management in children but may not be tolerated in the elderly owing to the cardiovascular depression associated with high doses of volatile anesthetics.

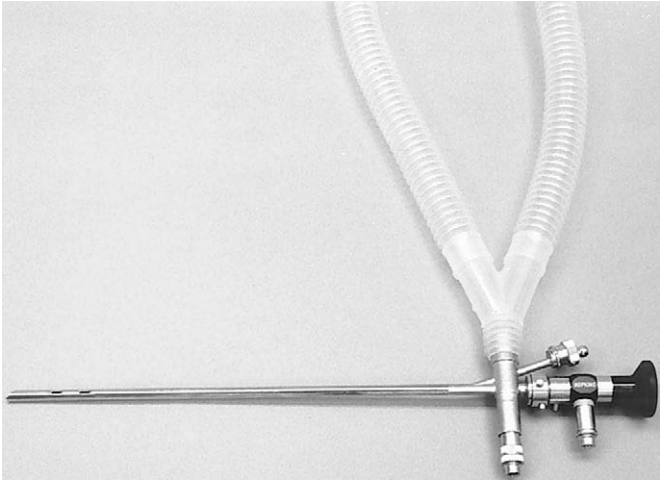

Figure 59-36 Photograph of a ventilating rigid bronchoscope with an anesthetic circuit attached to the side arm. In this photograph there is a telescopic lens sealing the proximal end of the bronchoscope. (*From Kaplan J, Slinger P [eds]: Thoracic Anesthesia, 3rd ed. Philadelphia, Churchill Livingstone, 2003.*)

In cases, for which the use of muscle relaxants is not contraindicated, a short-acting agent (succinylcholine) can be used initially to facilitate intubation with either a small SLT or the rigid bronchoscope. Nondepolarizing relaxants may be needed for prolonged procedures such as stent placement or tumor resection. Mouthguards should be used to protect the upper and lower teeth and gums from the pressure of the bronchoscope. Remifentanil and propofol infusions can be administered if an intravenous regimen is the planned anesthetic.[155] This is a useful technique if the surgeon needs repeated access (for suction or instrumentation) to the open airway because it maintains the level of anesthesia and avoids contaminating the operating room with exhaled anesthetic vapors.

In cases in which a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser is used, the inspired fraction of oxygen should be maintained in the lowest acceptable range (i.e., < 40% if possible) according to patient oxygen saturation, to avoid the potential for fire in the airway (see Chapter 77). Because any common material (including porcelain and metal) can be perforated by the Nd:YAG laser it is best to avoid any potentially combustible substance in the airway when the Nd:YAG laser is used.[156] Because of its high energy and short wavelength the Nd:YAG laser has several advantages for distal airway surgery over the CO_2 laser, which is used in upper airway surgery: the Nd:YAG laser penetrates tissue more deeply so it causes more coagulation in vascular tumors, and it can be refracted and passed in fibers through a flexible or rigid bronchoscope. However, there is a higher potential for accidental reflected laser strikes and there is more delayed airway edema.

Rigid bronchoscopes have different sizes, with diameters commonly ranging from 3.5- to 9-mm diameters, with a ventilating side port to facilitate ventilation when the bronchoscope is placed into the airway. If excessive leak of tidal volume occurs around the bronchoscope with positive-pressure ventilation, it may be necessary to place throat packs to facilitate ventilation. Continuous communication with the surgeon or pulmonologist is necessary in case desaturation occurs. If desaturation does occur it must be corrected by stopping surgery and allowing the anesthesiologist to ventilate and oxygenate the patient, either via the rigid bronchoscope or by removing the bronchoscope and ventilating with a mask or endotracheal tube.

Pulse oximetry is vital during rigid bronchoscopy because there is a high risk of desaturation. There is no simple way to monitor $ETCO_2$ or volatile anesthetics because the airway remains essentially open to atmosphere. For prolonged procedures, it is useful to perform repeated arterial blood gas analysis to confirm the adequacy of ventilation. An alternative is to interrupt surgery and ventilate the patient with a standard circuit and a mask or endotracheal tube to assess the $ETCO_2$.

Unlike during fiberoptic bronchoscopy via an endotracheal tube, with rigid bronchoscopy the airway is never completely secure and there is always the potential for aspiration in patients at increased risk, such as those with a full stomach, hiatal hernia, or morbid obesity. It is always best to defer rigid bronchoscopy to decrease the aspiration risk if possible in these patients. When there is no benefit to be gained by deferring and/or the airway risk is acute (e.g., aspiration of an obstructing foreign body) there is no simple solution and each case will need to managed on an individual basis depending on the context and weighing the competing risks.

Other uses of the rigid bronchoscope that require anesthesia include dilation for benign airway stenosis, core out of malignant lesions in the trachea, laser ablation of endobronchial and carinal tumors, and therapeutic bronchoscopic interventions before surgical resection of lung cancer. Additionally, interventional bronchoscopy is often used for the management of airway complications after lung transplantation.

Complications of rigid bronchoscopy include airway perforation, mucosal damage, hemorrhage, postmanipulation airway edema, and potential airway loss at the end of the procedure. In some situations, it may be necessary to keep the patient intubated with a small (i.e., 6.0 mm ID) SLT after a rigid bronchoscopy if an edematous airway is suspected or the patient is not able to be extubated. These patients may require the use of corticosteroids and racemic epinephrine via nebulization in the postoperative period.

Mediastinoscopy

Mediastinoscopy is the standard method for the evaluation of mediastinal lymph nodes in the staging of NSCLC. In addition, mediastinoscopy is used to aid in the diagnosis of anterior/superior mediastinal masses.[157] The most common mediastinal diagnostic procedure is a cervical mediastinoscopy in which a small transverse incision (2 to 3 cm) is made in the midline of the lower neck in the suprasternal notch. The pretracheal fascial plane is dissected bluntly and the mediastinoscope inserted toward the carina (Fig. 59-37). An alternative procedure is a parasternal (or anterior) mediastinoscopy with a small incision made through the interchondral space or the space of the excised second costal cartilage. Left parasternal mediastinoscopy may be used for staging some left upper lobe lesions because of the lymphatic drainage of the left upper lobe. Cervical mediastinoscopy and anterior mediastinotomy have been advocated as the most reliable techniques for establishing histologic diagnosis in patients with superior vena cava obstruction.[158]

Morbidity related to mediastinoscopy ranges from 2% to 8%. The most severe complication of mediastinoscopy is major hemorrhage, which may require emergent thoracotomy. Central airway obstruction due to compression of the trachea may occur during induction of anesthesia or during the manipulation of the mediastinoscope near the trachea. Other potential complications include compression of the innominate artery, pneumothorax, paresis of the recurrent laryngeal nerve, phrenic nerve injury, esophageal injury, chylothorax, and air embolism.[159]

For patients undergoing cervical mediastinoscopy, it is important to review the chest radiograph and CT scan or the magnetic resonance (MR) image of the chest for the presence of a mass that might obstruct the airway during the preoperative evaluation. It is possible to perform mediastinoscopy with local anesthesia. This may be an option (most commonly using anterior mediastinoscopy) with an anterior mediastinal mass in a cooperative adult with a compromised airway. However, patient coughing or movement could result in surgical complications. The majority of these patients require general anesthesia with placement of an SLT. In some centers, the operating room table is rotated 90 degrees; thus, extension of the anesthesia breathing circuit may be necessary. After a shoulder roll pack is placed, the SLT should be stabilized and secured because the potential for dislodgment of the tube exists. An arterial line is not necessarily used in these cases. However, it is mandatory to monitor the pulse in the right arm (pulse oximeter on the right hand, arterial line,

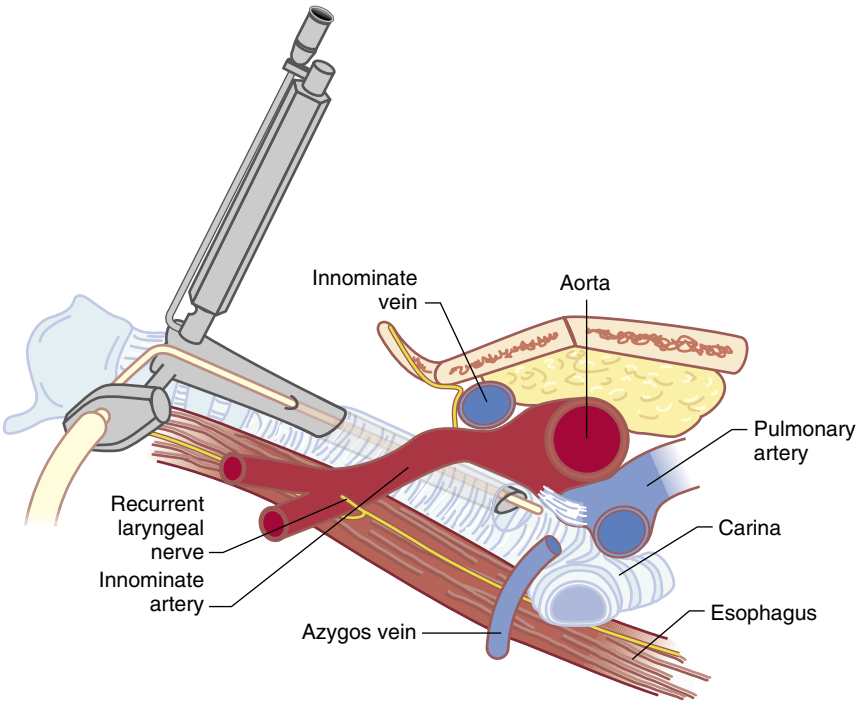

Figure 59-37 Diagram of a mediastinoscope in the pretracheal fascia along with relevant surrounding structures. Note the innominate artery immediately anterior to the mediastinoscope. The azygos vein drains into the superior vena cava, which has been omitted from the drawing because it would cover the location of the mediastinoscope. (*From Kaplan J, Slinger P [eds]: Thoracic Anesthesia, 3rd ed. Philadelphia, Churchill Livingstone, 2003.*)

or the anesthesiologist's finger) because compression of the innominate artery by the mediastinoscope may occur and the surgeon usually is not aware that this is happening. The innominate artery supplies not only the right arm but also the right common carotid. Patients who do not have good cerebral collateral circulation (it is generally not possible to predict which patients these are) are at risk for cerebrovascular ischemia with innominate compression. A noninvasive blood pressure cuff is placed on the left arm to confirm the correct systolic pressure in case of suspected innominate compression.

Mild mediastinal hemorrhage may respond to conservative measures: the patient can be placed in the head-up position, the systolic pressure kept in the 90s, and the wound tamponaded with surgical sponges. However, massive hemorrhage requires an emergent thoracotomy to stop the bleeding (Table 59-20). A bronchial blocker can be passed through the lumen of the existing lung-isolation device if lung isolation is required because it is often difficult to change to a DLT while the surgeon is tamponading the wound. An arterial line should be placed (if not placed previously) to measure arterial blood pressure. If hemorrhage originates from a tear in the superior vena cava, volume replacement and drug treatment may be lost into the surgical field unless they are administered through a peripheral intravenous line placed in the lower extremity.

Table 59-20 Anesthetic Management of Mediastinoscopy Hemorrhage

1. Stop surgery and pack the wound. There is a serious risk that the patient will get too close to the point of hemodynamic collapse if the surgery-anesthesia team does not admit soon enough that there is a problem.
2. Begin the resuscitation and call for help, both anesthetic and surgical.
3. Obtain large-bore vascular access in the lower limbs.
4. Place an arterial line (if not placed at induction).
5. Prepare for massive hemorrhage with blood warmers and rapid infusers.
6. Obtain cross-matched blood in the operating room.
7. Place a double-lumen tube or bronchial blocker if the surgeon believes thoracotomy is a possibility.
8. Once the patient's condition is stabilized and all preparations are made, the surgeon can re-explore the cervical incision.
9. Convert to sternotomy or thoracotomy if indicated.

Pneumothorax is an infrequent complication of mediastinoscopy. Pneumothorax that occurs intraoperatively (as evidenced by increased peak inspiratory pressure, tracheal shift, distant breath sounds, hypotension, and cyanosis) requires immediate treatment by chest tube decompression. All patients must have a chest radiograph taken in the postanesthesia care unit after mediastinoscopy to rule out pneumothorax.

When mediastinoscopy causes injury to the recurrent laryngeal nerve, it can be permanent in approximately 50% of the cases. If injury to the recurrent laryngeal nerve is suspected, the vocal cords should be visualized while the patient is spontaneously breathing. If the vocal cords do not move or are in a midline position, consideration has to be given to the problem of postoperative laryngeal obstruction.

During mediastinoscopy, the tip of the mediastinoscope is intrathoracic and therefore it is directly exposed to pleural pressure. A venous air embolus can occur if patients are breathing spontaneously because of the development of negative intrathoracic pressure during inspiration if venous bleeding occurs. The use of controlled positive-pressure ventilation during this procedure minimizes the risk of air embolism. Autonomic reflexes may result from compression or stretching of the trachea, vagus nerve, or great vessels. With an uncomplicated mediastinoscopy, the patient can be extubated in the operating room and discharged home the same day.

Endobronchial Ultrasound–Guided Biopsy

Various alternative techniques are available for obtaining pathology specimens from the mediastinal lymph nodes. These include CT-guided percutaneous needle aspiration, conventional bronchoscopy with transbronchial needle aspiration, and endobronchial ultrasound–guided biopsy. Endobronchial ultrasonography (EBUS) employing a radial probe through a working channel of the flexible fiberoptic bronchoscope can be used to identify mediastinal and hilar lymph nodes.[160] Under direct endobronchial ultrasonography guidance with fine-needle aspiration for mediastinal staging, an ultrasound puncture bronchoscope can be used to assist with the safe and accurate diagnostic interventional bronchoscopy of the mediastinal and hilar lymph nodes.

Management of these patients is often done at a satellite location, either in the bronchoscopy facility or CT suite. In general, these patients are managed with topical anesthesia (aerosolized lidocaine) and conscious sedation (e.g., fentanyl and/or midazolam). EBUS may replace mediastinoscopy as the standard method of staging lung cancer before resection.

Pulmonary Surgery

Any given pulmonary resection can be accomplished by a variety of different surgical approaches. The approach used in an individual case will depend on the interaction of several factors, which include the site and pathology of the lesion(s) and the training and experience of the surgical team. Common thoracic surgical approaches and their generally accepted advantages and disadvantages are listed in Table 59-21.

Video-assisted Thoracoscopic Surgery

Video-assisted thoracoscopic surgery is the procedure of choice for the diagnosis and management of diseases of the pleura, nondiagnosed peripheral pulmonary nodules, and interstitial lung disease. Since the start of the modern era of thoracoscopic surgery in the early 1990s, VATS has been proposed as a less invasive approach than open procedures. Today it is a well-accepted and established procedure and has become the first choice technique for lung biopsies, pleurectomies, sympathectomies, and other various pulmonary disorders.[161]

In addition, VATS may be used in a variety of other surgical procedures. Specific centers routinely perform lobectomies under VATS, and some centers perform VATS with the aid of a robotic system. Other surgeries, such as spinal fusion and scoliosis, have been performed with VATS. The advantage of VATS, when compared with open thoracotomy, include (1) reduced hospital length of stay, (2) less blood loss if no mishaps occur, (3) less pain, (4) improvement in pulmonary function when compared with open thoracotomy,[162] (5) early patient mobilization with early recovery and rapid return to work and daily activities, and (6) less inflammatory reaction, as measured by cytokine response in patients undergoing VATS lobectomy compared with open thoracotomy.[163]

VATS lobectomy has been demonstrated to be a safe and effective procedure to treat early-stage NSCLC.[164] Thoracoscopic lobectomy is performed with a limited number of ports (one to three) and an access incision of approximately 5 cm in length.[165] The advantage of the VATS technique is that the ribs are not spread. VATS procedures are commonly performed in the lateral decubitus position; however, bilateral VATS procedures, such as bilateral wedge resections or lung volume reduction, can be performed in the supine position.

Thoracoscopic surgery can be performed under local, regional, or general anesthesia with two-lung ventilation or OLV.[166] For minor diagnostic procedures VATS can be done in the awake patient. Intercostal nerve blocks performed at the level of the incision and two interspaces above and below provide adequate analgesia. Partial collapse of the lung on the side of surgery occurs when air enters the pleural cavity. When using local anesthesia with the patient awake, it is hazardous to insufflate gases under pressure into the hemithorax in an attempt to increase visualization of the pleural space. Although many patients suffer from advanced pulmonary disease, changes in Pao_2, $Paco_2$, and cardiac rhythm are usually minimal during the procedure when it is performed under local anesthesia and the patient is

Table 59-21 Comparison of Surgical Approaches for Pulmonary Resections

Incision	Pro	Con
Posterolateral thoracotomy	Excellent exposure to entire operative hemithorax	Postoperative pain ± respiratory dysfunction (short and long term)
Lateral muscle-sparing thoracotomy	Decreased postoperative pain	Increased incidence wound seromas
Anterolateral thoracotomy	Better access for laparotomy, resuscitation, or contralateral thoracotomy especially in trauma	Limited access to posterior thorax
Axillary thoracotomy	Decreased pain Adequate access for first rib resection, sympathectomy, apical blebs or bullae	Limited exposure
Sternotomy	Decreased pain Bilateral access	Decreased exposure of left lower lobe and posterior thoracic structures
Trans-sternal bilateral thoracotomy ("clam shell")	Good exposure for bilateral lung transplantation	Postoperative pain and chest wall dysfunction
Video-assisted thoracoscopic surgery (VATS)	Less postoperative pain and respiratory dysfunction	Technically difficult with central tumors and chest wall adhesions

breathing spontaneously.[167] However, it is recommended that a high F_{IO_2} is delivered via a facemask to overcome the shunt due to the loss in lung volume caused by the unavoidable pneumothorax.

For most invasive procedures VATS is performed under general anesthesia with a DLT or a bronchial blocker to achieve OLV. Lung collapse will take longer when a bronchial blocker is used; if rapid lung collapse is needed, a DLT may be the preferred choice. If the procedure is short in duration and the lung needs to be deflated for only a brief period, blood gases are not routinely monitored during the procedure. However, for patients undergoing prolonged VATS procedures such as lobectomy or for patients with marginal pulmonary status, an arterial line and measurement of arterial blood gases is required. Paravertebral blocks have been used with a single dose of local anesthetics and have been shown to reduce pain after thoracoscopic surgery for 6 hours.[168]

Anesthetic complications are rare during this procedure, although it is possible that any structure that the surgeon has to manipulate may be damaged. The anesthesiologist needs to be aware of the potential for conversion to open thoracotomy if massive bleeding ensues or the surgeon is unable to localize the lung nodule to be sampled. The majority of thoracoscopic surgery requires placement of a chest tube postoperatively. It is important to have a functional chest tube with underwater seal drainage so that extubation can be performed safely.

Lobectomy

Lobectomy is the standard operation for the management of lung cancer because local recurrence of the tumor is reduced compared with lesser resections. Lobectomy is commonly performed via open thoracotomy or VATS. Occasionally, if the clinical staging of the lung cancer is advanced, an elective lobectomy is converted to a bilobectomy (right lung) or pneumonectomy during the operation. Although a posterolateral thoracotomy is the classic incision for lobectomies, anterolateral and muscle-sparing lateral incisions have also been used.

Postoperative analgesia is commonly performed with thoracic epidural analgesia (TEA) or paravertebral analgesia (see "Postoperative Analgesia" later). An arterial line for management of arterial blood gases and measurement of systemic blood pressure is used in all patients requiring an open thoracotomy or major VATS surgery. In addition, a large-bore intravenous catheter should be placed to facilitate rapid transfusion if necessary. Patients undergoing a lobectomy must be kept normothermic, normotensive, and with an acceptable Pa_{O_2} and oxygen saturation, particularly during OLV. Patients should have a thermal blanket on the lower extremities to prevent hypothermia and its deleterious effects during HPV. Potential intraoperative problems include damage to the airway while using lung-isolation devices and the potential for bleeding or hypoxemia during OLV. After the lobe and blood vessels have been dissected, a test maneuver is performed with the surgeon clamping the surgical bronchus to confirm that the specific lobe is extirpated. This maneuver is accomplished by unclamping the limb of the DLT connector of the respective side or, in the case of a bronchial blocker, by deflating the blocker balloon and re-expanding the lung with manual ventilation. During VATS lobectomy, owing to the interference to the surgical field caused by reinflating the residual lobe, the anesthesiologist may be asked to fiberoptically inspect the bronchial tree to confirm patency of the bronchus of the noninvolved lobe. Once the lobectomy has been performed, the bronchial stump is usually tested with 30 cm H_2O positive pressure in the anesthetic circuit to detect the presence of air leaks. A patient undergoing an uncomplicated lobectomy can be usually extubated in the operating room provided preoperative respiratory function is adequate (see "Preoperative Assessment" earlier) and the patient is alert, warm, and comfortable ("AWaC").

Pancoast tumors are carcinomas of the superior sulcus of the lung and can invade/compress local structures, including the lower brachial plexus, subclavian blood vessels, stellate ganglion (causing Horner's syndrome), and vertebrae. Lobectomy may require a two-stage procedure with an initial operation for posterior instrumentation/stabilization of the spine. During lobectomy, extensive chest wall resection may be required and massive transfusion is a possibility. Peripheral lines and monitoring should be in the contralateral arm due to frequent compression of the ipsilateral vessels during surgery.

Sleeve Lobectomy

Bronchial sleeve resections are performed for neoplasms or benign strictures. Bronchogenic carcinoma is the most frequent indication for a sleeve lobectomy, followed by carcinoid tumors, endobronchial metastases, primary airway tumors, and bronchial adenomas. Sleeve resections have been associated with shorter intensive care unit stays and periods of postoperative mechanical ventilation. Sleeve lobectomy involving parenchyma-sparing techniques in patients with limited pulmonary reserve is an alternative surgery for patients who cannot tolerate a pneumonectomy. Overall survival is higher and with fewer locoregional recurrences after sleeve lobectomy. The sleeve technique involves mainstem bronchial resection without parenchymal involvement and possibly resection of pulmonary arteries to avoid pneumonectomy (Fig. 59-38).

Patients undergoing sleeve lobectomy require lung isolation with a contralateral DLT or endobronchial tube (i.e., use of a right-sided DLT for a left sleeve lobectomy). High-frequency jet ventilation (HFJV) can be used for resections close to the tracheal carina. For a sleeve lobectomy involving transplantation of vessels, heparinization is necessary. In these cases, thoracic epidural catheters should not be manipulated for 24 hours after heparin administration. During pulmonary arterioplasty uncontrollable bleeding may occur. For this reason, large-bore intravenous catheters should be used. Patients undergoing sleeve lobectomy are usually extubated in the operating room before transfer to the postanesthesia care unit. Immediate- and long-term survival is better after sleeve lobectomy compared with right pneumonectomy for comparable stages of right upper lobe cancer.[169]

Pneumonectomy

Complete removal of the lung is required when a lobectomy or its modifications is not adequate to remove the local disease and/or ipsilateral lymph node metastases. Atelectasis and pneumonia occur after pneumonectomy as they do after lobectomy but may in fact be less of a problem per se due to the absence of residual parenchymal dysfunction on the operative side. However, the mortality rate after pneumonectomy exceeds that for lobectomy because of postoperative cardiac complications and acute lung injury. The overall operative mortality for the first 30 days after pneumonectomy ranges from 5% to 13%. Mortality correlates inversely with the surgical case-volume.[170]

Thoracotomy for pneumonectomy is usually performed through a standard posterolateral incision. The mediastinal pleura

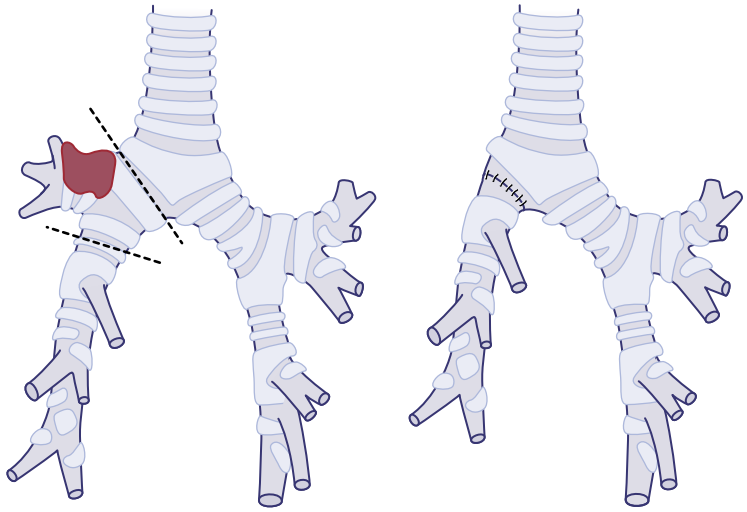

Figure 59-38 Diagram of the surgical procedure for a right upper sleeve lobectomy. Note that it will not be possible to position an endobronchial tube or bronchial blocker in the ipsilateral right mainstem bronchus during this procedure. (*From Shields TW: Surgical therapy for carcinoma of the lung. Clin Chest Med 14:121, 1993.*)

are incised, and the pulmonary artery, the superior and inferior pulmonary veins, and the mainstem bronchus are evaluated for resectability. After all vessels are stapled, stapling of the bronchus occurs and the entire lung is taken from the chest. A test for air leaks is generally performed at this point, and reconstruction of the bronchial stump is completed. The bronchial stump should be as short as possible to prevent a pocket for the collection of secretions.

There is no consensus among thoracic surgeons on the best method of management of the postpneumonectomy space. If suction is applied to an empty hemithorax or a chest drain is connected to a standard underwater-seal system it may cause a mediastinal shift with hemodynamic collapse. Some thoracic surgeons do not place a chest drain after a pneumonectomy. Some thoracic surgeons prefer to use a temporary drainage catheter to add or remove air. The removal of air, ranging from 0.75 up to 1.5 L, is necessary to empty the chest and to keep the mediastinum ("balanced") and the trachea in the midline. Some surgeons place a specifically designed postpneumonectomy chest drainage system with both high- and low-pressure underwater relief valves to balance the mediastinum.[171] A chest radiograph is mandatory after the patient arrives in the postanesthesia care unit or in the surgical intensive care unit to assess the mediastinal shift.

The patient scheduled to undergo a pneumonectomy is considered at high risk for perioperative morbidity and mortality. Patients undergoing a pneumonectomy commonly receive a thoracic epidural catheter for postoperative analgesia, unless there is a contradiction. The placement of large-bore intravenous lines is necessary in case blood products need to be administered. An invasive arterial line is placed for measurement of beat-to-beat blood pressure and to monitor arterial blood gases. A central venous pressure catheter is recommended to help guide intravascular fluid management, specifically in the postoperative period.

A major lung resection, such as pneumonectomy, decreases ventilatory function and has significant effects on the right ventricular function.[172] Immediately after pneumonectomy, the right ventricle may dilate and the right ventricular function decreases. Increased right ventricular afterload is due to an increase in pulmonary artery pressure and pulmonary vascular resistance. This is considered to be one of the main causes of right ventricular dysfunction after a major lung resection.

Management of lung isolation in a pneumonectomy patient can be achieved with a DLT, bronchial blocker, or SLT. When using a DLT for a pneumonectomy patient, it is optimal to use a device that does not interfere with the ipsilateral airway (i.e., for a right pneumonectomy, a left-sided DLT). If a left-sided DLT or bronchial blocker is used for a left pneumonectomy, it must be withdrawn before stapling the bronchus to avoid accidental inclusion into the suture line.

Specific areas of concern in the management of the patient undergoing pneumonectomy include (1) fluid management, (2) intraoperative tidal volume, and (3) acute lung injury post surgery. Fluid administration after major lung resection continues to be an issue. In a retrospective report by Zeldin and associates, the risk factors that were identified for the development of acute lung injury ("postpneumonectomy pulmonary edema") were a right-sided pneumonectomy, increased perioperative intravenous fluid administration, and increased urine output in the postoperative period.[172a] A more recent study by Licker and colleagues has shown that the excessive administration of intravenous fluids in thoracic surgical patients (more than 3 L in the first 24 hours) is an independent risk related to an acute lung injury.[173] There is reasonable clinical evidence that excessive fluid administration is associated with the development of an acute lung injury, which has a high mortality rate after pneumonectomy.[29] Consequently, pneumonectomy patients should have restricted intraoperative fluid administration while preserving renal function. Some cases may require the use of inotropes/vasopressors to maintain hemodynamic stability while restricting fluids (see Table 59-17).

Respiratory failure is a leading cause of postoperative morbidity and mortality in patients undergoing pneumonectomy. A retrospective report involving 170 pneumonectomy patients showed that patients that received median tidal volumes greater than 8 mL/kg had a greater risk of respiratory failure in the postoperative period after pneumonectomy.[174] In contrast, patients who received tidal volumes less than 6 mL/kg were at lower risk of respiratory failure. Schilling and coworkers[175] have shown that a tidal volume of 5 mL/kg during OLV significantly reduces the inflammatory response to alveolar cytokines. Considering these factors, it is prudent to use lower tidal volumes (i.e., 5 to 6 mL/kg, ideal body weight) in the pneumonectomy patient and limit peak and plateau inspiratory pressures (i.e., <35 and 25 cm H_2O, respectively) during OLV.

The incidence of acute lung injury (postpneumonectomy pulmonary edema) after pneumonectomy is only 4%. However, the mortality rate is 30% to 50%. The etiology seems multifactorial. One study[173] has identified four independent risk factors for acute lung injury after pulmonary resection; these include (1) pneumonectomy, (2) excessive administration of fluids in the intraoperative period, (3) high intraoperative ventilatory pressure index (combined airway pressure and time), and (4) preoperative alcohol abuse. The incidence of an acute lung injury is greater for a right- versus left-sided pneumonectomy. The presentation is biphasic. The primary form has a clinical onset during the first 72 hours. The secondary, or late form, appears after 72 hours and is usually related to other complications such as aspiration, bronchopleural fistula, or surgical complications. At the present time only symptomatic management is appropriate. This includes fluid restrictions, diuretic administration, low ventilatory pressures, and tidal volumes (if mechanical ventilation is used) and measures to decrease the pulmonary artery pressure. Although pneumonectomy is associated with mild postoperative pulmonary hypertension during exercise, right ventricular systolic function is usually minimally affected.[13]

Extrapleural Pneumonectomy

Extrapleural pneumonectomy is a therapeutic option for selected patients with malignant pleural mesothelioma.[176] Significant improvement in survival has been achieved in patients who have an advanced malignant pleural mesothelioma with extrapleural pneumonectomy and high-dose radiotherapy in the postoperative period. Extrapleural pneumonectomy involves an extensive resection that may include lymph nodes, pericardium, diaphragm, parietal pleura, and the chest wall. The anesthetic management of the extrapleural pneumonectomy patient is characterized by significant loss of blood due to chest wall vessel involvement. In these patients, it is recommended that a central venous pressure catheter be used to guide intravascular fluid administration and ensure large-bore intravenous access. During tumor dissection, venous return to the heart may be compromised because of multiple factors, including blood loss, compression effect by the tumor in superior vena cava, or surgical causes. If excessive bleeding ensues, it must be replaced to maintain an acceptable hematocrit and the coagulation profile kept within normal limits. Because of extensive tumor resection and the potential for a pericardial resection in right-sided surgery, cardiac herniation or hemodynamic instability can appear postoperatively after the patient is turned from lateral decubitus to supine position. It is common to ventilate these patients for a short period postoperatively owing to the extended duration of the surgery and the large fluid shifts. If a DLT is used intraoperatively, the DLT is usually replaced at the end of the case with an SLT (see "Lung Isolation" earlier).

Sleeve Pneumonectomy

Tumors involving the most proximal portions of the mainstem bronchus and the carina may require a sleeve pneumonectomy. These are most commonly performed for right-sided tumors and can usually be performed without cardiopulmonary bypass (CPB) via a right thoracotomy. A long SLT can be advanced across into the left mainstem bronchus during the period of tracheobronchial anastomosis. HFPPV has also been used for this procedure, and the combined use of HFPPV and a DLT has been described.[177] Because the carina is surgically more accessible from the right side, left sleeve pneumonectomies are commonly performed as a two-stage operation: first a left thoracotomy and pneumonectomy, then a right thoracotomy for the carinal excision. The complication rate and mortality are higher and the 5-year survival (20%) significantly lower than for other pulmonary resections. Postpneumonectomy pulmonary edema is particularly a problem after right sleeve pneumonectomy.

Limited Pulmonary Resections: Segmentectomy and Wedge Resection

A limited pulmonary resection is one in which less than a complete lobe is removed. The two procedures fitting this definition are segmentectomy and wedge resection. Segmentectomy is an anatomic pulmonary resection of the pulmonary artery, vein, bronchus, and parenchyma of a particular segment of the lung. Segmentectomy is usually performed as surgical therapy for patients with primary lung cancer and limited cardiorespiratory reserves. In contrast, a wedge resection is a nonanatomic removal of a portion of the lung parenchyma with a 1.5- to 2.0-cm margin and can be accomplished by open thoracotomy or VATS. Wedge resections are most commonly performed for diagnosis of lung lesions with unknown histology or as palliation in patients with metastatic lesions in the lungs from distant primary tumors. Lung cancers that are considered for limited resection are usually less than 3 cm and are located in the periphery of the lung with regional lymph nodes free of metastatic cancer.

A group of patients considered for limited pulmonary resection are those who develop a new primary lesion after a previous lobectomy or pneumonectomy. The patient with compromised lung function presents a greater risk in the intraoperative period (hypoxemia during OLV or prolonged intubation after surgery). Cerfolio and colleagues[178] reported that lung cancer patients with compromised pulmonary function can safely undergo limited pulmonary resection if selected appropriately. Segmentectomies and wedge resections can be performed with any of the standard thoracotomy or VATS incisions. Segments that are most commonly resected are in the upper lobes or the superior segments of the lower lobes.

Anesthetic technique and monitoring are essentially the same as for larger pulmonary resections. To facilitate surgical exposure and achieve OLV, it is necessary to use either a DLT or a bronchial blocker. If the patient had a previous contralateral lobectomy or a pneumonectomy, selective lobar collapse with the use of a bronchial blocker will facilitate surgical exposure while maintaining oxygenation. In selected cases the combined use of a DLT and a bronchial blocker will allow selective lobar collapse/ventilation in the ipsilateral lung.[179] It is very important to use low tidal volumes (i.e., 3 to 5 mL/kg) during selective lobar ventilation, particularly in patients with previous pneumonectomy to prevent overinflation in the remaining lobes.

Segmentectomy plays a significant role in the management of patients with a second primary lung cancer. Many of these patients have previously undergone thoracic surgery that includes previous lobectomy or pneumonectomy; therefore, the potential for increased intraoperative bleeding is always a risk. In addition, because many of these patients have compromised lung function, early extubation may not be feasible. A common complication after surgery is an air leak. Chest tubes are placed to maximize postoperative expansion and minimize space complications. Suction and underwater seal chest drainage is used in the postoperative period.

Anesthetic Management for Specific Surgical Procedures

Esophageal Surgery

Esophageal surgery is performed for both malignant and benign disease and may be curative or palliative. General considerations that apply to almost all esophageal surgery patients include an increased risk of aspiration due to esophageal dysfunction and the possibility of malnutrition.

Esophagectomy

Esophagectomy is a palliative and potentially curative treatment for esophageal cancer and may occasionally be required for some benign obstructive lesions that do not respond to conservative therapy. It is a major surgical procedure and is associated with high morbidity and mortality rates (10%-15%). There is an inverse correlation between perioperative mortality and surgical volume, and the cure rate of esophageal cancer with esophagectomy is between 10% and 50%. There are multiple surgical procedures for esophageal cancer (Table 59-22) that combine some or all of three fundamental approaches: (1) transthoracic approach, (2) transhiatal approach, and (3) minimally invasive surgery (laparoscopic/thoracoscopic or robotic esophagectomy).[180] The incidence of respiratory complications has been reported to be between 18% and 26% for both the transthoracic and transhiatal esophagectomy approaches.[181] One study showed that the development of acute respiratory distress syndrome (ARDS) occurred in 14.5% of patients and acute lung injury in 24%.[182] Complications associated with the gastroesophageal anastomosis are anastomotic leakage/dehiscence (5% to 26%) and stenosis (12% to 40%).

Transthoracic Approach

Transthoracic esophagectomy is commonly a two-phase procedure. The first phase involves a laparotomy performed with the patient in the supine position and the creation of a neoesophagus tube using the stomach. The second phase involves a right-sided thoracotomy in the left lateral position and esophageal reconstruction through the thoracic route. Some surgeons may perform this procedure through a single extended left thoracoabdominal incision.

The anesthetic management for these patients includes the use of standard monitors and an invasive arterial line and a central venous pressure catheter due to the large fluid shifts. Access to the right internal jugular is not a problem, but there is always a possibility of a surgical esophageal anastomosis in the left neck contraindicating access to the left internal jugular. A thoracic epidural catheter is usually placed to provide postoperative analgesia. Because of the wide number of dermatomes that must be covered for both incisions by the epidural infusion, it is best to use hydrophilic opioids (e.g., hydromorphone) in combination with local anesthetics in preference to lipophilic opioids. Most patients with an esophageal carcinoma have gastric reflux; for this reason, precautions (including a rapid-sequence induction with cricoid pressure) should be taken to protect the airway against aspiration.

During the second phase (right thoracotomy), a left-sided DLT or a right-sided bronchial blocker is required to facilitate lung collapse. Because esophagectomy requires a prolonged period of OLV, this procedure is marked by an important inflammatory response. Michelet and associates[183] have shown that the use of protective ventilatory strategies during OLV decrease the proinflammatory systemic response. This decreased response can be achieved by delivering 5 mL/kg of tidal volume and a PEEP of 5 cm H_2O to the dependent lung, instead of the 9 mL/kg of tidal volume that is conventionally used during esophagectomy.

Manipulation of the esophagus during thoracotomy may compromise venous return, which can cause hypotensive episodes. Early extubation in the operating room is encouraged if the patient meets standard criteria for extubation. If extubation is not possible, the DLT should be replaced for an SLT and mechanical ventilation used in the postoperative period.

Table 59-22 Surgical Approaches for Esophagectomy and Esophagogastrectomy

Surgery	Incisions	Anesthetic Considerations
Laparotomy and right thoracotomy "Ivor Lewis"	Two incisions: upper abdominal midline, then right thoracotomy at 5th to 6th intercostal spaces	One-lung ventilation necessary. Repositioning supine to right-lateral intraoperatively.
Transhiatal "Orringer" (lower third lesions; may be used for mid third in some centers)	Two incisions: upper abdominal midline then left neck	Hemodynamic instability from cardiac compression during blunt intrathoracic dissection. Possibility of occult perforation of tracheobronchial tree during blunt dissection (leave endotracheal tube uncut in case of need to advance into bronchus) No vascular access in left neck
Left thoracoabdominal (lower esophageal lesions only)	One incision: left lateral thoracotomy extended to left upper lateral abdominal	One-lung ventilation desirable
Combined chest, abdominal, and neck ("three hole") (upper/midesophageal lesions)	Three incisions: right thoracotomy, then laparotomy, then left neck	One-lung ventilation necessary Repositioning lateral to supine intraoperatively No vascular access in left neck
Thoracoscopy plus laparotomy or laparoscopy	One or two incisions, plus video port access Thoracoscopy to avoid blunt dissection in chest Neck incision at end	One-lung ventilation necessary Potentially prolonged surgery

Transhiatal Approach

Airway management is with an SLT. Apart from this, anesthetic management is essentially the same as for a transthoracic approach. Of special concern is that the blunt/blind manual dissection of the thoracic esophagus by the surgeon through the hiatus during this approach is often associated with cardiac compression and sudden severe hypotension. Also, this blind dissection can cause vascular or distal airway injuries if the tumor is adherent. It is a good practice not to cut the endotracheal tube for this procedure in case of surgical perforation of the trachea or bronchus, necessitating advancement of the endotracheal tube into a mainstem bronchus for emergent OLV.

Minimally Invasive Approach

Minimally invasive esophagectomy involves the use of laparoscopic, thoracoscopic, or robotic surgical approaches. For a laparoscopic approach, distention of the peritoneum may produce hemodynamic changes due to the intragastric pressure generated by carbon dioxide insufflation. In these cases, it is important to adjust ventilatory parameters to achieve an optimal $Paco_2$. For the thoracoscopic approach, a left-sided DLT or a bronchial blocker is required. During robotic surgery, the use of a lung-isolation device is required to achieve OLV. Special considerations for robotic surgery include protecting the patients against any injury related to the robot and not moving the operating room table while the robot is being used. The thoracoscopic-assisted esophagectomy has several advantages, including less blood loss, less pain, and a shorter length of hospitalization. This method does, however, require a prolonged duration of surgery.

Patients undergoing esophagectomy require third-space fluid administration and periodically inotropic support. In addition, all patients undergoing esophagectomy require a nasogastric tube, which must be well-secured at the end of the operation. Respiratory complications, including the development of an acute lung injury, may be present after an esophagectomy. Intrathoracic anastomotic leakage is a feared major complication after esophageal surgery and carries a high mortality rate of 4% to 30%.[184] To treat this potential complication, nasogastric decompression and nutritional support should be used. Severe leakage usually occurs in the early postoperative period as a consequence of gastric necrosis, and it may present as respiratory symptoms and signs of shock. Even though there is a very high mortality rate, prompt surgical intervention is recommended. Patients older than 80 years of age have an increased risk of mortality after esophagectomy, independent of comorbidity.[185]

Esophageal Surgery for Benign Disease

Hiatal Hernia

Although most patients with gastroesophageal reflux have a hiatal hernia, most patients with a hiatal hernia do not have significant reflux.[186] Patients with heartburn have a lowered barrier pressure and may be at increased risk for regurgitation of gastric contents. Two types of hiatal hernia have been described. Type I hernias, also called sliding hernias, make up approximately 90% of esophageal hiatal hernias. In this type, the esophagogastric junction and fundus of the stomach have herniated axially through the esophageal hiatus into the thorax (Fig. 59-39). The term *sliding* refers to the presence of a sac of parietal peritoneum. The lower esophageal sphincter is cephalad to the diaphragm and may not respond appropriately to increased abdominal pressure. Thus, a reduced barrier pressure during coughing or breathing leads to regurgitation. The type II, or paraesophageal, hiatal hernia, is characterized by portions of the stomach herniating into the thorax next to the esophagus. In the presence of a type II hernia, the esophagogastric junction is still located in the abdomen. The most common complications from type II hernias are blood loss, anemia, and gastric volvulus.

Figure 59-39 Chest radiograph of a patient with a hiatal hernia and a dilated intrathoracic stomach who was scheduled for hiatal hernia repair via a left thoracotomy. An air-fluid level can be seen in the stomach behind the heart. These patients are at high risk for aspiration on induction of anesthesia.

The goal of surgical repair of a sliding hernia is to obtain competence of the gastroesophageal junction. Because restoration of the normal anatomy is not always successful in preventing subsequent reflux, several antireflux operations have been developed, such as the Nissen fundoplication. Repair of hiatal hernia can be performed via a thoracotomy, laparotomy, or minimally invasively.

Benign Esophageal Stricture

Chronic reflux of acidic gastric contents can lead to ulceration, inflammation, and eventually stricture of the esophagus. The pathologic changes are reversible if the acidic gastric contents cease their contact with the esophageal mucosa. Surgery may be necessary if medical treatment and dilatations are inadequate. There are two types of surgical repair, both of which are usually approached via a left thoracoabdominal incision. Gastroplasty after esophageal dilatation interposes the fundus of the stomach between esophageal mucosa and the acidic milieu of the stomach. The remaining fundus may be sewn to the lower esophagus to create a valve-like effect. The second type of repair is resection of the stricture and the creation of a thoracic end-to-side esophagogastrostomy. Vagotomy and antrectomy are performed to

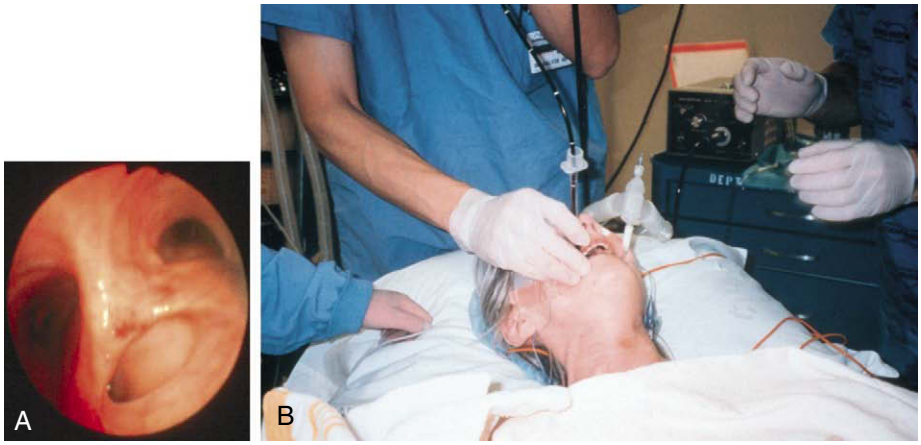

Figure 59-40 A, Fiberoptic bronchoscopic photograph of a tracheoesophageal fistula due to esophageal cancer. The fistula is seen posteriorly at the level of carina at 5 o'clock. The left mainstem bronchus is at 9 o'clock and the right mainstem bronchus at 2 o'clock. **B,** Photograph of the fiberoptic-guided placement of bilateral endobronchial tubes (5-mm ID microlaryngoscopy tubes) for repair of tracheoesophageal fistula in the same patient. eliminate stomach acidity, and a Roux-en-Y gastric drainage procedure is performed to prevent alkaline intestinal reflux.

Esophageal Perforation and Rupture

There are multiple causes of esophageal perforation, including foreign bodies, endoscopy, bougienage, traumatic tracheal intubation, gastric tubes, and oropharyngeal suctioning. Iatrogenic causes are the most common, with upper gastrointestinal endoscopy being the most frequent cause. A rupture is a burst injury often due to uncoordinated vomiting, straining associated with weight lifting, childbirth, defecation, and crush injuries to the chest and abdomen. The rupture is usually located within 2 cm of the gastroesophageal junction on the left side. Rupture is due to a sudden increase in abdominal pressure with a relaxed lower esophageal sphincter and an obstructed esophageal inlet. In contrast to a perforation, in the presence of a rupture, the stomach contents enter the mediastinum under high pressure and the patient becomes symptomatic much more abruptly.

In addition to chest and/or back pain, patients with intrathoracic esophageal perforation or rupture may develop hypotension, diaphoresis, tachypnea, cyanosis, emphysema, and hydrothorax or hydropneumothorax.[187] Radiologic studies may reveal subcutaneous emphysema, pneumomediastinum, widening of the mediastinum, pleural effusion, and pneumoperitoneum. These patients will rapidly develop mediastinitis and sepsis if not treated surgically, so repair and drainage is an emergency procedure usually performed via a left or right thoracotomy.

Achalasia

Achalasia is a disorder in which there is a lack of peristalsis of the esophagus and a failure of the lower esophageal sphincter to relax in response to swallowing. Clinically, the patients have esophageal distention that may lead to chronic regurgitation and aspiration. The goal of treatment is to alleviate the distal obstruction. This can be done by either esophageal dilatation or surgery. Dilatation, which carries with it the risk of perforation, can be achieved by mechanical, hydrostatic, or pneumatic means. The surgical repair consists of a Heller myotomy, which is an incision through the circular muscle of the esophagogastric junction. The myotomy is often combined with a hiatal hernia repair to prevent subsequent reflux. This can be performed via thoracotomy, laparotomy, or laparoscopy.[188] The Dor operation is a modification of the procedure in which a stent is inserted into the muscular defect created by the myotomy to prevent muscular reapposition and, thus, recurrent dysphagia.[189]

Esophagorespiratory Tract Fistula

Esophagorespiratory tract fistula in an adult is most often due to malignancy. Occasionally, the fistula is benign and may be due to injury by a tracheal tube, trauma, or inflammation. Of the malignant fistulas, approximately 85% are secondary to esophageal cancer. In contrast to the pediatric patient with esophagorespiratory tract fistulas, which usually connect the distal esophagus to the posterior tracheal wall, these fistulas may connect to any part of the respiratory tract.[190] In most cases, the fistula can be seen on esophagoscopy or bronchoscopy. In malignant cases, the goal of surgery is usually palliation. The technique of lung isolation will depend on the location of the fistula. One option in adults with a distal tracheal fistula is the use of bilateral small (5-6 mm ID) endobronchial tubes (Fig. 59-40).[191]

Zenker's Diverticulum

Zenker's diverticulum is actually a diverticulum of the lower pharynx. It arises from a weakness at the junction of the thyropharyngeus and cricopharyngeus muscles just proximal to the esophagus. It is commonly considered as an esophageal lesion because of its proximity to the upper esophagus and because the underlying cause may be a failure of relaxation of the upper esophageal sphincter during swallowing. Early symptoms may be nonspecific, with dysphagia and complaints of food sticking in the throat. As the diverticulum enlarges, patients describe noisy swallowing, regurgitation of undigested food, and supine coughing spells. Recurrent aspiration and pneumonia may develop.

The major concern for anesthesia is the possibility of aspiration on induction of general anesthesia for excision of the diverticulum.[192] Even prolonged fasting does not ensure that the diverticulum will be empty. The best method to empty the diverticulum is to have the patient express and regurgitate the contents

immediately before induction. Many of these patients will be used to doing this on a regular basis at home. Because the diverticulum orifice is almost always above the level of the cricoid cartilage, cricoid pressure during a rapid-sequence induction does not prevent aspiration and may contribute to aspiration by causing the sac to empty into the pharynx. Surgical excision is usually done through a lower left neck incision.

The safest method of managing the airway for these patients may be awake fiberoptic intubation. However, these have been managed without incident using a modified rapid-sequence induction without cricoid pressure and with the patient supine and head up 20 to 30 degrees. Other considerations in these patients include the possibility of perforation of the diverticulum when passing an orogastric or nasogastric tube or an esophageal bougie.

Tracheal Resection

Tracheal resection and reconstruction is indicated in patients who have a tracheal obstruction as a result of a tracheal tumor, previous tracheal trauma (most commonly due to postintubation stenosis), congenital anomalies, and vascular lesions. For patients who have operable tumors, approximately 80% undergo segmental resection with primary anastomosis, 10% undergo segmental resection with prosthetic reconstruction, and the remaining 10% undergo placement of a T-tube stent.

Diagnostic studies are reviewed as part of the preoperative evaluation. Linear tomography of the trachea is considered the most accurate tool to define the degree, level, and length of the lesion. The CT scan is a useful diagnostic tool to evaluate extratracheal or extrabronchial involvement by a tumor. Bronchoscopy is one of the definitive diagnostic tests for tracheal obstruction. In cases of moderate to severe obstruction, fiberoptic bronchoscopic examination is usually deferred until the time of definitive treatment, such as surgical intervention. Bronchoscopy for a patient with tracheal stenosis should be carried out in the operating room where the surgical and anesthesia teams are present and ready to intervene should loss of airway occur. An advantage of rigid bronchoscopy over flexible bronchoscopy is that it can bypass the obstruction and provide a ventilation pathway if complete obstruction occurs. During surgery, all patients should have an invasive arterial catheter placed to facilitate measurement of arterial blood gases, as well as measure arterial blood pressure. Central venous pressure or pulmonary artery catheters are only used if the patient requires CPB.

A variety of methods for providing adequate oxygenation and elimination of CO_2 have been used during tracheal resection. The different alternatives include (1) standard orotracheal intubation, (2) insertion of a sterile SLT into the opened trachea or bronchus distal to the area of resection, (3) HFJV through the stenotic area, (4) HFPPV, and (5) the use of CPB.

Induction of anesthesia in patients with a compromised airway requires good communication between the surgical team and the anesthesiologist. The surgeon should always be in the operating room during induction and available to manage a surgical airway if this becomes necessary.[193] A rigid bronchoscope must be immediately available. The patient should be thoroughly preoxygenated with 100% O_2 prior to the initiation of inhalation induction. The safest and most commonly recommended method of induction is with spontaneous ventilation. The use of sevoflurane is recommended because, of all the inhaled anesthetics, it has the least irritant effects in the airway. When adequate depth of anesthesia is achieved, topicalization of the airway with local anesthetics is done with 4% lidocaine and mask ventilation is reconfirmed. Bronchoscopy can then be performed to assess the airway and location of the stenosis or lesion. The airway should be secured before using muscle relaxants. Short-acting muscle relaxants, such as succinylcholine, are preferable initially.

One airway management technique is with an SLT that is placed above the tracheal lesion, under direct flexible fiberoptic bronchoscopy guidance after induction of general anesthesia. The tube is then manipulated by the surgeon distal to the mass or the area of stenosis. This technique is limited to patients with relatively mild stenosis, and the presence of an SLT in the surgical field makes completion of the tracheal anastomosis more difficult.

Another technique is to insert an endotracheal or endobronchial tube into the opened trachea distal to the site of resection. Initially, either a small SLT is passed distal to the obstruction or a standard SLT is placed proximal to it. All further tracheal and endobronchial intubations are performed preferably with an armored sterile tube passed into the airway, which is surgically opened distal to the lesion.

With a low tracheal lesion, a right thoracotomy provides the optimal surgical exposure. A sterile SLT is used to provide ventilation to the lung distal to the resection. After the posterior anastomosis is completed, the endobronchial tube is removed and the original SLT is advanced past the site of resection (Fig. 59-41). This technique can also be used for carinal resection.

A third technique for airway management during tracheal resection includes HFJV through a small-bore endotracheal tube or catheter.[194] With this technique, a small-bore uncuffed catheter is placed through the stenotic area and ventilation is accomplished by intermittently exposing the lung to a high flow of fresh gas through the catheter. Oxygen jets entrain ambient air, which in turn provides the volume necessary for adequate ventilation. Disadvantages of this technique include (1) possible inadequate escape of air around the jet catheter during exhalation when the catheter is passed through a tight stenotic area causing barotrauma, (2) plugging of the catheter with blood, (3) displacement of the catheter, (4) aspiration of blood, and (5) technical difficulties with high-pressure injectors. The catheters used for HFJV have an internal diameter ranging from 2 to 5 mm, with a length of either 45 or 50 cm. In these patients, the trachea is intubated orally and the lungs ventilated with intermittent positive-pressure ventilation until the trachea is transected. Then HFJV is initiated through a fine catheter inserted in the SLT and positioned either in the distal trachea or left mainstem bronchus. Other techniques that have been used for oxygenation during distal airway resections include HFPPV, helium-oxygen mixtures, and CPB.

After the tracheal resection is completed, most patients are kept in a position of neck flexion to reduce tension on the suture line. A thick chin-sternum suture may be placed for several days to maintain neck flexion or a cervical splint may be used.[195] A small SLT or tracheostomy tube (preferably uncuffed) or a T-tube with upper limb 0.5 to 1 cm above the vocal cords may be inserted at the end of surgery in cases when glottic edema is a concern or for patients requiring ventilatory support. If a tracheostomy is performed, it will be done distal to the anastomosis. Early extubation is highly desirable. If a patient requires reintubation, it should

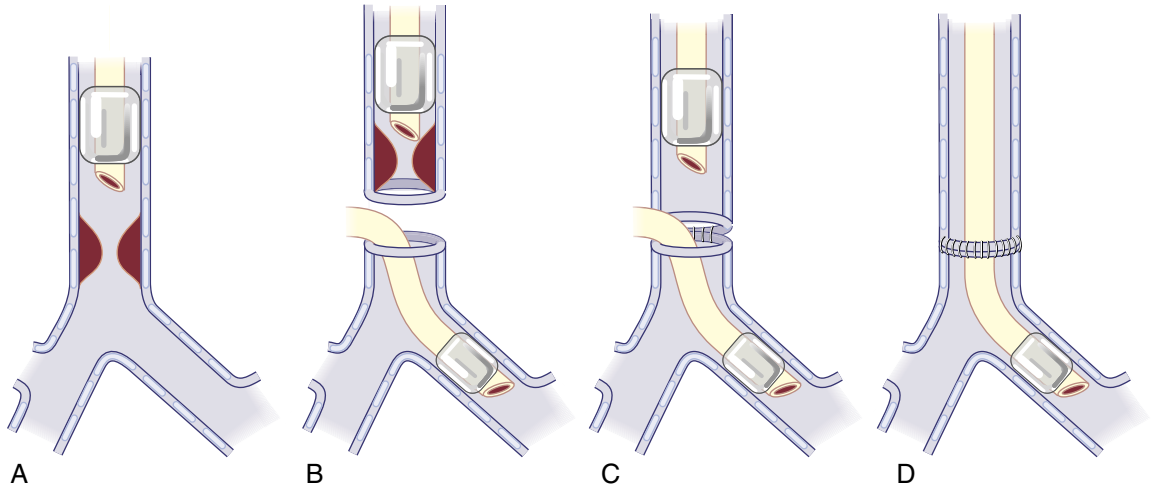

Figure 59-41 Airway management and surgical procedure for resection of a low tracheal lesion. **A,** Initial intubation above the lesion. **B,** Left endobronchial intubation distal to the lesion after the trachea has been opened. **C,** Placement of sutures for the posterior anastomosis. **D,** The endobronchial tube has been removed, and the original endotracheal tube has been advanced distal to the anterior anastomosis into an endobronchial position. (*Modified from Geffin B, Bland J, Grillo HC: Anesthetic management of tracheal resection and reconstruction. Anesth Analg 48:884, 1969.*)

be performed with a flexible fiberoptic bronchoscope by advancing an SLT under direct vision over the bronchoscope and then placing it in the patient's trachea. The patient is kept in a head-up position to diminish swelling. Racemic epinephrine, corticosteroids, diuretics, and fluid restriction may be useful in these cases to decrease airway edema.

One of the complications in the postoperative period is tetraplegia, with hyperflexion of the neck having been implicated as a potential cause. In these cases, it is necessary to cut the chin stitch. Tracheal extubation can be challenging. An infusion of propofol and remifentanil, with fiberoptic bronchoscopy guidance and full patient cooperation, can aid extubation.[196]

Bronchiectasis/Lung Abscess/Empyema

Bronchiectasis is a disease that causes localized, irreversible dilatation of part of the bronchial tree. Involved bronchi are inflamed and easily collapsible, resulting in airflow obstruction and impaired clearance of secretions. Bronchiectasis is associated with a wide range of disorders, but it usually results from necrotizing bacterial infections. It may require surgery if it causes hemoptysis or recurrent pneumonia. An abscess is a nonanatomic area of liquefactive necrosis of the lung often distal to an obstruction or following pneumonia (Fig. 59-42). An empyema

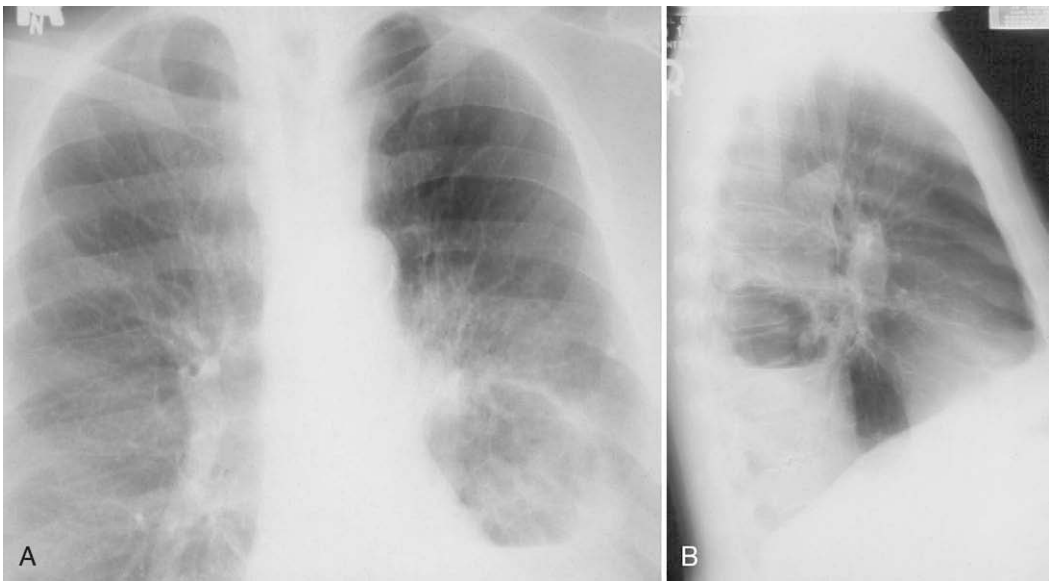

Figure 59-42 Posteroanterior (**A**) and lateral (**B**) chest radiographs of a patient with a lung abscess distal to an obstructing carcinoma of the left lower lobe. The diagnostic thick wall of the abscess and the air-fluid level can be appreciated in the left lower thorax. These patients are at risk for soiling of uncontaminated lung regions during surgery from pus in the abscess. The optimal method of lung isolation is with a double-lumen tube.

Figure 59-43 **A,** Chest radiograph of a patient immediately postoperatively after a right pneumonectomy. **B,** The same patient on postoperative day 6. This is a normal postpneumonectomy film. The right hemithorax is gradually filling with serous fluid. **C,** The same patient on postoperative day 7. The patient had the sudden onset of severe dyspnea, desaturation, and coughing. The chest radiograph reveals a decrease in the fluid level in the right hemithorax. This is diagnostic of a bronchopleural fistula caused by dehiscence of the bronchial stump.

is a collection of pus between the visceral and parietal pleural layers that is often a complication of pneumonia or surgery. Empyema complicating lung resections occurs in 2% to 16% of cases and with a 40% increase in the associated perioperative mortality rate. Mortality further increases when the empyema is associated with a bronchopleural fistula. Surgical interventions for patients with empyema include decortication (the method of choice when the underlying lung is unable to expand due to a thick inflammatory coat) or open window thoracostomy (the ideal method for drainage of the pleural cavity to control septic symptoms in patients with postpulmonary resection empyema).[197] In less severe cases, tube drainage, antibiotic irrigation, and débridement may be sufficient.

All of these infective indications for thoracic surgery are less common in the developed world since the introduction of antibiotics. Anesthetic considerations during surgery for these infective indications include the need for lung isolation to protect uninvolved lung regions from soiling by pus in the infected areas. Also, owing to the inflammation, surgery is technically more difficult and there is a greater risk of massive hemorrhage.

Some of these patients may present with sepsis at the time of surgery. In these patients the placement of a thoracic epidural catheter is not recommended. These patients require lung isolation, preferably with a DLT. The DLT facilitates suctioning of debris and copious secretions that are present in the tracheobronchial tree. Patients undergoing a decortication may have massive blood loss. If the lung has been chronically collapsed, expansion should be done gradually to avoid the development of pulmonary edema on re-expansion. Extubation in the operating room is encouraged if the patient meets standard criteria for extubation.

Bronchopleural Fistula

A bronchopleural fistula may be caused by (1) rupture of a lung abscess, bronchus, bulla, cyst, or parenchymal tissue into the pleural space; (2) the erosion of a bronchus by carcinoma or chronic inflammatory disease; or (3) stump dehiscence of a bronchial suture line after pulmonary resection. Pneumonectomy patients have an incidence of bronchopleural fistula, ranging from 2% to 11%,[198] with a mortality ranging from 5% to 70%.

The diagnosis of bronchopleural fistula is usually made clinically. After pneumonectomy, the diagnosis is based on the sudden onset of dyspnea, subcutaneous emphysema, contralateral deviation of the trachea, and a decrease of fluid level on serial radiographs of the chest (Fig. 59-43). In lobectomy patients, persistent air leak, purulent drainage, and expectoration of purulent material are usually diagnostic indicators of a bronchopleural fistula. When the fistula appears after removal of a chest tube, the diagnosis of bronchopleural fistula is made on the basis of fever, purulent sputum, and a new air-fluid level in the pleural cavity on the chest radiograph.

The diagnosis is confirmed by bronchoscopic examination. Additionally, bronchography and sinograms of the fistula may be used to confirm the diagnosis. Other diagnostic methods include the injection of an indicator, such as methylene blue, into the pleural space and subsequent recovery of the indicator from sputum. Accumulation of radionuclide in the pleural space after inhalation of xenon or a mixture of O_2 and N_2O to detect the presence of a bronchopleural fistula can also be used as indicators.[199]

If the disruption occurs early in postpneumonectomy patients, it is possible to resuture the stump. Late or chronic postpneumonectomy bronchial disruption is managed with drainage or with the Clagett procedure, which includes open pleural drainage and the use of a muscle flap to reinforce the bronchial stump. In nonpneumonectomy cases, if the lung expands to fill the thoracic cavity, the air leak can usually be controlled with chest tube drainage alone. However, if the fistula is large and a significant leak through a large persistent pleural space occurs, it is unlikely that the fistula will close, and surgical resection is necessary

The patient with a bronchopleural fistula presents several intraoperative challenges for the anesthesiologist; these include (1) the need for lung isolation to protect healthy lung regions, (2) the possibility of tension pneumothorax with positive-pressure ventilation, and (3) the possibility of inadequate ventilation due to air leak from the fistula. Preoperatively, it is useful to estimate the loss of tidal volume through the bronchopleural fistula, which may be done in two ways. First, one should determine whether air bubbles flow intermittently or continuously through the chest tube. If air bubbles flow intermittently, then the fistula is small. In contrast, when a patient has a large bronchopleural fistula or bronchial rupture, air will bubble continuously through the water-seal chamber of the chest tube drainage system. Second, the size of the bronchopleural fistula may be quantified by the difference between inhaled and exhaled tidal volumes. In a nonintubated patient, this may be determined with a tight-fitting mask and a

fast-responding spirometer. In an intubated patient, it is determined by direct attachment of the spirometer to the endotracheal tube. The larger the air leak, the greater the need to isolate the bronchopleural fistula with the use of a lung-isolation device (a DLT or an independent bronchial blocker).

Several nonsurgical approaches (i.e., the use of various mechanical ventilation/chest tube drainage systems) have been used for the treatment of patients with a bronchopleural fistula. These approaches consist of OLV and differential lung ventilation, including high-frequency ventilation, PEEP to the pleural cavity equal to intrathoracic PEEP, and unidirectional chest tube valves.

For patients undergoing operative repair, the ability to adequately deliver positive-pressure ventilation intraoperatively must be carefully considered before surgery. A chest drain should be placed before induction to avoid the possibility of tension pneumothorax with positive-pressure ventilation. If a fistula is small, chronic, and uninfected, an SLT can be used safely. If the air leak is significant, then a DLT is the best choice for delivering positive-pressure ventilation. The DLT can provide positive-pressure ventilation to the normal lung without loss of minute ventilation through the fistula and prevent the hazard of contamination of the uninfected lung with infected material when the patient is turned to the lateral decubitus position.

The safest method of obtaining lung isolation is awake fiberoptic intubation with a DLT.[200] However, this requires a cooperative patient and excellent topical anesthesia and is often not an option. Another option is to maintain spontaneous ventilation during induction and intubation until lung isolation is secured. This avoids the possibility of inadequate positive-pressure ventilation due to air leak but is not well tolerated in older patients with significant comorbidity. If the patient has a post-pneumonectomy fistula, the DLT or SLT must be guided under direct vision with the assistance fiberoptic bronchoscopy and the tip of the endobronchial lumen should be placed in the existing lung (e.g., for right-sided fistula a left-sided tube). After the chest is opened, if an excessive leak is encountered when using an SLT, ventilation can be improved by lung packing and manual control of the air leak.

One option to avoid instrumentation of the airway in patients with bronchopleural fistula after pneumonectomy is the use of thoracic epidural anesthesia with intravenous sedation during minimally invasive surgery.[201] An alternative method of ventilating patients with multiple bronchopleural fistulas is the use of high-frequency oscillatory ventilation with permissive hypercapnia. This avoids barotrauma to the nonoperative lung, decreases bronchopleural fistula air leak, and optimizes the operative outcome.[202] The advantage of high-frequency oscillatory ventilation over conventional mechanical ventilation is that it uses lower peak airway pressure and may decrease the air leak across the fistula. Early extubation in the operating room should be attempted in all patients undergoing fistula repair to avoid barotrauma to the surgical stump from positive-pressure ventilation in the postoperative period.

Blebs, Bullae, Cysts, and Pneumatoceles

Blebs

A bleb is a subpleural collection air under the visceral pleura caused by a ruptured alveolus. The air dissects through the pulmonary parenchyma and enlarges to form a bubble on the surface of the lung. Blebs most commonly occur at the apices of the lung and can rupture into the interpleural space, causing a pneumothorax. A single episode of spontaneous pneumothorax is usually treated conservatively with chest tube drainage until the air leak has stopped. Resection of blebs is commonly indicated for recurrent pneumthoraces, bilateral pneumothoraces, or prolonged chest tube drainage. Resection of blebs after a single pneumothorax may be indicated if the patient's occupation exposes him or her to significant rapid fluctuations in atmospheric pressure (e.g., flight crews or scuba divers). Resection is most commonly combined with a procedure to obliterate the pleural space by partial pleurectomy or pleural abrasion. Resection of blebs is most often performed by VATS. Although VATS procedures per se are generally associated with limited need for postoperative analgesia, pleurectomy or abrasion is very painful.

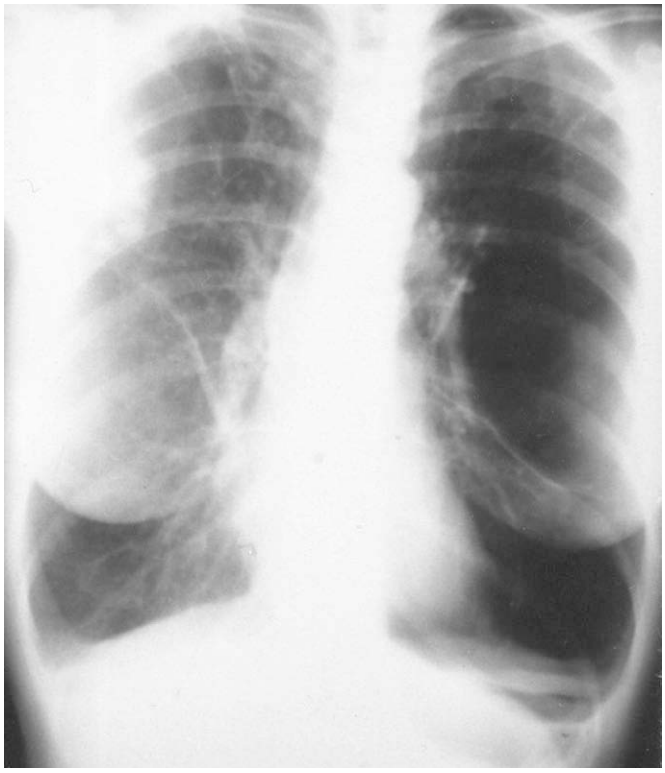

Figure 59-44 Chest radiograph of a patient with severe emphysema and multiple bullae, including giant bullae of the left upper land lower lobes.

Bullae

Bullae are thin-walled air-filled intraparenchymal lung spaces caused by the loss of alveolar structural tissue (Fig. 59-44). These are usually associated with emphysema, but their exact cause is unclear. Although there is some confusion over terminology in this area, bullous-like lesions of the lung associated with congenital malformations or secondary to trauma or infection are more correctly termed pneumatoceles or cysts. There are no universally accepted surgical indications for resection of lung bullae. A patient with symptomatic dyspnea and a giant bulla (or bullae) that occupies more than 30% of a hemithorax, and in whom a radiograph and CT scan suggest that reasonably functional lung tissue can be restored to a more anatomically favorable position, should be considered for bullectomy. Factors that support the

effect of the bullae as a cause of a patient's dyspnea are a restrictive pattern of spirometry (proportional decrease of both FEV_1, and FVC) and a discrepancy in lung volume studies in which the FRC measured by plethysmography exceeds the FRC measured by helium dilution by more than 2 L.

In the usual tidal volume range, bullae are more compliant than normal lung and fill preferentially during spontaneous ventilation. However, beyond the normal tidal volume range, bullae become much less compliant and the intrabulla pressure rises acutely as airway pressure increases. Measurement of in vivo intrabullae pressures in patients using fine needles both before and during anesthesia showed no evidence of a valve mechanism.[36] All bullae studied communicated with the central airways, although some very slowly. The typical compression pattern seen on radiography or CT is most likely due to secondary elastic recoil of normal lung regions (see Fig. 59-5). Intrabulla pressure at FRC corresponds with the mean airway pressure averaged over the respiratory cycle. Thus, during spontaneous ventilation, the intra-bulla pressure will be negative with respect to surrounding lung tissue. However, whenever positive pressure is used, the intra-bulla pressure will rise in relation to surrounding lung regions. There is a risk of hyperinflation and rupture whenever positive pressure is used. The complications of bulla rupture can be life threatening due to hemodynamic collapse from tension pneumothorax or inadequate ventilation due to a resultant bronchopleural fistula.

Relief of dyspnea symptoms and improved pulmonary function are well documented in patients after resection of giant bullae with most patients showing an increase in FEV_1 of more than 0.3 L and excellent short-term improvement in quality of life, but with a decrease in improvement by 3 years.[203] Hypercapnia is not a contraindication to bullae resection. Lung infection must be meticulously treated preoperatively. Outcome depends on patient age, smoking history, and cardiac status. In the postoperative period lung air leaks are the major complication.

The surgical approach can be by traditional or modified thoracotomy, sternotomy, or VATS. Laser resection may decrease the incidence of air leaks. Various nonsurgical thoracoscopic and bronchoscopic procedures such as the subsegmental injections of fibrin glue have been used to deal with these air leaks.

The anesthetic considerations for bullectomy are similar to those for a patient with a bronchopleural fistula with the exceptions that it is best not to place a chest drain prophylactically because this may enter the bulla and create a fistula and there is not the risk of soiling healthy lung regions from extrapleural fluid that exists with fistulas. For induction of anesthesia it is optimal to maintain spontaneous ventilation until the lung or lobe with the bulla or bleb is isolated.[204] When there is a risk of aspiration or it is believed that the patient's gas exchange or hemodynamics may not permit spontaneous ventilation for induction, the anesthesiologist will have to use small tidal volumes and low airway pressures during positive-pressure ventilation until the airway is isolated.

Cysts

Congenital bronchogenic cysts are products of abnormalities in the tracheobronchial budding process of lung organogenesis. They may occur peripherally within the lung parenchyma (70%) or centrally attached to the mediastinum or hilum. Bronchogenic cysts become problematic if they become enlarged, exerting a mass effect on functional lung or mediastinal structures or if they rupture and create a pneumothorax, or if they become infected. Small cysts without communications to a bronchus are asymptomatic and may be incidentally noted as round, clearly demarcated lesions on chest radiographs. Communicating cysts often produce air-fluid levels, are prone to recurrent infection, and may trap air by a ball-valve mechanism risking rapid expansion or rupture. Infected cysts may be obscured by surrounding pneumonia or may be difficult to differentiate from an empyema. CT scans help differentiate cystic from solid lesions. Conservative surgical excision of bronchogenic cysts is generally recommended whether or not a bronchial communication is evident.

Pulmonary hydatid cysts are watery, parasitic cysts containing larvae of the dog tapeworm *Echinococcus granulosus*.[205] Echinococcosis is a relatively common cause of pulmonary cysts in endemic areas (Australia, New Zealand, South America, and some third world regions). Hydatid cysts may grow in diameter by as much as 5 cm per year and become medically problematic in several ways. By mass effect they may exert pressure on adjacent structures (e.g., bronchus, great vessels, esophagus). Spontaneous or traumatic rupture may occur, sending fluid, parasites, or laminated debris into adjacent tissue, bronchus, pleura, or the circulation (systemic emboli). Hypersensitivity reactions, bronchospasm, and anaphylaxis can result. Drainage into the bronchi may cause dramatic expulsion of fluid with respiratory distress or asphyxiation, depending on the amount of fluid involved. Rupture into the pleural space may result in a large hydropneumothorax, severe dyspnea, shock, suffocation, or anaphylaxis. Rupture becomes more dangerous and more likely as cysts become larger. It is recommended that any cyst larger than 7 cm be removed.

Small, intact, peripheral cysts are often easily enucleated without loss of lung parenchyma. Segmentectomy or lobectomy is indicated when single or multiple cysts occupy most of the segment or lobe. Patients with suppurative cysts should be prepared for surgery with postural drainage and antibiotics. Lung isolation and/or reduced airway pressure during dissection may be helpful in preventing herniation of the cyst. Increased airway pressure at the time of delivery may aid removal of the cyst. The multiple bronchial openings in the residual cavity must then be identified and closed. Multiple "leak tests" with saline in the residual opening may be required to locate all bronchial openings. An alternative surgical strategy is to inject hypertonic saline into the cyst to sterilize it, followed by aspiration of the contents and removal of the evacuated cyst.

Pneumatoceles

Pneumatoceles are thin-walled, air-filled spaces generated by pulmonary infections or trauma. They usually appear in the first week of a pneumonia and resolve spontaneously within 6 weeks. As with other lung cysts, potential complications of pneumatoceles include secondary infection and enlargement as a result of air entrapment, with possible rupture or displacement and compression of normal lung. Adverse hemodynamic consequences may result either from a tension pneumothorax or a tension pneumatocele. The latter is unusual and is presumed to result from a one-way valve mechanism, usually in the setting of positive-pressure mechanical ventilation.[206] Occasionally, surgical decompression is required and has been performed by percutaneous needle aspiration, catheter drainage, or chest tube drainage under CT or fluoroscopic guidance. Rarely is thoracoscopic or open surgical drainage or excision required.

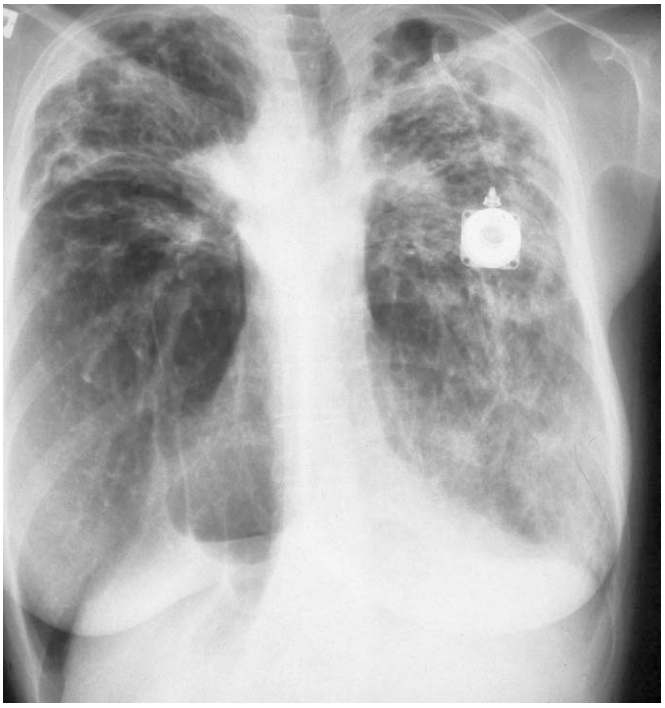

Figure 59-45 Chest radiograph of a patient with cystic fibrosis as indication for bilateral lung transplantation. The chest image shows a typical pattern of bronchiectasis. A subcutaneous intravenous injection reservoir is seen over the upper left chest.

Lung Transplantation

End-stage pulmonary disease is one of the most common causes of death. Lung transplantation is a definitive treatment for these patients (see Chapter 67). Indications and contraindications to lung transplantation are summarized in Table 59-23. Approximately 1500 lung transplantations are performed annually worldwide; the number is limited by the supply of donor organs. Recipients fall into four major categories (by frequency of indication):

1. COPD
2. Cystic fibrosis (CF) (Fig. 59-45) and other congenital forms of bronchiectasis
3. Pulmonary fibrosis: idiopathic, associated with connective tissues disorders, etc.
4. Primary pulmonary hypertension

There are also several other, rarer indications such as primary bronchoalveolar lung cancer, lymphangioleiomyomatosis, and so on.[207] Depending on the patient's pathophysiology, there are several surgical options: single-lung transplantation, bilateral sequential lung transplantation, en-bloc double-lung transplantation, heart-lung transplantation, and living-related lobar transplantation. An overall 5-year survival rate of 50% is the benchmark, but depends on recipient age and diagnosis. Survival is generally better with double- than single-lung transplants with the exception of elderly pulmonary fibrotic patients, where there is no outcome difference between the two procedures.

Anesthetic airway management is most commonly with a DLT. The advantage of a DLT in transplantation is that it allows direct continuous access to both lungs for suctioning, oxygenation, and examination of the bronchial anastomoses. Several advances have allowed the use of DLTs for transplantation. The use of segmental bronchial lavage at induction via an SLT, before placement of the DLT facilitates suctioning via the DLT in patients with copious secretions. Improved DLT designs with shorter endobronchial segments and increased familiarity of anesthesiologists with fiberoscopic lobar anatomy has aided positioning of DLTs.

Monitoring includes invasive arterial and pulmonary catheters and TEE in most centers. Anesthetic maintenance is based mainly on intravenous infusions owing to the frequent need for airway access (e.g., suctioning, bronchoscopy),

Table 59-23 Indications and Contraindications for Lung Transplantation

Indications
Untreatable end-stage pulmonary, parenchymal, and/or vascular disease
Absence of other major medical illnesses
Substantial limitation of daily activities
Projected life expectancy < 50% with 2- to 3-year predicted survival
NYHA class III or IV functional level
Rehabilitation potential
Satisfactory psychosocial profile and emotional support system
Acceptable nutritional status
Disease-specific mortality exceeding transplant-specific mortality over 1 to 2 years
Relative Contraindications
Age > 65 years
Critical or unstable clinical conditions (e.g., shock, mechanical ventilation or ECMO)
Severely limited functional status with poor rehabilitation potential
Colonization with highly resistant or virulent bacteria, fungi, or mycobacteria
Severe obesity defined as a body mass index > 30 kg/m^2
Severe or symptomatic osteoporosis
Other medical conditions resulting in end-organ damage (e.g., diabetes mellitus, systemic hypertension, peripheral vascular disease, patients with coronary artery disease status post coronary artery stenting or PTCA)
Absolute Contraindications
Untreatable advanced dysfunction of another major organ system (e.g., heart, liver, or kidney)
Active malignancy within the previous 2 years
Noncurable chronic extrapulmonary infection
Chronic active viral hepatitis B, hepatitis C, or HIV
Significant chest wall/spinal deformity
Documented nonadherence or inability to follow through with medical therapy, office follow-up, or both
Untreatable psychiatric or psychologic condition associated with inability to cooperate or comply with medical therapy
Absence of a consistent or reliable social support system
Substance addiction (e.g., alcohol, tobacco or narcotics) that is either active or within the previous 6 months

NYHA, New York Heart Association; ECMO, extracorporeal membrane oxygenation; PTCA, percutaneous transluminal coronary angioplasty; HIV, human immunodeficiency virus.

Based on Orens JB, Estenne M, Arcasoy S, et al: International guidelines for the selection of lung transplant candidates: 2006 update—a consensus report from the Pulmonary Scientific Council of the International Society for Heart and Lung Transplantation. J Heart Lung Transplant 25:145, 2006.

which causes problems maintaining a stable level of inspired anesthetic vapor. In spite of advances in lung preservation techniques, it is optimal to limit the donor lung ischemic period to 4 hours.

There are wide variations in the frequency of use of CPB during lung transplantation: some centers always use CPB and some centers almost never use it. CPB temporarily decreases postoperative gas exchange, increases intraoperative blood loss, and increases the duration of postoperative mechanical ventilation. There is no net decrease in short- or long-term mortality attributable to CPB. Extracorporeal membrane oxygenation (ECMO) is used in some centers in place of CPB intraoperatively[208] and is also used increasingly for postoperative respiratory support.

The intraoperative anesthetic complications depend, in large part, on the underlying lung disease. Emphysema patients are prone to hypotension on induction from positive-pressure ventilation (see earlier). Problems in cystic fibrosis patients include the inability to deal with thick bronchial secretions and to adequately ventilate these patients. These patients, because they have both increased inspiratory and expiratory flow resistances, may benefit from slow inspiratory phase ventilation with a high airway pressure.[209] Because of the severely decreased lung compliance this method of ventilation causes little hemodynamic compromise in this subgroup of patients, if air trapping is avoided. Other recipient disease-specific problems include hemodynamic collapse on induction due to right-sided heart dysfunction in primary pulmonary hypertensives, the poor tolerance of pulmonary fibrotic patients for OLV, and the risk of pneumothoraces in patients with lymphangiomyomatosis.

Subsequent Anesthesia for the Pulmonary Transplant Recipient

Many lung transplant recipients subsequently require anesthesia for related, or unrelated, surgical problems.[210] The frequency with which they present for surgery may be due to complications of immunosuppression (e.g., infection, tumor, renal failure) or of the transplantation (e.g., bronchial stenosis, bronchiolitis obliterans). Most transplant recipients can be managed according to routine anesthetic practice, including optimal perioperative respiratory care, antibiotic prophylaxis, and maintenance of immune suppression. Results of recent blood gas analysis, chest radiographs, and CT scans are vital in managing these patients. Most adults will have bronchial anastomoses, and there will be no problem with endotracheal intubation. If endobronchial intubation or a DLT is used, a bronchoscopy should be performed first to assess the bronchial anastomoses and the intubation should be with fiberoptic guidance.

Single-lung transplant recipients with native lung emphysema are a specific concern. They have a marked imbalance in pulmonary compliance, with the native lung highly compliant and the donor lung of normal or reduced (if there is rejection) compliance. However, the major proportion of the pulmonary blood flow is usually to the allograft. With standard methods of positive-pressure ventilation they may develop dynamic hyperinflation of the emphysematous lung with hemodynamic instability and problems with gas exchange. These patients may require the use of a DLT and independent lung ventilation techniques to reduce the airway pressure and minute ventilation in the native lung if positive-pressure ventilation is required.

Lung Volume Reduction

Although resection of bullae is a well-established thoracic surgical procedure, the use of multiple wedge resections to reduce lung volume and improve symptoms in severe emphysema (lung volume reduction) is a procedure in evolution. First proposed in the 1950s, this operation had a worldwide resurgence of interest in the 1990s[211] as a bridge or alternative to lung transplantation. The exact indications and the suitable patient population are still being clarified. The medical advances that have permitted the rebirth of this operation are multidisciplinary and include surgery (bovine pericardial reinforced lung stapling), anesthesia (thoracic epidural analgesia, lung-isolation techniques), and radiology (CT, lung scintigraphy). Depending on the patient and center this procedure may be unilateral or bilateral and performed by thoracotomy, sternotomy, or VATS. The surgery is more effective in patients with heterogeneous lung disease in which the most severely affected areas (often apical) can be resected than in patients with homogeneous types of emphysema (e.g., α_1-antitrypsin deficiency). Patients with extremely severe disease (FEV_1 or DLco < 20% predicted) have poor survival after surgery.[212]

Immediate postoperative improvements in symptoms and pulmonary function are often remarkable; many patients are able to discontinue or reduce home oxygen therapy. These changes are due to a decompression of the airways and a reduction of airflow resistance and work of breathing,[213] which results in a dramatic fall in auto-PEEP (intrinsic PEEP) with a corresponding increase in dynamic compliance. In spite of the encouraging changes in early postoperative pulmonary function, the improvement in respiratory function due to this surgery is transient.[214] However, this must be viewed in the context of the short life expectancy of patients with this degree of emphysema and the potential for improvement in their quality of life from the operation.

Anesthetic management is similar to that for other patients with severe COPD having thoracic surgery (see earlier) with the risk of hypotension on induction due to auto-PEEP and the need for excellent analgesia to avoid postoperative mechanical ventilation.[215] This procedure is now performed in some centers using one-way valves placed bronchoscopically in the most involved segments to cause collapse of severely emphysematous distal lung regions,[216] thus avoiding surgery.

Pulmonary Hemorrhage

Massive hemoptysis is defined as expectoration of more than 200 mL of blood in 24 to 48 hours. The most common causes are carcinoma, bronchiectasis, and trauma (blunt, penetrating, or secondary to a pulmonary artery catheter). Death can occur quickly due to asphyxia. Management requires four sequential steps: lung isolation, resuscitation, diagnosis, and definitive treatment. The anesthesiologist is often called to deal with these cases outside the operating room. There is no consensus on the best method of lung isolation for these cases. The initial method for lung isolation will depend on the availability of appropriate equipment and an assessment of the patient's airway. All three basic methods of lung isolation have been used: DLTs, SLTs, and bronchial blockers. Fiberoptic bronchoscopy is usually not helpful to position endobronchial tubes or blockers in the presence of torrential pulmonary hemorrhage, and lung isolation must be guided by clinical

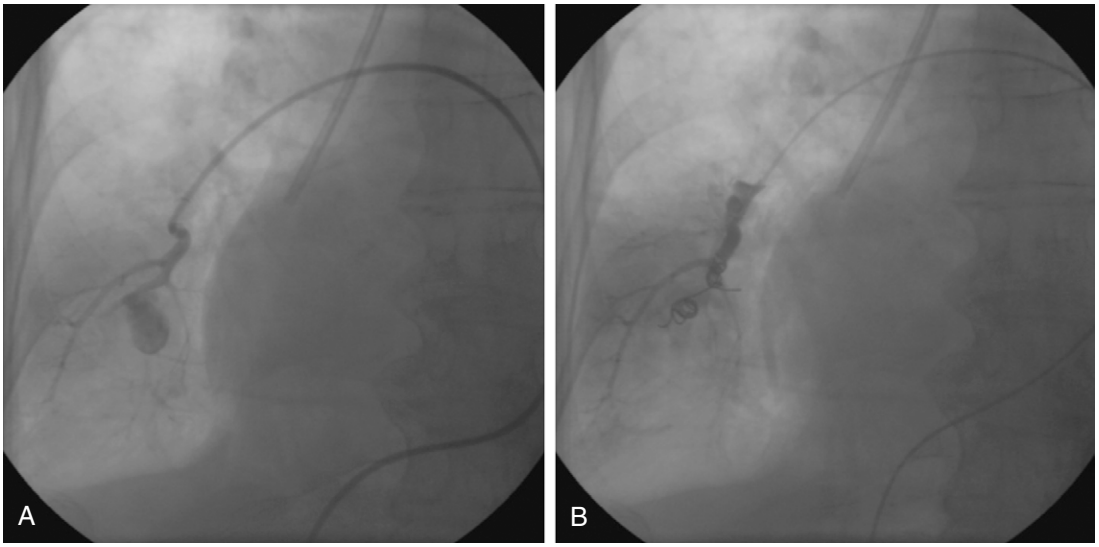

Figure 59-46 **A,** Radiographic dye injection showing a false aneurysm of the pulmonary artery of the right lower lobe after massive hemoptysis induced by pulmonary artery catheter rupture. **B,** A coil has been placed by interventional radiology in the false aneurysm of the right lower pulmonary artery in the same patient. Dye injection shows that the aneurysm has embolized with no further leakage.

signs (primarily auscultation). DLTs will achieve rapid and secure lung isolation. Even if a left-sided tube enters the right mainstem bronchus only the right upper lobe will be obstructed. However, suctioning large amounts of blood or clots is difficult through the narrow lumens of a DLT. An option is initial placement of an SLT for oxygenation and suctioning and then replacement with a DLT either by laryngoscopy or with an appropriate tube exchanger. An uncut SLT can be advanced directly into the right mainstem bronchus or rotated 90 degrees counterclockwise for advancement into the left mainstem bronchus. A bronchial blocker will normally pass easily into the right mainstem bronchus and is useful for right-sided hemorrhage (90% of pulmonary artery catheter–induced hemorrhages are right sided). Except for cases with blunt or penetrating trauma, after lung isolation and resuscitation have been achieved, diagnosis and definitive therapy for massive hemoptysis are now most commonly performed by radiology (Fig. 59-46).[217]

Pulmonary Artery Catheter–Induced Hemorrhage

Hemoptysis in a patient with a pulmonary artery catheter must be assumed to be caused by perforation of a pulmonary vessel by the catheter until proven otherwise. The mortality rate may exceed 50%. This complication seems to be occurring less than previously, possibly related to stricter indications for the use of pulmonary artery catheters and more appropriate management of pulmonary artery catheters with less reliance on wedge measurements. Therapy for pulmonary artery catheter–induced hemorrhage should follow an organized protocol with some variation depending on the severity of the hemorrhage (Table 59-24).

During Weaning from Cardiopulmonary Bypass

Weaning from CPB is one of the times when pulmonary artery catheter–induced hemorrhage is most likely to occur. Management of the pulmonary artery catheter during CPB by withdrawal from a potential wedge depth and observing the pulmonary artery pressure waveform to avoid wedging during CPB may decrease the risk of this complication. When hemoptysis does occur in this situation there are several management options available (Fig. 59-47). The anesthesiologist should resist the temptation to rapidly reverse the anticoagulation in order to quickly discontinue CPB because this can lead to fatal asphyxiation from hemorrhage. Resumption of full CPB ensures oxygenation while the tracheobronchial tree is suctioned and then visualized with fiberoptic bronchoscopy. The use of a pulmonary artery vent may be required to decrease the pulmonary blood flow sufficiently to define the bleeding site (usually the right lower lobe). The pleural cavity should be opened to assess the lung parenchymal damage. Conservative management with lung isolation, avoiding lung resection, is optimal therapy if possible. In patients with persistent hemorrhage who are not candidates for lung resection, temporary lobar pulmonary artery occlusion with a vascular loop during and after weaning from CPB may be an option.

Post-tracheostomy Hemorrhage

Hemorrhage in the immediate postoperative period after a tracheostomy is usually from local vessels in the incision such as the anterior jugular or inferior thyroid veins. Massive hemorrhage 1 to 6 weeks postoperatively is most commonly caused by tracheoinnominate artery fistula.[218] A small sentinel hemorrhage occurs in most patients before a massive hemorrhage. The man-

Table 59-24 Management of the Patient with a Pulmonary Artery Catheter–Induced Pulmonary Hemorrhage

1. Initially position the patient with the bleeding lung dependent.
2. Perform endotracheal intubation, oxygenation, airway toilet.
3. Obtain lung isolation with endobronchial double- or single-lumen tube or bronchial blocker.
4. Withdraw the catheter several centimeters, leaving it in the main pulmonary artery. Do not inflate the balloon (except with fluoroscopic guidance).
5. Position the patient with the isolated bleeding lung nondependent. Provide positive end-expiratory pressure to the bleeding lung if possible.
6. Transport patient to medical imaging for diagnosis and embolization if feasible.

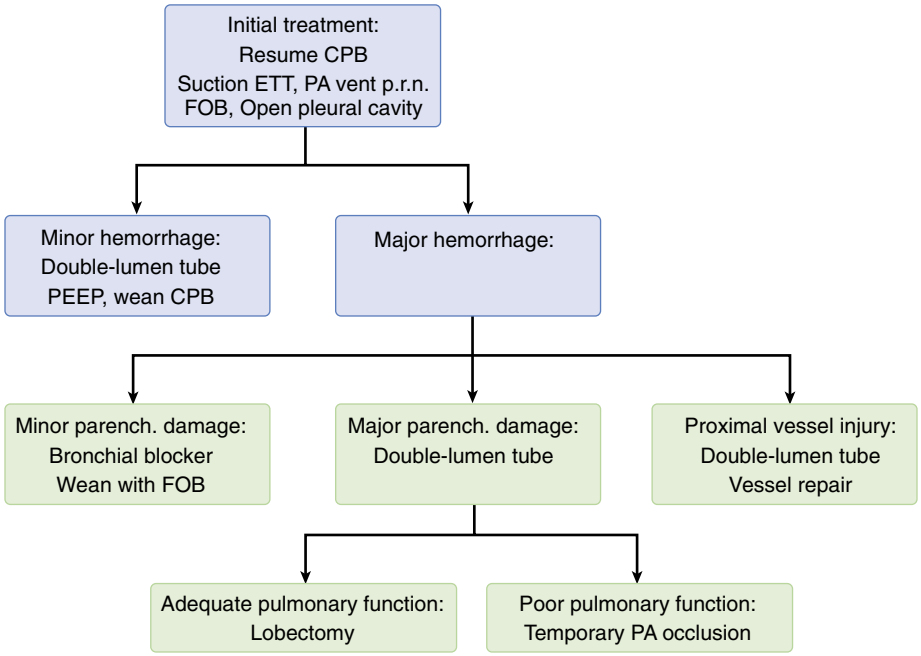

Figure 59-47 Flow diagram of management of massive hemoptysis during weaning from cardiopulmonary bypass (CPB). ETT, endotracheal tube; PA, pulmonary artery; FOB, fiberoptic bronchoscopy; Parenc., lung parenchyma.

agement protocol for tracheoinnominate artery fistula is outlined in Table 59-25.

Pulmonary Thromboendarterectomy

Pulmonary thromboendarterectomy is a potentially curative procedure for chronic thromboembolic pulmonary hypertension (CTEPH). CTEPH is a progressive disorder that responds poorly to conservative therapy, and PTE is the most appropriate treatment with a perioperative mortality of approximately 4%, which is less than lung transplantation. A majority of patients with CTEPH present for medical evaluation late in the disease because many have not had an obvious episode of deep venous thrombosis or pulmonary embolus and the progression of the disease is insidious. Patients present with severe dyspnea on exertion and signs of right-sided heart failure. Surgical candidates have hemodynamically significant pulmonary vascular obstruction (pulmonary vascular resistance > 300 dynes•sec•cm^{-5}) with potentially accessible proximal areas of thromboembolus.

An inferior vena cava filter is often placed prophylactically before surgery. Surgery is performed via a midline sternotomy with CPB with or without periods of deep hypothermic circulatory arrest (DHCA). Anesthetic management is essentially the same as for a patient with primary pulmonary hypertension for lung transplantation with the exception that there is no need for lung isolation so airway management is with a standard endotracheal tube. Monitoring includes femoral and pulmonary artery catheters, TEE, processed electroencephalography, and rectal/bladder temperatures.[219]

These patients are at risk for hemodynamic collapse from right ventricular failure from hypotension during induction of general anesthesia. Induction may be performed with etomidate or ketamine to avoid hypotension. Support of systemic vascular resistance with norepinephrine or phenylephrine is usually required. If DHCA is used, it is preceded by mannitol, methylprednisolone, and pentothal to try to decrease cerebral cellular edema and to improve free-radical scavenging. The speed of warming and cooling is controlled on CPB to maintain a temperature gradient less than 10°C between blood and bladder/rectal temperatures. Periods of DHCA are usually limited to 20 minutes. Massive pulmonary hemorrhage occurs rarely during CPB in these cases. Management of pulmonary hemorrhage is according to the algorithm outlined in Figure 59-47. The instillation of phenylephrine, 10 mg, and vasopressin, 20 units, diluted in 10-mL saline via the endotracheal tube may be beneficial. Postoperatively, the patients are kept sedated, intubated, and ventilated for at least 24 hours to decrease the risk of reperfusion pulmonary edema. Norepinephrine or vasopressin infusions may be used to elevate the systemic vascular resistance and decrease cardiac output to decrease pulmonary blood flow.

Table 59-25 Management of Tracheoinnominate Artery Fistula Hemorrhage

1. Overinflate the tracheostomy cuff to tamponade the hemorrhage.

If this fails:

2. Replace the tracheostomy tube with an oral endotracheal tube. Position the cuff with fiberoptic bronchoscopic guidance just above the carina.
3. Use digital compression of the innominate artery against the posterior sternum using a finger passed through the tracheostomy stoma.

If this fails:

4. Slowly withdraw the endotracheal tube and overinflate the cuff to tamponade.
5. Then proceed with definitive therapy: sternotomy and ligation of the innominate artery.

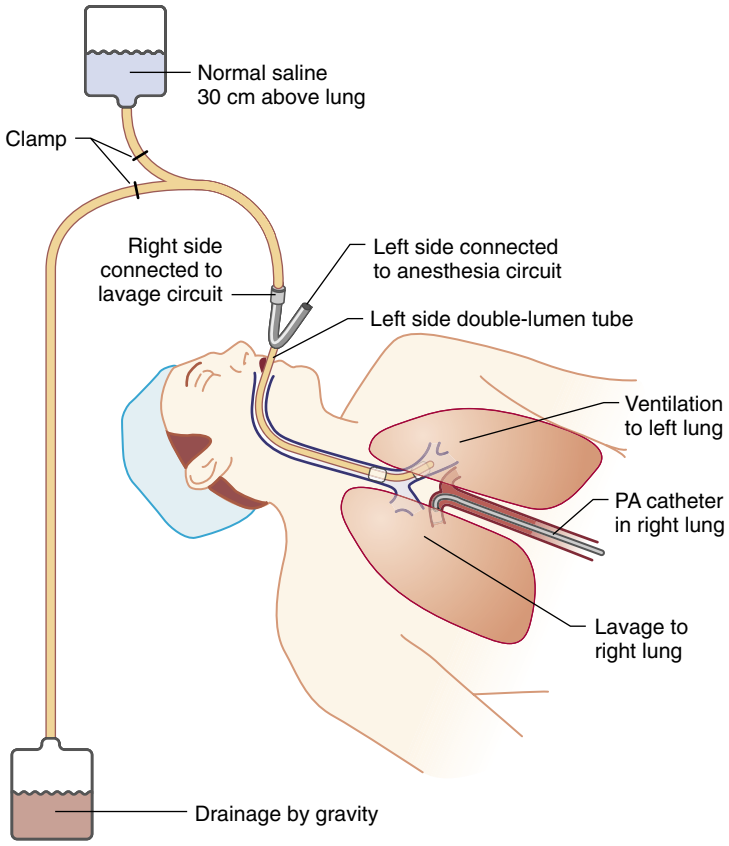

Figure 59-48 Technique for bronchopulmonary lavage. A double-lumen tube allows ventilation to the left lung during lavage of the right lung (and vice versa). Normal saline is infused and drained by gravity; clamps on the connection tubes determine the direction of fluid flow. (*From Benumof JL: Anesthesia for Thoracic Surgery. Philadelphia, WB Saunders, 1987.*)

Bronchopulmonary Lavage

Bronchopulmonary lavage is a treatment during which up to 10 to 20 L of normal saline is instilled then drained in 500 to 1000-mL aliquots through one side of a DLT into one lung under general anesthesia.[220] It may then be performed on the contralateral lung during the same anesthetic or during a subsequent anesthetic after a period of several days for recovery. It is the most effective treatment modality for symptomatic pulmonary alveolar proteinosis. This lung disease results from accumulation in the alveoli of a lipoproteinic material similar to surfactant. Since the introduction of bronchopulmonary lavage by Ramirez-Rivera in 1965, the prognosis of pulmonary alveolar proteinosis has greatly improved. Other pathologic states that have been treated by bronchopulmonary lavage include cystic fibrosis, asthma, radioactive dust inhalation, lipoid pneumonitis, and silicosis, all without convincing success.

Radiologic imaging, CT, and ventilation-perfusion scans help to determine the most impaired lung, which will be lavaged first. Monitoring is essentially the same as for a standard pulmonary resection. Some centers also monitor central venous or pulmonary artery pressures or TEE.[221] General anesthesia is induced and maintained with intravenous infusions as for lung transplantation. Airway management is with a left-sided DLT. Precise placement of the tube is confirmed by fiberoptic bronchoscopy, and air-tight isolation is determined by monitoring inspired and expired tidal volumes with side-stream spirometry. Tube dislodgment and flooding of the nonlavaged lung is a major complication of this procedure. Specifically during lavage of the left lung, the pressure of saline in the lung will tend to push the bronchial cuff of the DLT proximally. To prevent this it is recommended that the anesthesiologist maintain his or her hand on the DLT, securing it firmly at the patient's mouth, throughout the entire procedure. The pulmonary compliance of the ventilated lung needs to be continuously monitored to diagnose any liquid spillage from the lavage lung.

The patient is kept in the supine position during the procedure. To improve the effectiveness of the lavage, ventilation with F_{IO_2} 100% for a few minutes is initiated after induction to denitrogenate both lungs. OLV is instituted with the nonlavage lung. A disposable irrigation and drainage system is used to instill approximately 1 L of warm normal saline (37°C) into the lavage lung (Fig. 59-48). The irrigating liquid is suspended 30 cm above the patient's mid-chest level to the lavage lung. Thereafter, the saline is rapidly drained by gravity into a container positioned 60 cm below or with the assistance of a small level of suction (<20 cm H_2O). This process is repeated as needed until the effluent fluid is clear. Chest physiotherapy—mainly percussion, vibration, and pressure—is applied during the filling and the drainage phases. The use of flannel protects the patient's chest wall from trauma due to physiotherapy during the percussion. If the cumulative total of the instilled fluid volume exceeds the drainage volume by more than 1000 mL a hydrothorax should be suspected and the procedure should be interrupted while an intraoperative chest radiograph is obtained to rule this out.

Because of transmitted hydrostatic pressure from the lavage lung to the pulmonary circulation, oxygenation increases during the filling phase and decreases during the emptying phase in

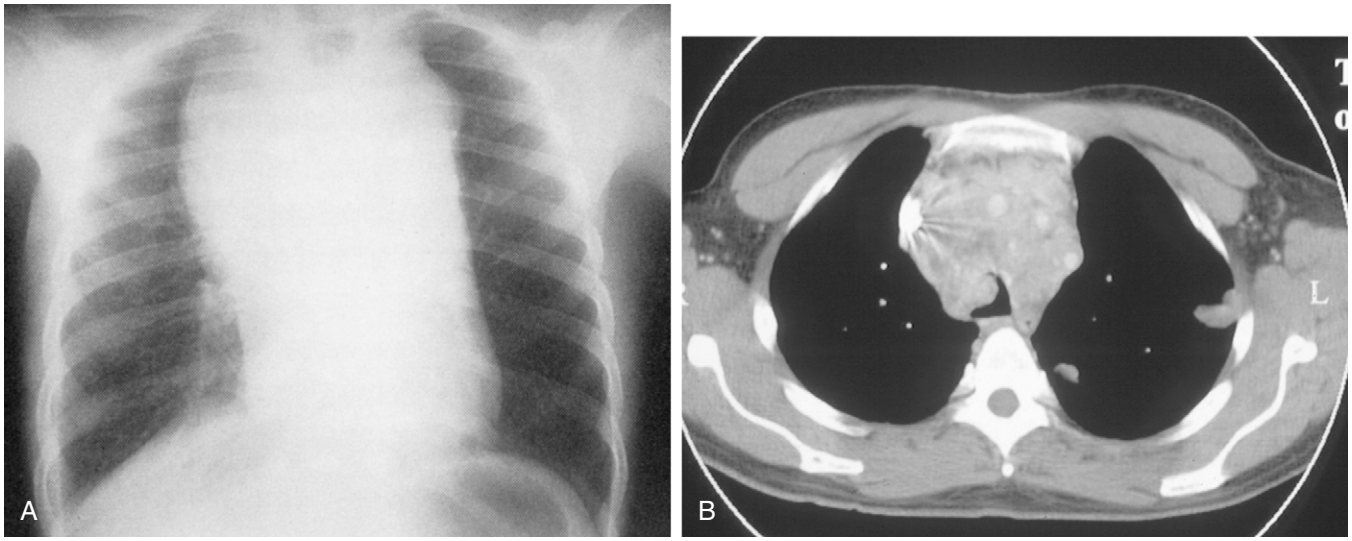

Figure 59-49 A, Chest radiograph of an adult patient with an anterosuperior mediastinal mass. This mass was a lymphoma. **B,** A thoracic contrast-enhanced CT scan just above the level of the carina shows partial compression of the carina and right mainstem bronchus. This patient has an "uncertain" airway (see text).

synchrony with changes in the pulmonary blood flow distribution. These changes are usually transient and well tolerated. In severely hypoxemic patients presenting for bronchopulmonary lavage a variety of maneuvers have been used (e.g., inflation of a pulmonary artery catheter balloon in the pulmonary artery of the lavage lung while adding nitric oxide to the ventilated lung[222] or the use of ECMO) to maintain oxygenation.

Usually 10 to 15 L is instilled and more than 90% is recovered, leaving a deficit of less than 10%. At the end of the procedure the lavaged lung is thoroughly suctioned. A dose of furosemide (10 mg) is administered to increase diuresis of absorbed saline. If the plan is to proceed to a lavage of the contralateral lung there is a period of at least 1 hour of two-lung ventilation to allow recovery of the lavaged lung, during which arterial blood gases are monitored. If there is a persistent large alveolar-arterial oxygen gradient the procedure is terminated at this stage. After the procedure, after re-intubation with a single-lumen tracheal tube, inspection with fiberoptic bronchoscopy is performed for suctioning. Conventional ventilation with PEEP is continued, usually for less than 2 hours. Alveolar infiltrates seen on the chest radiography immediately after lavage normally clear within 24 hours. Observation in the intensive care unit for 24 hours is part of the routine procedure. Before the contralateral lavage, compliance and oxygenation should have recovered, at least to their initial values as measured before the first lavage. At that time, oxygenation is usually not a problem because the treated lung will be used to support gas exchange during the procedure. Some patients require lavage every few months, whereas others remain in remission for years.

Mediastinal Masses

Patients with mediastinal masses, particularly masses in the anterior or superior mediastinum, or both, present unique problems for the anesthesiologist. Patients may require anesthesia for biopsy of these masses by mediastinoscopy or VATS, or they may require definitive resection via sternotomy or thoracotomy. Tumors of the mediastinum include thymoma, teratoma, lymphoma, cystic hygroma, bronchogenic cyst, and thyroid tumors. Mediastinal masses may cause obstruction of major airways, main pulmonary arteries, atria, and the superior vena cava. During induction of general anesthesia in patients with an anterior or superior mediastinal mass, airway obstruction is the most common and feared complication. It is important to note that the point of tracheobronchial compression usually occurs distal to an endotracheal tube (Fig. 59-49) and it is not possible to forcibly pass a tube through the airway once it has collapsed. A history of supine dyspnea or cough should alert the clinician to the possibility of airway obstruction on induction of anesthesia. Life-threatening complications may occur in the absence of symptoms in children. The other major complication is cardiovascular collapse secondary to compression of the heart or major vessels (Fig. 59-50). Symptoms of supine presyncope suggest vascular compression.

Anesthetic deaths have mainly been reported in children. These deaths may be the result of the more compressible cartilaginous structure of the airway in children or because of the difficulty in obtaining a history of positional symptoms in children. The most important diagnostic test in the patient with a mediastinal mass is CT of the trachea and chest. Children with tracheobronchial compression greater than 50% on a CT scan cannot safely be given general anesthesia.[223] Flow-volume loops, specifically the exacerbation of a variable intrathoracic obstructive pattern (expiratory plateau) when supine, are unreliable[224] for predicting which patients will have intraoperative airway complications.[225] Transthoracic echocardiography is indicated for patients with vascular compression symptoms.

General anesthesia will exacerbate extrinsic intrathoracic airway compression in three ways. First, reduced lung volume occurs during general anesthesia and tracheobronchial diameters decrease according to lung volume. Second, bronchial smooth muscle relaxes during general anesthesia, allowing greater compressibility of large airways. And, third, paralysis eliminates the caudal movement of the diaphragm seen during spontaneous ventilation. This eliminates the normal transpleural pressure

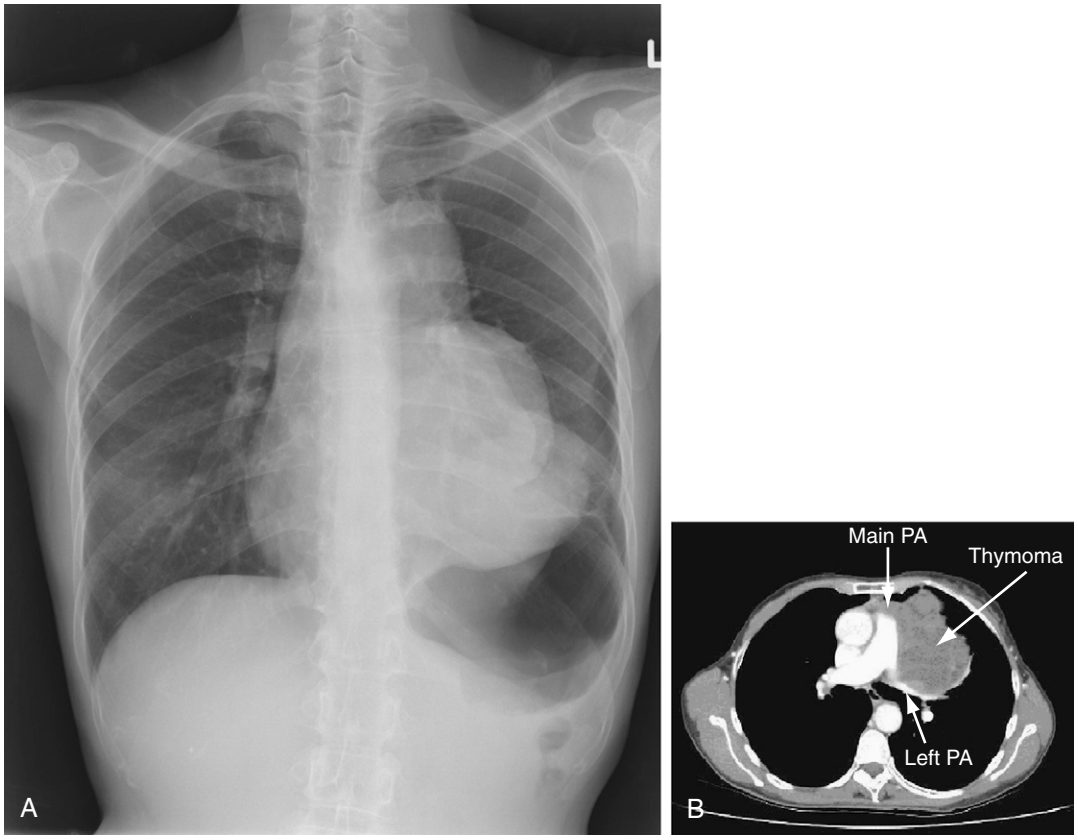

Figure 59-50 **A,** Chest radiograph of an adult patient with a thymoma who presented with symptoms of supine presyncope. **B,** Contrast CT scan shows the thymoma and partial compression of the main pulmonary artery (Main PA) with almost complete occlusion of the left pulmonary artery (Left PA).

gradient that dilates the airways during inspiration and minimizes the effects of extrinsic intrathoracic airway compression.

Management of these patients is guided by their symptoms and the CT scan (Tables 59-26 and 59-27). Patients with "uncertain" airways should have diagnostic procedures performed under local or regional anesthesia whenever possible. Patients with "uncertain" airways requiring general anesthesia need a step-by-step induction of anesthesia with continuous monitoring of gas exchange and hemodynamics. This "NPIC" (*noli pontes ignii consumere,* i.e., "don't burn your bridges") anesthetic induction can be an inhalation induction with a volatile agent such as sevoflurane or intravenous titration of propofol with or without ketamine, maintaining spontaneous ventilation until either the airway is definitively secured or the procedure is completed.[226] Awake intubation of the trachea before induction is a possibility in some adult patients if the CT scan shows an area of noncompressed distal trachea to which the endotracheal tube can be advanced before induction. If muscle relaxants are required, ventilation should first be gradually taken over manually to ensure that positive-pressure ventilation is possible and only then can a short-acting muscle relaxant be administered (Table 59-28).

Development of airway or vascular compression requires that the patient be awakened as rapidly as possible and then other options for the procedure be explored. Intraoperative life-threatening airway compression usually has responded to one of two therapies: either repositioning of the patient (it must be deter-

Table 59-26 Grading Scale for Symptoms in Patients with an Anterior or Superior Mediastinal Mass

Asymptomatic
Mild: Can lie supine with some cough/pressure sensation
Moderate: Can lie supine for short periods but not indefinitely
Severe: Cannot tolerate supine position

Table 59-27 Stratification of Patients with Mediastinal Masses Regarding Safety for General Anesthesia

A	**Safe**	(I)	Asymptomatic adult, CT minimum tracheobronchial diameter > 50% of normal
B	**Unsafe**	(I)	Severely symptomatic adult or child
		(II)	Children with CT tracheobronchial diameter < 50% of normal, regardless of symptoms
C	**Uncertain**	(I)	Mild/moderate symptomatic child with CT tracheobronchial diameter > 50% of normal
		(II)	Mild/moderate symptomatic adult with CT tracheobronchial diameter < 50% of normal
		(III)	Adult or child unable to give history

CT, computed tomographic scan.

Table 59-28 Management for All Patients with a Mediastinal Mass and an "Uncertain" Airway for General Anesthesia

1. Determine optimal positioning of patient preoperatively.
2. Secure airway beyond stenosis while awake if feasible.
3. Have rigid bronchoscope and surgeon available at induction.
4. Maintain spontaneous ventilation if possible ("NPIC": see text).
5. Monitor for airway compromise postoperatively.

mined before induction if there is a position that causes less compression and fewer symptoms) or rigid bronchoscopy and ventilation distal to the obstruction (this means that an experienced bronchoscopist and equipment must always be immediately available in the operating room for these cases). The rigid bronchoscope, even if passed into only one mainstem bronchus, can be used for oxygenation during resuscitation (see "Rigid Bronchoscopy," earlier).[227] Once adequate oxygenation has been restored, the rigid bronchoscope can be used to position an airway exchange catheter over which an endotracheal tube is passed after the bronchoscope is withdrawn. An alternative technique to secure the airway with rigid bronchoscopy is to first mount an endotracheal tube over a small rigid bronchoscope (e.g., 6 mm) and then perform rigid bronchoscopy using the bronchoscope to deliver the tube distal to the obstruction.[228]

Institution of femorofemoral CPB before induction of anesthesia is a possibility for some adult patients who are "unsafe" for NPIC general anesthesia. The concept of CPB "standby" during attempted induction of anesthesia is fraught with danger[229] because there is not enough time after a sudden airway collapse to establish CPB before hypoxic cerebral injury occurs.[230] Other options for "unsafe" patients include local anesthetic biopsy of the mediastinal mass or biopsy of another node (e.g., supraclavicular), preoperative radiotherapy with a nonirradiated "window" for subsequent biopsy, preoperative chemotherapy or short-course corticosteroids, and CT-guided biopsy of mass or drainage of a cyst. The salient points in managing a patient with an anterior or superior mediastinal mass include the following[231]:

1. In virtually all children and adults with a mediastinal mass diagnostic procedures and imaging and can be performed, if necessary, without subjecting the patient to the risks of general anesthesia.[232]
2. An extrathoracic source of tissue for diagnostic biopsy (pleural effusion or extrathoracic lymph node) should be sought as an initial measure in every patient.
3. Regardless of the proposed diagnostic or therapeutic procedure, the flat, supine position is never mandatory.
4. In the high-risk child (Table 59-29) without extrathoracic lymphadenopathy or a pleural effusion, prebiopsy corticosteroid therapy is justifiable.[233] In this case, coordination with oncologist, surgeon, and anesthesiologist is essential to organize timing of the biopsy. An alternative to preoperative corticosteroids in the cooperative high-risk patient includes irradiating the tumor while leaving a small area covered with lead for subsequent biopsy.

Table 59-29 Predictors of Airway Compromise in Children with a Mediastinal Mass

Anterior location
Histologic diagnosis of lymphoma
Superior vena cava syndrome
Radiologic evidence of major vessel compression or displacement
Pericardial or pleural effusion

Based on Lam JC, Chui CH, Jacobsen AS, et al. When is a mediastinal mass critical in a child? An analysis of 29 patients. Pediatr Surg Int 20:180, 2004.

With improved awareness of the risk of acute intraoperative airway obstruction in these patients, life-threatening events are now less likely to occur in the operating room. In children, these events now tend to occur preoperatively if the patient is forced to assume a supine position for imaging. In adults, acute airway obstruction is now more likely to occur postoperatively, in the recovery room.[234] Vigilance must be maintained throughout the entire perioperative period.

Thymectomy for Myasthenia Gravis

Myasthenia gravis is a disease of the neuromuscular junction; affected patients have weakness due to a decreased number of acetylcholine receptors at the motor end plate.[235] Patients may or may not have an associated thymoma. Thymectomy is frequently performed to induce clinical remission, even in the absence of a thymoma. The effects of muscle relaxants are modified by this disease; myasthenic patients are resistant to succinylcholine and extremely sensitive to nondepolarizing blockers (see Chapter 29). Thymectomy may be performed via full or partial sternotomy or a minimally invasive approach via a transcervical incision or VATS. For thymectomy with a thymoma, a sternotomy is used. In the absence of an identifiable tumor, minimally invasive techniques are commonly used. Ideally, the use of neuromuscular relaxation is avoided. Induction of anesthesia with propofol, remifentanil, and topical anesthesia of the airway facilitates intubation without the use of muscle relaxants. Alternatively, inhalational induction with a halogenated agent such as sevoflurane may be performed.[236] For sternotomy, combined general and thoracic epidural anesthesia is a useful technique.

Most patients take pyridostigmine, an oral anticholinesterase, and many patients are on immunosuppressive medication (e.g., corticosteroids). On the day of surgery, pyridostigmine dosing should ensure that the patient's usual regimen is provided during the immediate perioperative period. A few patients require intravenous dosing with neostigmine until they are able to resume oral intake of pyridostigmine. A scoring system was devised for prediction of the need for prolonged mechanical ventilation after thymectomy via sternotomy. Among the criteria that contributed to the predicted need for support were disease duration longer than 6 years, chronic respiratory illness, pyridostigmine dosage greater than 750 mg/day, and vital capacity less than 2.9 L. The relevance of this score has diminished with better preoperative preparation and minimally invasive surgery.[237] Referral for surgery early in the course of the disease and stabilization of symptoms with medication and plasmapheresis, combined with increased use of minimally invasive approaches, have made the need for postoperative ventilation infrequent. In optimized patients, mean hospital length of stay can be reduced to 1 day after minimally invasive, and 3 days after trans-sternal, thymectomy.[238] Patients should remain on their full medical regimen postoperatively. The remission from myasthenia gravis after thymectomy occurs slowly over a period of months to years.

Postoperative Management

Early Major Complications

There are multiple potential major complications that can occur in the immediate postoperative period after thoracic surgery, such as torsion of a remaining lobe after lobectomy, dehiscence of a bronchial stump, or hemorrhage from a major vessel. Fortunately these are infrequent, and when they do occur, the principles of management are as outlined earlier for common and specific procedures. Among these possible complications, two will be discussed in more detail: respiratory failure, because it is the most common cause of major morbidity after thoracic surgery, and cardiac herniation, because although it is rare, it is usually fatal if not quickly diagnosed and appropriately treated.

Respiratory Failure

Respiratory failure is a leading cause of postoperative morbidity and mortality in patients undergoing major lung resection. Acute respiratory failure after lung resection is defined as the acute onset of hypoxemia ($Pao_2 < 60$ mm Hg) or hypercapnia ($Paco_2 >$ 45 mm Hg) or the use of postoperative mechanical ventilation for more than 24 hours or reintubation for controlled ventilation after extubation. The incidence of respiratory failure after lung resection is between 2% and 18%. Patients with decreased respiratory function preoperatively are at increased risk of postoperative respiratory complications. In addition, age, presence of coronary artery disease, and the extent of lung resection play major roles in predicting postoperative mortality and morbidity. Crossover contamination, owing to failure of lung isolation intraoperatively during lung resection in patients with contaminated secretions, can result in contralateral pneumonia and postoperative respiratory failure.[239] Mechanical ventilation during the postoperative period after lung resection is associated with the risk of acquired nosocomial pneumonia and bronchopleural fistula.

Decreased pulmonary complications in high-risk patients are associated with the use of thoracic epidural analgesia during the perioperative period.[2] The prevention of atelectasis and secondary infections has been attributed to better preservation of the functional residual volume, efficient mucociliary clearance, and alleviation of the inhibiting reflexes acting on the diaphragm in patients receiving epidural analgesia.[240] Chest physiotherapy, incentive spirometry, and early ambulation are crucial to minimize pulmonary complications after lung resection. For an uncomplicated lung resection, early extubation is desirable to avoid potential complications that can arise due to prolonged intubation and mechanical ventilation. Current therapy to treat acute respiratory failure is supportive therapy that attempts to provide better oxygenation, treat infection, and provide vital organ support without further damaging the lungs.

Cardiac Herniation

Acute cardiac herniation is an infrequent, but well-described complication of pneumonectomy when the pericardium is incompletely closed or the closure breaks down.[241] It usually occurs immediately or within 24 hours after chest surgery and is associated with a greater than 50% mortality. Cardiac herniation may also occur after a lobar resection with pericardial opening or in other chest tumor resections involving the pericardium or in trauma.[242] When cardiac herniation occurs after a right pneumonectomy the clinical presentation is due to impairment of the venous return to the heart with a concomitant increase in central venous pressure, tachycardia, profound hypotension, and shock. An acute superior vena cava syndrome ensues due to the torsion of the heart.[243] In contrast, when the cardiac herniation occurs after a left-sided pneumonectomy there is less cardiac rotation but the edge of the pericardium compresses the myocardium. This may lead to myocardial ischemia, the development of arrhythmias, and ventricular outflow tract obstruction. Cardiac herniation occurs after chest closure due to the pressure differences between the two hemithoraces. This pressure difference may result in the heart being extruded through a pericardial defect.

Management for a patient with a cardiac herniation should be considered as dire emergent surgery. The differential diagnosis should include massive intrathoracic hemorrhage, pulmonary embolism, or mediastinal shift from improper chest drain management. Early diagnosis and immediate surgical treatment by relocation of the heart to its anatomic position with repair of the pericardial defect or by the use of analogous or prosthetic patch material is key to patient survival. Because these patients have undergone a previous thoracotomy, all precautions should be taken for a "redo" exploration. This includes the use of large-bore intravenous catheters and an arterial line. Maneuvers to minimize the cardiovascular effects include positioning the patient in the full lateral position with the operated side up. Because time is crucial, an SLT is used. Vasopressors or inotropes or both are required to support the circulation while exploration takes place. The use of TEE intraoperatively, after resuscitation and relocation of the heart, can be considered during pericardial patch repair to prevent excessive compression of the heart by the repair.[244] In general, patients undergoing an emergency thoracic re-exploration remain intubated and are transferred to the intensive care unit postoperatively.

Postoperative Analgesia (See Chapter 87)

Studies before 1990 consistently report a 15% to 20% rate of major respiratory complications (atelectasis, pneumonia, respiratory failure) within the first 3 days after thoracic surgery.[1] This time of onset may relate to the unique pattern of recovery of pulmonary function after thoracotomy, which shows a delay in the initial 72-hour postoperative period that is not seen with other major surgical incisions. The incidence of post-thoracotomy respiratory complications has shown an overall decline to less than 10% while the cardiac complication rate has not changed.[2] Improvements in postoperative care, specifically pain management, are the major cause of this decline.

There are multiple sensory afferents that transmit nociceptive stimuli after thoracotomy (Fig. 59-51). These include the incision (intercostal nerves T4-T6), chest drains (intercostal nerves T7-T8), mediastinal pleura (vagus nerve, CN X), central diaphragmatic pleura (phrenic nerve, C3-C5),[245] and ipsilateral shoulder (brachial plexus). There is no one analgesic technique that can block all these various pain afferents, so analgesia should be multimodal. The optimal choice for an individual patient will depend on patient factors (contraindications, preferences), surgical factors (type of incision), and system factors (available equipment, monitoring, nursing support). The ideal post-thoracotomy

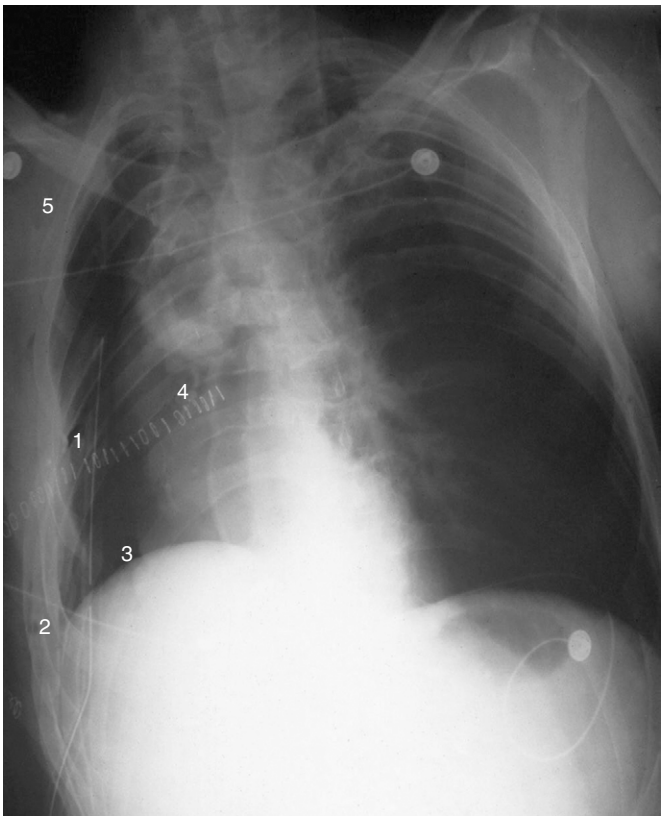

Figure 59-51 Multiple sources of afferent transmission of pain sensations after thoracotomy. 1, Intercostal nerves at the site of the incision (usually T4-6); 2, intercostal nerves at the site of chest drains (usually T7-8); 3, phrenic nerve afferents from the dome of the diaphragm; 4, vagal nerve innervation of the mediastinal pleura; 5, brachial plexus.

analgesic technique will include three classes of drugs: opioids, anti-inflammatory agents, and local anesthetics.

Systemic Analgesia

Opioids

Systemic opioids alone are effective in controlling background pain, but the acute pain component associated with cough or movement requires plasma levels that produce sedation and hypoventilation in most patients. Even when administered by patient-controlled devices, pain control is generally poor[246] and patients have interrupted sleep patterns when serum opioid levels fall below the therapeutic range.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs can reduce opioid consumption more than 30% after thoracotomy and are particularly useful treating the ipsilateral shoulder pain that is often present postoperatively and is poorly controlled with epidural analgesia. NSAIDS act through reversible inhibition of cyclooxygenase, which has anti-inflammatory and analgesic effects but can also be associated with decreased platelet function, gastric erosions, increased bronchial reactivity, and decreased renal function. Acetaminophen is an antipyretic/analgesic with weak cyclooxygenase inhibition and can be administered orally or rectally in doses up to 4 g/day. It is effective against shoulder pain and has a low toxicity compared with more potent cyclooxygenase-inhibiting NSAIDs.[247]

Ketamine

Low-dose intramuscular ketamine (1 mg/kg) is equivalent to the same dose of meperidine and causes less respiratory depression. Ketamine can also be administered as a low-dose intravenous infusion and may be useful in patients whose condition is refractory to other therapies or when there is a contraindication to more common techniques.[248] The possibility of psychomimetic effects with ketamine is always a concern but is rarely seen with analgesic, subanesthetic doses.

Dexmedetomidine

Dexmedetomidine, a selective adrenergic α_2-receptor agonist, has been reported as a useful adjunct for post-thoracotomy analgesia and can significantly decrease the requirement for opioids when used in combination with epidural local anesthetics. Maintenance infusion doses for analgesia in children and adults are in the range of 0.3 to 0.4 µg/kg/hr.[249] It is associated with some hypotension, but it seems to preserve renal function.

Local Anesthetics/Nerve Blocks

Intercostal Nerve Blocks

Regional blocks of the intercostal nerves supplying the dermatomes of the surgical incision can be an effective adjunct to methods of post-thoracotomy analgesia (see Chapter 52). These can be done percutaneously or under direct vision when the chest is open. The duration of analgesia is limited to the duration of action of the local anesthetic used and the blocks will need to be repeated to have any useful effect on postoperative lung function. Indwelling intercostal catheters are an option, but they can be difficult to position reliably percutaneously. Nerve blocks are useful supplements for the pain associated with the multiple small port incisions and chest drains following VATS. It is important to avoid injection into the intercostal vessels, which are adjacent to the nerve in the intercostal groove. It is also important to place the block near the posterior axillary line to be certain to block the lateral cutaneous branch of the intercostal nerve. Total bupivacaine dose for a single session of blocks should not exceed 1 mg/kg (e.g., for a 75-kg patient: 3 mL bupivacaine 0.5% with epinephrine 1:200,000 at each of five levels).

Intrapleural Analgesia

Intrapleural local anesthetics produce a multilevel intercostal block. The analgesia is extremely dependent on patient position, infusion volume, chest drains, and the type of surgery. In spite of occasional successes, most clinicians have not found the reliability of intrapleural techniques adequate to justify their use on a routine basis.[250]

Other Techniques

Application of a −60°C probe to the exposed intercostal nerves intraoperatively produces an intercostal block that can persist for up to 6 months. This can be moderately efficient to decrease postoperative pain but is associated with an incidence of chronic neuralgia that has led many centers to abandon the technique. Transcutaneous electrical nerve stimulation (TENS) may be useful in mild to moderate pain but is ineffective when pain is severe.[251]

Epidural Analgesia

The routine use of neuraxial analgesia for post-thoracotomy patients is a relatively recent concept. Spinal injection of opioids can have a duration of analgesia that approaches 24 hours after thoracotomy. Because of the concerns of possible infection with subarachnoid catheters and the need to repeat spinal injections, investigation and therapy have focused on epidural techniques. A meta-analysis of respiratory complications after various types of surgery has shown that epidural techniques reduce the incidence of respiratory complications.[252] Lumbar epidural analgesia has gradually been replaced by thoracic epidural analgesia for thoracic surgery in the 1990s. In a survey of U.S. teaching hospitals,[253] the majority of thoracotomies received a thoracic epidural between T3 and T8, with infusions of bupivacaine plus either fentanyl or hydromorphone. The evolution of routine thoracic epidural infusion analgesia has been delayed pending advances in technology and knowledge. The technology required was the development of portable, safe, and reliable infusion pumps, which did not delay postoperative ambulation. The knowledge required was in several areas: First, the importance of the synergy between local anesthetics and opioids for segmental thoracic analgesia was not appreciated originally. Combinations of local anesthetic and opioids provide better epidural analgesia at lower doses than either drug alone.[254] Second, the concern for patient risks due to postoperative neuraxial analgesia delayed widespread acceptance. The risks of respiratory depression and hemodynamic instability are largely due to the use of bolus injection techniques. The use of epidural infusions has an excellent record for patient safety when used on routine postoperative surgical wards.[255] The risk of accidental direct spinal cord trauma from thoracic epidural needles and catheters slowed the adoption of this technique by many anesthesiologists. A study of more than 4000 thoracic epidural analgesic placements in a German teaching hospital[256] documented no permanent neurologic sequelae and a 1% incidence of accidental dural puncture that was less than the expected risk of dural puncture for lumbar epidurals. Third, many anesthesiologists believe that thoracic epidural catheter placement is a difficult technique. The use of a paramedian approach to the epidural space in the midthoracic levels (Fig. 59-52) has improved the success rate for many clinicians.

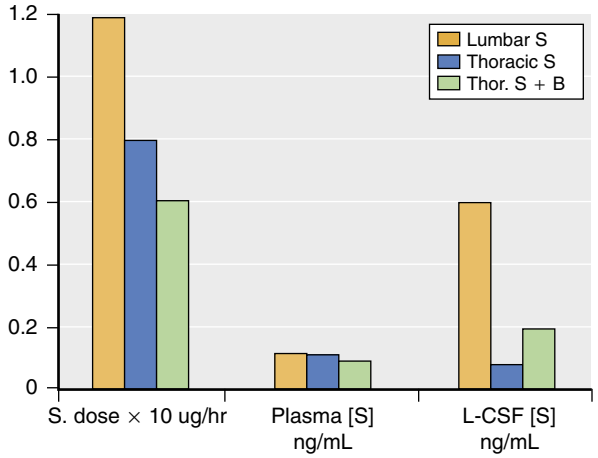

Figure 59-53 Differences in the pharmacology of post-thoracotomy epidural infusions of lumbar sufentanil (Lumbar S), thoracic sufentanil (Thoracic S), and thoracic sufentanil plus bupivacaine (Thor. S + B). Thoracic S + B produced significantly superior analgesia with movement with lower total sufentanil dosage (S. dose) and lower plasma levels (Plasma [S]) than the other two techniques. Note that, in spite of lower dosage, Thoracic S + B patients had higher mean lumbar cerebrospinal fluid (CSF) sufentanil levels than the thoracic sufentanil group measured by separate lumbar punctures at 24 and 48 hours postoperatively. This suggests a pharmacokinetic mechanism with local anesthetics that facilitates transfer of epidural opioid into the CSF. (*Based on data from Hansdottir V, Wostenborghs R, Nordberg G: The pharmacokinetics of continuous epidural sufentanil and bupivacaine infusion after thoracotomy. Anesth Analg 83:394, 1996.*)

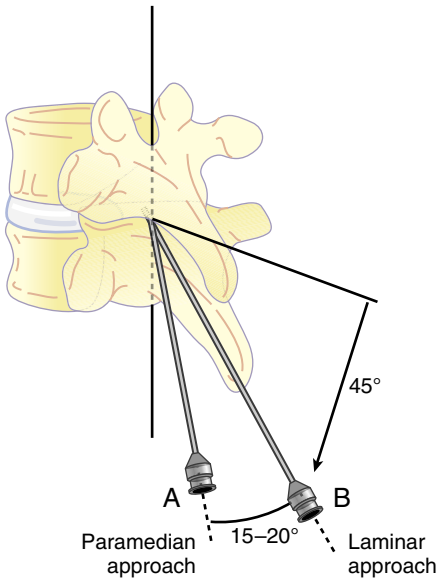

Figure 59-52 The paramedian approach (A) to the epidural space is now favored by most anesthesiologists at the midthoracic levels. The needle is inserted 1 cm lateral to the superior tip of the spinous process and then advanced perpendicular to all planes to contact the lamina of the vertebral body immediately below. The needle is "walked" up the lamina at an angle rostrally (45 degrees) and medially (20 degrees) until the rostral edge of the lamina is felt. The needle is advanced over the edge of the lamina, seeking a loss of resistance on entering the epidural space after transversing the ligamentum flavum. The laminar approach (B) is favored by some practitioners. The needle is inserted next to the rostral edge of the spinous process and advanced straight without any angle from the midline. (*Reprinted with permission from Ramamurthy S: Thoracic epidural nerve block. In Waldman SD, Winnie AP [eds]: Interventional Pain Management. Philadelphia, WB Saunders, 1996.*)

Research has shed light on the pharmacology that underlies the synergy between local anesthetics and opioids to produce segmental epidural analgesia. In a double-blind randomized study, Hansdottir and coworkers[257] compared epidural infusions of lumbar sufentanil, thoracic sufentanil, and thoracic sufentanil plus bupivacaine for post-thoracotomy analgesia. Infusions were titrated for equianalgesia at rest. Thoracic sufentanil plus bupivacaine provided significantly better analgesia with movement and less sedation than the other infusions. Although sufentanil dosages and serum levels were significantly lower in the combined sufentanil plus bupivacaine group than in the other two groups, lumbar cerebrospinal fluid levels of sufentanil at 24 and 48 hours were higher in the combined group than in the thoracic sufentanil group (Fig. 59-53). This suggests that the local anesthetic facilitates entry of the opioid from the epidural space into the cerebrospinal fluid.

In patients with severe emphysema, thoracic epidural analgesic doses of bupivacaine do not cause any significant reduction in lung mechanics or increase in airway resistance.[258] In volunteers, a thoracic level of epidural blockade increases FRC.[259] This increase is largely due to an increase in thoracic gas volume caused by a fall in the resting level of the diaphragm without a fall in tidal volume. Although it is possible to deliver an opioid to the spinal cord receptors via a lumbar epidural catheter in adequate amounts for thoracic analgesia, the beneficial and synergistic effects of local anesthetics on respiratory mechanics require a thoracic epidural catheter.

Differences in lipid solubility that create relatively minor clinical differences in the effects of opioids when used systemically cause major differences in the effects of these same opioids when used neuraxially (Fig. 59-54). The highly lipid-soluble agents (e.g., fentanyl, sufentanil) are associated with narrow dermatomal spread, rapid onset, and low incidence of pruritus/nausea and can be potentiated by epinephrine. However, these lipid-soluble agents have significant absorption and systemic effects when used as epidural infusions.[260] For incisions that cover many dermatomes (e.g., sternotomy) or for procedures that have combined abdominal and thoracic incisions (e.g., esophagectomy) the hydrophilic opioids (e.g., morphine, hydromorphone) are preferable.

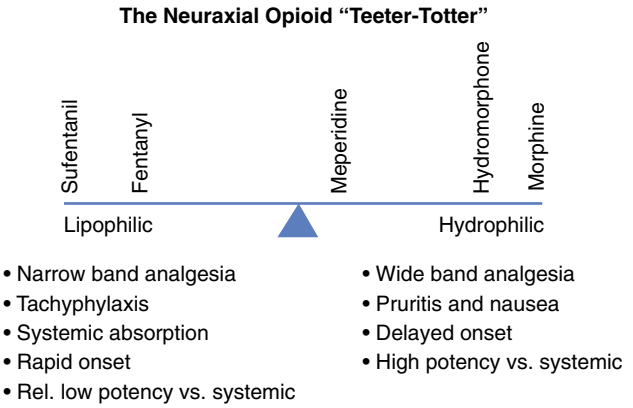

Figure 59-54 The neuraxial opioid "teeter-totter." When choosing an opioid to use for epidural analgesia the anesthesiologist needs to balance the pros and cons of each agent in the clinical context. A major pharmacokinetic factor that determines the effects and side effects of the neuraxial opioids is their lipid solubility. Low-lipid-solubility agents (i.e., hydrophilic, e.g., morphine) tend to produce a wider band of analgesia with slower onset and offset and more minor side effects. Highly lipid-soluble (lipophilic) agents can cause central nervous system effects from systemic absorption when used for prolonged periods, and patients develop tachyphylaxis. Meperidine has a lipid solubility toward the middle of the range, but the accumulation of active metabolites is a concern. Patient factors to be weighed in choosing a neuraxial opioid include the rostral-caudal width of the analgesia band required (thoracotomy versus sternotomy versus thoracoabdominal incision) and the anticipated duration of the epidural infusion. Paravertebral Block

The paravertebral space is a potential space deep to the endothoracic fascia that the intercostal nerve traverses as it passes form the intervertebral foramen en route to the intercostal space (see Fig. 59-55). A catheter can be placed in the thoracic paravertebral space either percutaneously or by approaching the space anteriorly and directly when the chest is open intraoperatively (see Chapter 52).

For the open direct-vision technique, an epidural catheter is first passed into the open hemithorax via a Tuohy needle through an intercostal space in the lateral chest wall. To site the catheter, the surgeon then makes a small incision in the parietal pleura and fascia covering the paravertebral gutter and, with blunt dissection, threads the tip of the catheter close to the neurovascular bundle of the next cephalad space (Fig. 59-56).[261] An absorb-

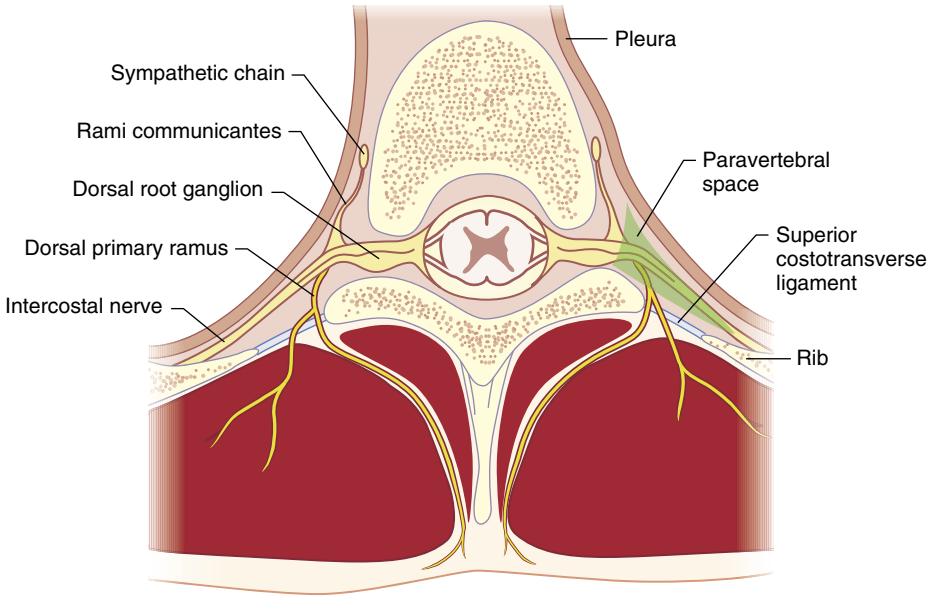

Figure 59-55 Diagram of the paravertebral space. The space is bounded medially by the vertebral body, posteriorly by the costotransverse ligaments and the heads of the ribs, and anteriorly by the endothoracic fascia and parietal pleura. (*From Conacher ID, Slinger PD: In Kaplan J, Slinger P [eds]: Thoracic Anesthesia, 3rd ed. Philadelphia, Churchill Livingstone, 2003.*)

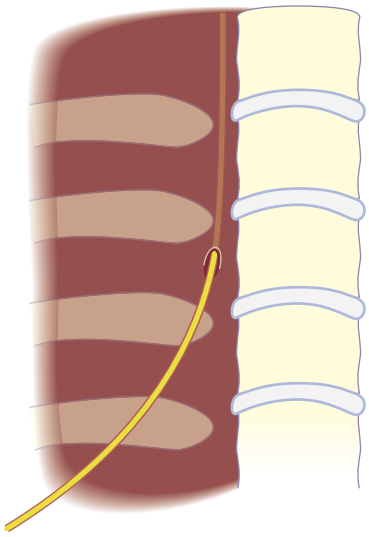

Figure 59-56 A method of open direct-vision placement of a paravertebral catheter intraoperatively. The epidural catheter is passed into the paravertebral space through a small defect created in the extrapleural (endothoracic) fascia. The proximal end of the catheter is then brought out of the chest through a separate needle puncture in an intercostal space near the chest drains. (*From Conacher ID, Slinger PD: In Kaplan J, Slinger P [eds]: Thoracic Anesthesia, 3rd ed. Philadelphia, Churchill Livingstone, 2003.*)

able suture is often used to reseal the wound and limit the leakage of local anesthetic.

There is also a combined percutaneous/direct-vision method in which the tip of the Tuohy needle is advanced percutaneously into the paravertebral space under direct vision either during open thoracotomy or VATS. The tip of the needle is seen to enter the paravertebral space and the pleura is not punctured. Saline is injected via the Tuohy needle to hydrodissect the paravertebral space, and an epidural catheter is passed into the pocket that has been created in the paravertebral space and then secured at the skin.

Paravertebral local anesthetics provide a reliable multilevel intercostal blockade that tends to be unilateral with a low tendency to spread to the epidural space. Clinically, the analgesia is comparable to that from epidural local anesthetics.[262] Studies comparing paravertebral versus thoracic epidural analgesia for thoracotomies have suggested the following advantages for paravertebral blockade[263]: comparable analgesia, fewer failed blocks, decreased risk of neuraxial hematoma, and less hypotension, nausea, or urinary retention. Because there is the option to place the paravertebral catheter under direct vision, this may contribute to the lower incidence of failed blocks versus thoracic epidural analgesia.

Paravertebral infusions in combination with NSAIDs and systemic opioids are a reasonable alternative to epidural techniques in children or patients with contraindications to neuraxial blockade.[56] When common therapeutic doses are used (e.g., 0.1 mL/kg/hr of bupivacaine 0.5%), serum bupivacaine levels can approach toxic levels by 4 days.[264] An alternative regimen for paravertebral infusions is lidocaine 1%, 1 mL/10 kg/hr, maximum 7 mL/hr. It has not yet been demonstrated if paravertebral analgesia can contribute to a decrease in respiratory morbidity in high-risk cases, which has been shown for thoracic epidural analgesia.[265]

Postoperative Pain Management Problems

Shoulder Pain

After thoracotomy up to 80% of patients with a functioning epidural block describe ipsilateral shoulder pain. Shoulder pain occurs after both thoracotomy and VATS and is thought to be primarily referred pain of diaphragmatic irritation transmitted by phrenic nerve afferents.[246] Other factors, including position during operation and major bronchus transection, have been incriminated, although the mechanisms are not clear. Several other causes of shoulder pain should be considered when evaluating a patient with shoulder pain postoperatively:

1. A chest drain placed too far into the apex of the hemithorax will irritate the parietal pleura and cause shoulder pain (Fig. 59-57). The postoperative chest radiograph should be checked and the chest drain partially withdrawn if this is suspected as the cause.
2. The posterior end of a large posterolateral thoracotomy incision may not be well blocked by a functioning thoracic epidural block, and this may be described as shoulder pain. The extent of the sensory block should be determined on the skin. If inadequate block is a possibility, the thoracic epidural analgesia can be "topped up."
3. Patients with chronic arthralgia of the shoulder may experience an exacerbation from the intraoperative positioning of the ipsilateral arm. It is important to ask about shoulder problems preoperatively and to position the arms in a manner that does not exacerbate shoulder problems.

Shoulder pain is refractory to thoracic epidural analgesia and requires anti-inflammatory agents with or without opioids.

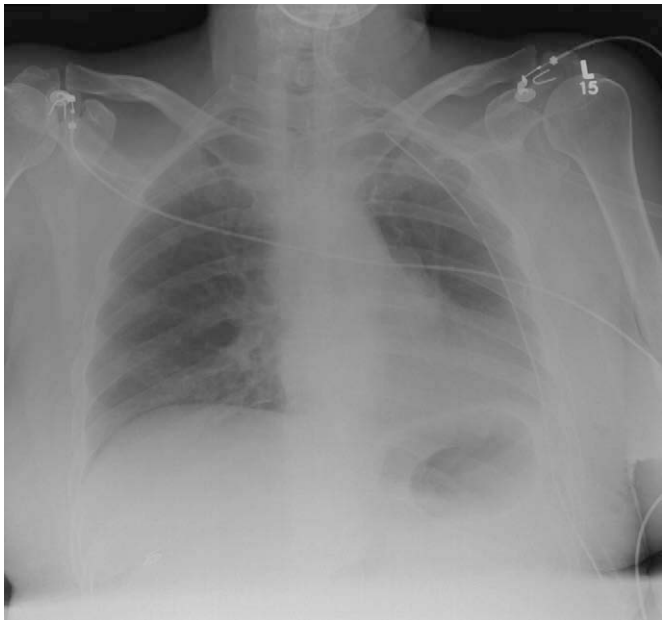

Figure 59-57 Postoperative chest radiograph of a patient who complained of left shoulder pain after a left VATS lobectomy. This pain was due to irritation of the apical parietal pleura by a chest drain that was inserted too far into the hemithorax. The pain resolved when the chest drain was partially withdrawn

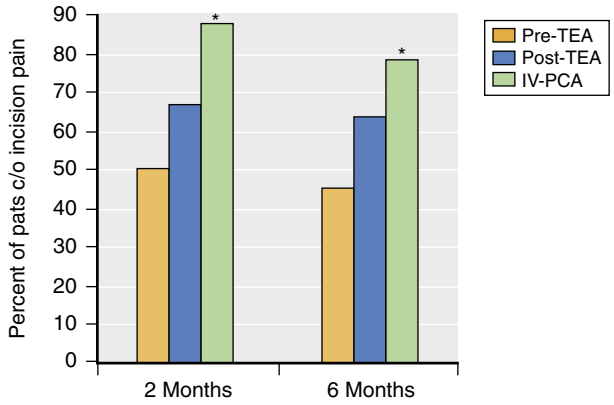

Figure 59-58 A comparison of the effects of three different analgesia regimens on the percentage of patients complaining of incisional pain (%pats c/o incis. pain) 2 and 6 months after thoracotomy. Pre-TEA, patients treated with a thoracic epidural infusion of local anesthetic and opioid before, during,and after surgery; Post-TEA, a group of patients in whom the TEA was only used postoperatively; IV-PCA, a group of patients who received postoperative intravenous patient-controlled opioid analgesia. The use of TEA, started before the surgical incision, was associated with less short- and long-term pain than IV-PCA (* = $P < .05$). (*Based on data from Sentürk M, Ozcan PE, Talu GK, et al: The effects of three different analgesia techniques on long-term postthoracotomy pain. Anesth Analg 94:11, 2002.*)

Shoulder pain is usually transient and often is resolved completely by the second postoperative day. There are several reports of the use of nerve blocks to treat post-thoracotomy shoulder pain. Phrenic nerve infiltration and interscalene brachial plexus block[266] have had some success but carry a risk of causing diaphragm dysfunction.

Post-thoracotomy Neuralgia and Chronic Incisional Pain

The transition of acute pain syndromes, associated with thoracic surgery, to chronic ones such as post-thoracotomy neuralgia may be partially preventable with analgesic regimens that prophylactically block nerves and desensitize peripheral nerve endings and dorsal horn cells of nerves that are damaged by surgery (Fig. 59-58).

Management of Opioid-Tolerant Patients

The opioid-tolerant patient requiring thoracic surgery presents a significant challenge. Patients may be using physician-prescribed opioids for pain related to their thoracic pathologic process or other chronic pain syndromes. Active abusers of narcotics or those in a rehabilitation program, receiving daily methadone, also are included in this group. Whenever possible, patients should take their regular analgesia or methadone preoperatively; otherwise, substitute opioids must be provided. The opioid doses required to produce adequate postoperative analgesia are increased.

A multimodal analgesic regimen is optimal. A choice must be made regarding the method of increased opioid delivery, either systemically or through an epidural solution. Increased narcotic may be provided in the epidural solution, or standard narcotic concentrations may be used in the epidural solution with additional systemic narcotic. De Leon-Casasola[267] reports that higher epidural doses of opioid are able to curtail the appearance of narcotic withdrawal in most patients. More frequently, the patient receives a standard or slightly increased concentration of opioid in the epidural infusion and additional systemic opioid to minimize the occurrence of withdrawal. A convenient way to provide drug delivery in patients not immediately able to take oral medication is in the form of a transdermal fentanyl patch. Systemic opioids can be provided as a continuous intravenous infusion or in oral format.

Patient-controlled analgesic techniques are often difficult to manage in these patients, and they may be best managed with fixed dosage regimens that are modified as needed. Ultimately, after dose titration, the patient may be receiving both increased epidural opioid and greater than preoperative doses of systemic opioid, without significant side effects. Patients in whom epidural bupivacaine-morphine analgesia is inadequate may respond to a switch to bupivacaine-sufentanil.[268] Patients in drug rehabilitation programs with methadone may be reluctant to modify their methadone dose perioperatively, having struggled to establish a stable dose in the past. They frequently can take their full methadone dose throughout the perioperative period.

Supplemental therapies to be considered for these patients include adding epinephrine, 5 µg/mL, to the epidural infusion solution and the addition of low-dose continuous intravenous ketamine infusions.[269] All opioid-tolerant patients require frequent adjustment of analgesic doses. Despite this, pain scores of 4 to 5/10 with movement are often the lowest achievable. The increased analgesic requirements of opioid-tolerant patients are for a longer duration postoperatively than the usual need for analgesia in opioid-naive patients.

60 Anesthesia for Cardiac Surgical Procedures

Key Points

1. The most common causes of central nervous system injury or dysfunction in cardiac surgical patients are thought to be microemboli and macroemboli.
2. After coronary revascularization, mortality was far lower in patients with normal renal function (0.9%) than in patients with acute renal failure (63%).
3. In addition to activating the extrinsic and intrinsic hemostatic pathways, cardiopulmonary bypass (CPB) directly affects platelet function through the effects of hemodilution, hypothermia, and contact activation by bypass circuit materials.
4. When choosing anesthetic agents and doses during induction and maintenance, one should consider any pharmacodynamic properties that might affect blood pressure, heart rate, or cardiac output, as well as the desirability of "early" extubation (i.e., within a few hours after the operation is completed).
5. Patients undergoing "redo" cardiac surgery (i.e., those who have had a previous median sternotomy) warrant special concern about the possibility of sudden massive hemorrhage.
6. Right ventricular dysfunction or failure may also occur after CPB because of inadequate myocardial protection, inadequate revascularization with resultant right ventricular ischemia or infarction, preexisting pulmonary hypertension, intracoronary or pulmonary air embolism, chronic mitral valve disease, or tricuspid regurgitation.
7. Numerous clinical approaches have been shown to measurably reduce the inflammatory response in cardiac surgical patients: modification of surgical and perfusion techniques, modification of circuit components, and pharmacologic strategies.
8. No single anesthetic "recipe" is suitable for all patients undergoing coronary artery bypass graft (CABG) procedures.
9. Randomized trials comparing off-pump CABG with on-pump CABG have not found convincing or consistent evidence to support one approach over another.
10. Types of procedures that are performed in the cardiac catheterization laboratory include (1) electrophysiologic assessment of rhythm disorders and management by ablation or by implantation of devices, (2) biventricular pacing for heart failure, (3) stenting of abdominal or thoracic aortic aneurysms, (4) balloon dilation and stenting for valvular and subvalvular lesions, and (5) the use of occlusion or umbrella devices to close an atrial or ventricular septal defect or a patent ductus arteriosus. Sedation or anesthesia improves the efficacy and safety of many procedures.
11. Even after uncomplicated cardiac surgery, a midline sternotomy (or thoracotomy) causes a significant reduction in total lung capacity, vital capacity, forced expiratory volume in 1 second, and functional residual capacity.
12. In 2007, the Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists published a joint statement on practice guidelines for transfusion and blood conservation in cardiac surgery.

Cardiovascular Disease in the 21st Century

The "Graying" of America

An estimated 79,400,000 American adults (1 in 3) have one or more types of cardiovascular disease (CVD), and of those, 37,500,000 are estimated to be 65 years or older.[1] Data from the Framingham Heart Study of the National Heart, Lung, and Blood Institute (NHLBI), which collected follow-up data from participants for 44 years and from their offspring for 20 years, indicate that the average annual rate of first major cardiovascular events rises from 7 per 1000 for men aged 35 to 44 years to 68 per 1000 for men aged 85 to 94.[2] For women, the rates are comparable but occur approximately 10 years later in life, although this gender gap narrows with advancing age. In 2007, the estimated direct and

indirect cost of CVD in the United States was $431.8 billion.[1] Data for 2004, the most recent available, estimate that 6,363,000 inpatient cardiovascular operations and procedures were performed in the United States.[3] Mortality data show that CVD is the underlying cause of death in 36.3% of the 2,398,000 deaths that occurred in 2004 (1 in every 2.8 deaths) in the United States.[1] In fact, CVD claims more lives each year than cancer, chronic lower respiratory diseases, diabetes mellitus, and accidents combined do.[4] As the U.S. population ages, these proportions will only increase.

Gender and Cardiac Disease

Data indicate that the lifetime risk for CVD is 2 in 3 for men and 1 in 2 for women after 40 years of age.[1] The fact that CVD kills twice as many women as breast cancer does (more than half a million women each year) has led to campaigns such as the NHLBI's *The Heart Truth* campaign and the American Heart Association's *Go Red for Women* campaign.[5-8]

Whether female gender is a risk factor for short- or long-term mortality after cardiac surgery is a subject of ongoing debate. Many studies of in-hospital mortality after coronary artery bypass grafting (CABG) surgery in men versus women have revealed a significantly higher unadjusted in-hospital mortality for women.[9-11] In a study of 15,440 patients, female gender independently predicted higher in-hospital mortality even when all comorbid conditions were taken into account.[11]

Other studies, however, do not show any survival handicap for female cardiac surgical patients. A large study by Koch and colleagues[12] used propensity-matching techniques to show that female gender was not associated with increased in-hospital mortality. Similarly, in other studies that showed a significant unadjusted increase in perioperative mortality in women versus men, this difference was no longer significant when the data were adjusted for age, cardiovascular risk factors, and body size.[13,14]

Several studies of the effects of gender on CABG outcomes have shown that women are more likely than men to need CABG surgery urgently or on an emergency basis.[9,10,14] Urgent or emergency performance of CABG surgery is generally a result of intractable myocardial ischemia or infarction. Therefore, the results of a study by Vaccarino and coworkers,[15] which showed increased in-hospital mortality in women versus men admitted for acute myocardial infarction (MI), are cause for concern. The reason for this difference in mortality is unclear; in some cases, women with significant coronary artery disease may not be appropriately identified and referred for more invasive studies.

In cardiac surgical patients, technical factors undoubtedly play a critical role in determining short- and long-term mortality in patients undergoing CABG.[16] Some studies have noted lower in-hospital mortality in women who undergo off-pump surgical revascularization than in women treated with on-pump surgery.[17-19] However, data on the long-term results of off-pump versus on-pump surgery are not yet available for either gender.

Regarding long-term survival, several studies have found that 5-year post-CABG survival is actually better in women than in men,[13,14,20] even though other studies have shown that women's short-term survival is poorer than men's after CABG.[9-11] Part of the difference in long-term survival may be attributable to preexisting gender differences in longevity: in the United States, women live an average of 5.2 years longer than men.[4] Therefore, it may be that a woman who undergoes CABG surgery is at greatest risk for mortality during the perioperative period. If she can survive this period, however, she should live as long as, if not longer, than a man. Nevertheless, once discharged from the hospital, women apparently have more difficult recovery than men do in terms of their rate of persistent symptoms and hospital readmission.[21]

As further knowledge about gender-specific risk factors accumulates, means may be devised to mitigate these factors and thus improve outcomes.

Genetic Influences on Cardiac Disease

Although mortality from coronary artery disease has decreased in the past 35 years, such mortality has consistently been higher in black patients than white patients. Furthermore, there are racial disparities in outcomes after CABG; both unadjusted mortality and mortality adjusted for patient characteristics are higher in black than in white patients.[22] There is also racial disparity in the use of cardiovascular procedures to address chest pain.[23] In fact, as an unfortunate consequence of the public release of quality information through CABG "report cards" in certain states, institutions and individual surgeons may use "racial profiling" in selecting patients for CABG.[24] For example, in New York State, physician avoidance of racial and ethnic minorities, who may be at higher risk for poor outcomes, may have temporarily widened the disparity in CABG use between white versus black and Hispanic patients.[24] At least one study, however, suggests that racial differences in the frequency of cardiovascular procedures reflect "overuse" among whites rather than "underuse" among blacks.[25]

Patients with complex comorbid conditions are exposed to "controlled trauma" in the cardiac surgical operating room. Genome-wide linkage analysis has been used to identify genetic determinants of patients' responses to this sort of trauma and thus to complex cardiovascular outcomes such as MI and stroke (Fig. 60-1). For example, functional genetic variants in cytokine and leukocyte-endothelial interaction pathways have been shown to be independently associated with the severity of myonecrosis

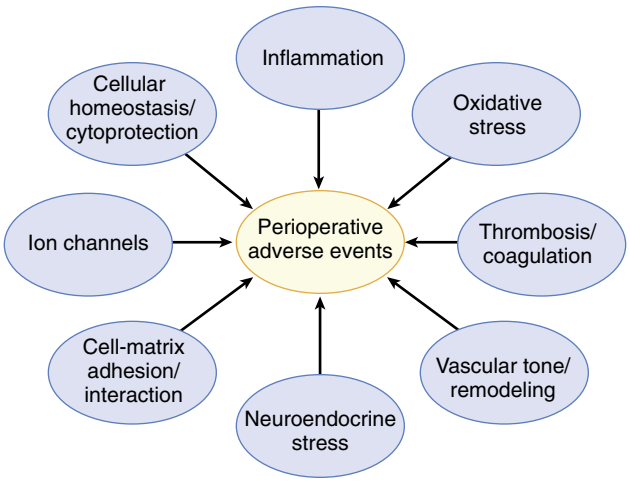

Figure 60-1 Biologic systems and mechanistic pathways genetically associated with perioperative adverse events. *(Redrawn from Podgoreanu MV, Schwinn DA: New paradigms in cardiovascular medicine: Emerging technologies and practices: Perioperative genomics. J Am Coll Cardiol 46:1965-1977, 2005.)*

after cardiac surgery.[26] Additionally, common genetic variants of C-reactive protein and interleukin-6 are significantly associated with risk for stroke after cardiac surgery.[27] C-reactive protein and P-selectin genes may also modulate susceptibility to cognitive decline after cardiac surgery.[28] These findings suggest a pivotal role of inflammation in cardiac surgery–related myocardial and neurologic injury.

Postoperative renal dysfunction, another common complication of cardiac surgery, is not easily predicted from preoperative factors. To address this problem, one study assessed 12 candidate genetic variants and found several alleles that had a strong association with renal injury.[29] When added to the clinical risk factors typically used to predict postoperative renal dysfunction, this genetic information increased predictive accuracy fourfold, but only in whites; there was only a twofold improvement in blacks, suggesting that genetic risk factors may differ among racial groups.

Genetic factors have been associated with other postoperative complications of cardiac surgery as well, including bleeding and coagulopathy[30,31] and respiratory complications that necessitate prolonged mechanical ventilation[32] after cardiac surgery. Additionally, responses to medications commonly used in the perioperative period exhibit genetic variance that can affect morbidity and mortality.[33,34]

Approach to Anesthesia for Adult Cardiac Patients

Preoperative Evaluation, Preparation, and Monitoring

Heart and Vascular System

Electrocardiography

Standard monitoring of cardiac surgical patients via the electrocardiogram (ECG) often involves using the five-lead electrode system (see Chapter 42).

Despite appropriate lead selection and the use of automated ST-segment monitoring, perioperative ECG monitoring has important limitations. Visual inspection of the ECG on the monitor has low sensitivity in diagnosing ischemic changes, and automated ST-segment analysis depends on the computer's ability to accurately set the isoelectric and J-point reference points. During cardiac surgery, the set points should be checked before and after bypass and when there have been any significant persistent changes in the patient's heart rate because the reference points chosen at the beginning of the procedure may not be accurate for conditions that may exist later.

Arterial and Central Venous Pressure Monitoring

Invasive arterial cannulation and monitoring are considered to be a standard of care for cardiac surgical patients. Patient risk factors and comorbid conditions often necessitate real-time, beat-to-beat assessment of arterial perfusion pressure, changes in volume associated with surgery, and arterial blood gases. Furthermore, during nonpulsatile cardiopulmonary bypass (CPB), noninvasive blood pressure recordings are not accurate.

Although the radial artery is the most commonly accessed site, the femoral, brachial, ulnar, dorsalis pedis, posterior tibial, and axillary arteries can be also used. When cannulating a radial artery, one should consider the native state of the collateral circulation in the hand and possible surgical use of a radial artery free graft as an arterial conduit. If a radial arterial graft is to be harvested, it is usually taken from the nondominant hand or arm; thus, the arterial line should be placed on the dominant side.

Central venous pressure (CVP) monitoring and central venous access are essential during cardiac surgery. Central venous catheters, in addition to monitoring CVP, provide portals for volume replacement, pharmacologic therapy, and insertion of other invasive monitors such as pulmonary artery (PA) catheters. An internal jugular vein is most commonly selected because it provides ease of approach and optimal distance from the operative field. A femoral or subclavian vein can be considered as well, but groin access can be challenging in obese patients and may be inappropriate if placement of a femoral bypass cannula or harvesting of a vein graft is necessary. The subclavian approach is also imperfect because it is associated with a greater propensity for catheter obstruction during sternal retraction.

Ultrasound is increasingly being used to guide the placement of central venous catheters and to reduce complications associated with them. In many patients, use of a central venous catheter may offer a better risk-benefit ratio than use of a PA catheter.[35]

Pulmonary Artery Catheterization

The PA catheter is a flow-directed catheter typically placed through a catheter "introducer" in the central venous compartment via the internal jugular, subclavian, or femoral vein (see Chapter 40). Pulmonary capillary wedge pressure (PCWP) can both overestimate and underestimate left ventricular (LV) filling pressure. A summary of these variables is included in Box 60-1. There is some evidence that in certain clinical situations, right

Box 60-1 Conditions Resulting in Discrepancies between Pulmonary Capillary Wedge Pressure and Left Ventricular End-Diastolic Pressure

PCWP > LVEDP

Positive-pressure ventilation

PEEP

Increased intrathoracic pressure

Increased pulmonary vascular resistance

Left atrial myxoma

Mitral valve disease (e.g., stenosis, regurgitation)

PCWP < LVEDP

Noncompliant left ventricle (e.g., ischemia, hypertrophy)

Aortic regurgitation (premature closure of the mitral valve)

LVEDP > 25 mm Hg

LVEDP, left ventricular end-diastolic pressure; PAC, pulmonary artery catheter; PCWP, pulmonary capillary wedge pressure; PEEP, positive end-expiratory pressure.

Adapted from Tuman KJ, Carroll CC, Ivankovich AD: Pitfalls in interpretation of pulmonary artery catheter data. Cardiothorac Vasc Anesth Update 2:1, 1991.

ventricular (RV) end-diastolic volume and index correlate better with LV preload and cardiac index (CI) than PCWP does.[36-40]

The risk-benefit ratio involved in use of PA catheter data, including pressures, derived indices, and waveforms, has been a subject of controversy for 3 decades.[41,42] In a review of the literature, Murphy and coauthors[42] reported that since 1970, more than 1500 articles and abstracts have been published that have variously found PA catheters to be beneficial, neutral, or detrimental with respect to patient morbidity and outcome. Large clinical trials have not shown any clear outcome benefits in critically ill patients monitored with PA catheters.[43-46] However, the limitations of trials and studies that have examined the efficacy of PA catheter monitoring include inadequate sample size, lack of randomization, lack of standardized therapeutic intervention guided by PA catheter findings, medically uncertain (unvalidated) treatment goals and therapies, inappropriate use of PA catheters in low-risk patients, and inadequate user knowledge and skill.[42] With the recent, better-constructed clinical trials of PA catheters, the debate will probably continue.

It is acknowledged that there have been only a few randomized trials of goal-directed therapy in cardiac surgical patients.[47,48] Standardization of PA catheter measurements and therapeutic interventions guided by these measurements is needed to fully assess the value of the PA catheter—or any monitor—in improving patient outcome.[41,49] American Society of Anesthesiologists (ASA) practice guidelines for PA catheter use, created by a task force after a review of the literature and expert opinion, concluded that there is incomplete evidence to support the use of PA catheters, primarily because of deficiencies in "study design and performance," and that monitoring with a PA catheter is "both appropriate and necessary in selected surgical patients" based on preexisting patient risk factors (which would increase perioperative risk), procedural factors (major surgical procedures that in and of themselves significantly increase perioperative risk), and practice setting (because the PA catheter is useful only if the physicians and nurses have knowledge of and skill competence with it).[50] Expert opinion does not support routine use of the PA catheter in low-risk patients[35,42] unless it can be justified by clinical judgment and the factors noted by the ASA task force.[50] An optimal risk-benefit ratio may be achieved only by pairing use of the PA catheter in appropriate patients with treatment protocols that have been proved to be effective.[41]

Echocardiography

Since its introduction to operating rooms in the early 1980s, transesophageal echocardiography (TEE) has established itself as extremely helpful both as a monitoring system and as a tool for the hemodynamic management of patients under general anesthesia. The use of TEE to make intraoperative diagnoses is now well established (see Chapter 41).[51]

Intraoperative evaluation of valvular function with the use of TEE has proved to be of immense importance, not only because TEE can directly visualize the cardiac structures but also because it can measure blood flow velocity.[52] Also, TEE is routinely used to monitor for the presence of retained intracardiac air after open chamber procedures such as valvular surgery. Additionally, TEE's ability to image the thoracic aorta in real time is an invaluable aid in correctly positioning intra-aortic balloon pumps (IABPs).[53] Similarly, TEE plays a central role in the insertion of ventricular assist devices (VADs) (please see the later section "Heart Failure").[54]

Evaluation for diastolic dysfunction should be part of the routine echocardiographic examination of cardiac surgical patients. Patients with preexisting diastolic dysfunction are prone to post-CPB complications, including difficulty separating from CPB and the need for more vasoactive support in the intensive care unit (ICU).[55] Figure 60-2 illustrates a practical approach to evaluating diastolic dysfunction.

Contraindications to the placement of a TEE probe may necessitate the use of an alternative imaging modality in certain patients. Intraoperative epicardial echocardiography is an alternative to TEE for assessing the ascending aorta and the aortic arch, as well as for diagnosing intracardiac disease.[52]

Central Nervous System

Many patients undergoing cardiac surgery are at risk for central nervous system (CNS) injury as a result of advanced age and comorbid diseases, in addition to the surgical risk of embolization and hypoperfusion and the inflammatory response associated with CPB. Type I CNS complications (fatal or nonfatal stroke or transient ischemic attack) occur in 3.1% of CABG patients.[56]

To predict stroke after CABG surgery, a risk index has been developed (Fig. 60-3) that uses weighted factors, including age and history of neurologic disease, vascular disease, diabetes, previous CABG, unstable angina, and pulmonary disease.[57] Subsequent research has also identified gender as a risk factor for stroke in cardiac surgical patients.[58,59]

The elevated risk for type I CNS injury in patients undergoing CABG combined with another open cardiac surgical procedure, such as valve repair or replacement, is higher than the risk after CABG alone. Wolman and coworkers[60] reported an 8.4% incidence of type I CNS complications in 273 patients undergoing these combined procedures. Similarly, a large retrospective analysis of more than 16,000 patients in Germany revealed a risk of stroke approaching 10% in patients undergoing double or triple valve replacement without CABG.[61]

The types of CNS injury that cardiac surgical patients may incur are not limited to frank ischemic or embolic stroke but also include more subtle neurocognitive dysfunction, which has a variety of causes (Table 60-1). Newman and associates[62] found that 53% of CABG patients in their study showed evidence of new neurocognitive dysfunction at the time of discharge from the hospital. In fact, after initial improvement in many patients, 42% had persistent neurocognitive deficits 5 years after surgery. Data are inconsistent regarding whether the risk of neurocognitive decline is higher after open versus closed cardiac procedures.[63,64] Furthermore, in a study of CABG versus percutaneous transcoronary angioplasty, new neurocognitive deficits were present with equal incidence after either procedure (at 6 weeks and 1 year).[65]

CNS Monitoring

The most common causes of CNS injury or dysfunction in cardiac surgical patients are thought to be microemboli and macroemboli. Additional causes of and contributors to CNS injury include cerebral hypoperfusion, inflammatory effects, cerebral edema, pharmacologic effects, dysfunction of the blood-brain barrier, and genetic risk factors (see Table 60-1). Increasing understanding of the etiology of injury and dysfunction in the CNS has prompted the development of methods to monitor intraoperative brain function and guide interventions to ameliorate postoperative focal deficits and cognitive dysfunction. However, widespread application of intraoperative CNS monitoring has lagged because

Table 60-1 Causes of Cognitive Dysfunction after Cardiac Surgery

Cause	Possible Settings
Cerebral microemboli	Generated during CPB (mobilization of atheromatous material or entrainment of air from the operative field; injection of gas into the venous reservoir of the CPB apparatus)
Global cerebral hypoperfusion	Hypotension; occlusion by an atheromatous embolus leading to stroke
Inflammation (systemic and cerebral)	Injurious effects of CPB as a result of blood interacting with the foreign surfaces of the pump oxygenator; upregulation of proinflammatory cyclooxygenase mRNA
Cerebral hyperthermia	Hypothermia during CPB; hyperthermia during and after cardiac surgery, e.g., during aggressive rewarming
Cerebral edema	Edema from global cerebral hypoperfusion or hyponatremia; increased cerebral venous pressure from cannula misplacement
Blood-brain barrier dysfunction	Diffuse cerebral inflammation; ischemia from cerebral microembolization or increased intracranial pressure
Pharmacologic influences	Anesthetic-related cognitive damage; necrosis of neonatal brains; proteomic changes
Genetic influences	Effects of single-nucleotide polymorphisms on risk for Alzheimer's disease or for acute coronary syndromes and other thrombotic disorders

CPB, cardiopulmonary bypass; mRNA, messenger ribonucleic acid.

no adequately powered, randomized, prospective clinical studies have been conducted to demonstrate the efficacy of any particular monitoring method.[66] The scope of this chapter does not allow an in-depth discussion of each available monitoring technique and does not include monitoring used in aortic surgery, such as somatosensory or motor evoked potentials. However, a brief review of monitors that are commonly used for CNS assessment and protection is appropriate.

Transesophageal and Epiaortic Echocardiography TEE allows direct visualization of the first segment of the ascending aorta, the mid-distal segment of the aortic arch, and a good portion of the descending thoracic aorta. However, the distal segment of the ascending aorta and the proximal midportion of the aortic arch cannot be visualized well because of the interposition of the trachea and bronchi between the TEE probe and these aortic structures. Instead, epiaortic imaging with a hand-held, high-frequency probe placed on the ascending aorta or aortic arch can be used to visualize aortic segments that are in the TEE probe's "blind spot."

Katz and coworkers[67] were among the first investigators to link the echocardiographic finding of protruding atheromas with elevated stroke risk in cardiac surgical patients. The grading system developed for their study is still commonly used to assess the overall atheroma burden of the aorta (Table 60-2). The severity of atheromatous disease of the aorta is a strong predictor of death and stroke after CABG.[68] Patients with atheromatous disease of the ascending aorta tend to be older, have a higher incidence of smoking in their history, have symptoms or a diagnosis of peripheral vascular disease, and have an increased risk for preoperative neurologic events.[69] Using TEE to guide cannula placement or treatment selection when indicated significantly reduced the stroke rate in a series of 500 consecutive patients versus controls in a state-wide database.[70] The addition of epiaortic scanning of the ascending aorta increases the sensitivity of intraoperative echocardiography in identifying significant atheromatous disease in this segment of the aorta. Certainly, this combination of techniques is superior to surgical palpation in detecting such disease.[71,72]

Transcranial Doppler Transcranial Doppler (TCD) involves ultrasonic interrogation of blood flow through the middle cerebral or common carotid arteries. Red blood cells (RBCs) reflect ultrasound energy back to the transducer; the exact frequency of the reflected sound varies with the velocity of each RBC. These velocities can be processed and displayed by pulsed-wave spectral analysis or nonspectral M-mode.

Classically, TCD has been used to detect emboli moving through the middle cerebral artery. Emboli, whether solid or gaseous, have higher acoustic impedance than RBCs do and show up as high-intensity "blips" on the spectral or nonspectral display. One early study using TCD showed increased embolic load in patients without arterial line filtration and a trend toward poorer function on postoperative tests of neurocognition in these patients.[73]

One of the primary limitations of TCD technology has been its inability to discern gaseous from solid emboli. Newer TCD monitors are capable of simultaneously generating Doppler frequencies of 2.0 and 2.5 MHz. Recent studies are inconclusive regarding the sensitivity and specificity of the technology.

Another application of TCD technology is measurement of cerebral blood flow velocity and documentation of changes from baseline during cardiac surgery with various techniques: traditional CPB, off-pump coronary revascularization, minimally invasive CABG, valve procedures involving nontraditional cannula placement or intra-aortic "endoclamp" occlusive balloon catheters, or deep hypothermic circulatory arrest with selective antegrade or retrograde cerebral perfusion.[74] In one study of patients undergoing operations on the great vessels requiring circulatory arrest and retrograde cerebral perfusion, TCD-guided cannula placement and retrograde cerebral perfusion reduced postoperative confusion, delirium, and agitation.[75]

Table 60-2 Grading Aortic Atherosclerosis

Aortic Atheromatous Disease	Echocardiographic Findings
Grade 1	Normal or mild intimal thickening
Grade 2	Severe intimal thickening No protruding atheromas
Grade 3	Atheroma protruding less than 5 mm into the lumen
Grade 4	Atheroma protruding 5 mm or more into the lumen
Grade 5	Atheroma of any size with a mobile component

From Béïque FA, Joffe D, Tousignant G, Konstadt S: Echocardiography-based assessment and management of atherosclerotic disease of the thoracic aorta. J Cardiothorac Vasc Anesth 12:206-220, 1998.

The general limitations of TCD technology include the following: (1) the quality of information is heavily user dependent, (2) accuracy requires stable and precise probe placement, (3) information is affected by patient characteristics such as skin thickness, and (4) signal acquisition is dependent on probe design and thus varies among probe models.

CNS Monitoring Summary The difficulties involved in using neuromonitoring in cardiac surgery include the fact that monitors are global in nature and cannot monitor focal areas of injury. Furthermore, there is a paucity of adequately powered prospective studies that would allow evidence-based recommendations about CNS monitoring. Despite these limitations, neuromonitoring will undoubtedly continue to receive significant research effort.

Renal System

In a healthy individual, about 20% of the total cardiac output (about 1 L/min) is received by the kidneys. The percentage of oxygen consumption versus total-body oxygen utilization does not usually exceed about 10%. Despite such a low oxygen extraction ratio, the kidneys are extremely sensitive to hypoperfusion occurring as a result of hypotension.

A number of control mechanisms maintain a strict balance of medullary oxygenation. In the event of failure of these control mechanisms, the outer medullary region is at risk for hypoxic injury, which can lead to acute tubular necrosis.

Perioperative monitoring of renal function is reviewed in Chapter 45.

In addition to fluid loss, the myocardial depression and peripheral vasodilation caused by most anesthetics can also compromise organ perfusion. In the kidneys, arteriolar glomerular filtration pressure is maintained by vasoconstriction of the efferent arterioles. Efferent arteriolar vasoconstriction and, ultimately, maintenance of glomerular filtration pressure are dependent on angiotensin II. Long-term treatment with angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin II receptor blockers can enhance the decline in perfusion pressure caused by anesthetic medications. Fluid replacement or use of a vasoconstrictor should be considered as a means of maintaining adequate organ perfusion.

For patients undergoing cardiac surgery, factors related to CPB add further complexity. The systemic inflammatory response and loss of pulsatile flow during CPB and hypoperfusion may contribute to the development of renal failure after cardiac surgery.[77-79] The best available evidence of the role that fluid balance plays in the development of nephropathy comes from studies performed with radiocontrast dye. The intrarenal hemodynamic disturbances caused by such dye seem to produce ischemic injury comparable to that associated with cardiac and aortic surgery.[76] Hydration of patients before administration of contrast material appears to have a protective effect on the kidneys.[80]

Some studies suggest that increases in creatinine are smaller after CABG surgery performed off-pump than after CABG surgery with CPB, but the evidence for this finding is mixed.[81,82] Regardless, conventional wisdom holds that urine flow greater than 0.5 mL/kg/hr should be maintained during the perioperative period, although randomized studies are lacking at this time to confirm this statement.[77]

Renal impairment after cardiovascular surgery remains a major cause of perioperative mortality and morbidity. Mangano and colleagues[83] found that after coronary revascularization, mortality was far lower in patients with normal renal function (0.9%) than in patients with acute renal failure (ARF) (63%). Unfortunately, no strategy, other than maintaining normovolemia, appears to be uniformly effective in preventing postoperative renal impairment.[76]

Endocrine System: Glucose, Thyroid Hormone, and Hormone Replacement Therapy

Glucose Control

Hyperglycemia in surgical patients is a consequence of the inflammatory or "stress" response to the trauma of surgery. Components of this response include an endocrine response (i.e., increased production of "counter-regulatory" hormones such as cortisol, growth hormone, glucagon, and catecholamines) (Fig. 60-4), an immune response resulting in increased cytokine production, an autonomic response resulting in increased sympathetic stimulation, and altered insulin signaling. These changes increase glucose production, decrease glucose elimination during CPB, and induce insulin resistance, thereby causing hyperglycemia.[84]

Although cardiac surgery without CPB initiates a stress response, CPB increases this response manyfold.[84] The degree of hyperglycemia depends on several variables associated with the use of CPB, such as the pump prime fluid selected, the degree of hypothermia induced, and the medications administered.

Older patients, diabetic patients, and patients with coronary artery disease are particularly prone to perioperative hyperglycemia, the deleterious effects of which include reduced vasodilation in response to ischemia, decreased response to vasodilator therapy, decreased collateral coronary circulation, increased levels of reactive oxygen species, reduced constitutive nitric oxide synthesis, reduced adenosine triphosphate–regulated activation of potassium channels, and reduced responses to ischemic or anesthetic preconditioning.[85]

Hyperglycemia may increase operative risk in patients undergoing cardiovascular procedures; it has been associated with increased mortality and morbidity, including a higher incidence of deep sternal wound infections and longer hospital stay.[85] Evidence suggests that in critically ill patients who receive insulin therapy to keep blood glucose levels between 4.4 and 6.1 mmol/L (80 to 110 mg/dL) for a few days after complicated, high-risk, or extensive surgery or trauma, survival improves and morbidity decreases.[86] However, in a recent randomized trial,[87] cardiac surgical patients whose glucose levels were maintained at 80 to 100 mg/dL during the intraoperative and postoperative periods by means of intensive insulin therapy did not have less mortality or morbidity than those who received conventional glucose management (i.e., treatment of glucose levels >200 mg/dL). In fact, the investigators noted a statistically nonsignificant increase in the incidence of death and stroke (Table 60-3) in the intensive insulin treatment group. Although various limitations of the study were noted by the investigators, these findings raise concern about the routine implementation of intensive insulin therapy during cardiac surgery.

In diabetic patients undergoing cardiac surgery, hyperglycemia may only partly explain an increased risk for adverse outcomes. Immunologic abnormalities common to diabetic patients, such as decreased chemotaxis, phagocytosis, opsonization, bacterial killing, and antioxidant defense, also promote adverse outcomes by increasing diabetic patients' risk of infection.[88]

Thyroid Hormone

Abnormal thyroid function ultimately affects cardiac function in many ways (Table 60-4). During cardiac surgery, the effect of CPB on thyroid hormone production is uncertain. Results of studies vary and have shown both increased and decreased levels of thyroid hormone during or immediately after CPB. Factors that might contribute to low levels of thyroid hormone include hypothermia, nonpulsatile blood flow, and reduced conversion of thyroxin (T_4) to triiodothyronine (T_3). However, initial reports that intravenous T_3 hormone administration improves cardiac function were contradicted in subsequent investigations.[89]

On the other hand, preexisting thyroid dysfunction can occasionally be severely aggravated by CPB. For example, hypothyroidism is more common in female than in male CABG patients.[90] Zindrou and associates[91] noted a 17% higher mortality rate in women who underwent CABG while receiving thyroxine replacement therapy for hypothyroidism than in women who did not require hormone replacement. In the same study, no difference was noted among men with and without thyroid hormone replacement therapy (HRT).

Hypothyroidism is associated with impaired contractility and an enhanced risk for MI. A review of the literature by Edwards and colleagues concluded that ensuring a perioperative euthyroid state in women with hypothyroidism who were undergoing CABG might be helpful in reducing the perioperative mortality of these patients.[16]

Hormone Replacement Therapy

According to the database of the Society of Thoracic Surgeons (STS), women account for 29% of CABG patients. Female sex may be an independent risk factor for operative mortality, low-output syndrome, and MI in CABG surgery.[16,92]

Although HRT has been a focus of investigation in postmenopausal women for possible protection from CVD, prospective randomized studies have not demonstrated that HRT is beneficial in either primary or secondary prevention of coronary

artery disease.[93-95] In fact, taking HRT may increase women's risk for adverse cardiovascular events.

Single-center, retrospective studies of female CABG patients have noted lower mortality in those taking HRT at the time of admission.[96-98] A multicenter study found a trend toward lower mortality in women receiving HRT but no statistically significant effect of HRT on mortality or morbidity.[99] The investigators concluded that women taking HRT should not discontinue it before or after surgery. However, a recent task force report on gender guidelines for CABG published by the STS concluded that

Table 60-4 Effects of Thyroid Dysfunction on Hemodynamics and Cardiac Function

Parameter	Normal Values	Hyperthyroidism	Hypothyroidism

given the potential risk for thromboembolic events posed by HRT, the wisdom of continuing HRT in patients undergoing CABG is uncertain.[16]

Hematologic System

The impact of CPB on the human hematologic system is well known. Bleeding is the primary complication of cardiac surgery requiring CPB. In fact, 15% to 20% of the blood product use in the United States is associated with cardiac surgery.[100-102] The global cost is also impressive; it is reported that worldwide, 1 to 1.25 million adult cardiac operations are performed annually, with a price tag of 50 billon U.S. dollars per year.[102] Beyond the economic burden of blood product transfusion in cardiac surgery is evidence that there are important clinical ramifications as well: transfusion has been associated with increased rates of hospital mortality,[103] perioperative infection and sepsis,[104] pulmonary dysfunction, prolonged mechanical ventilation,[105] and renal dysfunction,[106] as well as a persistent reduction in quality of life after surgery.[107]

Anticoagulation in Cardiopulmonary Bypass

Heparin Since its discovery by Jay McLean, MD, in 1915, heparin has stood the test of time and remains the primary anticoagulant used in cardiac surgery requiring CPB. The mechanism underlying heparin's anticoagulant effect revolves around the heparin molecule's ability to bind simultaneously to antithrombin III (AT III) and thrombin. The binding process is mediated by a unique pentasaccharide sequence that binds to AT III. The proximity of AT III and thrombin, mediated by the heparin molecule, allows AT III to inhibit the procoagulant effect of thrombin by binding to the active-site serine residue of the thrombin molecule. The inhibitory effect of AT III is increased 1000-fold in the presence of heparin. The heparin–AT III complex can affect several coagulation factors, but factor Xa and thrombin are most sensitive to inhibition by heparin, and thrombin is 10 times more sensitive to the inhibitory effects of heparin than factor Xa is.[108]

Only about a third of heparin molecules in a dose of heparin contain the critical pentasaccharide segment that is needed for high-affinity binding to AT III.[109] Thus, relatively large doses are required to produce the anticoagulant effect necessary for CPB. In fact, dosing of heparin for CPB is somewhat empirical. After a baseline activated clotting time (ACT) is measured (the normal range is 80 to 120 seconds), a dose of 300 to 400 U/kg is given in intravenous bolus form. Subsequent heparin dosing for extracorporeal circulation is targeted at maintaining ACT values greater than 480 seconds.

The dose of heparin used in patients undergoing CPB is based on early landmark work published by Bull and coauthors in 1975.[109a] A small study that sought evidence of thrombin activity during CPB in primates and pediatric patients found results supporting a safe lower limit for ACT of at least 400 seconds.[110] In 1979, Doty and colleagues[111] proposed a simplified dosing regimen guided by ACT values without dose-response curves. The data and recommendations that these few studies produced are the primary references for current heparin dosing protocols.

Despite heparin's historic and continued role in anticoagulation for patients maintained on CPB, it is not a perfect anticoagulant. Intrinsic and extrinsic pathway coagulation occurs despite heparin administration, and platelets can still be activated by contact with the bypass circuitry and by heparin directly.[112,113]

Table 60-5 Clinical Factors Affecting the Activated Clotting Time

Hemodilution	Prolongs the ACT in the presence of heparin
Hypothermia	Prolongs the ACT
Thrombocytopenia	Prolongs the ACT
Platelet inhibitors	Prolongs the ACT
Platelet lysis	Shortens the ACT
Aprotinin	Prolongs the ACT with celite activator
Surgical stress	Shortens the ACT

ACT, activated clotting time.

Alternative anticoagulants are discussed briefly in the section "Heparin-Induced Thrombocytopenia."

Using ACT to monitor the efficacy of heparin is not an exact science. There is tremendous variability in patients' anticoagulation response to a given dose of heparin. Hence, ACT values correlate poorly with actual heparin concentrations.[114] A brief review of anticoagulation monitoring in CPB follows.

Monitoring of Anticoagulation Since the publication of Bull and colleagues' early work, ACT has been the mainstay of anticoagulation monitoring in cardiac surgery requiring CPB. Whole blood is added to a tube containing a contact-phase activator, celite or kaolin, and a small iron cylinder. The sample is warmed to 37°C, and the tube is rotated. Clot formation is detected by retracting the iron cylinder, which disrupts a magnetic field.[115]

Several clinical variables can affect the ACT (Table 60-5). Additionally, ACT values can vary with the manufacturer of the machine and between adult and pediatric populations. Some authors argue that because of these interfering factors, the ACT alone is not an adequate monitor of heparin efficacy and that simultaneous or adjunctive monitoring of the heparin concentration should also be used during CPB.[114] Prolongation of the ACT by non–heparin-related clinical factors, such as hypothermia, hemodilution, or quantitative or qualitative platelet abnormalities, requires the anesthesiologist to reduce heparin doses to keep the ACT at a set, arbitrary level. Because the ACT correlates poorly with the measured heparin concentration, it is possible that this dose reduction can render the heparin concentration inadequate, even when the ACT remains within an acceptable range. There are point-of-care (POC) monitors, such as the Hepcon HMS system, that use a protamine titration assay to calculate the heparin concentration. Despotis and colleagues[116] argue that monitoring the heparin concentration and giving larger doses of heparin actually protect the hemostatic system and may decrease transfusion requirements. However, other investigators have not been able to confirm better hemostatic protection with higher doses of heparin because markers of ongoing coagulation are essentially the same whether traditional ACT monitoring or monitoring of the heparin concentration is used.[117]

The high-dose thrombin time (HiTT) correlates well with the heparin concentration, both before and during CPB.[118] Unlike the ACT, HiTT is not affected by hemodilution and hyperthermia; in addition, it is a more specific test of heparin's effect on thrombin, and it appears to possess less artifactual variability.[112] Aprotinin and preoperative heparin infusions do not affect HiTT values.[119,120]

Protamine and Reversal of Anticoagulation Protamine, which has been in clinical use about as long as heparin, remains the heparin reversal agent of choice in cardiac surgery. The protamine dose required to reverse heparin is somewhat controversial. The amount quoted in most cardiac anesthesia texts is 1 to 1.3 mg of protamine for every 100 units of heparin. The question to be answered revolves around which end point one uses in the protamine calculation: the total amount of heparin used for the procedure or the amount present in the patient at the time of reversal. In current practice, dosing usually follows one of the following protocols:

1. Protamine is administered according to the total amount of heparin given for the procedure, specifically, 1 to 1.3 mg protamine per 100 units of heparin. This method may result in luxuriant protamine doses, which reduces any theoretical or real risks of heparin rebound but may put the patient at higher risk for the anticoagulant effect of protamine.[115]
2. Another practice involves the use of calculated heparin concentrations obtained automatically from a heparin concentration monitoring system, such as the Hepcon HMS system, or graphically derived by plotting ACT values throughout the procedure and creating heparin dose-response curves. The amount of protamine used in this method is based on the circulating concentration of heparin in the patient at the time of reversal. Because theoretically there is no excess protamine, these patients might be at risk for heparin rebound and could require additional protamine.[117,121]

Hemostatic Effects of Cardiopulmonary Bypass The hemostatic effects of CPB are myriad. Exposure of blood to the surfaces of the bypass circuitry is a profound stimulus for inflammatory upregulation, and activation of the hemostatic system is a component of the normal inflammatory response. According to traditional models of hemostasis, CPB is thought to activate the intrinsic and extrinsic hemostatic pathways and to directly affect platelet functionality. Current concepts in vascular biology and hemostasis implicate tissue factor–bearing leukocytes and endothelial cells activated by the inflammatory stimulus of bypass and circulating tissue thromboplastin generated from the surgical field.[122-124] Activation of the intrinsic pathway can occur by activation of factor XII to factor XIIa on the various surfaces of the bypass circuit.[122,125] Generation of thrombin by the tissue factor pathway assumes a primary role in CPB-associated hemostatic abnormalities (Fig. 60-5).[124,126]

In addition to activating the extrinsic and intrinsic hemostatic pathways, CPB directly affects platelet function through the effects of hemodilution, hypothermia, and contact activation by bypass circuit materials. Platelets express numerous glycoproteins on their surface that serve as receptors for several circulating ligands, such as fibrinogen, thrombin, and collagen (Fig. 60-6).[122] The components of the bypass circuit adsorb circulating proteins that can serve as foci for platelet attraction and adherence. These surface-bound platelets activate and release the contents of their cytoplasmic granules, which can then serve as localized sources of thrombin generation or embolize to initiate microvascular thrombosis.[127] The resulting functional platelet disorder can complicate hemostasis after CPB is terminated and heparin is reversed by protamine.

Fibrinolytic activity is also increased by CPB. Contact activation of factor XII, prekallikrein, and high-molecular-weight kininogen leads to fibrinolytic activation through activation of endothelial cells to produce tissue plasminogen activator (t-PA) and lysis of fibrin strands and the fibrin precursor fibrinogen (Fig. 60-7).[122,128]

Endothelial cells themselves are vulnerable to inflammatory activation by the effects of CPB. Vascular endothelium is an active substrate that expresses and releases anticoagulant and procoagulant factors.[123] Endothelial cells, when exposed to hypoxia or inflammatory mediators during bypass, can induce a relatively prothrombotic state that leads to upregulation of tissue factor, accelerated platelet adhesion, and increased expression of leukocyte adhesion molecules (Fig. 60-8).[122,123]

Unique Clinical Considerations in Cardiac Surgery

Antithrombin III Deficiency/Heparin Resistance Heparin resistance has been defined as an ACT of less than 480 seconds after 500 U/kg of heparin is administered intravenously. Others have defined heparin resistance as an ACT of less than 400 seconds at any time during the course of CPB and heparin administration. A more accurate term to describe the clinical findings is "altered heparin responsiveness."[129] In a recent, small study of cardiac surgery patients stratified by their history of preoperative heparin use, altered heparin responsiveness was found in approximately 40% of the patients who had received preoperative heparin therapy.[130] Reported risk factors for altered heparin responsiveness include AT III levels less than 60% of normal, preoperative heparin therapy, a platelet count less than 300,000/mm^3, and age younger than 65 years.[131] In a second, larger study, Ranucci and coworkers[132] found heparin resistance in 20% of the patients studied and confirmed that AT III activity levels, platelet counts greater than 300,000/mm^3, and heparin pretreatment—but not age—were risk factors for heparin resistance. Ranucci and colleagues also found a small group of patients in their cohort with normal or supranormal AT III activity who had altered heparin responsiveness that did not respond to the administration of AT III. The precise mechanism of action of an altered response to heparin is unclear. The usual treatment is supplemental doses of heparin. In refractory cases, treatment with fresh frozen plasma (FFP), AT III concentrate, or recombinant AT III usually restores heparin responsiveness.[133,134]

Heparin Rebound Heparin rebound is clinical bleeding that occurs within approximately 1 hour of protamine neutralization. It is accompanied by coagulation test results indicating residual heparinization, such as a prolonged partial thromboplastin time or thrombin time and increased anti–factor Xa activity. Mechanisms of heparin rebound include slow dissociation of protein-bound heparin after protamine clearance, more rapid clearance of protamine than heparin, lymphatic return of extracellular sequestered heparin, or clearance of an unknown heparin antagonist. Heparin rebound is treated with supplemental protamine.

Heparin-Induced Thrombocytopenia Heparin-induced thrombocytopenia (HIT) is an immune-mediated prothombotic disorder that occurs in patients exposed to heparin. Antibodies form against the protein platelet factor 4 (PF4) when PF4 has formed a complex with heparin. Although PF4 is found in only trace amounts in human plasma and is stored in platelet granules, the presence of heparin increases plasma concentrations of PF4 15- to 30-fold by displacing bound PF4 on endothelial cell sur-

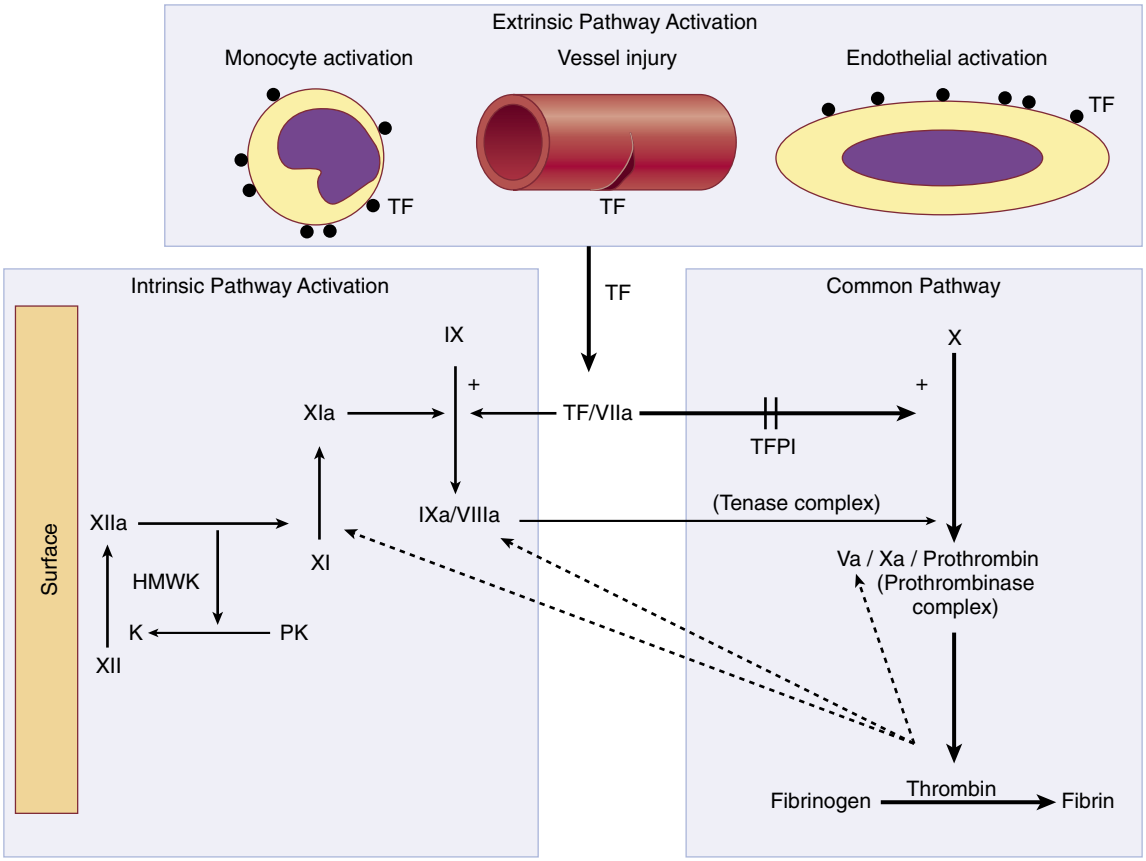

Figure 60-5 Coagulation can be activated during cardiopulmonary bypass (CPB) by the intrinsic pathway, with surface adsorption and activation of factor XII, high-molecular-weight kininogen (HMWK), and prekallikrein (PK). Activation of the extrinsic pathway during CPB occurs with tissue injury, as well as with systemic inflammation, and leads to monocyte and endothelial expression of tissue factor (TF). TF, in combination with factor VIIa, starts the common pathway with the activation of factor X to factor Xa. Assembly of the prothrombinase complex on phospholipid surfaces leads to the production of thrombin and conversion of fibrinogen to fibrin. Tissue factor pathway inhibitor (TFPI) inhibits TF/VIIa. Thrombin can overcome this TFPI blockade by activating factors XI, VIII, and V and initiating activation of factor X by the tenase complex. K, kallikrein. *(From Kottke-Marchant K, Sapatnekar S: Hemostatic abnormalities in cardiopulmonary bypass: Pathophysiologic and transfusion considerations. Semin Cardiothorac Vasc Anesth 5:187-206, 2001.)*

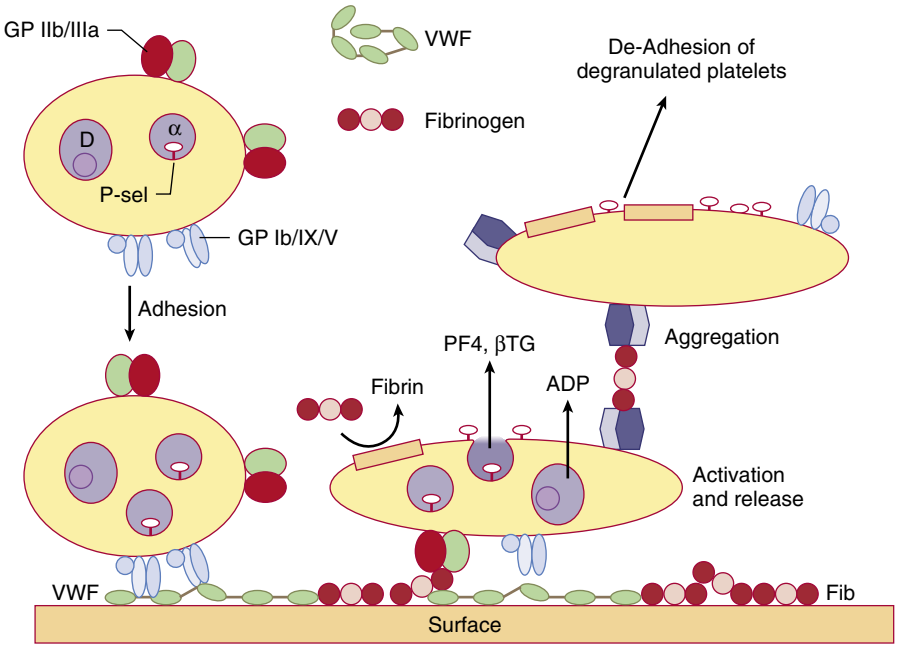

Figure 60-6 Platelet activation by cardiopulmonary bypass materials is facilitated by rapid adhesion and conformational alteration of plasma proteins, including von Willebrand factor (VWF) and fibrinogen. Platelets adhere to VWF through the glycoprotein (GP) Ib/IX/V surface glycoprotein and to fibrinogen through the GP IIb/IIIa receptor. Platelet adhesion stimulates intracellular signaling, which leads to degranulation of alpha granules (platelet factor 4 [PF4] and β-thromboglobulin [βTG]) and phospholipid reorganization with the formation of coagulation complexes and fibrin formation. Release of adenosine diphosphate (ADP) from dense granules and activation of the GP IIb/IIIa receptor also occur and lead to the aggregation of platelets to the adherent layer. Because of shear forces, adherent and aggregated platelets can detach from the membrane and circulate in a degranulated state or form small microaggregates that lodge in the distal vasculature. *(From Kottke-Marchant K, Sapatnekar S: Hemostatic abnormalities in cardiopulmonary bypass: Pathophysiologic and transfusion considerations. Semin Cardiothorac Vasc Anesth 5:187-206, 2001.)*

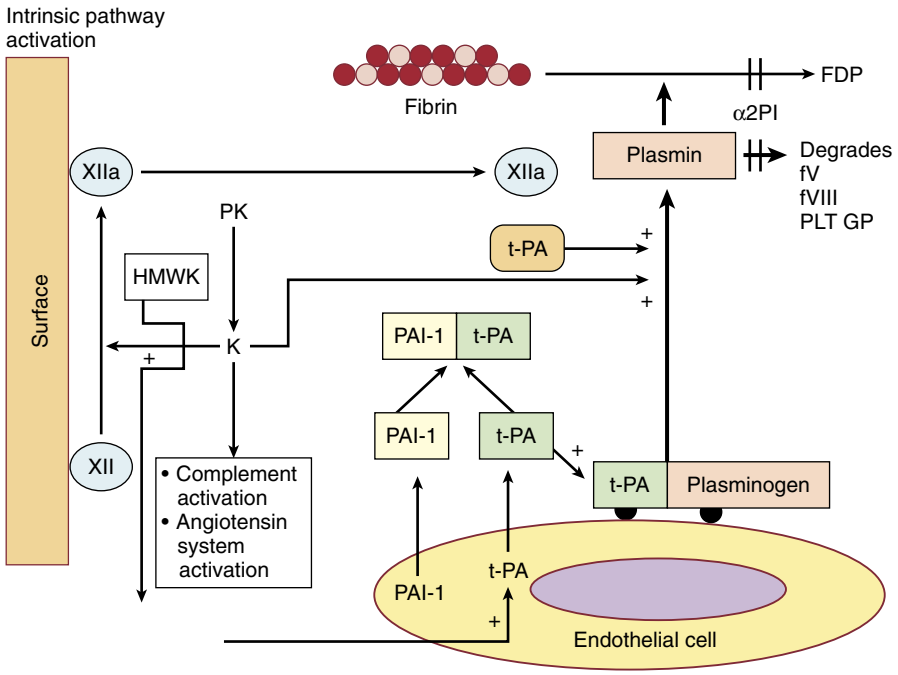

Figure 60-7 The fibrinolytic system results in the degradation of fibrin by plasmin. The intrinsic factors participate in the fibrinolytic system. Adsorption and activation of factor XII, high-molecular-weight kininogen (HMWK), and prekallikrein (PK) occurs on the cardiopulmonary bypass material surfaces. Kallikrein (K) and factor XIIa participate in the conversion of plasminogen to plasmin. Plasminogen is also activated by tissue plasminogen activator (t-PA), which is released from endothelial cells, along with its inhibitor PAI-1. Plasmin not only degrades fibrin but also degrades coagulation factors V and VIII and platelet surface glycoproteins (PLT GP). Kallikrein plays additional roles in the activation of complement and the angiotensin system, and HMWK accelerates fibrinolysis by stimulating endothelial production of t-PA. FDP, fibrin degradation product. *(From Kottke-Marchant K, Sapatnekar S: Hemostatic abnormalities in cardiopulmonary bypass: Pathophysiologic and transfusion considerations. Semin Cardiothorac Vasc Anesth 5:187-206, 2001.)*

faces making it available to bind with heparin. Binding of the resulting PF4-heparin complex to platelets leads to immunologically mediated platelet activation.

The hallmark of findings in patients with HIT is a decrease in the platelet count to less than 100,000 or to less than 50% of the baseline count.[135] The incidence of seroconversion after bypass and heparin exposure is quite high (20% to 50%).[135-137] However, the reported prevalence of HIT after CPB is only 1% to 3%.[137] Thus, the risk of HIT in cardiac surgery patients with postoperative seroconversion is less than 10%. The strength of the immunologic response, not the mere presence of PF4/heparin antibodies, may determine which patients are prone to HIT and are at risk for thromboembolic complications.[135,137]

Clinically, HIT is categorized into type I (platelet counts >100,000) and type II (platelet counts <100,000), and it is sometimes accompanied by clinical thrombosis.[129] Regardless of the clinical manifestation, it is challenging to anticoagulate patients with preoperative type I or type II HIT who need to be exposed

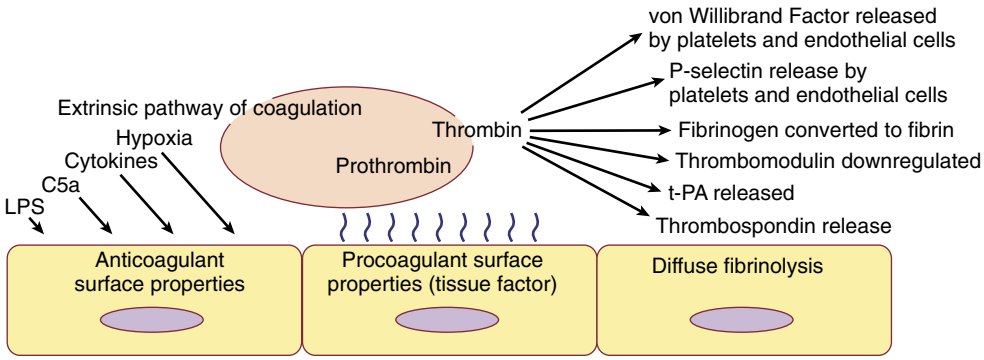

Figure 60-8 Procoagulant endothelial cell activation. When endothelial cells are activated, they express tissue factor, which converts prothrombin to thrombin. Thrombin has multiple biologic actions: (1) stimulation of the release of von Willebrand factor and P-selectin, which cause platelet clumping and platelet/neutrophil/endothelial cell adhesion; (2) conversion of fibrinogen to fibrin, the solid component of clot; (3) downregulation of the thrombomodulin/protein C and S systems; (4) release of tissue plasminogen activator (t-PA), which catalyzes the formation of plasmin; and (5) release of thrombospondin, which binds to t-PA, prevents its breakdown by plasminogen activator inhibitor-1 (PAI-1), and accelerates the formation of plasmin. LPS, lipopolysaccharide. *(From Boyle EM Jr, Verrier ED, Spiess BD: Endothelial cell injury in cardiovascular surgery: The procoagulant response. Ann Thorac Surg 62:1549-1557, 1996.)*

to CPB. In this situation, the use of nonheparin anticoagulation must be considered.

It is preferred, when possible, to defer surgery until antibody titers have become undetectable or only weakly positive. If surgical postponement is not practical, other therapeutic options must be considered. Lepirudin and argatroban are approved by the Food and Drug Administration (FDA) for use in patients with HIT-related thrombosis. Bivalirudin has been approved by the FDA for use in percutaneous interventions. To date, four clinical trials have tested bivalirudin as an anticoagulant for CPB in patients with HIT.[138-141] However, no drug other than heparin has FDA approval for specific use as an anticoagulant in patients during CPB.[129] Table 60-6 and Box 60-2 summarize the therapeutic options and alternative anticoagulant strategies for the patient with HIT whose operation cannot be deferred until seronegativity is documented.

Protamine Reactions Protamine is associated with several hemodynamic effects that can be categorized by their manifestations and mechanism.[142] Adverse reactions to protamine range from seemingly innocuous hypotension to more profound and hemodynamically significant reactions that have been linked to increased in-hospital mortality.[143,144] The clinical expression of these reactions serves as a starting point for understanding the mechanistic relationships. Commonly, what is seen is either (1) isolated hypotension, with normal to low filling pressure and normal airway pressure, or (2) hypotension accompanied by elevated PA pressure, evidence of bronchoconstriction with elevated airway pressure, evidence of acute RV failure on visual inspection or intraoperative echocardiography, or any combination of these findings. The first manifestation is usually mild and responds to volume infusion, slowing of protamine infusion, and gentle titration of vasoactive medications. The second can be profound and could result in global cardiovascular collapse or necessitate a return to CPB because of intractable RV failure. Fortunately, catastrophic hypotension and intractable RV failure are relatively rare events on the spectrum of protamine reactions.[145,146]

Table 60-6 Alternative Anticoagulants for the Treatment of Heparin-Induced Thrombocytopenia

Anticoagulant	Dosing (Therapeutic Range)	Pharmacokinetics ($t_{1/2}$)	Comment
Agents Approved for the Treatment of HIT			
Danaparoid sodium (Orgaran)	Bolus: 2250 U* Infusion: 400 U/hr × 4 hr then 300 U/hr × 4 hr then 200 U/hr, with monitoring by anti–factor Xa levels (0.5-0.8 anti-Xa U/mL†)	Renal metabolism (25 hr [anti–factor Xa activity], 2-4 hr [anti–factor IIa activity])	Approved for the treatment and prevention of HIT-associated thrombosis in the European Union, Canada, New Zealand, and Australia Withdrawn from U.S. market in April 2002 because of the potential for in vivo cross-reactivity (rare), which is not predictable by in vitro testing. Thus, cross-reactivity testing is not recommended before use
Lepirudin (Refludan)	Bolus: 0.4 mg/kg‡ Infusion: 0.15 mg/kg/hr (target aPTT range, 1.5-2.5 × baseline‡§)	Renal excretion (80 min)	Approved in the United States, Canada, and the European Union for the treatment of HIT-associated thrombosis; $t_{1/2}$ rises considerably in patients with renal failure; high rate of antihirudin antibodies (40% -60%) that are not usually clinically significant; anaphylaxis reported after lepirudin bolus (rare), especially with a repeat treatment course
Argatroban (Novastan in some non-U.S. jurisdictions)	2 µg/kg/min without an initial bolus (target aPTT range, 1.5-3.0 × baseline§)	Hepatobiliary excretion (40-50 min)	Approved in the United States and Canada for prevention and treatment of HIT-associated thrombosis (identical therapeutic dose regimens used for both indications); argatroban increases the INR, so a higher therapeutic range is required during overlapping argatroban/warfarin
Investigational Agents for the Treatment of HIT			
Bivalirudin (Angliomax)	0.15-0.20 mg/kg/hr without an initial bolus (target aPTT range, 1.5-2.5 × baseline§¶)	Enzymic > renal (25 min)	Approved in the United States for anticoagulation during percutaneous coronary interventions (non-HIT); low $t_{1/2}$ and enzymic metabolism are theoretical advantages over lepirudin for cardiac surgery in patients with HIT (under current investigation)
Fondaparinux (Arixtra)	Uncertain	Renal (17-20 hr)	Approved for DVT prophylaxis after orthopedic surgery; theoretically, lack of in vitro cross-reactivity with HIT antibodies suggests that it may be efficacious in patients with HIT (not yet studied for this indication)

*Adjust the intravenous danaparoid bolus for body weight: less than 60 kg, 1500 U; 60 to 75 kg, 2250 U; 75 to 90 kg, 3000 U; greater than 90 kg, 3750 U.
†Anticoagulant monitoring by anti–factor Xa levels is not always necessary but is preferred (when available) for very small or large patients, patients with renal failure, or those with life- or limb-threatening thrombosis.
‡In the absence of life-threatening thrombosis or when treating isolated HIT, it may be prudent to omit the initial bolus and to aim for an aPTT of 1.5 to 2.0 times baseline.
§The patient's baseline aPTT (when available) is generally preferred for calculating the target aPTT range.
¶Anecdotal experience in HIT.
aPTT, activated prothrombin time; DVT, deep venous thrombosis; INR, international normalized ratio; $t_{1/2}$, half-time.

Box 60-2 Anticoagulation Options for Cardiac Surgery

A. Acute HIT (documented thrombocytopenia, detectable HIT antibodies, with or without thrombosis)
   Defer surgery if possible. Follow antibody titers. Go to C.
   Surgery not deferrable; choose an alternative anticoagulation strategy
   1. Bivalirudin
   2. Lepirudin
   3. Epoprostenol plus heparin
   4. Tirofiban plus heparin
   5. Danaparoid (requires anti-Xa monitoring)

B. Subacute HIT (diagnosed recent HIT, resolution of thrombocytopenia, HIT antibody titers still positive)
   Defer surgery if possible. Follow antibody titers. Go to C
   If surgery is not deferrable, use
   1. An off-pump technique, with bivalirudin or alternative nonheparin anticoagulant used if needed
   2. Heparin if the antibody test is only weakly positive
   3. Acute HIT options above

C. Previous HIT (prior diagnosis of HIT, antibodies no longer detectable)
   Use heparin (ensuring no long-term exposure to heparin from invasive lines in the intensive care unit). Reverse completely with protamine

HIT, heparin-induced thrombocytopenia.
From Warkentin TE, Greinacher A: Heparin-induced thrombocytopenia and cardiac surgery. Ann Thorac Surg 76:2121-2131, 2003.

Mechanistic explanations for protamine reactions include mast cell degranulation, endothelial release of nitric oxide, and hypotension associated with rapid infusion.[129,146] Both immunologic and nonimmunologic anaphylactoid reactions may cause the more hemodynamically significant manifestations. Anaphylactoid reactions include protamine sensitivity reactions, which are classically immunologic or allergic in nature in that they are mediated by IgE antibody, and nonimmunologic mechanisms, which may involve IgG antibodies or complement activation.[129,147-149]

A study by Kimmel and associates[150] found that neutral protamine Hagedorn (NPH) insulin use, documented fish allergy, and a history of nonprotamine medical allergies were independent risk factors for protamine hypersensitivity reactions. In this study, 39% of patients about to undergo cardiac surgery had one or more of these risk factors. Other possible, but unconfirmed risk factors include previous exposure to protamine, a history of vasectomy, decreased LV function, and hemodynamic instability.[129,150] The site of injection does not influence the incidence of protamine reactions.[151] Interestingly, thromboxane receptor inhibition prevents heparin-protamine–induced pulmonary hypertension in sheep,[152] whereas in humans, preoperative aspirin use may be protective.[151] Pretreatment with histamine blockade is not preventive.[153]

The following principles summarize the treatment options for patients at risk for intraoperative protamine reactions:

1. Protamine should be administered slowly, over a period of 5 minutes or longer.[129]
2. In patients with documented protamine allergy, consideration might be given to using non–heparin-based CPB (as used in patients with HIT), performing off-pump coronary artery bypass (OPCAB) without using heparin, using nonprotamine heparin reversal agents such as PF4, administering heparinase, or even foregoing heparin reversal.[129]
3. The hypotension associated with protamine reversal of heparin is often ameliorated by simply slowing or pausing the protamine infusion while volume is infused through intravenous lines or the aortic cannula. Vasoactive medications, such as phenylephrine or ephedrine, or increased inotropic support may be necessary.
4. Severe or intractable hypotension, with or without evidence of pulmonary circulatory involvement, bronchospasm, or overt RV failure, demands immediate aggressive attention, intervention, and planning for a potential return to CPB. Steps to consider include the following:
   a. Reheparinization can be carried out to prepare the patient for return to CPB and to reduce heparin-protamine complex size. If hemodynamics permits, a low dose of heparin (70 U/kg) might be tried first while treatment continues, followed by a full CPB dose of heparin (300 U/kg) if it becomes necessary to return the patient to CPB.[129]
   b. Inotropic support, either by infusion or by intermittent boluses, is warranted. Epinephrine and milrinone are acceptable options, and isoproterenol may be considered as well.
   c. If hemodynamics allows, nebulized albuterol is helpful in the management of bronchospasm and elevated airway pressure.
   d. Hypotension accompanied by direct or echocardiographic evidence of acute RV distention and failure should prompt immediate consideration of return to CPB. Hypotension accompanied by pulmonary hypertension and acute severe RV failure can become a vicious cycle leading to RV ischemia and further dysfunction because of high RV intracavitary pressure and decreased coronary perfusion of the right ventricle.
   e. Consideration should be given to not rechallenge a patient who has had a significant adverse event related to protamine. Pharmacologic alternatives to protamine could be considered, or a decision can be made to not reverse heparin.

Hypercoagulable States Over the past decade, the use of antifibrinolytics has become common in cardiac surgery requiring CPB. Recently, as it relates to perioperative risk in cardiac surgery and noncardiac surgery, the role of congenital thrombophilic states has been considered.[154] These states may be important in light of current practices that involve pharmacologically inhibiting fibrinolytic pathways in cardiac surgical patients. The factor V Leiden (FVL) deficiency mutation is the most common inherited thrombophilic disorder, with a prevalence of 3% to 7% in white populations. Mechanistically and clinically, FVL deficiency has been implicated in thrombotic complications in cardiac operations, most often those involving a period of circulatory arrest and the use of antifibrinolytics.[155-158] In a review of FVL deficiency, Donahue[154] gives the following summation and recommendations:

- Cardiac surgery patients who carry the FVL deficiency mutation bleed less than noncarriers do.
- Early graft thrombosis may be increased in patients with FVL deficiency.
- Increased thrombotic risk in FVL deficiency with the use of antifibrinolytics (ε-aminocaproic acid [EACA], aprotinin, tranexamic acid [TA]) is a pharmacologically theoretical risk.
- Anecdotal evidence suggests that in patients with FVL deficiency who are exposed to deep hypothermic cardiac arrest (DHCA), antifibrinolytics increase the risk for thrombosis.

For further information on congenital thrombophilic states, the reader is referred to a review article by Crowther and Kelton.[159]

Anticoagulated Patients Undergoing Cardiac Surgery Antithrombotic therapy in cardiac surgery patients has many roles and applications. Patients with ischemic heart disease can be managed acutely or chronically with pharmacologic agents that may include aspirin, AT III inhibitors (heparins), direct thrombin inhibitors, or an array of platelet inhibitors (adenosine diphosphate [ADP] receptor inhibitors and glycoprotein IIb/IIIa [GP IIb/IIIa] receptor inhibitors). Patients with a history of peripheral or central vascular disease, valvular heart disease, or low–ventricular ejection states may likewise be managed with some form of antithrombotic therapy that may also include warfarin. Frequently, patients arrive for surgery while taking multiple antithrombotic medications. Thus, postoperative bleeding is a common but challenging complication of cardiac surgery, especially when it involves CPB.

The advancement of percutaneous interventions such as angioplasty and intracoronary stent deployment for ischemic heart disease has led to the use of antithrombotic medications, especially antiplatelet drugs, to maintain stent patency and prevent stent occlusion. The most recent American College of Cardiology/American Heart Association (ACC/AHA) guidelines for percutaneous coronary intervention (PCI) give both aspirin and clopidogrel a class I recommendation (based on evidence and a consensus agreement that the therapy is beneficial) for use in the pericatheterization period and in the long term (e.g., up to a year after placement of a drug-eluting stent).[160] In addition, GP IIb/IIIa receptor inhibitors and low-molecular-weight heparin (LMWH) have received either class I or class IIa recommendations for use in the postintervention period.[160] Because these recommendations have led to the widespread use of heparin in patients who undergo PCI, it can be challenging to treat these patients if they require urgent or emergency conversion to surgical revascularization.

Consensus has not been reached regarding whether aspirin and newer antiplatelet agents, if recently administered, increase the risk for bleeding after cardiac surgery. There is evidence for and against the ability of aspirin to increase mediastinal chest tube output and transfusion requirements.[161-164] In the European and U.S. literature, the ADP receptor antagonist clopidogrel (Plavix) has been associated with increased perioperative blood loss, an elevated risk for reoperation, increased mortality, and increased packed RBC and clotting factor use.[165-171] This trend has even been purported to occur in the OPCAB population.[172] However, one study did not show an association between the preoperative use of clopidogrel and increased bleeding and reoperation rates.[173]

Patients with a history of GP IIb/IIIa receptor blockade as a part of management of their acute coronary syndrome are at risk for increased bleeding and blood component use when given abciximab, especially within 12 hours of surgery.[174-177] Shorter-acting GP IIb/IIIa receptor antagonists have not been associated with increased bleeding or adverse outcomes. In fact, a study of dogs undergoing CPB found less platelet consumption, better platelet function, and less postoperative bleeding when the dogs were treated with eptifibatide.[178] Additionally, the PURSUIT (Platelet Glycoprotein IIb-IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy) trial showed that eptifibatide reduced death and MI at 7 days to 6 months after surgery.[179]

Enoxaparin, an LMWH, has been associated with increased transfusion rates and an increased risk for surgical re-exploration.[180,181] LMWH may also decrease heparin responsiveness.[182] Although LMWH is a weaker anticoagulant overall than heparin is, it has greater antithrombotic activity.[183]

Finally, patients with active, uncorrected use of warfarin who undergo surgery always have undesirable bleeding. The long-acting effects of warfarin usually require factor replacement, especially after surgery involving CPB.

In summary, patients who undergo cardiac surgery with preexisting, pharmacologically induced inhibition of the hemostatic system may have undesirable post-CPB bleeding. Diagnosis and treatment of this complication should be consistent, regardless of whether the derangement is a function of CPB itself, coexisting pharmacologic inhibition, or both. Management and treatment guidelines are discussed in the section addressing post-bypass bleeding and coagulopathy.

Induction of Anesthesia and the Prebypass Period

Premedication

The anesthesiologist should ensure that appropriate medications are administered with a sip of water on the morning of surgery. With a few exceptions, patients should receive their usual long-term medications on the day of surgery, particularly β-adrenergic blocking agents. The clinician should be aware that ACEIs, if administered on the day of surgery, may increase the patient's propensity for hypotension.[184] With respect to aspirin, it is well recognized that aspirin administration in the early postoperative period reduces the risk of ischemic complications after CABG surgery.[185] However, patients receiving aspirin immediately before surgery may have more mediastinal bleeding and greater transfusion requirements. A consensus statement published by the American College of Chest Physicians recommends starting aspirin administration within 6 hours after CABG surgery, regardless of whether preoperative aspirin therapy is discontinued.[186] A consensus statement published by the STS recommends that aspirin be continued until the time of surgery in patients at high risk for coronary thrombosis (i.e., those with unstable angina or recent MI). On the other hand, in patients undergoing unquestionably elective cardiac surgery, the STS recommends that aspirin be discontinued for 3 to 5 days beforehand because active platelet aggregation is less of a risk factor for ischemia in these patients.[187] Likewise, clopidogrel is usually discontinued 5 to 7 days before elective cardiac surgery.[187] Decisions about stopping administration of antiplatelet drugs and about surgical timing with respect

to bleeding risk are facilitated by platelet function testing, particularly with newer testing systems.[188]

The prospect of undergoing cardiac surgery provokes anxiety in most patients. Furthermore, insertion of intravenous and arterial catheters is painful and occurs before anesthesia is induced. The resultant anxiety and pain can lead to undesirable sympathetic stimulation resulting in tachycardia and hypertension. The first step in preventing this cycle is thoroughly explaining the anticipated anesthetic techniques and procedures to the patient. Premedication with a narcotic or anxiolytic agent (or both) to mitigate pain and anxiety is usually indicated before the patient is transported to the operating suite. Supplemental intravenous drugs—commonly midazolam and fentanyl—are often necessary during radial artery cannulation before induction of anesthesia. However, in patients with low cardiac output secondary to congestive heart failure (HF), sedation should be performed judiciously to avoid myocardial depression and resultant hypotension. Moreover, in patients with significant pulmonary hypertension, oversedation and respiratory depression leading to hypercapnia or hypoxia must be avoided.

Induction of Anesthesia

Anesthetics and techniques for induction of anesthesia should be selected with consideration of the patient's cardiac pathophysiology and other comorbid conditions. No single "recipe" can guarantee hemodynamic stability during anesthetic induction. Hypotension may result from a relatively hypovolemic state and vasodilation secondary to a reduction in sympathetic tone induced by anesthetics. Hypotension is particularly common in patients with poor LV function. Conversely, in patients with good myocardial function, hypertension may occur during induction because of preinduction anxiety or sympathetic stimulation caused by laryngoscopy and endotracheal intubation.

It is obviously important to cannulate the radial artery or an alternative site before induction of anesthesia to monitor arterial pressure on a beat-to-beat basis. If the radial artery is being harvested as a vascular conduit, the contralateral radial or brachial artery or a femoral artery may be used. Noninvasive blood pressure measurement can be used to check the accuracy of pressure readings if the arterial catheter is "positional" or "dampened." Of course, basic monitors, including the ECG and pulse oximeter, should also be used during induction of anesthesia. During any cardiac surgical procedure, central venous access is necessary to facilitate volume infusion, possibly including transfusion therapy, and to ensure that vasoactive agents are administered directly into the central circulation. A central venous catheter, a PA catheter, or both can be placed either before or after anesthesia is induced, although an increasing number of anesthesiologists defer central line placement until after anesthetic induction. The urinary bladder catheter, nasogastric tube, TEE probe, and any additional temperature monitors (e.g., a nasopharyngeal probe) are positioned after induction of anesthesia.

When choosing anesthetic agents and doses during induction and maintenance, one should consider any pharmacodynamic properties that might affect blood pressure, heart rate, or cardiac output, as well as the desirability of "early" extubation (i.e., within a few hours after the operation is completed). Anesthesia is most commonly induced with an opioid and a sedative-hypnotic (etomidate, thiopental, or propofol). It should be remembered that all anesthetics decrease blood pressure by decreasing sympathetic tone, decreasing systemic vascular resistance (SVR), inducing bradycardia, or directly depressing myocardial function. The only exception is ketamine, which has sympathomimetic effects; however, in patients with catecholamine depletion, ketamine's sympathomimetic effects may not counterbalance its direct negative inotropic effects. Because of their pharmacologic complexities, all anesthetics should be administered judiciously in patients who are critically ill or who have poor LV function.

Muscle relaxants are usually given early in the sequence of induction, particularly if relatively high doses of opioids are administered, to minimize chest wall rigidity. In addition, the vagolytic effects of pancuronium nicely counteract the vagotonic effects of high doses of opioids. Another muscle relaxant may be selected if maintaining a relatively slow heart rate is a primary consideration.

With the routine use of "fast-track" anesthesia techniques, including a trend toward earlier extubation, volatile agents are often chosen as the primary maintenance anesthetic. The predominant effect of isoflurane, desflurane, and sevoflurane is dose-dependent vasodilation with resultant decreases in SVR and blood pressure. These volatile agents may have an advantage in inducing preconditioning, which is particularly important in patients undergoing either CABG with CPB or OPCAB, in which myocardial ischemic insults are likely. Multiple cardioprotective effects of the volatile anesthetics have been studied, including triggering of the preconditioning cascade and mitigation of reperfusion injury.[189-192] However, nitrous oxide is avoided by most cardiac anesthesiologists because of its ability to increase gaseous bubble size and its undesirable effect on pulmonary vascular resistance (PVR).

The Pre–Cardiopulmonary Bypass Period

After induction of anesthesia, several important details must be remembered. Methods for positioning the arms vary according to institutional practice but must avoid causing brachial plexus injury by hyperextending the arms, ulnar nerve injury by improperly padding the olecranon, radial nerve injury by compressing the upper part of the arm against the sternal retractor support posts, or finger injury by entrapping the finger against the metal edge of the surgical table. Proper positioning also ensures that arterial catheters previously placed in the radial, ulnar, or brachial arteries are not "dampened." The head should be padded and occasionally repositioned during the procedure to prevent occipital alopecia, which can occur several days postoperatively. The eyes should be taped, possibly lubricated, and definitely free from pressure. Pressure-related injury to any soft tissue will potentially be exacerbated by hypothermia and decreased perfusion during CPB. All monitors and tubing should be checked after final positioning to ensure that none are kinked, entrapped, tangled, or inaccessible. Additionally, antibiotics must be administered (with documentation) within 1 hour of incision (vancomycin within 2 hours). Arterial blood gases and blood chemistry (electrolytes, glucose, and calcium) should be measured shortly after anesthesia is induced.

During the prebypass period, the anesthesiologist's major goal is to maintain hemodynamic and metabolic stability of the patient while making preparations for CPB. The degree of surgical stimulation varies markedly during this period. Patient positioning, preparation of the skin, and harvesting of the saphenous vein or veins cause only minimal sympathetic stimulation. Therefore, hypovolemic patients and those with poor ventricular function may be susceptible to hypotension during these periods. On the

other hand, chest incision, sternal splitting, and harvesting of the internal mammary artery (IMA) involve more intense surgical stimulation. These events may cause hypertension, tachycardia, and dysrhythmias, even in previously hypotensive patients. Just before initiation of CPB, during cannulation of the great vessels, surgical stimulation is again minimal, and manipulation of the heart and great vessels may transiently decrease venous return and cause a precipitous decline in blood pressure.

The anesthesiologist must be ready to treat hemodynamic aberrations. Specific cardiovascular medications to have immediately available include phenylephrine, ephedrine, calcium chloride, epinephrine, atropine, lidocaine, esmolol, and nitroglycerin. Other drugs that should be readily available include norepinephrine, vasopressin, nitroprusside, nicardipine, magnesium, potassium, and amiodarone. Of course, heparin (systemic dose plus supplemental doses) must also be immediately available. Although protamine should be accessible during the postbypass period, many institutions require that protamine be stored in unique packaging or in a separate, nearby location to prevent inadvertent inappropriate or premature administration.

In preparation for CPB, anticoagulation must be achieved. Heparin is still the standard agent used and is administered through a central venous catheter at an initial dose of 300 U/kg. Onset is almost immediate, but generally, the drug is allowed to circulate for 3 to 5 minutes before its effect is measured. The ACT must increase to at least 300 seconds before CPB is initiated, although most institutions use at least 400 seconds as their standard. Additional heparin is administered, if necessary, to increase the ACT to the desired level.

After heparinization, the next major step in the prebypass phase is vascular cannulation (Figs. 60-9 and 60-10).[193] One or more large veins or the right atrium (RA) is cannulated so that all systemic venous blood is diverted to the pump oxygenator; additionally, a large artery, usually the ascending aorta, is cannulated so that oxygenated blood is delivered back to the arterial

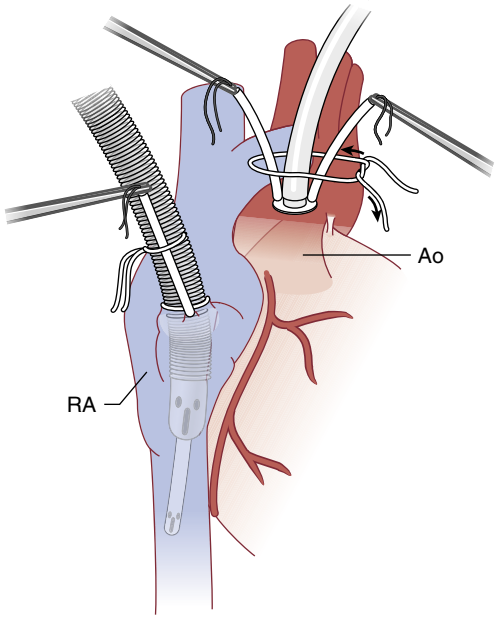

Figure 60-10 Aortic (Ao) and single, double-staged, right atrial (RA) cannulation. Notice the drainage holes of the venous cannula in the right atrium and inferior vena cava. *(From Connolly MW: Cardiopulmonary Bypass. New York, Springer-Verlag, 1995, p 59.)*

circulation. Heparin is always administered before cannulation. Usually, arterial cannulation is established before venous cannulation to allow rapid volume or blood resuscitation if necessary. Complications of aortic cannulation include arterial dissection, hemorrhage and resultant hypotension, inadvertent cannulation of the aortic arch vessels, and embolic phenomena caused by dislodged atherosclerotic plaque or by air introduced into or entrained around the aortic cannula. Complications of venous cannulation include hypotension from blood loss, dysrhythmias, and surgical mechanical compression of the heart or great vessels. When arterial cannulation is successful and the cannula has been inspected to ensure that no air is present, volume can be administered in 100-mL increments to treat bleeding and hypovolemia. If necessary, dysrhythmias are treated by cardioversion, medications, or rapid initiation of CPB.

Patients undergoing "redo" cardiac surgery (i.e., those who have previously had a median sternotomy) warrant special concern about the possibility of sudden massive hemorrhage. Frequently, the surgeon will elect to use an oscillating saw in these patients, but mediastinal structures adherent to the underside of the sternum may nevertheless be injured. If the RA, right ventricle, great vessels, or an existing coronary graft is cut, the surgeon may elect to initiate CPB on an emergency basis. Therefore, the anesthesiologist should have a systemic dose of heparin prepared. As soon as the patient is heparinized, the femoral or aortic arterial cannula is inserted, and the cardiotomy suckers may be used to create venous return (the so-called sucker bypass). At least 2 units of blood should also be immediately available for all redo cases.

Onset of Cardiopulmonary Bypass

With the onset of CPB, to guard against malposition of the aortic or venous cannula, the perfusionist checks the aortic inflow line pressure and for signs of inadequate venous return, while the anesthesiologist checks for persistently low arterial pressure, uni-

lateral blanching of the face, or any swelling in the neck veins, face, or conjunctiva. Once full bypass is established and aortic ejection by the heart has ceased, ventilation and inhaled drugs can be discontinued. If a PA catheter is present, it is pulled back 3 to 5 cm to minimize the risk of pulmonary perforation as the pulmonary arteries collapse. Prebypass urine output is recorded and emptied so that urine output during CPB can be monitored separately. The TEE probe may be used to watch for LV distention with the onset of CPB, which may indicate aortic valve regurgitation or other hemodynamic problems. Once CPB is established, the probe is left in the unlocked (neutral) position until the cardiac chambers are de-aired and the patient is weaned from CPB.

To ensure adequate anesthetic depth, supplemental intravenous sedative-hypnotics are administered, or a volatile agent is administered via a vaporizer connected to the oxygenator gas inlet of the CPB circuit. Administration of muscle relaxant is continued to prevent spontaneous ventilation, movement, or shivering during hypothermia and rewarming.

Weaning from Cardiopulmonary Bypass

Preparations for Weaning from Cardiopulmonary Bypass: The "CVP" Mnemonic

Fortunately, for most patients, separation from CPB is a relatively uneventful process. Several criteria should be met in all cardiac surgical cases before attempting weaning from CPB. Romanoff and Royster[194] suggest a mnemonic, "CVP," to help the clinician remember the main tasks necessary for successful termination of CPB (Table 60-7).

The first "C" stands for "cold" and refers to the patient's temperature at the time of weaning from CPB, which should be 36°C to 37°C. Neither the temperature of the venous blood returning to the CPB circuit nor nasopharyngeal temperature should ever exceed 37°C because hyperthermia may increase the risk for postoperative neurologic complications (please see the section on temperature).

The second "C" stands for "conduction" and refers to cardiac rate and rhythm. A heart rate of 80 to 100 beats/min is usually desirable. Bradycardia is treated with epicardial pacing wires and with β-adrenergic agents that have chronotropic and dromotropic, as well as inotropic properties. Tachycardia (i.e., heart rate >120 beats/min) is also undesirable. Sinus tachycardia may be due to anemia, hypovolemia, "light" anesthesia, or the administration of chronotropic agents; treatment is tailored to the presumed cause. Rhythm is also an important factor in optimizing cardiac output. Third-degree atrioventricular (AV) block requires pacing, ideally AV pacing. Sinus rhythm is preferable, particularly in patients with poor LV compliance, who are especially dependent on an "atrial kick" to achieve adequate filling. If supraventricular tachycardia is present, direct synchronized cardioversion is often warranted. In addition, pharmacologic therapy with amiodarone, esmolol, verapamil, or adenosine may be used in the initial treatment of or to prevent the reoccurrence of supraventricular tachycardia.

The third "C" stands for "cardiac output" or "contractility." Contractility may be estimated from TEE and cardiac output can be measured with a PA catheter, if available.

The fourth "C" refers to "cells" (i.e., RBCs). The patient's hemoglobin concentration should be 7 to 8 g/dL or slightly higher before weaning from CPB. If the hemoglobin concentration is less than 6.5 g/dL when rewarming commences, the perfusionist and anesthesiologist can consider hemoconcentration or transfusion of a unit of packed RBCs.

The fifth "C" stands for "coagulation," which means that in patients at risk for coagulation abnormalities, the prothrombin time, partial thromboplastin time, and platelet count should be measured a few minutes after protamine is administered. Examples of patients at risk for coagulation abnormalities include those with long CPB times; those with extreme hypothermia, elective circulatory arrest, or both during CPB; and those with chronic renal failure. Platelet function tests may be useful in patients taking platelet inhibitors such as clopidogrel or aspirin.

The first "V" is for "ventilation" of the lungs. As CPB is discontinued, the venous outflow line is gradually occluded, and PA blood flow is gradually restored. Pulmonary ventilation and oxygenation must be reestablished to allow the lungs to again become the site of gas exchange. Ideally, the lungs are initially reinflated "by hand" with a few sustained inflations to a peak pressure of about 30 cm H_2O. If an IMA has been grafted to a coronary artery, the anesthesiologist must examine the surgical field during these inflations to ascertain that the grafted artery is not overstretched, which could disrupt the distal anastomosis. Additionally, the compliance of the lungs is judged by these initial inflations, and bronchodilators can be administered if necessary. The surgeon should remove any fluid or blood from the pleural spaces and ensure that any pneumothorax is treated with a chest tube.

The second "V" is for "visualization" of the heart, both directly in the surgical field (where the right-sided chambers are visible) and on TEE, to estimate global and regional contractility. Furthermore, the degree of chamber filling (hypovolemic, euvolemic, or distended) can be estimated. In addition, one can perform a final check for air within the cardiac chambers with TEE.

The third "V" is for "vaporizer," which means that if volatile agents were used to ensure lack of awareness or to control blood pressure during CPB, the clinician should consider reinstituting a low dose immediately after weaning. However, because all of the volatile agents decrease contractility and blood pressure, these effects can confuse the differential diagnosis of hypotension and myocardial dysfunction during weaning.

The final "V" is for "volume expanders." When all products from the pump have been exhausted and if blood transfusion is

not indicated, crystalloid and albumin or hetastarch should be readily available to rapidly increase preload if necessary.

As for the letter "P in the "CVP" mnemonic, Romanoff and Royster explain that the first "P" represents the need to be aware of "predictors" of adverse cardiovascular outcome. For example, a preoperative low ejection fraction (EF) and prolonged duration of CPB often predict difficulty in weaning the patient from CPB and the need for inotropic support. In addition, emergency surgery in patients with an acute coronary syndrome may lead to myocardial stunning. Furthermore, inadequate surgical repair (e.g., incomplete coronary revascularization) may result in ongoing ischemia.

The second "P" is for "pressure." Calibration and rezeroing are accomplished shortly before starting to wean the patient from CPB. Any discrepancy between distal (usually radial) arterial pressure and central aortic pressure should be recognized. Occasionally, the surgeon may need to insert a temporary aortic root cannula or a longer-lasting femoral arterial cannula to accurately monitor systemic blood pressure during and after termination of CPB.

The third "P" is for "pressors" (i.e., vasopressors and inotropic agents), which should be immediately available. Likewise, a vasodilator (e.g., nitroglycerin, nicardipine, or nitroprusside) should be immediately available.

The fourth "P" is for "pacer" because an external pacemaker should be readily available for all patients. Pacing is often needed to treat bradycardia. In patients with heart block, ideally an AV sequential pacemaker is used to maintain the atrial "kick."

The fifth "P" is for "potassium" because hypokalemia may contribute to dysrhythmias and hyperkalemia may result in conduction abnormalities. In addition, the patient's ionized Ca^{2+} level is usually checked; most clinicians have a low threshold for administering additional calcium chloride. Furthermore, magnesium (2 to 4 g) is generally administered before CPB is terminated. Although magnesium's efficacy in preventing postoperative atrial or ventricular dysrhythmias has not been clearly demonstrated,[195] hypomagnesemia is common after CPB, and the risk-benefit ratio for administering a 2- to 4-g dose is low.

The final "P" is for "protamine."

Termination from Cardiopulmonary Bypass

After ventilation has been reestablished, venous return to the pump is reduced by gradually clamping the venous line. The patient's intravascular volume is carefully increased by continued inflow via the aortic or other arterial cannula. Ventricular distention should be avoided because it increases wall tension and myocardial oxygen consumption. Pump flow into the aorta is lowered, in effect moving into a "partial bypass" phase wherein some of the venous blood is still going into the pump and some passes through the right ventricle and lungs to be ejected into the aorta by the left ventricle. When loading conditions are optimal and contractility appears adequate, the aortic inflow line may be clamped to separate the patient from CPB.

If CPB has been successfully terminated but cardiac performance is not optimal, preload can be increased by infusing additional blood from the pump into the aortic cannula, usually in 100-mL increments in adult patients. Monitoring left intraventricular volume in a qualitative fashion by observing the right ventricle directly and with TEE, as well as monitoring filling pressures, gives a good estimate of the adequacy of preload. At this point the anesthesiologist and surgeon jointly determine whether myocardial performance is adequate, which can best be accomplished by using TEE to observe the global and regional function of both ventricles. Supplemental information can be obtained by measuring cardiac output, if possible. Afterload can also be optimized at this point. Elevated systolic blood pressure should be avoided to prevent excessive stress on suture lines in the heart and aorta. Usually, 95 to 125 mm Hg is a desirable systolic pressure in adult patients in the postbypass period. If the patient is hemodynamically unstable and additional time is needed to administer initial or additional inotropes or vasoconstrictors, CPB can be reinstituted by unclamping the venous outflow line and directing all flow to the oxygenator again.

When protamine is administered, reinstitution of CPB becomes a more complicated process because the patient must first be reheparinized. Therefore, final checks of cardiac function, heart rate and rhythm, preload, afterload, and perfusion should be made jointly by the anesthesiologist and surgeon. The venous cannula or cannulas are usually removed after the initial test dose of protamine is given. Many surgeons remove the aortic cannula only after at least half of the protamine dose has been administered. The rate and mode of protamine administration (incremental small boluses versus continuous infusion) vary according to institutional and individual clinicians' practices, but a large dose of protamine should never be administered as a rapid bolus.

The Postbypass Period

Common Problems after Cardiopulmonary Bypass

Awareness

The potential for patient awareness must be assessed during and after CPB. Although patients may sweat during the rewarming period, usually because of perfusion of the thermoregulatory site in the hypothalamus with warm blood, sweating may also be due to awareness as the brain becomes normothermic during rewarming. Awareness may be more likely if considerable time has elapsed since any sedative-hypnotic or narcotic has been administered, if small doses of anesthetic agents were administered during CPB, or if the patient is young. Use of the bispectral index (BIS) monitor to guide isoflurane administration during and after CPB has been suggested.[196] However, falsely high BIS values during cardiac surgery have been attributed to interference from pump head rotation, pacemakers, and hypothermia itself.[197,198] Consideration should be given to continuing to administer a volatile agent once pulmonary ventilation is reestablished and to administering additional sedative/hypnotic doses, a narcotic agent, or both. Some clinicians begin infusing an agent such as propofol or dexmedetomidine shortly after weaning the patient from CPB and plan to continue it during and after transport to the ICU or cardiac recovery area.

Another important decision to be made is whether additional muscle relaxant is needed during and after weaning from CPB. Although patient movement may serve as an indication of patient awareness, such movement can be extremely dangerous if it results in dislodgement of the aortic or venous cannulas. Furthermore, shivering can occur because of the "afterdrop" in temperature after a period of hypothermic CPB and should be prevented by administering a muscle relaxant.

Cardiovascular Decompensation

Failure of the left or right ventricle is one of the common causes of cardiovascular decompensation during or shortly after weaning from CPB. Such failure may result in part from preexisting chronic ventricular dysfunction exacerbated by the ischemia-reperfusion injury that occurs during CPB with cardioplegia-induced cardiac arrest. In operations involving revascularization for coronary artery disease, myocardial injury resulting in postbypass ischemia or infarction is particularly likely. Causes include thrombosis or particulate or air emboli in a coronary graft or a native coronary artery, kinking of the graft, a distal suture causing constriction, coronary spasm, incomplete myocardial preservation during CPB, and incomplete revascularization secondary to distal disease or inoperable vessels. When valvular heart disease is present, there may be native valve gradients, a prosthetic valve may be malpositioned or malfunctioning, or ventricular dysfunction may be unmasked after mitral valve replacement or repair for mitral regurgitation (MR).

Usually, LV dysfunction is amenable to inotropic therapy or combination therapy with positive inotropic and vasodilator agents to optimize cardiac output. Sympathomimetic amines (i.e., catecholamines such as epinephrine, norepinephrine, dopamine, and dobutamine) and phosphodiesterase inhibitors (e.g., milrinone) are commonly used as first-line therapy. (Please refer to Chapters 16 and 23 for specific drug pharmacology and doses.) Small boluses of ephedrine (5 to 20 mg) or diluted epinephrine (2 to 10 μg) may be administered initially to temporarily treat ventricular dysfunction and hypotension while infusions are being prepared. Milrinone, an inodilator, improves cardiac output but significantly reduces SVR; concomitant use of an arterial vasoconstrictor is often necessary. Nitroglycerin is usually administered if ischemia is suspected. Occasionally, a mechanical assist device, such as an IABP or VAD, is necessary.

RV dysfunction or failure may also occur after CPB because of inadequate myocardial protection, inadequate revascularization with resultant RV ischemia or infarction, preexisting pulmonary hypertension, intracoronary or pulmonary air embolism, chronic mitral valve disease, or tricuspid regurgitation (TR). RV failure may be evidenced by RV distention and hypokinesis on TEE, as well as by elevations in CVP and pulmonary artery pressure (PAP). Therapy for RV failure includes inotropic support; milrinone, dobutamine, and isoproterenol are first-line agents. Other pharmacologic agents occasionally used to achieve pulmonary vasodilation include nitroglycerin, nitroprusside, prostaglandin E_1 (PGE_1), B-type natriuretic peptide (e.g., nesiritide), sildenafil, or inhaled agents such as nitric oxide and prostacyclin (prostaglandin I_2 [PGI_2, epoprostenol]). In addition, levosimendan, a new drug that is a myofilament Ca^{2+} sensitizer with inotropic and vasodilatory effects, is available clinically in Europe and undergoing evaluation in the United States.[199] It has been used in cardiac surgical patients with difficulty weaning from CPB or with severe LV or RV failure after mitral valve replacement.[200,201] Of course, hypoxemia should be avoided and hyperventilation should be instituted to decrease $Paco_2$ and PVR. Rarely, patients may require support with a right VAD.

Vasodilation with low SVR is another common cause of immediate post-CPB cardiovascular decompensation that may cause unacceptable hypotension. Predisposing factors include chronic administration of medications such as ACEIs, severe anemia with decreased viscosity, acid-base disturbances, and sepsis. Treatment with infusion of a vasoconstrictor agent such as phenylephrine, norepinephrine, or vasopressin is usually successful.

Dysrhythmias

Either supraventricular or ventricular arrhythmias may occur in the immediate postbypass period. Atrial fibrillation (AF) is the most common dysrhythmia after cardiac surgery, although it usually develops 2 to 5 days postoperatively. AF or atrial flutter occurring in the immediate postbypass period can often be converted to normal sinus rhythm with synchronized cardioversion, especially if sinus rhythm was present before CPB. Hypokalemia should be corrected. Magnesium is thought to have a low risk-benefit ratio and may modify the ventricular response rate and promote conversion to sinus rhythm.[195,202] Pharmacologic agents are available as well. Frequently, amiodarone is used both initially and as a continuous infusion.[202] Other agents that are occasionally used for initial treatment include esmolol, verapamil, and adenosine.

Ventricular flutter or fibrillation must be treated immediately with defibrillation. Internal paddles are applied directly to the heart to deliver 10 to 20 J of electricity. If ventricular arrhythmias persist or recur, an antiarrhythmic drug, usually lidocaine or amiodarone, is infused.

Usually, if bradycardia, complete heart block, or asystole develops after CPB, temporary epicardial pacing wires are used to provide electrical pacing, preferably AV sequential pacing. If an organized atrial rhythm is absent (e.g., patients with AF) and the ventricular response rate is slow, ventricular pacing is the only option. However, with this mode of pacing there is no atrial "kick," which would otherwise promote adequate filling of the LV chamber. Loss of the atrial kick is particularly detrimental in patients with poor LV compliance.

Bleeding and Coagulopathy

Although inadequate surgical hemostasis is the most common reason for blood loss after CPB, coagulation abnormalities certainly do occur and can contribute to unacceptable microvascular bleeding. Historically, the most common causes of excessive bleeding in cardiac surgical patients have been related to fibrinolysis and platelet activation induced by CPB, especially in elderly patients.[203]

Platelet dysfunction is frequently implicated in postbypass bleeding.[204] Exposure of blood to the oxygenator and CPB circuitry causes platelet activation, degranulation, and aggregation. Furthermore, relative thrombocytopenia commonly occurs after CPB as a result of hemodilution and platelet sequestration, adhesion, and destruction. Usually, these CPB-related platelet abnormalities are not clinically important because coagulopathies requiring platelet therapy do not develop in most patients who undergo cardiac surgery.[188] Nevertheless, bleeding difficulties develop in a subset of patients. Chen and colleagues[166] found that preheparinization testing of platelet function with ADP-mediated aggregometry can identify patients at highest risk for perioperative bleeding and transfusions and may further reduce perioperative transfusion requirements (Fig. 60-11).

Another cause of coagulopathy is thrombin production and fibrinolysis. Thrombin is produced by the extrinsic and intrinsic coagulation pathways and by activated platelets and is only partially suppressed by heparin during CPB. Ongoing

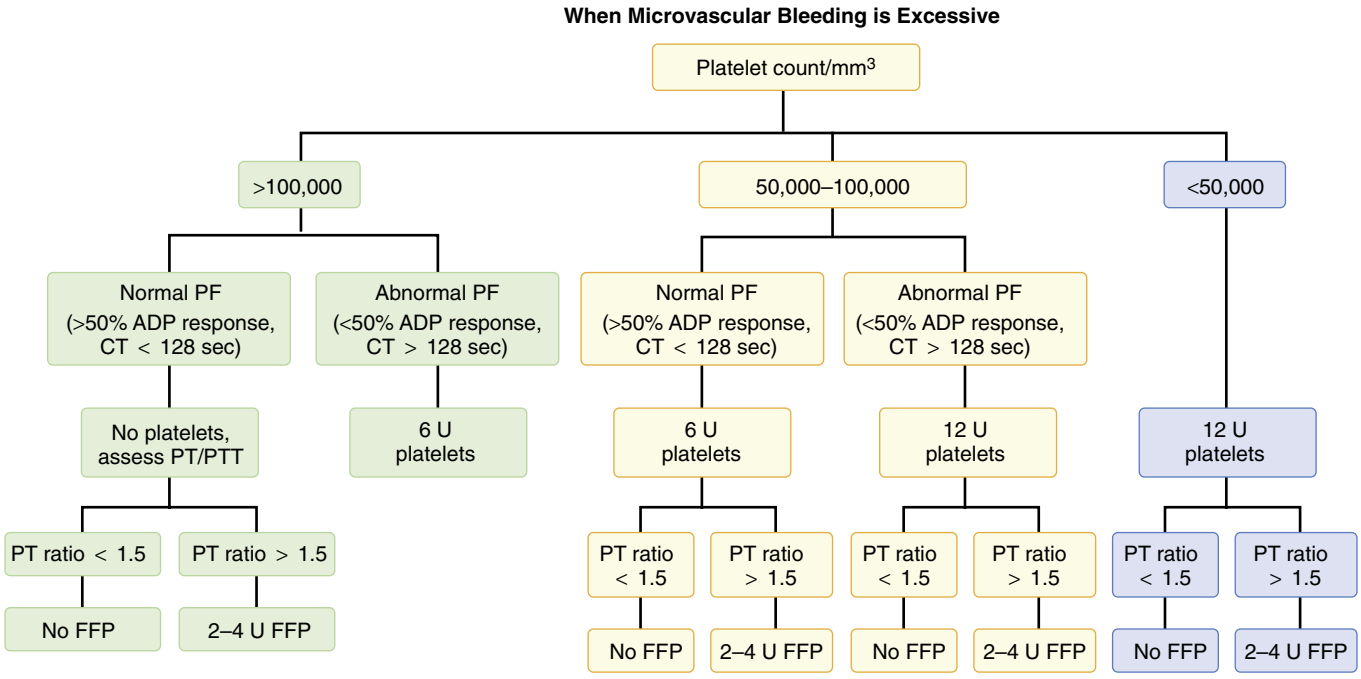

Figure 60-11 Bleeding management algorithm used for the treatment of excessive microvascular bleeding. ADP, adenosine diphosphate; CT, closure time; FFP, fresh frozen plasma; PF, platelet function; PT, prothrombin time; PTT, partial thromboplastin time. U, units. *(Reprinted with permission from Chen L, Bracey AW, Radovancevie R, et al: Clopidogrel and bleeding in patients undergoing elective coronary artery bypass grafting. J Thorac Cardiovasc Surg 128:425-431, 2004.)*

thrombin generation during CPB results in low-grade consumption of multiple factors in the coagulation cascade. If CPB is prolonged, these factors may be depleted. Fibrinolysis, an intrinsic response to coagulation, is activated by the t-PA that is released by injured endothelial cells. With excessive fibrinolysis, depletion of fibrinogen can result in consumptive coagulopathy. In addition, fibrinolysis exerts important deleterious effects because fibrin degradation products and plasmin inhibit platelet function.

An evidence-based approach to the diagnosis and treatment of residual, unacceptable post-CPB microvascular bleeding and to thorough surgical hemostasis dictates timely detection and treatment of specific causes of coagulopathy. Patients with this complication benefit from point-of-care (POC) testing and incorporation of this testing into a transfusion algorithm. Algorithms are designed to minimize unnecessary and indiscriminate blood product transfusions.[166,205-208]

Pulmonary Complications

Pulmonary complications immediately after CPB vary from mild to severe and include atelectasis, bronchospasm, hemothorax, pneumothorax, endobronchial intubation, mucous plugs or blood clots in the endotracheal tube, pulmonary edema, and pulmonary dysfunction that varies from a mild increase in the alveolar-arterial O_2 gradient to a form of adult respiratory distress syndrome (ARDS) known as "postperfusion lung syndrome."

Atelectasis is a common cause of decreased arterial oxygenation in the postbypass period because during CPB, either the lungs are not ventilated or very small tidal volumes are used. Ideally, the lungs are fully reinflated "by hand" before machine ventilation is reestablished during weaning from CPB. Patients with chronic obstructive pulmonary disease (COPD) or any preexisting tendency toward bronchospasm may experience an exacerbation during CPB. Treatment includes inhaled β_2-agonists (e.g., albuterol), inhaled anticholinergic agents (e.g., ipratropium), epinephrine, and corticosteroids.

Hemothorax is caused by the accumulation of blood and clot in the pleural cavity, which should be surgically removed before chest closure. Pneumothorax may result from entry of the pleural cavity during dissection of the IMA or from excessive positive-pressure ventilation of the lungs. Pneumothorax may not be manifested until after chest closure; it is treated by insertion of a chest tube.

Endobronchial intubation may occur when the head is partially hidden from the anesthesiologist's view. Expansion of both lungs should be checked during initial full ventilation before weaning from CPB, when the chest is open, so that a good view of both lungs may be obtained. If there is any blood or mucus in the endotracheal tube, it should be suctioned during and after weaning from CPB.

Pulmonary edema may be cardiogenic because of preexisting HF exacerbated by the additional fluid load in the pump prime. Ultrafiltration during CPB and diuresis during and after CPB may minimize such pulmonary edema. Noncardiogenic pulmonary edema (i.e., ARDS) may occur after prolonged CPB with sequestration of neutrophils in the pulmonary capillaries and elevation of lysosomal enzyme activity resulting in a localized "inflammatory response" and increased capillary permeability. Other causes of ARDS include multiple pulmonary emboli and transfusion reactions.

Metabolic Disturbances

Hypokalemia is relatively common after CPB and may contribute to the development of dysrhythmias. Causes include diuresis secondary to preoperative diuretics, mannitol administration during CPB, alkalemia, and hyperglycemia treated with insulin administration. Hypokalemia may be corrected by carefully monitored

administration of potassium via an infusion pump at a rate of 10 to 20 mEq/hr, with frequent measurement of potassium, as well as glucose and arterial blood gases.

Hyperkalemia also occurs occasionally after CPB and is usually caused by large doses of cardioplegia or, occasionally, large amounts of blood products. Hyperkalemia is more likely to occur if renal function is impaired. Occasionally, hyperkalemia is severe enough to interfere with conduction. It can be treated with moderate hyperventilation or the administration of calcium or glucose and insulin, or both.

Hypocalcemia can occur after CPB, particularly in bleeding patients who are receiving multiple blood transfusions with large amounts of citrate. This phenomenon is exacerbated by hypothermia and low-output states. Hypocalcemia is corrected by the administration of 10% calcium chloride in 5- to 10-mg/kg doses.

Hypomagnesemia is common in the postbypass period and is due to hemodilution with magnesium-free fluids during CPB. Many centers routinely administer 2 to 4 g of magnesium during weaning or after CPB in an attempt to minimize the incidence of ventricular and atrial arrhythmias.[195,202]

Hyperglycemia is extremely common after CPB (please see the earlier section "Endocrine System: Glucose, Thyroid Hormone, and Hormone Replacement Therapy"). A few centers wait until the postoperative period to begin insulin therapy.[209] Most centers treat glucose levels greater than 200 mg/dL with intermittent doses of insulin or with an insulin infusion, although some centers treat cardiac surgical patients more aggressively in an attempt to keep glucose levels below 150 mg/dL.[84,85,88] In a recent study, patients were randomized to intensive intraoperative insulin treatment (to maintain glucose levels at 80 to 100 mg/dL) or to standard insulin treatment (to keep glucose levels below 200 mg/dL).[87] Surprisingly, the investigators reported a statistically nonsignificant increase in the incidence of death and stroke in the intensive insulin treatment group. Further study is needed to determine how aggressively hyperglycemia should be treated during surgery.[86]

Chest Closure

Hemodynamic deterioration may occur during chest closure because of cardiac tamponade in patients with ongoing bleeding. Other reasons for severe hypotension during chest closure include hypovolemia, ischemia secondary to kinking of an arterial or venous coronary graft, and impairment of RV contractility and venous return in patients with significant myocardial edema. TEE is often particularly useful in determining the cause of hypotension during chest closure because tamponade, hypovolemia, RV or LV global dysfunction, and severe new wall motion abnormalities can be quickly recognized with this monitor. Reopening the chest may be necessary while treatment is instituted. Occasionally, the patient's sternum cannot be closed because of hemodynamic instability; in such cases, only skin closure is attempted, and plans are made to return to the operating room for sternal wiring after a period of myocardial recovery in the ICU.

Transport to the Intensive Care Unit

After all incisions are closed and dressings are applied, provided that the patient is hemodynamically stable, the next step is transport to the ICU. Monitoring should not be completely interrupted even for a few moments—the ideal transport monitoring system has a "brick" that can be ejected from the operating room monitor and is compatible with the transport monitor. If such equipment is not available, sequential disconnection of monitoring devices is advised so that an "on-line" monitor is always visible.

On arrival at the ICU or cardiac recovery area, monitoring devices should be transferred in the same careful way. Changes in patient status necessitating changes in volume infusion, vasoactive drugs or doses, pacemaker settings, or ventilator settings and concerns about bleeding potential should be reviewed with ICU personnel. The anesthesiologist should remain with the patient until hemodynamic and overall stability is ensured.

Cardiopulmonary Bypass

CPB is a form of extracorporeal (*extra* = "outside of," *corporeal* = "the body") circulation (ECC) in which the patient's blood is rerouted outside the vascular system and the function of the heart, the lungs, and to a lesser extent the kidneys is temporarily assumed by surrogate technology. The circuitry and equipment used to facilitate this substitution are topics of the next section of this chapter.

Circuitry and Equipment

The goal of ECC is to provide a motionless and bloodless field for the surgeon by rerouting blood away from the area of surgical interest. The most common and most complicated ECC procedure is CPB, which involves rerouting the patient's entire cardiac output around both the heart and lungs. Other ECC techniques include left heart bypass (LHB), cardiopulmonary support (CPS), and extracorporeal membrane oxygenation (ECMO).

The pumps, tubing, artificial organs, and monitoring systems used in CPB are diagrammed in Figure 60-12. Simply stated, venous blood is intercepted as it returns to the RA and diverted through the *venous line* of the CPB circuit to a *venous reservoir*. The *arterial pump* functions as an artificial heart by withdrawing blood from the reservoir and propelling it through a *heat exchanger*, an artificial lung (the *oxygenator*), and an *arterial line filter* before returning it through the *arterial line* to the patient's arterial system. Additional pumps and components are used to assist in the operation to manage shed blood (the *pump sucker*), decompress the heart (*vent*), and deliver *cardioplegia solution*.

Blood Tubing

The tubing used to connect the various components and conduct blood into and out of the patient's vascular system is medical-grade polyvinyl chloride (PVC). For decades, the blood-tubing interface was untreated PVC. However, the newer generation of PVC tubing has surface coatings and other modifications that significantly alter the bioactivity of the surface. Collectively, these coatings have been shown to reduce markers of subclinical coagulation, attenuate the elevation of cytokines and other inflammatory markers, and shorten intubation times.[210-213]

Venous Reservoirs

Blood reservoirs perform an important function in the conduct of CPB by facilitating the displacement of a large volume of blood out of the circulation at strategic times during the operation.

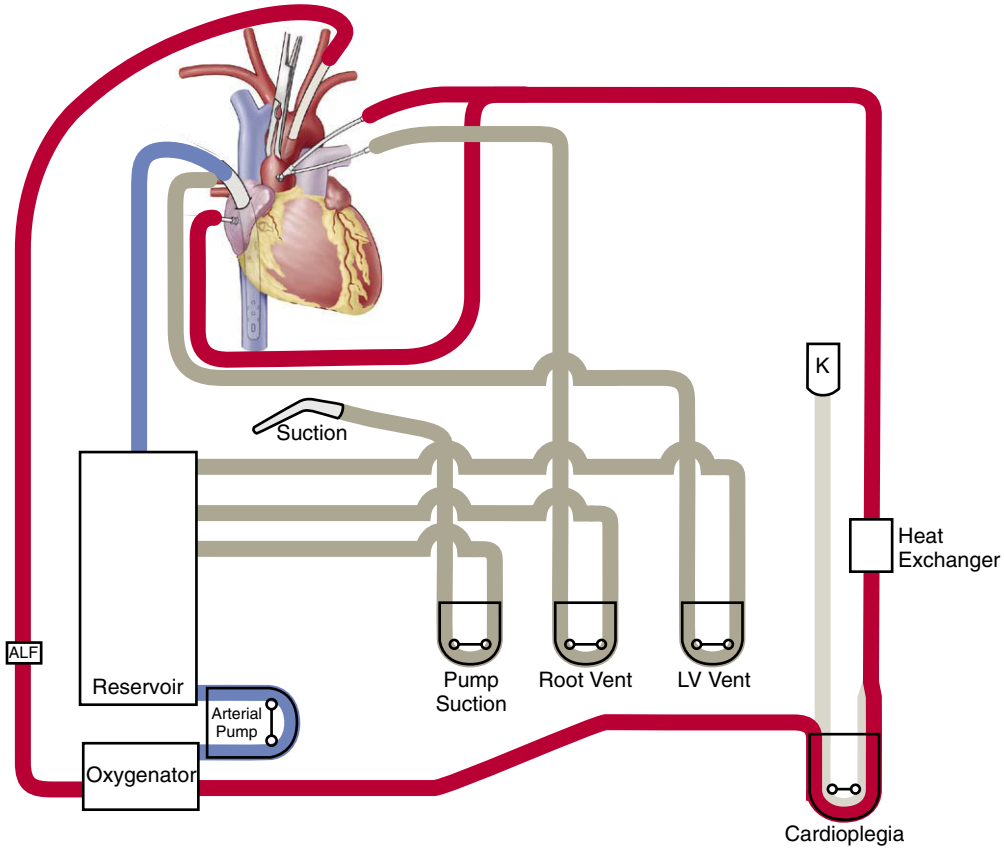

Figure 60-12 A typical cardiopulmonary bypass circuit interfaced with a patient.

Positioned between the venous line and the arterial pump, blood reservoirs may be collapsible plastic bags or clear plastic hard-shelled containers. Hard-shelled reservoirs include an integral filtration mechanism with a screen and depth filters through which blood must pass before leaving the outlet of the vessel. Almost universally, hard-shelled reservoirs have integrated positive and negative pressure release valves, which are necessary for the application of suction to the reservoir to augment venous drainage.

Arterial Pumps

The pumping device used to replace the function of the heart generally uses one of two primary technologies: a roller pump or a centrifugal pump. Roller pumps are positive-displacement pumps that function by occluding a point in a piece of tubing and then rolling the occlusive point of contact along a length of the tubing. This forces the fluid in the tubing to move forward in front of the occlusive point while simultaneously drawing in fluid behind the occlusive point. Centrifugal pumps, in contrast, are nonocclusive kinetic pumps that generate flow by magnetically coupling the high-speed revolution of a reusable motor to the plastic plates, fins, or channels inside a disposable cone. This produces a constrained vortex that propels fluid through the opening on the side of the cone while drawing fluid into the point of the cone. Both pump technologies are traumatic to the formed elements in blood; however, centrifugal pumps are thought to be less traumatic than roller pumps.[214,215]

Each type of pump poses unique risks that must be appreciated. Roller pumps, by virtue of their occlusive nature, are capable of generating extremely high positive and negative pressure and are also able to pump massive quantities of air. Consequently, the national standard of care requires that these pumps be servoregulated to automatically reduce their speed when high pressure or air is detected in the path of the blood. In contrast, centrifugal pumps, being nonocclusive, are unable to generate extremely high or low pressure. Additionally, if a large bolus of air is introduced into the disposable cone, the pump will deprime, rendering it unable to pump large volumes of air. However, the lack of a point of tubing occlusion inside the pump allows retrograde flow from the patient's high-pressure arterial system backward through the arterial line, filter, and oxygenator and ultimately into the low-pressure venous reservoir. This may occur whenever the pump's revolutions per minute are reduced below a critical threshold. A large-bore one-way valve can be positioned in the arterial line to eliminate the possibility of retrograde arterial flow and inadvertent patient exsanguination.

Heat Exchanger

Heat exchangers are essential to CPB because they facilitate management of the patient's blood temperature. Throughout the period of CPB, 20% to 35% of the patient's circulating blood volume is outside the body and is exposed to the ambient temperature of the operating suite, which can cause hypothermia. Therefore, in all CPB procedures there is an inherent need to warm the blood before CPB is terminated. Additionally, for many surgical procedures, some amount of hypothermia, from mild (35°C) to profound (18°C), is desirable to reduce the patient's metabolic rate. In these cases, the heat exchangers may be used

to reduce the temperature of the blood on initiation of CPB and then to warm the blood before the termination of CPB.

Oxygenator

The oxygenator substitutes for the patient's native lungs and performs the essential function of gas exchange. There are several similarities between the native lung and the oxygenator. Both have a gas phase and a blood phase, both are driven by passive diffusion gradients, and both use a membrane to separate the blood from the gas. In the oxygenator, the membrane is usually made from microporous polypropylene. This material is extruded into thin straws with an outer diameter of 200 to 400 µm, a wall thickness of 20 to 50 µm, and a total surface area of 2 to 4 m^2. Typically, oxygenators have a static priming volume of 135 to 340 mL and are capable of arterializing up to 7 L/min of typical venous blood.[216]

The native lung uses the conductive airways for both inspiration and expiration and is dependent on a certain tidal volume and respiratory rate to regularly refresh the gas in the alveolar space. The oxygenator, however, has separate gas inlet and outlet ports and can refresh the gas inside its gas space (the internal lumen of the straws) with a continuous flow or "*sweep*" of gas through the oxygenator. The blood space of an oxygenator is the space around the outside of the straws. Venous blood entering the oxygenator is directed across the outside of the fibers while gas is concurrently circulated through the inside of the fibers. Pressure gradients between the blood space and the gas space drive oxygen across the membrane and into the blood, whereas carbon dioxide is driven out of the blood and into the gas phase. Unlike the membrane in the native lung, however, the oxygenator's membrane is not a true membrane because the microscopic pores on the sides of the fibers (0.5 to 1.0 µm) are small enough to prevent plasma and the formed elements of blood from leaking through but are still large enough to allow gas to pass through. Therefore, care must be taken to ensure that the pressure in the gas space never exceeds the pressure in the blood space or gaseous emboli will form in the blood. In appreciation of the risks inherent in using a pressurized gas phase, most oxygenators are designed with multiple gas outlet ports. In any case, caution should be exercised to ensure that the outlet of the gas phase cannot become occluded.

Arterial Line Filter

In adult practice in the United States, arterial line filters are used in more than 95% of CPB procedures. These filters are placed in the arterial line as the last component through which blood passes before it returns to the patient. With pore sizes of 20 to 40 µm, arterial line filters increase patient safety by removing particulate and gaseous microemboli. To effectively remove bubbles from the blood path, arterial line filters must be continuously "purged" by allowing a small amount of blood to recirculate from the top of the filter back into the venous reservoir.

Sequence of Events

Although the approach to surgical procedures requiring CPB varies among institutions, all procedures loosely follow a predictable *sequence of events*. CPB at any institution requires circuit selection and priming, anticoagulation, cannulation, initiation and maintenance of CPB, myocardial protection, and finally, weaning and termination from CPB.

Circuit Selection and Priming

When selecting the components for an extracorporeal circuit, the perfusionist first calculates the highest blood flow that may be necessary during the procedure. Typically, the highest blood flow is approximately 2.4 to 3.0 L/min/m^2 or 60 to 70 mL/kg/min. The calculated flow is then compared with the "rated flow" for the components of the ECC circuit. This flow rating represents the highest blood flow at which the component can perform its function within the acceptable range of hydraulic forces (pressure and sheer stress) without causing an unacceptable amount of blood trauma.

The combination of components included in the ECC determines the "prime volume" of the circuit, or the volume of balanced electrolyte solution necessary to completely de-air the circuit. This prime volume is the main cause of the hemodilution associated with CPB. Therefore, the perfusionist must calculate the patient's resultant hematocrit (HCTr), which is the patient's predicted hematocrit after the patient's preoperative blood volume is mixed with the asanguineous prime volume of the ECC. The HCTr is computed by dividing the patient's calculated volume of RBCs into the calculated total volume of distribution represented by the addition of the ECC prime volume to the patient's blood volume (Box 60-3). An adult patient's intravascular volume of distribution will increase by 20% to 35% when CPB is initiated. This increased volume of distribution dilutes not only all of the proteins and formed elements of the blood but also plasma levels of drugs. If this dilution is not anticipated, the patient's depth of anesthesia and circulating concentrations of many pharmacologic agents may be reduced when CPB is initiated.

The solution used to prime the CPB circuit is generally a balanced electrolyte solution containing normal plasma concentrations of many of the standard blood ions. Various drugs may be added to the solution to attenuate the dilutional effect of CPB on those agents (e.g., albumin, heparin, bicarbonate) or to discourage edema formation or encourage diuresis of the prime fluid by the patient (e.g., mannitol).

Anticoagulation

With the circuit primed and the vessels exposed, standard procedure requires that the patient be fully anticoagulated before can-

Box 60-3 Resultant Hematocrit (HCT) Formula

HCTr = Patient's preoperative red blood cell volume/Total volume of distribution at the start of CPB

$$HCTr = (BVp \cdot HCT)/(BVp + PVc)$$

$$HCTr = (kg \cdot 75 \cdot HCT)/(kg \cdot 75) + PVc$$

where

HCTr = resultant hematocrit

nulation. Dosing of heparin and monitoring of the ACT have been discussed earlier in the chapter. Importantly, there are many commercial devices designed to monitor the ACT, and although the ACT is used as if it were a standardized test, the results produced by different instruments are far from standardized. We have shown that these devices, when used on the same pool of heparinized blood, can produce ACT results that vary by as much as 40% (Fig. 60-13).

The ACT test is not used to monitor heparin levels but to monitor the anticoagulant effects of heparin and other anticoagulants. Thus, elevated ACT measurements taken before, during, or after CPB may be influenced by variables other than heparin (e.g., hypothermia, hemodilution, and aprotinin).

POC heparin level tests are commercially available and may be used to monitor circulating heparin levels in CPB-supported patients. Indeed, some centers monitor both the circulating level of heparin and its anticoagulant effects and administer heparin intermittently throughout the procedure to maintain a predetermined therapeutic heparin level and a minimally acceptable ACT.

Heparin dosing may be based on the patient's weight (300 to 400 U/kg) or determined by a dose-response curve. Heparin dose-response curves are determined in vitro by measuring the ACT of the patient's blood at baseline (without heparin) and after a known concentration of heparin (2.5 U/mL) is added. By graphing the ACT in seconds against the blood concentration of heparin, one can extrapolate the blood concentration of heparin needed to achieve a target ACT acceptable for CPB. Most patients need 1.5 to 3.0 U/mL heparin to achieve an ACT of 480 seconds. A commercial device designed to automate this process is available, and from the patient's height, weight, sex, and heparin dose-response test results, the machine calculates the appropriate heparin dose to administer during CPB.

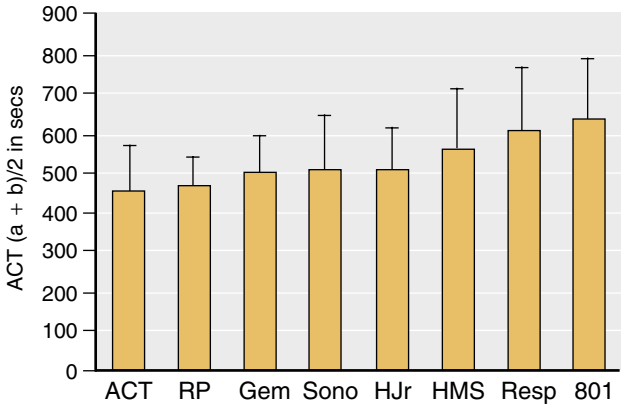

Figure 60-13 Results from eight different activated clotting time (ACT) tests from a group of heparinized patients undergoing cardiopulmonary bypass. Results may vary as much at 40% between different manufacturers' tests.

Cannulation

Every CPB procedure requires a high-flow cannula in a large vein and another in a large artery for withdrawing blood from and returning blood to the patient (Table 60-8). Most procedures include additional cannulas for administering cardioplegia solutions to the heart and removing (venting) blood and air from the chambers of the heart. Different surgical procedures require different cannulation techniques, the most common of which will be described here.

The target for venous cannulation is generally the RA. The RA is the central repository for all venous blood, and the right atrial appendage is conveniently accessible through a sternotomy. Although RA cannulation is optimal for most cardiac surgical cases, the cannula may not perform well when the heart is being

Table 60-8 Common Approaches to Venous and Arterial Cannulation for Cardiopulmonary Bypass

Procedure	Venous	Arterial	Cardioplegia	Vent	Comments
CABG	2-stage approach in the RA	Ascending aorta	Root and/or CS	Aortic root	Patients with low EF or failure to wean from CPB may benefit from LV venting
AVR	2-stage approach in the RA	Ascending aorta	Root and/or CS, plus hand-held selective once the root is open	LV and aortic root	None
MVR	Bicaval	Ascending aorta	Root and/or CS	LV and aortic root	None
Aortic root replacement, not including the arch	2-stage approach in the RA	Ascending aorta	Root and/or CS	LV and aortic root	The closer the repair gets to the head vessels, the more difficult aortic cannulation becomes
Aortic arch	2-stage approach in the RA	Axillary or femoral artery	Root and/or CS	LV and aortic root	CS cardioplegia unlikely if the coronaries are unobstructed
Redo procedures	Femoral vein	Femoral artery	Root and/or CS	Aortic root and/or LV	Only in extreme cases, i.e., when the heart is tightly adhered to the back of the sternum, or any time that the heart is lacerated during sternotomy
Other intracardiac procedures	Bicaval	Ascending aorta	Root and/or CS	LV and aortic root	Any procedure that requires opening the RA or excessive surgical retraction

AVR, aortic valve repair/replacement; CABG, coronary artery bypass grafting; CPB, cardiopulmonary bypass; CS, coronary sinus; EF, ejection fraction; LV, left ventricle; MVR, mitral valve repair/replacement; RA, right atrium.

retracted. Significant retraction of the heart is necessary to access some posterior coronary arteries for bypass or to access the mitral valve through a left atriotomy. Because of surgical retraction involving the RA, the venous cannulation site for mitral valve repair or replacement procedures is generally moved away from the RA to the superior and inferior venae cavae. If a single cannula is placed in each vena cava, venous blood can be intercepted just before it enters the RA so that the cannula can provide acceptable drainage throughout the procedure. The RA may also be approached through the femoral vein. A femoral venous cannula extends the entire length of the inferior vena cava and rests with its openings in the RA.

An improperly sized or positioned venous cannula will obstruct the flow of blood into the ECC circuit. This may elevate CVP and encourage extravasation of blood volume from the vascular compartment into the extracellular compartment (third spacing). Therefore, it is important to evaluate the performance of the venous cannula or cannulas on initiation of CPB. Properly placed venous cannulas will allow complete decompression of the right side of the heart, as indicated by a CVP and PAP of zero.

The ECC returns oxygenated blood to the patient through the arterial cannula. For CABG and valve procedures, the standard target for the arterial cannula is the portion of the ascending aorta below the aortic arch but still 3 to 4 cm above the aortic valve. The alternative approaches of axillary or femoral artery cannulation are used in procedures that require manipulation of much of the aortic root, arch, or both. Axillary artery cannulation is generally facilitated by the anastomosis of a tube graft to the side of the axillary artery to provide access for the arterial cannula without interrupting blood flow to the right arm. An added benefit of axillary cannulation for aortic arch procedures is that clamping the innominate artery allows antegrade cerebral perfusion to be performed during a period of circulatory arrest. Femoral arterial cannulation involves inserting the cannula through the femoral artery and into the abdominal aorta. Blood flow to the thorax is directed retrogradely up the aorta. Ischemia of the cannulated limb is a risk commonly associated with femoral arterial cannulation, and dissection of the cannulated artery is a risk associated with all arterial cannulation sites. Proper cannula placement should be confirmed before CBP is initiated.

With venous and arterial cannulas in place, the heart and the lungs can be bypassed. However, additional cannulas are needed to facilitate aortic cross-clamping and cardiac arrest. For example, cardioplegia cannulas can be placed in the ascending aorta, and then the aorta can be occluded by placing a large vascular clamp (i.e., a cross-clamp) across it. Occluding the aorta between the arterial cannula and the antegrade cardioplegia cannula interrupts blood flow from the arterial line of the ECC to the coronary arteries, thereby initiating a period of global myocardial ischemia. Intermittent or continuous administration of cardioplegia through the antegrade and retrograde cardioplegia cannulas serves to attenuate the ischemic insult (via a mechanism discussed later).

Bronchial pulmonary vascular connections deliver approximately 1% of the cardiac output to the lungs, where it is subsequently returned to the left side of the heart. In patients with chronic pulmonary disease, this recirculation may increase to more than 10% of cardiac output.[217] During the period when the aorta is cross-clamped, this blood volume will distend the left side of the heart and the pulmonary vasculature if the blood is not actively removed. Additionally, intracardiac procedures inherently introduce air into the left-sided chambers, and this air must be removed before the patient is weaned from CPB.

Vent cannulas facilitate decompression and de-airing of the heart. The heart is most commonly vented at the aortic root or directly from the left ventricle. Aortic root vents use the same cannula that is used to deliver antegrade cardioplegia and draw blood and air from the left ventricle across the aortic valve and into the reservoir of the ECC circuit. Because the antegrade cardioplegia needle has a small gauge and is positioned above the aortic valve, root vents have several significant limitations: they cannot be used when antegrade cardioplegia is being administered, and they are ineffective in decompressing the left ventricle when the cross-clamp has been removed. These limitations are not generally significant for an uncomplicated CABG procedure, but for CABG in patients with severely compromised ventricular function and for all intracardiac procedures, direct LV venting becomes essential. LV vents are typically introduced through the right superior pulmonary vein and advanced through the left atrium (LA), across the mitral valve, and into the left ventricle. The 10- to 14-Fr cannula used for this purpose offers significantly better venting capacity than the root vent does. Flows in the range of several liters per minute can be drawn through these cannulas when necessary, and because they are inserted directly inside the left ventricle, they are very effective in removing air bubbles that remain after an intracardiac procedure has been completed. Additionally, because the LV vent is separate from the cardioplegia cannula, it can be used to decompress the heart during antegrade cardioplegia administration, which may be necessary for patients with aortic insufficiency. Unfortunately, there are numerous case reports of patient injuries that resulted from air being pumped into the heart through malfunctioning vent lines.

Initiation and Maintenance of CPB

With the patient anticoagulated and cannulated, CPB may be initiated. Before initiating CPB, it is good practice to verify the patency of the arterial cannula. After proper position of the arterial cannula is confirmed, CPB may be initiated by removing the clamps on the venous line between the venous cannula and the reservoir. The patient's blood then passively drains into the ECC. Simultaneously, the arterial pump on the CPB machine begins to infuse the mixture of prime solution and autologous blood into the patient through the arterial cannula. It is very important to evaluate the performance of the venous and arterial cannulas during the initial seconds of CPB. The pressure in the arterial line of the ECC should be maintained below 300 mm Hg to prevent excessive trauma to the formed elements of the blood. Cannula position is evaluated mainly by examining the patient's hemodynamics. Provided that the venous cannula is adequately draining the venous return to the heart, right-sided heart pressure (CVP and PAP) should decrease to 0 mm Hg and become nonpulsatile, and arterial blood pressure should reach a normal mean pressure (60 to 90 mm Hg) while also becoming nonpulsatile.

The arterial trace usually becomes nonpulsatile as the heart is emptied and the pumping force is changed from the ventricle to the nonpulsatile arterial pump of the heart and lung machine. However, patients with aortic insufficiency will continue to have a pulsatile arterial trace despite complete venous drainage (CVP and PAP = 0 mm Hg) because of regurgitation of blood from the arterial cannula across the incompetent aortic valve and back into the left ventricle. If right heart pressure does not reduce to zero, the arterial trace remains pulsatile, and arterial pump flow cannot

be increased to full flow, the position of the cannulas must be re-evaluated. Once full flow has been achieved, the function of the heart and lungs will have completely made transition to the CPB machine, and the anesthesiologist may turn off the ventilator.

Initiation of CPB is often associated with a period of hypotension, which can be managed with the administration of an α-agonist (e.g., phenylephrine) into the venous reservoir of the ECC circuit (Fig. 60-14). While CPB is maintained, the adequacy of perfusion is continuously evaluated by monitoring hemodynamic variables. Blood flow from the arterial pump can be manipulated across a range of 1.6 to 3.0 L/min/m^2 to deliver an arterial blood pressure of 50 to 90 mm Hg and a mixed venous saturation ($S\bar{v}O_2$) greater than 65%. Any hypotension and hypertension that occur despite adequate flow and $S\bar{v}O_2$ can be treated by adjusting the patient's SVR with vasoconstrictors or vasodilators.

Arterial blood gas samples should be taken at least every 30 minutes to assess the performance of the oxygenator and to monitor the patient for the development of acidosis and proper anticoagulation status. Base deficit values of −5 or less can be corrected with sodium bicarbonate, but the underlying cause of the acid production should ultimately be addressed. Increased perfusion flow and pressure may be indicated. ACT values below the institutional parameter acceptable for CPB (usually ≥400 sec) should be treated with a heparin bolus administered into the ECC.

Urine output is also monitored during CPB as an indicator of perfusion flow and pressure. Poor urine production during CPB has not been shown to predict postoperative renal deficiency. Rather, age, preoperative renal function, the duration of CPB, and EF have been correlated with postoperative renal dysfunction.[81]

Myocardial Protection

To provide a motionless field for the surgeon, the heart is arrested in diastole by the administration of a potassium-enriched cardioplegia solution to the heart.

Interrupting myocardial electromechanical activity is the single most important step in reducing the heart's metabolism. Potassium-induced arrest alone reduces the heart's myocardial oxygen consumption by 90%. It is common to augment this reduction with hypothermia by administering cold cardioplegia solution. The combined influence of potassium arrest and myocardial temperatures lower than 22°C reduces myocardial oxygen consumption by 97% and enables the tissue to withstand complete interruption of blood flow for periods of 20 to 40 minutes. At the completion of surgery, myocardial arrest can be reversed by reperfusing the heart with warm normokalemic blood.

With regard to cardioplegia solutions, their ingredients vary considerably from institution to institution, the exception being potassium used as the arrest agent. Whereas some centers may use a very simple solution of potassium-enriched whole blood, others may choose a more complex solution with a variety of chemical additives. The trend in clinical practice has been to not use purely crystalloid cardioplegia solutions, and most centers now use some form of blood cardioplegia. The ratio of blood to crystalloid is generally 4:1 or 8:1. The crystalloid solution is often mixed with arterialized whole blood from the ECC circuit in an exact ratio by placing two different-sized tubes (the larger drawing from the arterial line of the ECC and the smaller drawing from the bag of cardioplegia) through a single roller pump and splicing the two tubes together downstream from the outlet of the pump. Generically, the chemicals added to the cardioplegia solutions are designed to make the solution slightly hypertonic to reduce edema, and these chemicals include a buffer to counter the heart's production of acidic metabolites and a substrate for energy or catalysts to assist the heart in production of adenosine triphosphate. Typically, solutions with two different potassium concentrations are used during the procedure. For induction of cardioplegic arrest, a "high-K" solution with a potassium concentration of approximately 20 to 30 mEq is used. After isoelectric arrest is induced, the solution is changed to a "low-K" mixture with a potassium concentration of about 10 mEq.

These solutions can be administered *antegradely* into the coronary arteries via the aortic root, through a needle placed between the aortic cannula and the aortic valve, or *retrogradely* into the coronary veins, via a balloon-tipped cannula placed in the coronary sinus. Antegrade cardioplegic delivery is the most physiologic approach. However, when the patient has pronounced coronary artery disease or aortic valve insufficiency, antegrade administration may not uniformly deliver cardioplegia to the myocardium. Retrograde cardioplegia administration also has limitations. For example, the free wall of the right ventricle and the posterior third of the septum (the distribution territory of the right coronary artery [RCA]) are poorly perfused by retrograde delivery.[218] Additionally, the microvascular areas of the heart that are perfused by retrograde cardioplegia are less able to sustain normal myocardial energy metabolism.[219] Thus, the most complete technique for myocardial protection involves both antegrade and retrograde delivery. In fact, it is not uncommon for cardioplegia to be delivered both antegradely and retrogradely simultaneously.

It is common for cardioplegia to be administered intermittently in a volume-dosing regimen. After an initial arrest dose of

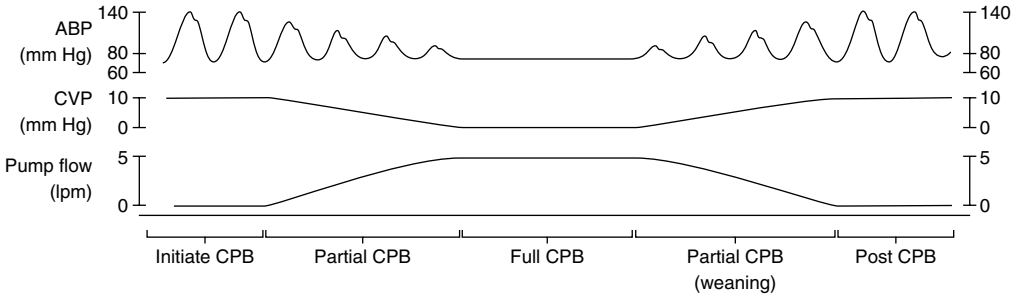

Figure 60-14 Illustration of a patient's hemodynamics before cardiopulmonary bypass (CPB), during the initiation of CPB, during full CPB, while weaning from CPB, and after CPB. ABP, arterial blood pressure; CPB, cardiopulmonary bypass; CVP, central venous pressure; lpm, liters per minute.

approximately 1000 to 1500 mL of "high-K" solution is administered, perfusion of the heart is suspended for a period of 10 to 40 minutes while the surgeon works on the heart. Then, periodically throughout the procedure, 200- to 500-mL doses of low-K solution are administered to deliver nutrients to the cells and maintain the potassium concentration. Intraoperative evaluation of the adequacy of myocardial protection is empirical and based on the quiescence of the ECG, the time since the last dose was administered, and the temperature of the heart. The filling state of the ventricular chambers should also be evaluated. If the vent lines are not keeping the heart empty, it will warm more quickly and the heart muscle will be under tension. This state increases myocardial oxygen consumption and reduces the adequacy of myocardial protection. To reinstitute electromechanical activity of the heart, warm normokalemic blood is infused into the coronaries. This may be done by administering a "hot shot" through the cardioplegia cannulas or by simply removing the cross-clamp.

Weaning and Termination of CPB

The process of weaning the patient from the heart and lung machine requires an increased level of communication and awareness between the anesthesiologist, perfusionist, and surgeon. Before weaning and termination, the patient should be rewarmed and the heart de-aired. Regular cardiac electrical activity should be confirmed and supported with a pacemaker if necessary. Ventilation of the lungs must be resumed and laboratory values confirmed and corrected if needed. By slowly reducing venous drainage to the ECC and transfusing volume from the reservoir to the patient, normal filling volume can be returned to the heart. As the cardiac output of the heart is returned to normal, flow from the arterial pump of the heart and lung machine is decreased and eventually terminated. Immediately after termination of CPB, the patient is often hemodynamically supported by volume replacement with the blood remaining in the ECC, frequently supplemented with vasopressors or inotropic agents (please see the earlier section "Weaning from Cardiopulmonary Bypass").

When the patient is hemodynamically stable, protamine can be administered to reverse the anticoagulatory effect of heparin. Administration of protamine to the patient is a sentinel event that must be communicated clearly between the anesthesiologist, perfusionist, and surgeon. In the event of inadvertent return of blood containing protamine to the ECC through the pump sucker, the blood remaining in the circuit may coagulate and render the circuit unusable for urgent reinstitution of CPB. Therefore, all cannulas should be removed before the action of heparin is fully reversed, and the blood remaining in the ECC should be salvaged by centrifugation or hemofiltration for return to the patient by the anesthesiologist.

Protamine inactivates heparin by irreversibly binding with the strongly acidic heparin molecule to form a stable salt with no anticoagulant effects. A commercial device such as the HMS machine can produce a protamine dose-response curve to calculate the dose of protamine necessary to neutralize the active heparin in circulation. In the absence of a protamine dose-response curve, many institutions calculate the protamine dose needed based on the total dose of heparin delivered to the patient, which usually results in the administration of 1 to 1.3 mg of protamine for every 100 units of heparin given. Protamine should be administered slowly over a period of 5 to 10 minutes to reduce the risk for hypotension. ACTs after protamine administration should return to baseline. An elevated ACT value may indicate residual heparin or may be the result of a coagulation deficiency requiring additional laboratory testing such as coagulation panel tests, heparin assays, platelet function analysis, thromboelastography, or any combination of such testing.

Other Issues

Temperature

Deliberate hypothermia is a reliable method of neuroprotection and is often used during routine CPB. Deep hypothermia unquestionably confers cerebral protection when the circulation must be arrested during cardiac surgery. Even mild hypothermia (as little as 1°C to 2°C) minimizes the severity of cerebral ischemia in animal models.[220]

Various suggested mechanisms for the neuroprotective effects of hypothermia have been tested in animal models (Table 60-9).[221] Hypothermia may attenuate the effects of cerebral ischemia by creating a favorable balance between oxygen supply and demand and by decreasing the cerebral metabolic rate of oxygen ($CMRO_2$). Hypothermia not only reduces the metabolic rate but also delays the release of excitatory amino acids, neurotransmitters that play an important role in the process of neuronal death.[222] Additionally, hypothermia reduces the permeability of brain arterioles and prevents blood-brain barrier dysfunction.[223] Hypothermia may also interfere with the inflammatory response by suppressing adhesion of polymorphonuclear leukocytes in the damaged region.[224]

However, after performing a meta-analysis, Rees and colleagues[225] concluded that there is no definitive evidence for a neuroprotective effect of hypothermia during routine CPB, although the studies examined in that analysis have some important limitations. For example, the timing of hypothermia may have limited its protective value. Hypothermia is always initiated after aortic cannulation and the onset of bypass, but macroembolization to the brain is unlikely during this period because the heart is excluded from the circulation by the aortic cross-clamp. Instead, evidence suggests that the periods of highest risk for microembolization and macroembolization are during and shortly after aortic manipulation, cross-clamping, and unclamp-

Table 60-9 Protective Effects of Hypothermia and Deleterious Effects of Hyperthermia during Cerebral Ischemia

Hypothermia	Hyperthermia
Favorable balance between O_2 supply and demand	Imbalance between O_2 supply and demand
↓ Excitotoxic neurotransmitter release	↑ Excitotoxic neurotransmitter release
↓ Blood-brain barrier permeability	↑ Blood-brain barrier permeability
↓ Inflammatory response	↑ Inflammatory response ↑ Free radical production ↑ Intracellular acidosis Destabilized cytoskeleton

ing[226,227] because aortic cannulation and cross-clamping are performed near the start of CPB, when the brain is not yet cold. Likewise, the aortic cross-clamp is removed near the end of CPB, usually after the patient has been rewarmed.

In contrast, hyperthermia is known to be deleterious. Elevation of body temperature by as little as 2°C decreases cerebral tolerance to ischemia. Hyperthermia delays neuronal metabolic recovery and increases excitotoxic neurotransmitter release, oxygen free radical production, intracellular acidosis, and blood-brain barrier permeability, with subsequent multifocal breakdown at sites in the thalamus, hippocampus, and striatum (see Table 60-9).[228,229] Hyperthermia also affects protein kinase activity and destabilizes the cytoskeleton. Clinically, fever and hyperthermia worsen the prognosis of hospitalized stroke patients.[230,231]

In the 1990s, some centers began using normothermic cardioplegia to improve cardiac outcomes while avoiding deliberate hypothermia.[232] This practice of "warm heart surgery" was debated because of concern that the neuroprotective effects of hypothermia would be lost. Subsequent studies produced inconsistent results with respect to the incidence of stroke and postoperative neurocognitive decline.[233] Such differences in neurologic outcome may have resulted from variations in the temperature management strategies used in different "warm heart surgery" studies; these variations ranged from allowing a downward "drift" that results in actual mild hypothermia to active rewarming that may have led to inadvertent cerebral hyperthermia.[234]

In patients undergoing CPB, cerebral hyperthermia during the rewarming period may aggravate any cerebral injury that has occurred.[235] Aggressive rewarming was once commonly practiced to prevent the "afterdrop" in temperature that usually occurs after CPB is discontinued, but this practice can cause cerebral hyperthermia at the exact moment when cerebral embolization is most likely. Therefore, rewarming should be gradual and should start early enough to achieve stability of the desired temperature before CPB is terminated.[236]

It is also important to be aware of the limitations of any temperature monitoring site used during CPB. Brain parenchymal temperature cannot be measured directly during cardiac surgery; rather, it must be estimated from tympanic, nasopharyngeal, esophageal, rectal, bladder, skin surface, pulmonary arterial, or jugular venous bulb temperature. However, there is poor concordance between cerebral temperature and temperatures measured at most of these sites.[237,238] Jugular bulb temperature is generally considered to be the "gold standard" because the proximity of the jugular bulb to the carotid origins and the aortic cannula makes jugular bulb temperature more similar to brain temperature than temperatures measured at other commonly used sites.[237,239] Temperatures measured at the nasopharyngeal, esophageal, bladder, rectal, or skin surface sites underestimate jugular bulb temperature during rewarming.[237,238] Because monitoring jugular bulb temperature is not usually feasible, monitoring the temperature of the blood in the arterial line that exits the oxygenator[237] or in the PA[238] may be the best ways to estimate global brain temperature.

Some clinicians advocate weaning high-risk patients from CPB at a temperature that is slightly lower than normal (approximately 35°C to 36°C). In a randomized, controlled study, Nathan and colleagues[240,241] showed that patients rewarmed to a lower than normal temperature (34°C) were significantly less likely to have postoperative cognitive deficits than were patients rewarmed to 37°C. Although this approach has advantages, postoperative hypothermia may increase a patient's risk for coagulopathy, hemodynamic instability, and shivering, which increases myocardial oxygen consumption.[242,243] All these factors must be considered if one is to select the best rewarming approach for an individual patient.

Hyperthermia that develops after surgery may be just as hazardous as intraoperative hyperthermia. Temperatures exceeding 38.5°C are common during the first 48 hours after cardiac surgery and occur in nearly 40% of patients.[244] This postoperative hyperthermia is known to be correlated with increased cognitive dysfunction 6 weeks after cardiac surgery.[245] Therefore, hyperthermia in the postoperative period should be treated with antipyretics and, if necessary, active body surface cooling.

In summary, patients maintained on CPB should be rewarmed early and slowly. No monitored temperature should be allowed to exceed 36.5°C to 37.0°C. This practice prevents cerebral overheating. In patients at high risk for adverse neurologic outcomes, limited rewarming (up to 36.0°C) followed by gradual (i.e., 4-hour) surface warming to 37.0°C may be considered as a means of preventing cerebral hyperthermia while minimizing the risk for postoperative hypothermia.[246]

Blood Gas Management (see also Chapter 49)

Temperature has a significant effect on the solubility of gases in solution. Specifically, in blood gas analysis, the CO_2 concentration (and consequently the pH) is profoundly altered by changes in temperature. As temperature decreases, $Paco_2$ decreases as CO_2 becomes more soluble in plasma. Therefore, inducing hypothermia during CPB poses a dilemma in terms of how best to approach acid-base management at lower temperatures, that is, whether *temperature-corrected* or *temperature-uncorrected* blood gas values should be used to manage the patient's care. This question has been the basis for a decades-old debate: α-stat versus pH-stat blood gas management (Table 60-10).

The α-Stat Hypothesis

In aqueous systems, neutrality (pN) is said to occur when $[H^+] = [OH^-]$. The dissociation of water is dependent on temperature; therefore, the pH value at which pN occurs varies with the temperature. Acid-base comparative physiologic studies of animals whose blood temperature varies (i.e., ectotherms and poikilotherms) suggest that blood and intracellular pH values parallel the temperature-related changes seen in the neutrality of water.[247] From these findings has emerged the α-stat strategy, which endeavors to maintain intracellular electrochemical neutrality across all temperatures.

Maintaining this neutrality requires an appropriate buffering system. It is thought that protein buffering is largely responsible for maintaining this temperature-pH relationship. Specifically, the imidazole group of the amino acid histidine has a p*K* value similar to that of blood. Therefore, if CO_2 stores are held constant during cooling, the ionization state (termed "alpha" [α]) will remain constant. This may be important because the ionization state affects both the structure and the function of proteins. Keeping the charge state constant (α-stat) by allowing blood pH to change with the neutrality of water is thought to be essential for maintenance of the most physiologically beneficial structure and function of enzymes during hypothermia. Research suggests that when the α-stat strategy is used, cerebral autoregulation remains largely intact until deep hypothermic temperatures are reached.[248]

Table 60-10 Summary of Blood Gas Management Strategies

Strategy	Goal	Implementation	Total CO_2 Content	Theoretical Benefits
Alpha-stat	Achieve electrochemical neutrality by maintaining a constant OH^-/H^+ ratio	Use normal *temperature-uncorrected* blood gas values	Constant	Preserves enzyme function and cerebral autoregulation
pH-stat	Maintain constant pH	Use normal *temperature-corrected* blood gas values	Increases	Produces more homogeneous brain cooling; decreases brain O_2 consumption
Combination	Maintain constant pH during cooling, then restore electrochemical neutrality before circulatory arrest	During the cooling phase, use *temperature-corrected* values, then switch to *temperature-uncorrected* values before interrupting flow. Use *temperature-corrected* values during the rewarming period	Initially increases during cooling, then returns to baseline	Produces homogeneous brain cooling, then restores neutrality; improves $CRMO_2$

To manage acid-base balance during hypothermic CPB by using the α-stat approach, one must maintain temperature-*un*corrected blood gas values. The term "*un*corrected" is often confusing because it refers to the values that are typically reported by the blood gas machine without programming the machine to correct the values to the actual temperature of the patient. For example, blood drawn from a patient undergoing CPB at 18°C is measured in a blood gas machine, which anaerobically warms the sample to 37°C and reports values at normothermia. With α-stat management, one would strive for normal temperature-uncorrected results, which would theoretically maintain intracellular electrochemical neutrality.

The pH-Stat Hypothesis

An alternative strategy is the pH-stat approach to acid-base management. The pH-stat strategy endeavors to maintain a constant pH despite changes in temperature. Hibernating animals tend to follow this strategy. To counter the tendency of cooling blood to follow the neutrality of the water curve and become more alkalotic as temperature decreases, these animals increase their blood CO_2 content and maintain normal pH at hypothermic body temperatures.[249]

Carbon dioxide is a potent cerebral vasodilator; therefore, the increase in CO_2 content during pH-stat management uncouples cerebral autoregulation; cerebral blood flow increases independent of cerebral metabolic demand.[250] These effects are thought to be neuroprotective for infants maintained on CPB who may have aortopulmonary collaterals and also to promote deep homogeneous cooling of the brain before circulatory arrest.[251,252] However, during rewarming, the higher cerebral blood flow that results from using pH-stat management may increase the embolic load sent to the brain.[253]

Using the pH-stat strategy with CPB involves managing blood gas parameters with temperature-*corrected* values by programming the blood gas machine to correct the values to the patient's body temperature. During bypass, decreasing blood temperature increases the solubility of CO_2 and, consequently, results in decreased $Paco_2$ values. Therefore, the perfusionist must either decrease the "sweep speed" of the air-oxygen mixture or, less commonly, add CO_2 to the oxygenator ventilation system to increase the CO_2 content and maintain a $Paco_2$ of 40 mm Hg (and normal pH) as the temperature of the blood decreases. It is important that the extracorporeal circuitry is equipped with an in-line blood gas analyzer so that $Paco_2$ levels can be continually monitored during CPB.

Which Strategy Is Best?

Currently, the debate about which acid-base strategy provides the best outcomes in patients is unsettled. In the adult patient population, several independent, prospective randomized trials have shown that using α-stat management during moderate hypothermia produces better neurologic outcomes than using pH-stat management does.[253-255] These and other data have led to an evidence-based recommendation (ACC/AHA class I, level A) that α-stat management be used in adults undergoing moderate hypothermic CPB.[256] It is unclear which strategy is superior in adults when deep hypothermia is used with or without circulatory arrest.

In pediatric CPB, a single prospective randomized trial showed no significant neurologic outcome benefit of the pH-stat strategy.[257] Other human and animal studies, however, suggest that pH-stat management may be more beneficial than α-stat management for infants.[251,258-262] These studies showed that pH-stat management produced more homogeneous cooling, less oxygen consumption, and better cerebral metabolic recovery than α-stat management did. The clear trend in pediatric CPB is to use pH-stat alone or in combination with α-stat (i.e., to use pH-stat during cooling and α-stat during rewarming) when deep hypothermia is used.[263]

Inflammatory Response to Cardiopulmonary Bypass

During the past 20 years, much has been written about the rapid and profound inflammatory response that CPB elicits. Surgical stress itself causes an inflammatory response, which CPB aggravates by subjecting the patient's blood to contact with foreign surfaces, ischemia-reperfusion, and gaseous and particulate microembolization, which initiate and amplify multiple redundant and interconnected immune cascades. With the onset of CPB, the increased expression of *initiator* substances (including endotoxin, tumor necrosis factor, and nuclear factor κB, as well as anaphylatoxins and cytokines) stimulates *effector* cells (including polymorphonuclear neutrophils, platelets, and endothelial cells) to upregulate adhesion molecules and release cytotoxic oxygen radicals and proteases. This response can produce tissue injury of varying degree in a variety of organ systems.[264,265]

Numerous clinical approaches have been shown to measurably reduce the inflammatory response in cardiac surgical patients (Fig. 60-15). These approaches can be loosely grouped into three primary categories: modification of surgical and perfusion techniques, modification of circuit components, and pharmacologic strategies.

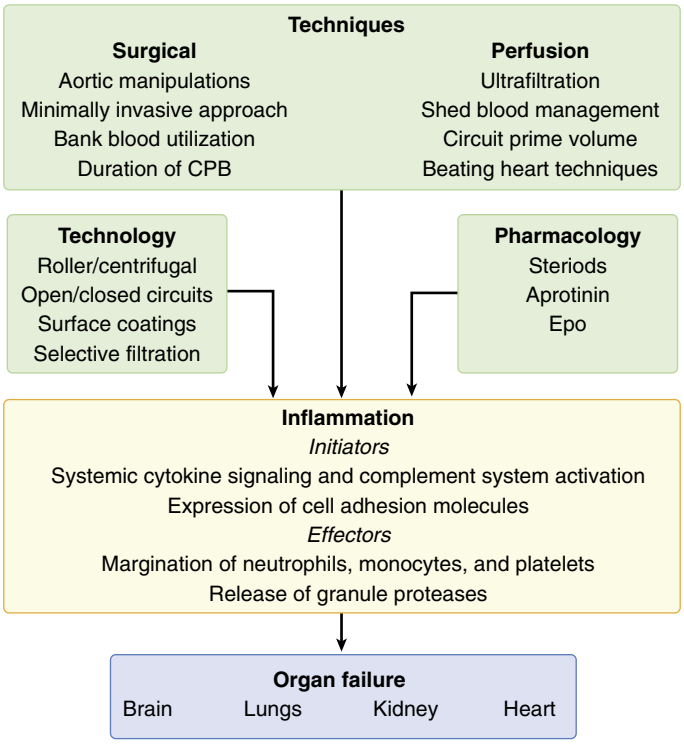

Figure 60-15 Brief review of the current understanding of the many variables that influence the inflammatory response in cardiopulmonary bypass patients. CPB, cardiopulmonary bypass.

Modification of Surgical and Perfusion Techniques

The movement toward minimally invasive cardiac surgery is at least partly motivated by the goal of reducing inflammation in the patient. The term *minimally invasive* may refer to procedures that use modified surgical techniques, including miniature incisions with or without robotic assistance, and to procedures that use classic surgical approaches but that minimize or eliminate the use of CPB and thus exposure to the ECC (e.g., OPCAB). Although OPCAB does not eliminate the patient's inflammatory response, it may produce less expression of inflammatory cytokines than CABG with CPB does.[266] However, it may be that the OPCAB-related reduction in inflammation is minimal in the days after surgery.[267]

Reasons for the lack of consensus about the exact contribution of CPB to the inflammatory process include the fact that perfusion practice is far from standardized.[256] A variety of perfusion techniques and technologies have been shown to reduce inflammation, including ultrafiltration,[268,269] shed blood management,[270] temperature management,[271] circuit miniaturization,[272,273] prime volume reduction,[274] and on-pump beating-heart techniques.[275]

Moreover, any improvements in outcomes that may be attributable to the use of OPCAB instead of standard CABG are probably not exclusively due to elimination of the ECC. Rather, minimizing or eliminating aortic manipulation, particularly in patients with severe atherosclerosis, may independently reduce the incidence of stroke.[276] Furthermore, a meta-analysis of randomized controlled trials comparing OPCAB and CABG with CPB confirmed that OPCAB was associated with a reduced risk for stroke and AF.[277]

Perfusion Technology

In addition to the ways in which perfusion technology is used, the type of technology used can moderate the inflammatory response to CPB. Evidence suggests that roller pumps may be less inflammatory than centrifugal pumps.[278,279] Some investigators have shown that using modified surface materials in the CPB circuit, such as heparin coatings, may reduce inflammation.[280-283] Additionally, selective filtration of leukocytes from the arterial circulation, the blood cardioplegia solution, or both may reduce inflammation,[284-286] although the efficacy of leukocyte-depleting filters in improving outcomes is controversial.[287,288]

Pharmacologic Strategies

Several pharmacologic agents have been shown to attenuate the inflammatory response to CPB. At the time of this writing, the serine protease inhibitor aprotinin is no longer being marketed; however, there is little question that it is effective in quelling hemostatic and inflammatory processes.[289]

In summary, several perioperative interventions may reduce the inflammatory response.[290,291] However, it is difficult to demonstrate the benefits of any one intervention in the clinical setting, where many other variables can also influence the inflammatory response and the clinical outcomes being measured.

Deep Hypothermic Circulatory Arrest

DHCA involves reducing the patient's core temperature to profoundly hypothermic levels (15°C to 22°C) before globally interrupting blood flow to the body, draining all the blood out of the patient, and collecting it in the ECC reservoir. In adults, this procedure is primarily used during surgical repair of the aorta, especially in cases of dissection or aneurysm involving the transverse arch.

Deliberate hypothermia with systemic cooling is the only reliable method of neuroprotection during complete global ischemia.[292] Some clinicians also put ice bags on the patient's head to augment or maintain cerebral cooling. Pharmacologic approaches to neuroprotection, such as steroids to reduce inflammation or barbiturates or propofol to induce burst suppression, are used in some centers, although there is scant evidence to support their efficacy in the setting of complete global ischemia.[293] Furthermore, if the electroencephalogram (EEG) is monitored, it is important to induce EEG isoelectricity with hypothermia before commencing the period of circulatory arrest rather than relying on supplemental barbiturates or propofol to provide neuroprotection.[294]

The equipment and circuitry of the heart and lung machine used for DHCA procedures are not generally different from that used for standard CPB procedures. Blood gas management during cooling and rewarming for DHCA procedures typically follows the α-stat management scheme in adult patients and the pH-stat management scheme in pediatric patients (see the earlier section "Blood Gas Management"). Systemic cooling is begun when CPB is initiated and is continued until the temperature of the patient is low enough to provide adequate protection for the anticipated duration of circulatory arrest. When deciding what temperature is "adequate," one must give top priority to protecting the brain. Because there is no clinically feasible method for measuring brain temperature, surrogate temperatures must be used to estimate

core temperature (see the earlier section "Temperature"). There is a time lag between the time that arterial blood reaches a target temperature and the time that the brain's parenchymal tissue equilibrates with the blood temperature. Consequently, when aggressive cooling is used, arterial blood temperature underestimates brain temperature. For an average-sized adult, cold arterial perfusion at full cardiac output flow should be continued for 20 to 30 minutes after the "goal" arterial blood temperature is reached to ensure that the brain has had sufficient time to cool. For an anticipated circulatory arrest period of 30 to 40 minutes, a temperature of 18°C to 20°C is probably adequate; however, slightly warmer temperatures may be acceptable if a shorter period of arrest is used or if cerebral perfusion is maintained.[295] It is also good practice to monitor multiple patient temperature sites, in addition to blood temperature, to observe their relative change over time during cooling and rewarming. Furthermore, the EEG provides a good pharmacodynamic end point for the cerebral effects of cooling; hypothermia-induced EEG isoelectricity should be present before elective circulatory arrest commences.[294]

As the patient cools, the viscosity of blood will increase. At temperatures of 18°C, the viscosity of blood with a hematocrit of 30% to 35% will increase to three to four times its normal level. Cardiac surgical textbooks suggest that hemodilution is important in minimizing any microcirculatory disturbances that may occur because of increased blood viscosity.[221] Consequently, some clinicians may target a hematocrit value that is appropriate to the patient's temperature during DHCA, approximately 18% to 20%. However, Duebener and colleagues[296] performed a study in piglets in which it was suggested that a hematocrit of 30% is preferable if DHCA is used.

When the patient has reached an appropriate core temperature as determined by temperatures measured at multiple sites and after there has been adequate time for equilibration, the arterial blood flow from the pump is stopped and the patient's blood is drained into the ECC reservoir. During the period of circulatory arrest, the blood in the ECC reservoir should be recirculated to prevent stasis and maintain the desired temperature. Gas flow to the oxygenator should be discontinued to prevent profound hypocapnia. Reperfusion should be initiated with cold blood. An initial period (5 to 10 minutes) of cold reperfusion is believed to enhance cerebral protection by removing accumulated metabolic products from the cerebral capillary beds while maintaining a low $CMRO_2$.[297]

The risk of neurologic injury after cardiac surgery involving DHCA extends into the postoperative period because cerebral vascular resistance is increased and cerebral blood flow is decreased for several hours after the procedure.[297] In addition, hyperthermia, possibly secondary to a systemic inflammatory response, is common in the postoperative period and should be treated aggressively.

In an effort to reduce the period of cerebral ischemia during the circulatory arrest period, selective cerebral perfusion techniques have been developed. Selective retrograde cerebral perfusion is delivered via a snared cannula introduced into the RA and advanced into the superior vena cava (SVC), and this type of perfusion can be initiated after the patient's systemic perfusion is discontinued. Cold oxygenated blood from the ECC can be administered at a flow rate (approximately 5 mL/kg/min) high enough to maintain SVC pressure between 35 and 40 mm Hg.[298] Selective antegrade cerebral perfusion can be accomplished by directly cannulating the left common carotid artery or can easily be delivered through the right common carotid when the aortic cannulation approach for CPB involves cannulation of the axillary or innominate artery.[295,299] This technique facilitates delivery of arterial return from the ECC to the entire circulatory system during cooling and rewarming or, with the addition of a clamp to the proximal innominate artery, selectively into the right common carotid and radial arteries. Because of the proximity of the arterial cannula to the right radial artery, arterial blood pressure monitored in the right radial artery may be significantly higher than pressure monitored in the left radial or femoral artery. Consequently, right radial arterial pressure should not be used to control perfusion during cooling and rewarming. Although there is still some debate about whether selective cerebral perfusion of any kind is necessary to achieve optimal neurologic outcome after DHCA procedures,[300] it is generally agreed that antegrade cerebral perfusion, when used properly, is superior to retrograde perfusion.[301]

Left Heart Bypass

If a descending aortic aneurysm or aortic dissection is to be surgically replaced with a tube graft, blood flow through the patient's thoracic aorta must be interrupted. The application of vascular clamps to this major vessel acutely increases the afterload of the heart and produces global ischemia in all parts of the body distal to the clamp. Patients with compromised cardiac function or those undergoing a surgical procedure in which the duration of ischemia will be unacceptably long require some method of circulatory support. Temporary interposition of a shunt (e.g., a Gott shunt) around the area of repair is the simplest approach but it does not offer the level of support that can be achieved with LHB or CPB.

For these procedures, the approach is usually through a left thoracotomy incision, which provides excellent access to the LA. The simplest approach to LHB is to withdraw blood from the LA with a centrifugal pump and return the blood to the patient's femoral artery. This *simple* LHB circuit gives the clinician excellent control of blood flow distal to the clamps and therefore the ability to manipulate the afterload that the heart must work against. However, the complexity of some surgical procedures requires that full CPB is used.

Complications of surgery are not uncommon in these patients and include hypoxia, hypothermia, and exsanguination. A double-lumen endotracheal tube or bronchial blocker is often used to isolate the left lung from the right. After left thoracotomy and exposure of the aneurysm, ventilation of the left lung is discontinued. Patients with preexisting lung dysfunction or traumatic lung injury associated with aortic dissection may have difficulty maintaining oxygenation with a single lung. Because of the large surgical exposure required and the sometimes extended duration of the procedure, it is not unusual for the patient to become hypothermic. Furthermore, these procedures carry an elevated risk of blood loss and the consequent need for rapid replacement of fluids and blood products. It is often advisable to use *complete* LHB to reduce these risks.

Figure 60-16 illustrates the simple- and complete-circuit approaches to LHB. The major difference between a complete LHB circuit and the standard CPB circuit is the position of the

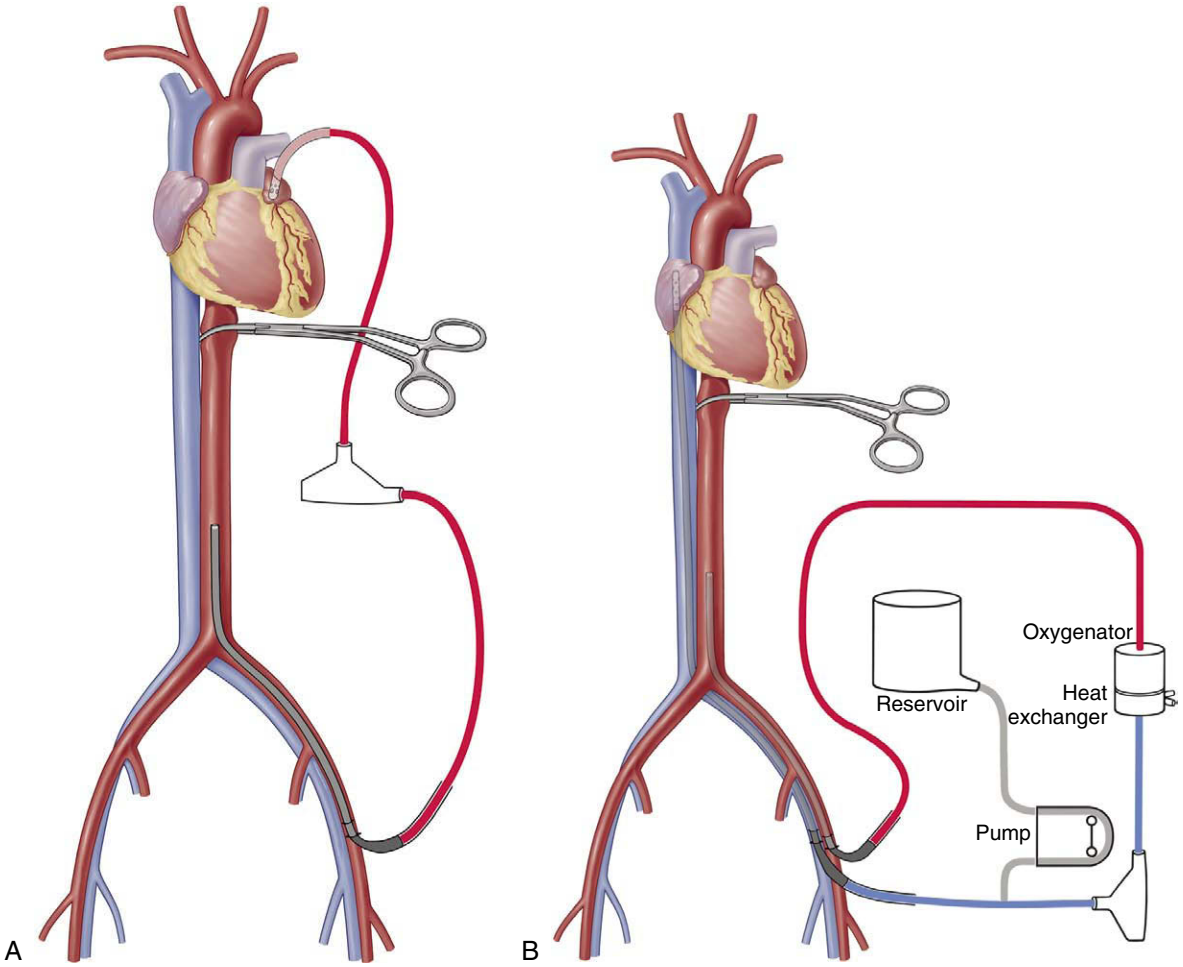

Figure 60-16 Left heart bypass (LHB) diagram. **A**, Simple LHB (left atrium [LA] – cone – femoral arery [FA]). **B**, Complex LHB (including an oxygenator, heart exchanger, and reservoir for fluid administration).

reservoir in the circuit and the position of the venous cannula in the patient. In a complete LHB circuit, the reservoir does not receive the blood returning from the patient as the CPB circuit does. With the reservoir out of the pathway of the blood, the effective surface area of the ECC is reduced, which attenuates contact activation of the blood and minimizes the need for high-dose heparinization.

In both circuits the management goal is the same—to keep arterial blood pressure above 60 mm Hg both proximal and distal to the aortic cross-clamp throughout the procedure. However, the complete LHB circuit gives the clinician the ability to manage hypoxia, hypothermia, and blood loss. The addition of an oxygenator to the circuit makes it possible to augment the patient's ventilation and oxygenation. The heat exchanger is used to maintain normothermia. The reservoir facilitates the addition of large volumes of fluid or blood products in the event of hemorrhage, hypovolemia, or both.

Cardiopulmonary Support and Extracorporeal Membrane Oxygenation Circuits

For all practical purposes, there is no difference between a CPS circuit and an ECMO circuit. Both consist of a CPB circuit without a reservoir, an arterial line filter, or any of the ancillary pumps that are used during cardiac surgery (i.e., pump suction, vent, and cardioplegia). Because the reservoir is removed from the circuit, these systems are considered to be "closed," which means that there is very little opportunity to remove emboli that enter the circuit from the venous line. Traditionally, an ECMO circuit has longer lengths of tubing, an arterial roller pump, and a silicone membrane oxygenator. The CPS circuit emphasizes minimalism in its design and has shorter lengths of tubing, a centrifugal arterial pump, and a hollow-fiber oxygenator.

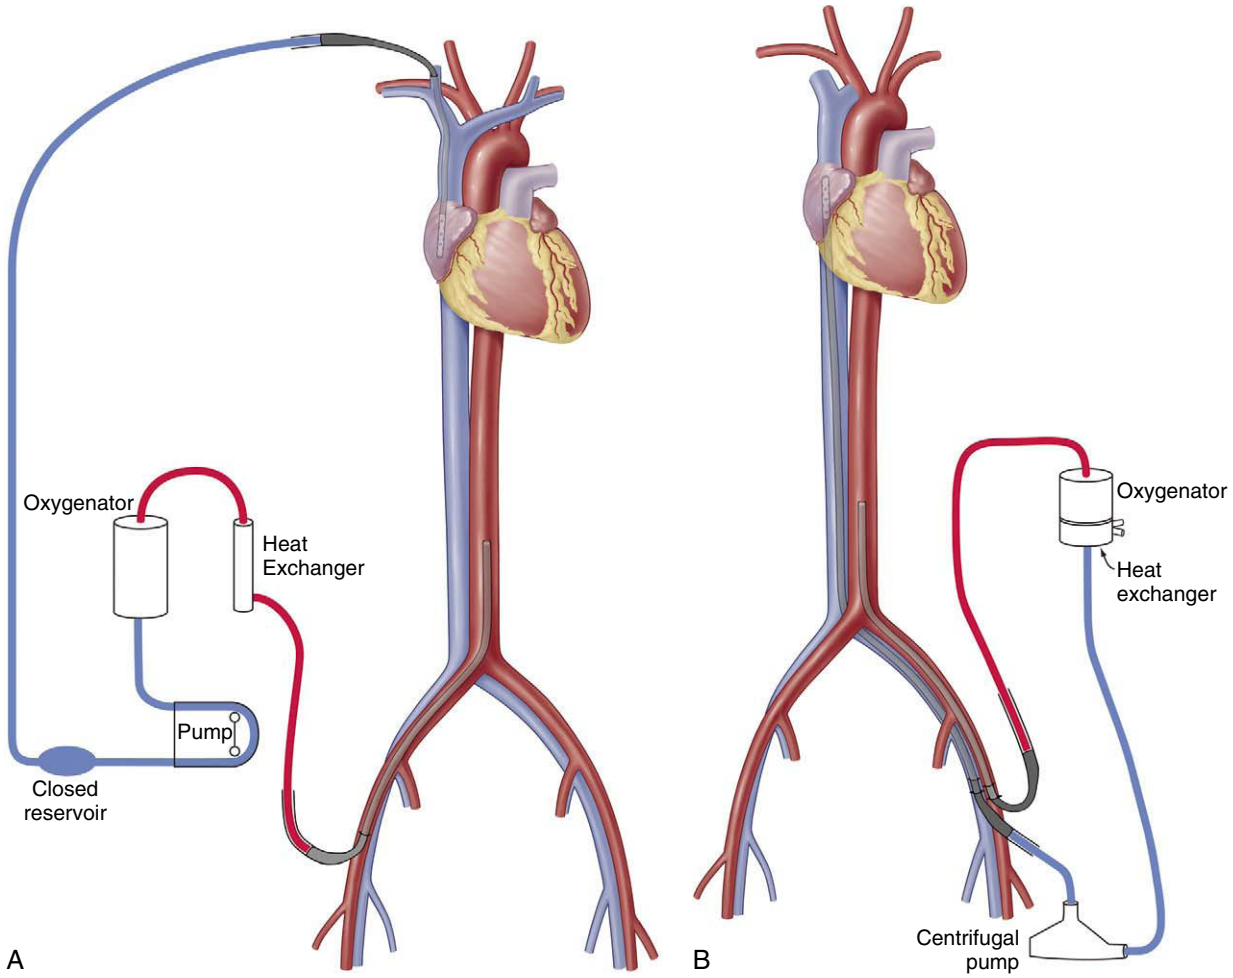

Figure 60-17 **A,** Patient cannulated via the internal jugular vein and femoral artery, with a traditional extracorporeal membrane oxygenation (ECMO) circuit. **B,** Patient cannulated via the femoral vein and femoral artery, with a simple cardiopulmonary support (CPS) circuit.

In intensive care settings, ECMO or CPS is used to support the heart, lungs, or both for days or weeks. The newer generation of centrifugal pumps and hollow-fiber oxygenators that have been developed over the past decade perform acceptably well during these long-term applications and are becoming more commonly used in desperate situations (Fig. 60-17).

Specific Cardiovascular Disease States

Coronary Artery Disease

On-Pump Coronary Artery Bypass Graft Surgery

Anesthetic management of patients undergoing CABG surgery with CPB or OPCAB surgery without CPB requires a basic understanding of coronary anatomy, the balance between myocardial oxygen supply and demand, and the determinants of myocardial ischemia.

Coronary Anatomy

Coronary arterial blood flows from the aorta through the left and right main coronary arteries. The left main coronary artery (LMCA) divides into the left anterior descending (LAD) and the left circumflex (LCx) arteries. The LAD artery courses anteriorly in the interventricular groove and gives rise to one, two, or three diagonal, and several septal, branches. The LAD itself terminates at the apex of the left ventricle. The diagonal branches of the LAD distribute blood to the anterolateral aspect of the heart. The septal branches of the LAD supply the interventricular septum, the bundle branches, and the Purkinje system. The other branch of the LMCA is the LCx artery, which courses along the left AV groove and gives rise to one to four obtuse marginal branches that supply the lateral wall of the left ventricle.

The RCA traverses the right AV groove and gives rise to acute marginal branches that supply the right anterior wall of the right ventricle. In 85% of the population, the RCA gives rise to the posterior descending artery (PDA), which supplies the posterior inferior aspect of the left ventricle ("right-dominant" system). In the other 15% of the population, this aspect of the left ventricle is supplied by a PDA arising from the LCx ("left-dominant"

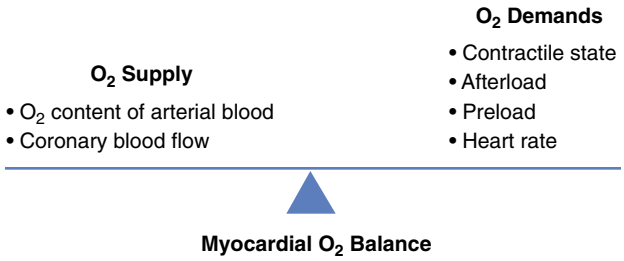

Figure 60-18 Factors determining myocardial oxygen supply and demand. *(From London M, Mittnacht A, Kaplan JA: Anesthesia for myocardial revascularization.* In *Kaplan's Cardiac Anesthesia, 5th ed. Philadelphia, Elsevier, 2006, p 594.)*

system) or both the RCA and the LCx systems ("codominant" system). The sinus node artery arises from the RCA distribution in 55% of the population and from the LCx arterial distribution in the other 45%.

Myocardial Oxygen Supply and Demand

The balance of oxygen supply versus demand is somewhat complex (Fig. 60-18). Extraction of O_2 from arterial blood is maximal at rest. As demand increases (with exercise or hemodynamic stress), the oxygen supply to the myocardium must also increase. Oxygen supply is determined by the oxygen content of arterial blood and by coronary blood flow.

The oxygen content of blood is dependent on hemoglobin-bound oxygen and, to a lesser extent, dissolved oxygen. Although a high hemoglobin level gives the blood high oxygen-carrying capacity, the minimum level of hemoglobin necessary to avoid ischemia has not been well defined in clinical studies. Factors that affect this limit include the severity of coronary artery disease, the heart rate, perfusion pressure, and myocardial wall thickness and tension. Furthermore, actual delivery of oxygen to myocardial tissue is dependent on release of oxygen from hemoglobin according to the oxyhemoglobin dissociation curve. A leftward shift of this curve caused by alkalosis, hypothermia, or low levels of 2,3,-diphosphoglycerate (which may be observed after the transfusion of a large volume of stored autologous blood) will decrease the release of oxygen.

The duration of diastole is another important factor affecting oxygen supply to the myocardium because 70% to 80% of coronary arterial blood flow occurs during the diastolic phase of the cardiac cycle. During the systolic phase, cardiac contraction increases intraventricular cavitary pressure and coronary vascular resistance, thus impeding myocardial perfusion. There is a nonlinear relationship between heart rate and the duration of diastole.[302] The total time per minute spent in diastole is a function of the heart rate. This is a major reason for the use of β-blockers as anti-ischemic agents both for long-term therapy and for preventing even small increases in heart rate during the perioperative period.

Determinants of blood flow in normal coronary arteries include the pressure differential across the coronary bed (coronary perfusion pressure) and coronary vascular resistance. The coronary perfusion pressure for the left ventricle is the aortic blood pressure during diastole minus left ventricular end-diastolic pressure (LVEDP); thus, elevations in LVEDP impede subendocardial blood flow. Because coronary stenosis causes vessels to dilate maximally distal to the stenosis, manipulation of coronary perfusion pressure becomes an important factor determining coronary blood flow (and preventing or treating myocardial ischemia). However, because the determinants of myocardial oxygen balance are complex, altering any one of them can produce multiple effects. For example, an increase in blood pressure increases coronary blood flow but also increases afterload, thereby increasing wall tension and oxygen demand.

In anesthetized patients undergoing anesthesia for coronary revascularization, vigilant monitoring for myocardial ischemia is necessary throughout the perioperative period.

Preoperative Evaluation and Management

Typically, patients undergoing cardiac surgery with CABG have had extensive preoperative assessment of their cardiac disease (see Chapter 34). Coronary artery anatomy should be noted, particularly a high-grade lesion in the left main or proximal LAD or triple-vessel disease. Ventricular function, assessed by angiography or echocardiography, is usually recorded as an estimated EF. Patients with an EF that is "normal" or greater than 50% have a low risk, whereas those having an EF of 25% to 50% have an intermediate risk for the development of postoperative low cardiac output syndrome (LCOS). Patients with an EF of less than 25% are at high risk. Patients with acute unstable angina, acute MI, or overt congestive HF are at very high risk. Those in cardiogenic shock, often with an IABP in situ, are at highest risk for LCOS and mortality.

Other cardiac pathophysiology discovered in the preoperative workup should be noted and understood, including valvular abnormalities such as concurrent MR, aortic stenosis (AS), aortic insufficiency, atrial or ventricular septal defect, or ventricular aneurysm. The anesthesiologist should be aware of any abnormal cardiac rhythm on the ECG or noted in the history, such as AF or other supraventricular tachycardia (which may lead to hemodynamic instability or increase the risk for an embolic neurologic complication), left bundle branch block or a prolonged PR interval (which may progress to a more advanced heart block), or a complete heart block, which may be underlying a paced rhythm. Antiarrhythmic therapy, either pharmacologic agents or devices such as a pacemaker or automatic implantable pacemaker/cardioverter-defibrillator (AICD), should be noted. Finally, the presence of pericardial effusion on the preoperative chest radiograph or echocardiogram has implications for hemodynamic compromise.

Surgical Considerations

Conventional (on-pump) CABG surgery is the most commonly performed procedure in cardiac surgery. A full median sternotomy performed with a sternal saw is standard. Ventilation of the lungs is halted briefly during sawing of the sternum to avoid a pleural tear. An oscillating saw may be used in patients with a previous sternotomy (redo). The risks of redo sternotomy include perforation of the right ventricle, damage to existing vein grafts, and ventricular fibrillation from transmission of electrocautery energy via preexisting sternal wires. Therefore, packed RBCs (2 units) should be immediately available and external defibrillation pads should be positioned before preparation and draping. Furthermore, surgical manipulation of previous vein grafts may result in embolization of atheroma and resultant ischemia. If a complication does occur during sternotomy or exposure of the heart and cannulation sites, emergency bypass may be established via cannulation of a femoral artery and vein.

If an IMA is to be used, the surgical table is elevated and often rotated somewhat to the left to facilitate surgical comfort in performing the dissection. Tidal volumes are also reduced to facilitate exposure. Administration of heparin usually occurs before clamping of the IMA pedicle, and papaverine may be injected into this vessel. The prebypass period for on-pump CABG may be relatively short (<1 hour) or may require several hours for dissection of the left IMA, right IMA, radial arteries, or any combination of these vessels. Harvesting of adequate venous conduits must also be accomplished for most CABG cases.

Before aortic cannulation, TEE or epiaortic echocardiography (or both) provides critical information regarding the presence and precise location of calcification or mobile atheromas in the aortic arch. TEE guidance for placement of the retrograde catheter into the coronary sinus may be requested by the surgeon. Insertion of the retrograde cannula may be difficult, and hemodynamic compromise or arrhythmias may necessitate rapid institution of CPB. After initiation of CPB, TEE may also be used to ensure correct placement of the LV vent, as well as to verify the absence of LV thrombus in patients with a recent anterior wall MI or aneurysm.[303]

Surgical and technical ischemic complications of CABG surgery include (1) poor-quality proximal or distal anastomoses of the grafts, (2) inadvertent incision of the coronary back wall leading to coronary dissection, (3) suturing the coronary artery closed, (4) inadequate vein graft length with stretching of the vein when the heart is filled, (5) excessive vein graft length leading to kinking of the vein, and (6) vein graft thrombosis.[304] Other causes of ischemia include (1) coronary embolization of air or atheromatous debris, (2) coronary spasm, and (3) vein graft stretching or occlusion of IMA flow secondary to overinflation of the lungs. Residual effects of cardioplegia, a ventricular aneurysm, or pericarditis may cause ST-segment elevation without actual ischemia.

Anesthetic Considerations

Monitoring for Ischemia Electrocardiography remains the standard to monitor for ischemia (see Chapter 42). For cardiac surgical patients, a display monitor that allows viewing of two ECG leads simultaneously, usually leads II and V_5, along with automated ST-segment analysis is preferred (see Chapter 42). PA catheters are used less commonly now than in the recent past because several recent observational and randomized studies have noted that such catheters do not improve outcome.[41,43,45] Certainly, the absolute PAP is not diagnostic of ischemia, although waveform changes may be more predictive; for example, the appearance of a new V wave on the PCWP tracing indicates ischemic papillary muscle dysfunction (see Chapter 40).

However, ECG changes and PA catheter waveform and pressure changes are less sensitive to ischemia than TEE-detected regional wall motion abnormalities are. Therefore, TEE is commonly used during revascularization procedures to assess regional wall motion by qualitative inspection of radial shortening and wall thickening (see Chapter 41). TEE usually provides better information than other modalities and is particularly valuable in assessing the patient after separation from CPB.

Selection of Anesthetic Agents No single anesthetic "recipe" is suitable for all patients undergoing CABG procedures. Most opioids, hypnotics, and volatile anesthetics have been used successfully in different combinations for induction and maintenance of anesthesia. Anesthetic drugs and doses are selected according to two main considerations, the first being LV function.[303] Patients with good LV function often have a strong sympathetic response to intense surgical stimulation such as sternotomy. If not adequately treated, tachycardia, hypertension, and ischemia result. Relatively large doses of anesthetics, often combined with β-blockers, vasodilators, or both, are required. On the other hand, in patients with poor LV function, hypotension may develop with the administration of anesthetics because of a reduction in cardiac output or vasodilation (or both). Such patients may require vasopressor or inotropic pharmacologic support, or both.

The second consideration for selection of anesthetic agents and doses is the probability of early extubation (within 4 to 6 hours of arrival in the ICU).[303] So-called fast-track management is becoming the standard, particularly for primary (first-time) isolated CABG (CABG without additional procedures such as valve replacement or ventricular aneurysmectomy). In making the decision to wean from ventilator support, clinicians (surgeons, anesthesiologists, and intensivists) assess whether the surgery was uneventful and whether the patient has normalized physiologic parameters. Such assessment includes observation for normothermia, absence of excessive bleeding or documented coagulopathy, and acceptable urine output, blood gases, and hematocrit. After weaning from sedation and assessment of neurologic status, patients must meet institutional criteria for extubation. Please see the earlier section "The Postbypass Period" and the later section "Problems in the Postoperative Period" for further details.

Off-Pump Coronary Artery Bypass Surgery

Surgical Considerations

The OPCAB grafting technique is performed through a full median sternotomy but avoids exposure to CPB. Currently, OPCAB revascularization accounts for 20% to 30% of all CAB operations.[305,306]

Potential sources of bypass grafts include the right and left mammary arteries, the saphenous veins, and the radial arteries. The pericardium is incised, reflected, and secured to the edges of the mediastinum. Special sternal retractors allow the placement of adjustable and flexible fixation devices that work by direct surface pressure on the myocardium, by suction, or by both methods. These devices stabilize the target vessel and allow the surgeon to "verticalize" the cardiac apex out of the pericardial well to access the posteriorly and laterally located vessels (Fig. 60-19).

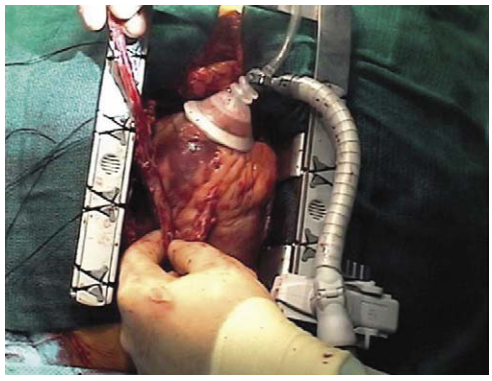

Figure 60-19 Verticalization of the cardiac apex in an off-pump coronary artery bypass (OPCAB) operation.

When the target vessel and surrounding myocardium are stabilized, an elastic ligature is placed circumferentially around the coronary artery to minimize bleeding as an arteriotomy is performed. Surgical visualization is also optimized by the application of a blower/mister, held by a surgical assistant, that releases sterile irrigation fluid aerosolized in carbon dioxide gas. Under these conditions, one or more distal coronary anastomoses are performed. The proximal connections of saphenous vein grafts or free arterial conduits are anastomosed directly to the aorta with a side-biting clamp. Alternatively, an indirect proximal connection is made via creation of a T-graft (end-to-side anastomosis) to a mammary artery that is still connected to a vascular pedicle on the subclavian artery.

Anesthetic Considerations

Anesthetic considerations for OPCAB revolve around hemodynamic perturbations. These are due to the compressive effects of myocardial stabilizers, altered ventricular filling secondary to verticalization of the cardiac ventricular apex, and the effects of myocardial ischemia in native coronary arteries or induced by temporary elastic suture ligation of a target vessel or decreased coronary perfusion caused by hemodynamic changes. Application of a surface stabilizer and an apical displacement device was associated with significant reductions in stroke volume, cardiac output, coronary blood flow, and mean arterial pressure in a porcine OPCAB model.[307,308] Biventricular filling is compromised, particularly in the thin-walled, easily compressed right ventricle.[308] Apical displacement and external compression can also distort the mitral valve annulus and lead to elevated atrial filling pressure, restricted diastolic filling, and MR.[309] Clinical studies have associated hemodynamic deterioration with the apical displacement that is necessary for grafting the RCA and circumflex artery distributions.[310-312] Furthermore, ischemia of distal myocardial segments occurs during the anastomosis of bypass grafts, and the degree of functional deterioration depends on the severity of the stenosis and the extent of collateralization.[313]

Patient monitoring includes a five-lead ECG and an invasive arterial pressure catheter. PAP and cardiac output measurements or continuous pulse contour cardiac output can be considered.[313] TEE is beneficial, but only to a limited degree, because verticalization of the heart and the application of external compression footplates cause suboptimal imaging. The mid-esophageal imaging view rather than the transgastric view may be best for continuous TEE monitoring while distal coronary anastomoses are being performed.

Because these patients are not on bypass, "rewarming" from hypothermia with the pump is not an option. Surface convective warming is somewhat limited because of the need for intrathoracic surgical exposure and access to the patient. Therefore, patient heating blankets and a warm operating room environment are essential to prevent unacceptable reductions in body temperature.

Hemodynamic changes in OPCAB surgery are initially treated by volume expansion with crystalloid, colloid, or both. Blood transfusion is considered in high-risk patients who arrive at the operating suite with preoperative anemia, which may be exacerbated by non–cell-containing fluid expansion and surgical blood loss during harvest of the mammary artery and anastomotic intervals. When intravascular fluid augmentation is inadequate, Trendelenburg positioning has been shown to be effective in restoring stroke volume, CI, and mean arterial pressure in animal models.[307,308] When increased mitral insufficiency further exacerbates the hemodynamic changes, repositioning the heart is a simple maneuver that may increase ventricular filling and normalize ventriculo-annular geometry.

Patients with abnormal LV function may tolerate poorly verticalization of the heart. Persistent hypotension can be treated by administering vasoactive medications, such as phenylephrine or vasopressin, or inotropic agents, especially when there is evidence of impaired tissue perfusion (CI <1.5, $S\bar{v}O_2$ < 60%, or poor urine output). Norepinephrine is a reasonable choice given that its adrenergic properties include α- and β-agonist effects at low doses. Ischemic changes manifested as ST-segment changes or new wall motion abnormalities on TEE can be treated by raising perfusion pressure through volume expansion, pharmacologic vasoconstriction, or inotropic support. Nitroglycerin should be used cautiously because preload reserves are usually compromised by changes in cardiac position in OPCAB surgery.

Persistent or worsening ECG changes or impending cardiovascular collapse warrants quick action on the part of the anesthesiologist and surgeon. One option is to have a low threshold for the insertion of small, flexible intracoronary stents into the open coronary anastomosis to allow some distal segment flow. Instituting full or partial CPB and placing an IABP are other therapeutic options. Emergency conversion from OPCAB to CABG with CPB, which occurs in approximately 3% of these cases,[314,315] is not an innocuous event. Such unplanned conversions are reportedly associated with an elevated risk for death, stroke, renal failure, wound infections, and respiratory failure.[315]

Outcomes

Short-term outcomes and the long-term efficacy of OPCAB surgery continue to be investigated and debated in the literature. The largest observational study, constructed from the New York State Cardiac Surgery Database, showed similar inpatient mortality rates in the on-pump CAB and OPCAB groups but lower rates of stroke and bleeding requiring reoperation and shortened length of stay in the OPCAB group.[316] However, the on-pump cohort had better 3-year survival and freedom from revascularization.[316] Randomized trials comparing OPCAB with on-pump CABG have not found convincing or consistent evidence to support one approach over another.[317,318]

A meta-analysis of randomized trials revealed that OPCAB produces a statistically significant reduction in the incidence of postoperative AF, but not in other adverse clinical outcomes, when compared with on-pump CABG.[319] However, there were trends suggesting that OPCAB reduced 30-day mortality, MI, and stroke.[319] In another meta-analysis, Lim and coworkers[320] used graft patency as an end point and concluded that OPCAB patients have worse patency rates and a statistically significant reduction in the number of grafts performed when compared with on-pump patients. These findings suggest that myocardial revascularization is more complete in CABG with CPB. Notably, however, recent large, retrospective reviews of traditional CABG versus OPCAB procedures have found a gender-specific benefit for women undergoing OPCAB surgery, with statistically significant reductions in mortality, stroke, and major adverse cardiac events.[305,321]

Minimally Invasive Surgery

Surgical Considerations

A minimally invasive direct coronary artery bypass (MIDCAB) grafting technique is accomplished through a limited anterior thoracotomy, usually a left-sided one, for revascularization of a

LAD arterial atherosclerotic lesion (Fig. 60-20). Patients selected for this operation may be relatively healthy and considered to be "low-risk" but have a complicated LAD lesion that is not ideally treated by PCI. Occasionally, MIDCAB is attempted in patients with a severely atherosclerotic aorta, in whom standard CPB is thought to incur an excessive risk for stroke because instrumentation and manipulation of the ascending aorta are necessary.

Although MIDCAB can involve surgical approaches to the RCA or PDA through a right anterior thoracotomy or subxiphoid laparotomy, a surgical approach through a left anterior thoracotomy to address LAD or circumflex arterial atherosclerotic disease is more common. The procedural details are similar; thus, only the left-sided approach is discussed here.

The left internal mammary artery (LIMA) is harvested under direct vision through the thoracotomy incision or by using thoracoscopic instruments or robotic technology through small port incisions. Single-lung ventilation is often requested for port-access harvesting of the LIMA in order to optimize surgical exposure and visualization. The pericardium is incised and reflected, and the target vessel or vessels are exposed. As in OPCAB performed through a median sternotomy, special myocardial stabilizers are used to isolate and transfix the site for coronary arteriotomy and the immediately adjacent myocardium, and elastic ligatures are placed around the vessel. Coronary flow is then interrupted while the LIMA is surgically anastomosed to the LAD. A vein graft or radial artery graft can also be connected to the LIMA pedicle graft (T-graft) if it is necessary to revascularize secondary lesions in the LAD or circumflex artery distributions.

Anesthetic Considerations

Management of anesthesia and hemodynamics for MIDCAB is similar to that for OPCAB surgery. Additionally, single-lung ventilation may be requested for harvesting of the LIMA graft, the coronary anastomosis, or both. Single-lung ventilation can be accomplished with a standard double-lumen tube, a bronchial blocker catheter placed through a standard endotracheal tube, or specialized endotracheal tubes (Univent).

Patients may have significant postoperative thoracotomy incisional pain, which must be managed to allow "fast-track" extubation, ambulation, and recovery. Pain management options include epidural narcotic analgesia delivered via a thoracic epidural catheter, intrathecal narcotic analgesia, local anesthetic nerve blocks extending a few levels above and below the thoracotomy, an intercostal analgesia catheter, and intercostal nerve cryoablation.

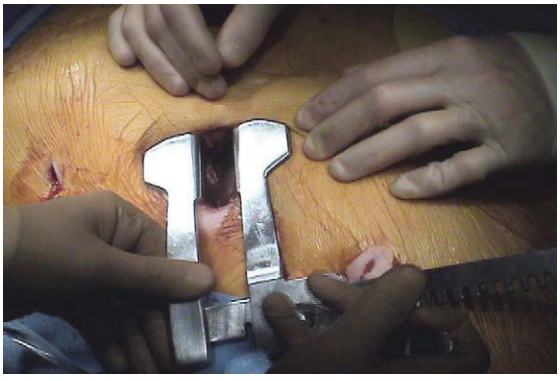

Figure 60-20 Left anterior thoracotomy for minimally invasive direct coronary artery bypass (MIDCAB).

Outcomes

Outcomes with MIDCAB are favorable. A large European retrospective study of more than 1300 MIDCAB patients reported 89.5% freedom from adverse events and angina at 5 years and 83.3% freedom at 7 years after surgery.[322] Studies comparing bare-metal stent PCI with MIDCAB surgical revascularization report similar or slightly lower rates of adverse cardiac or cerebrovascular events with MIDCAB and higher restenosis rates with PCI.[323-326] Finally, it is possible to combine MIDCAB surgical revascularization of the LAD with PCI in patients with complex multivessel disease, thereby creating a hybrid approach to coronary revascularization.[327,328]

Cardiac Valve Lesions

Mitral Valvular Disease

In the United States and other industrialized nations, mitral valve disease is usually caused by primary degenerative (i.e., age-associated) or inherited mitral valvular abnormalities or, increasingly, by ischemic heart disease resulting in functional mitral incompetence rather than by rheumatic heart disease. Primary or "organic" mitral valve disease involves abnormalities in the valve itself or in its subvalvar structural components. Mitral valve prolapse, myxomatous degeneration of the mitral valve, rheumatic mitral insufficiency, cleft mitral valve associated with an AV septal defect, and any infiltrative/fibrotic processes caused by systemic diseases are all associated with inherent structural abnormalities of the mitral valve. The most common indication for surgical repair or replacement of the regurgitant mitral valve is myxomatous degeneration, which includes mitral valve prolapse syndromes.[329] Chronic ischemic or functional MR is present in 10% to 20% of patients with coronary artery disease, and unlike primary valvular causes of MR, the morphology of the mitral valve is normal. Nonetheless, the long-term morbidity and mortality associated with this type of MR are significant.[330]

Anatomy of the Mitral Valve

The mitral valve leaflets are composed of segments, more easily discernible in the posterior leaflet, that are sometimes referred to as "scallops." In the Carpentier classification scheme,[331] the segments of the posterior leaflet are labeled P1, P2, and P3, with P1 being laterally oriented and P3 medial. The segments of the anterior leaflet are labeled A1, A2, and A3 and have the same medial/lateral orientation as the segments of the posterior leaflet (Fig. 60-21). This terminology is used to ensure accurate communication between the surgeon and the echocardiographer, who is often an anesthesiologist, as they attempt to localize valve abnormalities.

Mitral Stenosis

Pathophysiology The disease process of rheumatic mitral stenosis (MS) includes thickening and commissural fusion of the mitral valve leaflets and increased rigidity of the valve leaflets, as well as thickening, fusion, and contracture of the chordae and papillary heads. Furthermore, with long-standing rheumatic disease, some degree of calcification of the valve apparatus inevitably occurs. Physiologically, these changes result in obstruction at the level of the mitral valve.

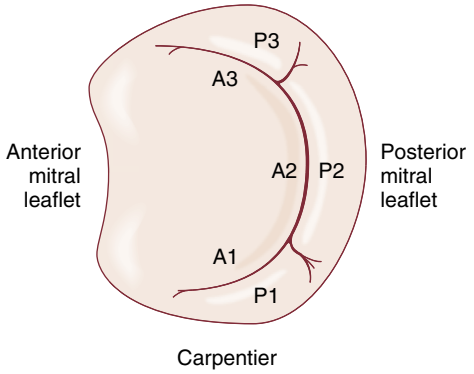

Figure 60-21 Standard terminology as applied to the mitral valve leaflets is illustrated in this image. The anterior and posterior mitral valve leaflets are each divided into three segmental regions. *(From Savage RM, Aronson S, Thomas JD, et al [eds]: Comprehensive Textbook of Intraoperative Transesophageal Echocardiography. Baltimore, Lippincott Williams & Wilkins, 2005, Figure 14.2.)*

The normal mitral valve orifice area is approximately 4 to 5 cm^2.[332] Symptoms can occur with a valve area of less than 2.5 cm^2 and can be precipitated by clinical events associated with increased cardiac output and consequent increased flow across the valve. Symptoms do not usually occur at rest unless the mitral valve area (MVA) has become less than 1.5 cm^2. Obstructed flow across the mitral valve is associated with a pressure differential or "gradient" across the valve. The more severe the MS, the greater the gradient, as long as flow across the valve is held constant.

Transmitral pressure gradients through the mitral valve are dependent on the volume flow rate. Severe MS may be present with a low measured or calculated gradient across the valve, such as in patients with right HF and pulmonary hypertension. An MVA estimate is a more independent measure of the severity of MS. Currently, MS is primarily diagnosed and monitored with echocardiography, although MVA can be calculated during catheterization by using the Gorlin equation. Assessment of severity by echocardiography includes two-dimensional planimetry of the valve orifice and Doppler-derived measurements of the gradient, pressure half-time, and deceleration time.

Management considerations in MS emphasize the pathophysiologic changes that occur in the LA, the pulmonary vasculature, the right heart, and the left ventricle. Obstructed mitral inflow with secondary increases in left atrial pressure (LAP) gradually produces enlargement of the LA, which can lead to the onset of AF, thromboembolic complications, or both, if low-velocity blood flow causes clot formation in the atrium or appendage.

Patients with MS and chronic AF are at increased risk for embolic stroke, at a rate of 7% to 15% per year.[333] Treatment may include anticoagulation with intravenous heparin or oral warfarin, pharmacologic rate control, and pharmacologic or electrical cardioversion for hemodynamically significant or acute-onset AF. In patients scheduled for cardioversion, TEE may need to be performed first to rule out the presence of a left atrial thrombus.[332]

Elevated LAP leads to passive increases in pulmonary venous and arterial pressure. Most patients with MS have pulmonary pressures greater than would be expected if they were estimated solely from elevations in LAP. These exaggerated pressures are secondary to reactive pulmonary vasoconstriction or histologic changes in the medial and intimal layers of pulmonary arteries and arterioles. Pulmonary pressures do exhibit a trend with the severity of MS, but pressures range widely with varying degrees of MS severity. In a study of 744 patients with severe MS, Otto and associates[334] found that multivariate predictors of elevated PVR and gradients across the pulmonary vascular bed included the transmitral pressure gradient, LVEDP, the MVA, and a history of chronic pulmonary disease.

The chronic elevation in pulmonary pressure caused by MS leads to compensatory and decompensatory changes in the right ventricle. Exposure to elevated pressure leads to compensatory RV hypertrophy; however, the response in the right ventricle is less efficient than in the left ventricle because of the right ventricle's shape, wall thickness, and smaller muscle mass. Because of the right ventricle's relative vulnerability, chronic pulmonary hypertension invariably leads to progressive RV dilation and eventual RV failure.

The effect of MS on the left ventricle is primarily due to obstruction of diastolic inflow. The narrowed mitral valve orifice leads to prolonged early diastolic mitral inflow and delayed filling of the left ventricle. Late diastolic filling, which occurs during atrial systole, is obviously compromised in patients who have AF secondary to MS. In cases of MS, pressure-volume loops are shifted to the left, so LVEDP and LV end-diastolic volume (LVEDV) are lower. Stroke volume is diminished, especially in clinical situations that result in an elevated heart rate and shortened diastolic filling intervals (Fig. 60-22).

LV function or contractility is assumed to be normal in most patients with MS. However, in a review of the literature, Klein and Carroll[335] showed that the assumption of preserved LV contractility in patients with MS is debatable. Instead, LV dysfunction may occur in as many as 30% of patients with MS. Proposed mechanisms include reduced filling of the left ventricle, muscle atrophy, inflammatory myocardial fibrosis leading to wall motion abnormalities, scarring of the subvalvular apparatus, abnormal patterns of LV contraction, reduced LV compliance with diastolic dysfunction, increased LV afterload leading to ventricular remodeling, right-to-left septal shift secondary to the effect of pulmonary hypertension on the right ventricle, and coex-

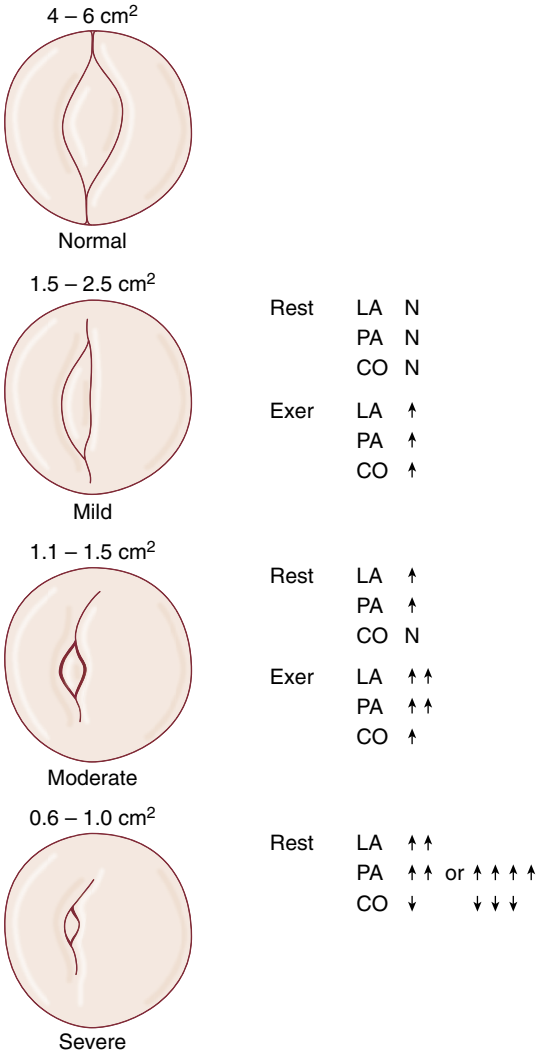

Figure 60-23 Diagrammatic representation of the hemodynamic changes that occur at various stages of severity of mitral stenosis. The valve area is listed above each stage. ↑, increased; ↓ decreased; CO, cardiac output; Exer, exercise; LA, left atrial pressure; N, normal; PA, pulmonary arterial pressure. *(From Rappaport E: Natural history of aortic and mitral valve disease. Am J Cardiol 35:221-227, 1975.)*

istent diseases such as systemic hypertension and coronary artery disease.[335] The hemodynamic changes associated with MS are summarized in Figure 60-23.

Anesthetic Management An understanding and appreciation of the pathophysiologic changes associated with MS form the foundation of anesthetic management in these patients. Primary concerns in patients with MS include management of ventricular preload, heart rate, coexisting pulmonary hypertension, and potentially diminished RV and LV contractile function. Most patients with valvular heart disease have an increased dependency on and sensitivity to ventricular preload. Flow through a stenotic mitral valve requires a higher than normal pressure gradient between the LA and the left ventricle. Thus, a reduction in preload, either from blood loss or from the venodilatory effects of anesthesia, can markedly affect stroke volume, cardiac output, and tissue perfusion. However, in higher grades of MS, LAP may be very high, and the difference between adequate filling pressure and an LAP that leads to congestive failure may be small. Thus, judicious fluid management is required.

In patients with MS, the heart rate should be kept within its normal range. Tachycardia may be poorly tolerated because of the decreased time for diastolic filling. Moreover, pressure gradients are somewhat flow dependent in MS. Elevated flow states, such as pregnancy and increased sympathetic activity from any source, can dramatically increase the pressure gradient across the valve and are reflected in elevated LAP or pulmonary venous pressure. Echocardiographically, the concept of valve gradients is derived through the use of a modified form of Bernoulli's equation, $\Delta P = 4v^2$, where "v" is the measured velocity of blood flow through the valve. Thus, any increase in the transvalvular flow rate caused by an increase in the heart rate has a significant impact on transvalvular flow dynamics and on LAP.

Atrial contributions to stroke volume may be elevated in MS patients who are in the early stages of the disease and not in AF. When AF has occurred, the atrial kick is lost. However, the most important factor in deterioration of the patient's clinical condition is tachycardia itself rather than loss of the atrial kick.

Contractility and SVR are usually preserved in MS. If anything, the left ventricle is chronically underloaded, but wall motion abnormalities or global systolic dysfunction may develop in a small percentage of MS patients. Usually, SVR is not a factor in augmenting forward flow because stroke volume is determined by the mitral valve orifice area and the diastolic filling interval. It may be appropriate to lower SVR for a left ventricle that has marked systolic dysfunction, but care must be exercised because a reduction in afterload is inevitably accompanied by a reduction in preload, which may not be desirable in patients with significant MS.

RV dysfunction probably poses a greater challenge in treating patients with MS than LV dysfunction does. The chronic elevations in LAP lead to pulmonary venous congestion, elevated pulmonary venous pressure, and eventually, elevated PAP. The right ventricle becomes hypertrophic and dilates in response to chronically elevated PAP. Long-standing elevations in pressure eventually cause RV contractile dysfunction. Although valve replacement may reduce pulmonary pressure, thereby unloading a dysfunctional right ventricle, the elevated PAP associated with long-standing MS may have a permanent component, especially in patients with comorbid pulmonary disease. Therefore, RV dysfunction can be persistent. In a patient with residual pulmonary vascular disease and RV dysfunction, supporting a failing or marginally functional right ventricle becomes the top clinical priority.

Monitoring for these patients includes standard noninvasive modalities and invasive monitoring of blood pressure, CVP, and intraoperative echocardiography. Monitoring PAP and cardiac output with a PA catheter may be very helpful, but care and judgment must be exercised given the propensity for PA rupture in patients with long-standing pulmonary hypertension. Inotropic support may be needed for patients with secondary RV dysfunction or failure. Epinephrine and milrinone are good therapeutic options. Management of RV dysfunction includes optimizing acid-base balance and using hypocapnia, hyperoxia, and possibly vasodilators to decrease PVR.

Mitral Regurgitation

MR can be classified as either organic (intrinsic valvular disease) or functional (i.e., related to nonvalvular components of the

mitral apparatus). It is common for MR to have a functional and an organic component, as in rheumatic valve disease resulting in annular or LV dilation with superimposed abnormalities of leaflet coaptation. In developed countries, the most common causes of MR are (1) myxomatous degeneration of the mitral valve resulting in annular dilation, chordal elongation and rupture, and redundant, prolapsing, or flail mitral valve leaflets and (2) mitral insufficiency caused by ischemic heart disease.

The severity of MR is assessed in the context of whether the MR is acute or chronic. Symptoms, physical examination, hemodynamics, and echocardiography all provide useful information for ascribing a severity grade (Table 60-11). Echocardiographic assessment is particularly important for guiding intraoperative decisions about the need for intervention and the adequacy of repair or replacement of the mitral valve. As with MS, several echocardiographic parameters, both two-dimensional and Doppler derived, can be used to grade the severity of MR (Table 60-12).

Pathophysiology The incompetent mitral valve allows retrograde passage of blood from the left ventricle into the LA during systole. The magnitude of the regurgitant volume is a function of the size of the regurgitant orifice, the pressure differential between the LA and the left ventricle, and the duration of the regurgitant cycle. Thus, higher systolic driving pressures, as in hypertension, can increase the regurgitant volume. Loading conditions are important as well, especially whenever functional changes in annular and LV geometry are important components of the mechanism of MR. These conditions should be considered during intraoperative evaluation of MR because anesthetic effects on afterload and preload can drastically alter the severity of MR from its baseline level, as seen during preoperative echocardiographic or catheterization assessment.

LV function and pressure tend to be normal in patients with chronic MR. The EF is often normal or supranormal unless the ventricle has decompensated with chronic MR or is acutely ischemic. A normal EF can be misleading, and masked ventricular dysfunction may be revealed after valve repair or replacement.

Table 60-11 Acute and Chronic Mitral Regurgitation

Characteristic	Chronic Compensated	Chronic Decompensated	Acute
Symptom onset	None	Gradual DOE	Abrupt CHF
Physical examination			
Blood pressure	Normal	Normal	↓
Pulmonary congestion	None	Variable	↑↑↑↑
Hemodynamics			
LA pressure	Normal	↑	↑↑
v wave	Absent	Variable	↑
Echocardiography			
LV size	↑	↑↑	Normal
LA size	↑	↑	Normal
MR jet v wave	Absent	Variable	↑

DOE, dyspnea on exertion; CHF, congestive heart failure; LA, left atrial; LV, left ventricular; MR, mitral regurgitation; arrows indicate relative increase (↑) or decrease (↓) in comparison to normal.
From Otto CM: Valvular heart disease: Prevalence and clinical outcomes. *In* Otto CM (ed): Valvular Heart Disease, 2nd ed. Philadelphia, WB Saunders, 2004, pp 1-17.

Table 60-12 Estimation of Severity of Mitral Valve Regurgitation

Method	Mild	Moderate	Severe
Secondary two-dimensional changes	Mild LAE	Moderate LAE	Severe LAE
Spatial area mapping with color Doppler	<4.0 cm^2	4.0-8.0 cm^2	>8.0 cm^2
Pulmonary venous flow profiles	Normal pattern, S waveform ≥ D waveform	Blunted pattern, S waveform < D waveform	Systolic flow reversal, S waveform < 0
Regurgitant volume	30-40 mL	40-60 mL	>60 mL
Regurgitant fraction	10%-30%	30%-50%	>55%
Regurgitant orifice area	<0.2 cm^2	0.3-0.4 cm^2	>0.4 cm^2
Vena contracta	≤0.3 cm		≥0.5 cm

LAE, left atrial enlargement; S, systolic; D, diastolic.
From Savage RM, Aronson S, Thomas JD, et al (eds): Comprehensive Textbook of Intraoperative Transesophageal Echocardiography. Baltimore, Lippincott Williams & Wilkins, 2005, pp 399-419.

The LA serves as a low-pressure pathway during systolic ejection, so EF overestimates ventricular function.

With acute onset of MR, LAP is elevated because there has been no time for left atrial compensatory changes to occur. A "v" wave may be present on the LAP, PAP, or PCWP recordings. In contrast, in chronic MR, the increases in LAP are less dramatic because of compliance changes in the LA as a function of chamber dilation.

The long-term sequelae of MR are related to chronic pressure and volume effects on the LA and left ventricle. The left ventricle is exposed to a chronic, isolated volume-overload state. Eccentric LV hypertrophy develops and causes chamber enlargement without significant increases in wall thickness. Forward cardiac output is preserved because of eccentric hypertrophy and the low impedance of the LA—a physiologic equivalent of afterload reduction. The larger stroke volume ejected by the left ventricle is composed of normal venous return into the LA plus the regurgitant volume from the previous cardiac cycle. In the early stages of MR, LVEDP is relatively normal because of compliance changes in the left ventricle. With time, however, compensatory eccentric hypertrophy fails to preserve LV systolic function, and gradual systolic failure ensues, as noted on pressure-volume loops (Fig. 60-24).

The LA is exposed to increases in volume and pressure. The LA dilates to compensate for the regurgitant volume during systole, and in the early stages of MR, preservation of nearly normal LAP and protection of the pulmonary vasculature is likely. Progressive left atrial enlargement commonly leads to AF, which occurs in about 50% of patients who are to undergo surgical correction of MR.[336] However, patients with MR appear to be at lower risk for thromboembolic complications than patients with MS are.[337] When LAP compliance thresholds are reached, LAP and PAP become elevated. Eventually, if chronically exposed to elevated PAP, the right ventricle progressively enlarges and RV dysfunction develops.

Anesthetic Management In anesthetic management of MR, the primary goal is maintaining forward systemic flow. In chronic, compensated MR, maintaining preload, judiciously

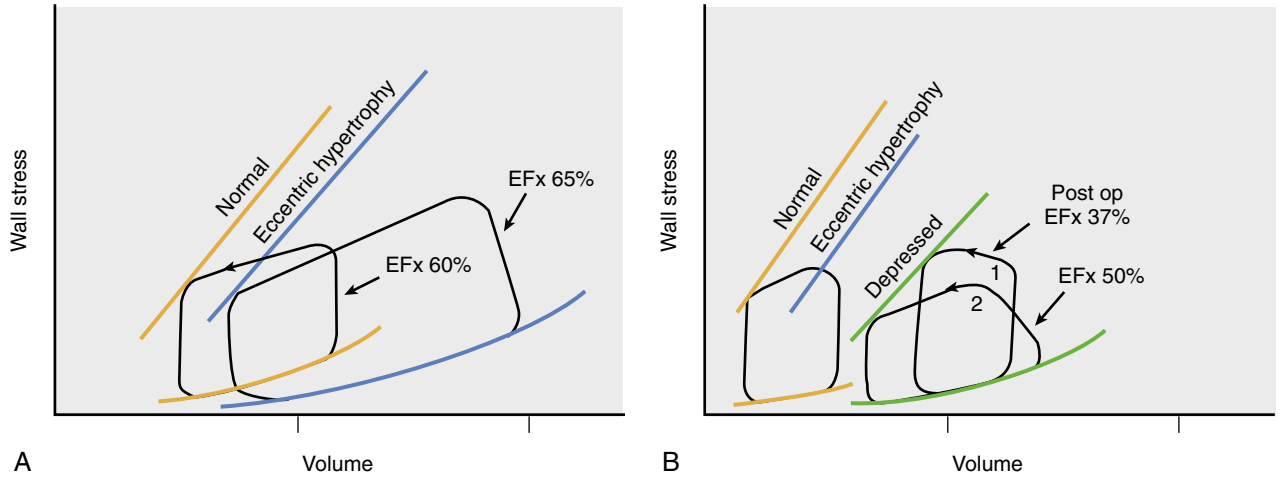

Figure 60-24 Diagram of wall stress-volume loops and end-systolic volume–wall stress relationships in severe mitral regurgitation. **A,** As in aortic regurgitation, the shift to the right of the diastolic and end-systolic relationships allows the volume-overloaded left ventricle to maintain a high stroke volume. Mean wall stress during ejection is somewhat reduced, and in mitral regurgitation the ejection fraction (EF) is high normal when contractility is normal. **B,** With the development of depressed contractility, the end-systolic wall stress–volume relationship is shifted to the right before surgery. Despite severely depressed contractility, the ventricle is able to deliver a nearly normal EF because of the very large ventricular volume and the relatively low mean wall stress during ejection (beat 2, ejection fraction = 50%). Contractility remains depressed after mitral valve replacement, and with correction of the low-impedance leak, the ventricle must now deliver the total stroke volume into the aorta against higher wall stress; the EF therefore falls to 37% (beat 1).

reducing afterload, and keeping the heart rate in the high-normal range may be adequate. General management goals can be summarized as follows:

PRELOAD As with most compensated forms of valvular heart disease, patients with hemodynamically significant MR are sensitive to ventricular loading conditions. Augmenting preload may be prudent in the interval before anesthetic induction. However, one must remember that MR is dynamic; ventricular distention can lead to expansion of an already dilated mitral annulus and thus worsen MR.

HEART RATE AND RHYTHM The heart rate should be maintained in the high-normal range (i.e., 80 to 100 beats/min). Bradycardia has dual detrimental effects on MR: it increases the duration of the systolic period, thereby prolonging regurgitation, and it increases the diastolic filling interval, which can lead to LV distention. A sinus rhythm is preferred, but there is less dependency on atrial kick than in stenotic valvular heart disease.

CONTRACTILITY In early compensated MR, LV contractility may be preserved. It is important to remember that EF indices are poorly correlated with LV systolic function in patients with moderate to severe MR and that underlying systolic dysfunction may be woefully underestimated. Hypotension in patients with significant MR can be managed to a certain degree by manipulating the heart rate and volume, but persistent hemodynamic instability may best be treated with inotropic support. Dobutamine, low-dose epinephrine, and milrinone are all acceptable inotropic choices, depending on the clinician's interpretation of the monitor data.

AFTERLOAD The general rule of thumb for patients with MR is to lower SVR so that forward cardiac output is maximized. Adequate anesthetic depth, systemic vasodilators, inodilators, and at times, mechanical reduction of afterload with an IABP may be clinical options, depending on the situation. Direct-acting α_1-agonists increase SVR and blood pressure, lower the heart rate, and may worsen the MR. Temporary use of small doses of ephedrine may be a better choice, after which inotropic support should be considered if there is a persistent need to augment pressure.

PULMONARY HYPERTENSION PAP and PVR may be elevated in patients with acute or long-standing MR. Secondary changes in RV size and function may be important clinical considerations. Factors that may increase PVR and unfavorably load an already dysfunctional right ventricle, such as hypoxia, hypercapnia, and acidosis, should be tested for and corrected whenever possible.

Finally, in the patient with acute severe MR and cardiogenic shock from ischemic rupture of a papillary muscle, pharmacologic support of the left ventricle, often accompanied by mechanical support with IABP counterpulsation, may be necessary.

Hypertrophic Obstructive Cardiomyopathy and the Mitral Valve

Classically, hypertrophic obstructive cardiomyopathy (HOCM) is a familial disease transmitted with autosomal dominant inheritance. Inheritance and phenotypic expression are heterogeneous and vary in manifestations. Some mutations in genes that code for cardiac sarcomere proteins can cause hypertrophy of segments of the ventricle. Septal involvement is common, but HOCM can involve other areas of the left ventricle as well. This disease is the most common cause of sudden cardiac death in young people, but it can also cause death and morbidity in older patients.

When the basal septum of the left ventricle is affected, the left ventricular outflow tract (LVOT) can narrow. Depending on the shape of the ventricle and the mitral valve, dynamic outflow tract obstruction can occur, paired with mitral valve insufficiency. As the outflow tract is narrowed by hypertrophy, the basal septum and the anterior leaflet of the mitral valve come into close proximity. The hypertrophy and the reduced septal-anterior leaflet distance can create a channel that narrows to the point of creating a pressure gradient across the outflow tract. This obstructed flow and its pressure gradient lead to progressive compensatory hyper-

trophy, which in turn further narrows the outflow tract and worsens the gradient. As blood is ejected through this narrowed outflow channel during systole, the velocity of blood increases through the narrowed orifice. This increased blood velocity creates a Venturi effect that pulls the anterior leaflet of the mitral valve or the chordal structures into the outflow tract, which results in mechanical and dynamic obstruction of the LVOT and MR because of a coaptation defect of the mitral valve. Echocardiographically, this is termed systolic anterior motion (SAM) of the mitral valve. Such dysfunctional mitral valve motion is seen in cardiac surgical patients who come for surgical management of known HOCM (i.e., for surgical myomectomy, mitral valve repair, or both).

Sometimes, SAM is noted preoperatively or as an incidental finding at the time of surgery in patients undergoing surgical revascularization or mitral valvular surgery. Furthermore, SAM may be created iatrogenically as a result of surgical mitral valve repair. In patients with MR who are to undergo mitral valve repair, echocardiographic assessment and surgical inspection are performed to elucidate the mechanism of the mitral insufficiency. There may be ruptured or elongated chordal attachments, redundant or prolapsing leaflet tissue, or annular dilation that reduces effective leaflet coaptation. Frequently, multiple contributing factors are present. Surgical treatment can involve just a simple annuloplasty ring in the case of isolated annular dilation, but it more commonly involves resection of diseased segments of the mitral valve, possibly chordal reassignment or reconstruction, and a ring valvuloplasty. Depending on LV geometry and size and the physical characteristics of the mitral valve, surgical repair may bring the anterior leaflet and the coaptation point of the valve into close approximation with the interventricular septum and the LVOT. That septal coaptation point can narrow enough to create a gradient in the outflow tract so that the anterior leaflet is pulled into the LVOT by the Venturi effect, thereby leading to obstruction and secondary mitral insufficiency. Discovery of this anterior displacement of the mitral coaptation point has led to the development of techniques for identifying patients at risk for this complication, as well as to the development of alternative surgical strategies, such as the sliding annuloplasty repair[338] and the Alfieri double-orifice repair technique,[339] to minimize its occurrence in patients with at-risk anatomy. Risk factors for postrepair SAM and outflow tract obstruction have been delineated in studies by Lee,[340] Maslow,[341] and their colleagues.

Anesthetic management of obstructive cardiomyopathy centers on fluid and pharmacologic interventions to decrease the magnitude of the obstruction and, at the same time, lessen the severity of the mitral insufficiency. Most patients with outflow tract abnormalities have normal to supranormal contractility. Generally, inotropic agents should not be used. The thick, hypertrophied ventricle usually has reduced compliance and is very load sensitive, so outflow tract obstruction increases in hypovolemic conditions. Optimizing preload and ventricular filling is appropriate in managing a patient with outflow tract obstruction and in assessing the need for surgical reconstruction of the LVOT, repair of the mitral valve, or both. Afterload reduction should be avoided because it worsens the obstruction. Conversely, increasing afterload decreases the trans–outflow tract gradient, which leads to a reduction in SAM and outflow tract obstruction. Hence, vasoconstrictors such as phenylephrine and vasopressin should be considered. In both congenital and iatrogenic LVOT obstruction, the degree of obstruction is dynamic. Obstruction is exacerbated by hypercontractile states and elevations in heart rate; therefore, reducing the heart rate with β-adrenergic blockade should be considered.

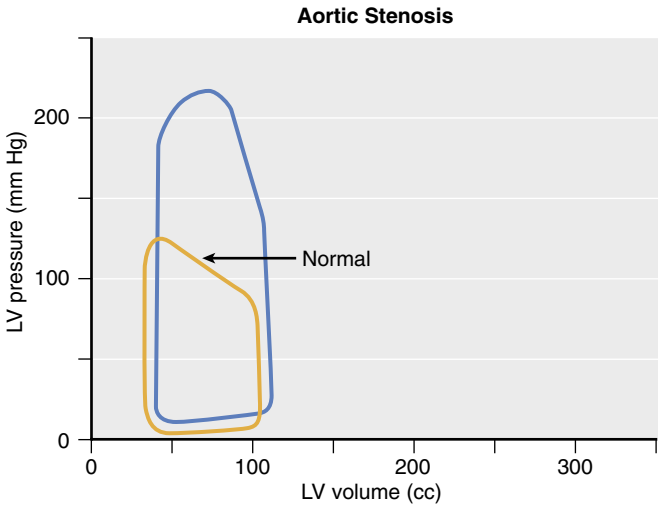

Figure 60-25 Pressure-volume loop in aortic stenosis. *(Adapted from Jackson JM, Thomas SJ, Lowenstein E: Anesthetic management of patients with valvular heart disease. Semin Anesth 1:239, 1982.)*

Continuous, skilled echocardiographic assessment and interpretation are important for optimal intraoperative management of these patients. Assessing the severity and mechanism of outflow tract obstruction and possibly the need to return to bypass to revise the repair or replace the valve are not innocuous decisions and they must be carefully made jointly by the anesthesiologist and the surgeon, ideally with input from the appropriate cardiologist.

Aortic Valvular Disease

Aortic Stenosis

PATHOPHYSIOLOGY Aortic stenosis (AS) is the most common cardiac valve lesion found in the United States. Figure 60-25 shows a typical pressure-volume loop for a patient with AS. The peak pressure generated by the left ventricle during systole is much higher because of the high transvalvular pressure gradient. Concentric LV hypertrophy develops as a result of the increase in pressure load (Fig. 60-26).

Aortic stenosis is usually caused by congenital defects in the valve because 1% to 2% of the population are born with a bicuspid aortic valve. Inheritance has been found to play a role, with an autosomal dominant pattern and variable penetrance.[342,343] A bicuspid aortic valve that does not yet show any signs of damage nevertheless tends to open and close with abnormal folding and creasing, thereby leading to scarring and calcification and ultimately culminating in AS with or without aortic regurgitation (AR). Although patients with a bicuspid aortic valve are asymptomatic until late in the disease process, severe, symptomatic AS or AR may develop in midlife. In addition, the abnormal motion of these bicuspid leaflets causes some turbulent flow into the aorta, which can eventually lead to dilatation and subsequent rupture or dissection.

Acquired AS is usually due to senile degeneration with sclerosis and calcification of the valve. There is a clear association between clinical risk factors for atherosclerotic disease and the

development of AS, including the process of chronic inflammation. The prevalence of AS increases with age; it is now seen in 2% to 4% of adults older than 65 years, and this prevalence is expected to increase.[344] In developed countries, rheumatic disease is a less common cause of AS, and it is usually associated with concomitant AR.

Anesthetic Management Premedication may alleviate a patient's anxiety regarding cardiac surgery, and it helps prevent perioperative tachycardia in patients with AS. Monitoring for these patients includes standard noninvasive modalities and invasive monitoring of blood pressure and CVP. Depending on the severity of the AS, the arterial line tracing can show some typical changes. Pulse pressure may be as low as 50 mm Hg or less. The upslope of the trace is delayed and has a prominent anacrotic notch, which occurs at a lower level as the severity of AS increases, whereas the dicrotic notch reduces in size or even disappears with progression of the disease. Insertion of a PA catheter may be considered for monitoring PAP and cardiac output during surgery and particularly in the postoperative period. A TEE probe is nearly always desirable if there are no contraindications to its placement.

Anesthetic management of patients with AS revolves around avoiding fluctuations in the patient's hemodynamics while achieving adequate anesthetic depth. Induction of anesthesia should not involve any medication that might have negative inotropic or vasodilatory effects. Any agents that might cause tachycardia should also be avoided. Furthermore, every effort should be made to ensure that the patient stays in sinus rhythm. In patients with AS, the "atrial kick" may contribute as much as 40% of the total cardiac output.[345] Therefore, to treat any possible arrhythmia, external cardioversion pads should be considered, preferably before induction of anesthesia.

Finally, it is important to realize that the presence of severe AS reduces the usefulness of cardiopulmonary resuscitation (CPR) for maintaining a cardiac output sufficient to meet the patient's physiologic needs. Table 60-13 summarizes the goals of anesthetic care of a patient with AS.

Aortic Regurgitation

Pathophysiology AR is flow of blood from the aorta backward into the left ventricle during the diastolic phase of the cardiac cycle. The overall prevalence of AR was noted to be 13% in men and 8.5% in women in the Framingham Offspring Study.[346] Chronic AR is more prevalent and carries a much better prognosis than acute AR does. However, the precise prevalence of AR—acute and chronic—remains unknown.[347]

Chronic and acute AR each have their own etiology. Causes of chronic AR include congenital lesions, degenerative processes, and rheumatic disease, but idiopathic causes seem to be the most common.[347] These processes cause malcoaptation of the aortic valve leaflets by causing abnormalities in the leaflets themselves or dilation of the aortic valve annulus, the aortic root, or both.[347]

Abnormalities of the aortic valve leaflets include congenital conditions (e.g., bicuspid aortic valve), endocarditis, rheumatic disease, inflammatory diseases, certain connective tissue diseases, and chest wall trauma causing injury to an aortic valve leaflet. Dilation of the proximal aortic root may be caused by annuloaortic ectasia resulting from long-term chronic hypertension or simply from the normal aging process. Other aortic valve annular or aortic root causes of AR include Marfan's syndrome, syphilis, connective tissue diseases, congenital diseases such as osteogenesis imperfecta and Ehlers-Danlos syndrome, and idiopathic causes.

Chronic Aortic Regurgitation Patients with chronic AR may remain asymptomatic for years or even decades. The left ventricle undergoes a process of remodeling caused by series replication of sarcomeres and the development of eccentric ventricular hypertrophy and chamber enlargement in the face of a chronically increasing volume of regurgitation (Fig. 60-26).[348] Although the pressure-volume loop is shifted far to the right in patients with chronic AR, LVEDP remains relatively normal because LDEDV increases slowly (Fig. 60-27). Forward flow is improved by peripheral vasodilation. Typically, a normal EF is maintained by a large stroke volume. However, over time, increases in LV wall stress and afterload result. Eventually, as LV dilation and hypertrophy progress, irreversible LV dysfunction develops, and patients become symptomatic. As a compensatory mechanism for poor cardiac output, sympathetic constriction of the peripheral vasculature occurs to maintain blood pressure, but this adaptation results in worsening of regurgitation and cardiac output.

Although patients with chronic AR can remain asymptomatic for decades, afterload reduction may become necessary as the disease progresses. A critical question that remains unanswered is at what point in the course of the disease should surgery be performed to prevent the development of irreversible LV dysfunction, especially in patients with severe chronic AR.[347]

Acute Aortic Regurgitation Acute AR is less common than chronic AR but carries a more ominous prognosis. Common causes of acute AR include trauma, bacterial endocarditis, and aortic dissection. Rarely, acute AR occurs as an idiopathic complication, such as after aortic valvuloplasty.[347] The pathophysiology of acute AR centers around the fact that it causes an acute increase in the volume coming into the left ventricle. Because the left ventricle has not had time to undergo the process of eccentric hypertrophy as it does in chronic AR, it is unprepared to accommodate this sudden increase in volume. As shown in Figure 60-27, this sudden increase in LVEDP causes a rightward shift in the pressure-volume loop.[348] A sympathetic response is activated; tachycardia and an increased contractile state are the chief compensatory mechanisms for maintaining adequate cardiac output.

Table 60-13 Goals for Anesthetic Care of Patients with Aortic Stenosis and Aortic Regurgitation

	Left Ventricular Preload	Heart Rate	Contractile State	Systemic Vascular Resistance	Pulmonary Vascular Regurgitation
Aortic stenosis	↑	↓ (sinus)	Maintain	↑	Maintain
Aortic regurgitation	↑	↑	Maintain	↓	Maintain

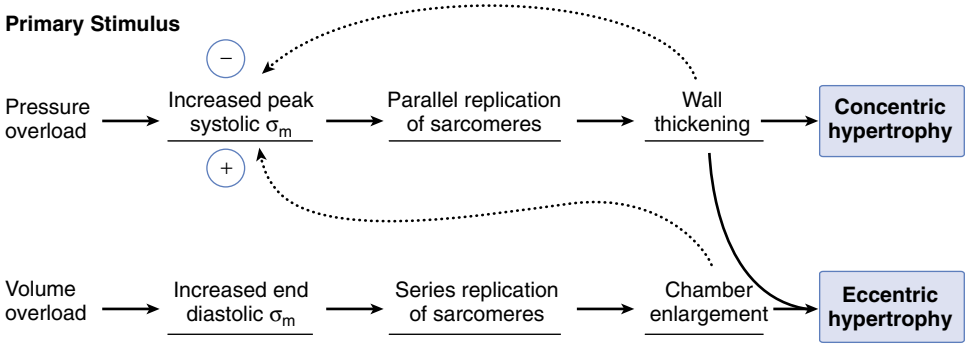

Figure 60-26 The increased peak systolic wall stress resulting from chronic pressure overload directly stimulates concentric ventricular hypertrophy, which tends to counteract or "normalize" the elevated ventricular wall stress. *(From Grossman W, Jones D, Mclaurin LP: Wall stress and pattern of hypertrophy in the human left ventricle. J Clin Invest 56:56, 1975.)*

Unless the AR is managed appropriately, these compensatory mechanisms rapidly fail. Furthermore, the sympathetic response also causes sympathetic constriction of the peripheral vasculature, thereby increasing SVR and further worsening the AR. LV function can deteriorate rapidly and necessitate emergency surgery. Vasodilator therapy may temporarily stabilize the patient during transport to the operating room.[347,349]

Anesthetic Management Anesthetic management of patients with AR should include maintenance of a relatively fast heart rate (approximately 90 beats/min) and a relatively low SVR while maintaining preload and contractility. Light premedication is recommended. Table 60-13 shows the anesthetic goals for inducing and maintaining anesthesia in patients with AR. In considering the choice of drugs for general anesthesia in these patients, medications that cause bradycardia or high blood pressure should be avoided because these changes worsen the degree of AR and can precipitate LV failure.

Preoperative placement of an arterial line is standard. During surgery and in the postoperative period, "high" arterial blood pressure is avoided in patients who undergo aortic valve replacement because the aortic incision creates the possibility of bleeding or aortic dissection. A central line is standard, and a PA catheter may be considered for monitoring cardiac function during and after the operation. In the prebypass period, TEE allows the anesthesiologist to ascertain the cause of the AR, assess the severity of the AR, and determine LV size and function. Furthermore, TEE assessment in the immediate postbypass period confirms proper positioning and function of the new valve.

Weaning from CPB may be complicated by preexisting LV dysfunction. Furthermore, mechanical aortic valve replacement results in a mild transvalvular pressure gradient. Therefore, inotropic agents may be needed to improve LV function. Preload augmentation must be continued to maintain filling of the dilated left ventricle.

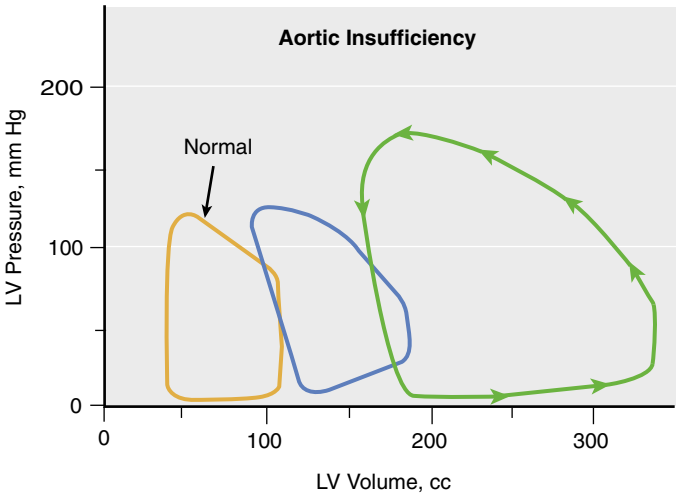

Figure 60-27 Pressure-volume loop in aortic regurgitation (AR). Acute AR, middle loop; chronic AR, right loop. *(Adapted from Jackson JM, Thomas SJ, Lowenstein E: Anesthetic management of patients with valvular heart disease. Semin Anesth 1:239, 1982.)*

Other Valvular Disease

Tricuspid Valve Disease

Tricuspid Regurgitation Right-sided valvular disease in adults is most often a manifestation of pulmonary hypertension secondary to intrinsic lung disease, pulmonary vascular disease, or left-sided cardiac disease. Primary TR can be rheumatic, traumatic, or infectious. Secondary or functional TR can be a manifestation of cor pulmonale, primary pulmonary hypertension, or left-sided cardiac disease that results in elevated pulmonary vascular pressure.

Tricuspid valvular disease is predominately regurgitant in nature. Patients with significant TR may have symptoms of dyspnea and evidence of elevated RA pressure (e.g., hepatomegaly, peripheral edema). Compensatory changes with long-standing TR involve RV and RA chamber dilation. Because of RA enlargement, many patients exhibit AF. Long-standing TR and RV enlargement can result in RV systolic dysfunction, which leads to further chamber enlargement, tricuspid annular dilation, and worsening of TR severity. If the tricuspid insufficiency is secondary to RV pressure overload states, as with pulmonary hypertension, RV hypertrophy ensues. This hypertrophy and increased RV pressure can lead to leftward displacement of the interventricular septum and impaired LV systolic and diastolic performance.

Anesthetic management concerns include preload preservation and appropriate inotropic support as dictated by the clinical situation. If the TR is secondary to elevations in pulmonary vascular pressure or resistance, efforts to reduce PVR will be beneficial. Forward flow can be maximized by high-normal heart rates. Surgical annuloplasty, although usually successful, can leave

residual TR or may create an elevated pressure gradient across the tricuspid valve.[350]

Tricuspid Stenosis Tricuspid stenosis (TS) is a relatively rare clinical finding in adults. Patients with TS may have significant RA enlargement and possibly AF. Chronic elevation of RA pressure leads to inferior vena cava dilation, jugular venous distention, and hepatic congestion. Clinical symptoms and signs can include hepatomegaly (with or without hepatic dysfunction), ascites, peripheral edema, fatigue, and dyspnea.[350,351]

TS results in reduced RV filling. The normal tricuspid valve area is 7 cm^2, and ventricular filling is compromised once the valve area falls below 1.5 cm^2. The severity of TS is usually assessed echocardiographically by measuring the Doppler-derived transvalvular gradient. Mild TS is associated with a gradient of 2 mm Hg or less; moderate TS, 2 to 6 mm Hg; and severe TS, greater than 6 mm Hg.

Anesthetic management centers on maintaining preload and controlling the heart rate. Overt tachycardia should be avoided because it significantly shortens the interval for diastolic filling, which needs to be prolonged in these patients. The target heart rate is not frank bradycardia because cardiac output may not be optimal, but the heart rate should be in the low-normal range. When AF is not part of the clinical picture, preserving atrioventricular synchrony is important to maintain RV output. Although RV inotropic failure is not usually a major concern in isolated TS, it may be when TS is a part of multivalvular heart disease or ischemic heart disease, thus warranting consideration of inotropic support. SVR should be maintained because the obstruction at the level of the tricuspid valve prevents a compensatory increase in preload if afterload declines.

Pulmonic Valve Disease

Pulmonic Stenosis Pulmonic valvular disease can be congenital or acquired. Pulmonic stenosis (PS) is caused by congenital valve abnormalities in 95% of cases.[350] Elevated transvalvular pressure gradients lead to RV hypertrophy, dilation, and eventual failure. Treatments include balloon valvuloplasty, surgical valvotomy, and valve replacement. Subvalvar muscular infundibular obstruction can result from long-standing PS. Tachycardia and hypovolemia can precipitate a dynamic clinical scenario in which outflow tract obstruction is accentuated. Management strategies include judicious heart rate control, preload maintenance, and inotropic support if RV systolic failure occurs.

Pulmonic Insufficiency Pulmonic insufficiency (PI) can result from the pulmonic valves being rendered incompetent during childhood balloon valvuloplasty for congenital PS or surgical valvotomy for the tetralogy of Fallot or its variants. PI may also be associated with rheumatic heart disease, pulmonary embolism, carcinoid, trauma, Marfan's syndrome, idiopathic dilation of the pulmonary trunk, and endocarditis.[350] Most patients are asymptomatic, but long-standing severe PI can lead to symptomatic RV dilation and failure, thus warranting replacement of the pulmonary valve.

Anesthetic management concerns include consideration of the primary cardiac or pulmonary disease that led to the pulmonic valvular insufficiency (e.g., endocarditis, emboli, and multifactorial causes of pulmonary hypertension). In primary PI, anesthetic management goals may include maintaining preload, supporting contractility, and reducing PVR by lowering $Paco_2$ and increasing Fio_2.

Minimally Invasive Procedures

Minimally invasive valve surgery was first reported by Cosgrove and Sabik[352] in 1996. In 1998, these investigators followed up with a summary report of 100 patients who underwent minimally invasive valve surgery through a right parasternal approach.[353] This report included 72 aortic and 28 mitral valve operations, and it described minimally invasive valve surgery as safe and "effective in reducing surgical trauma and cost." Reported benefits included improved cosmetic appearance, reduced pain, improved respiratory function, earlier extubation, less bleeding, fewer transfusions, and a safer approach for reoperative sugery.[353] Mihaljevic and colleagues,[354] who published a series of 1000 minimally invasive valve operations performed between 1996 and 2003, noted similar benefits, including reduced bypass and cross-clamp times, reduced stroke and MI rates, reduced length of hospital stay, and a higher rate of discharges home rather than to another facility. Other authors agree that minimally invasive valve surgery has evolved into a safe and efficacious option for many patients.[355]

Minimally Invasive Aortic Valve Surgery

The surgical approach to the aortic valve can be made through several different incisions, including a right parasternal incision, upper hemisternotomy, or lower hemisternotomy. A surgical decision may be made to perform femoral arterial cannulation. Alternatively, aortic cannulation may best be accomplished through an incision directly into the aorta or the axillary artery, particularly if aortic atheromatous disease precludes retrograde aortic arterial flow or direct cannulation of the ascending aorta. Venous bypass drainage can be accomplished by cannulating the RA (if surgical exposure is not compromised) or the femoral vein. Positioning of the distal drainage portion of the femoral vein cannulas into the inferior vena cava, RA, or distal segment of the superior vena cava is guided and confirmed by TEE (Fig. 60-28).

To reduce the incidence and magnitude of retained intracavitary LV air, CO_2 gas can be insufflated into the surgical field. Because surgical exposure is limited, sterile transcutaneous defibrillator pads should be placed, should the need to defibrillate arise. Other surgical and anesthetic concerns about the conduct of CPB and care of the patient are similar to those discussed in the sections on aortic valve surgery and CPB.

In general, anesthetic monitoring considerations are similar to those for standard approaches to valvular heart surgery.

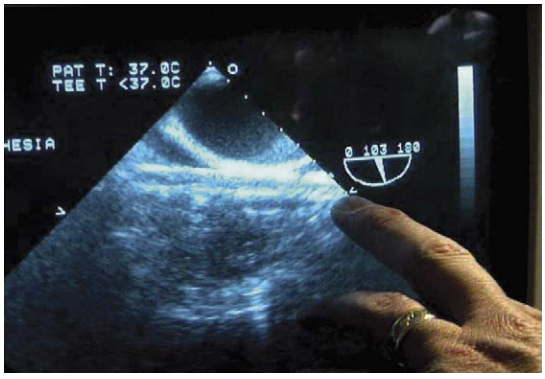

Figure 60-28 Venous cannula placement through inferior vena cava (IVC)–right atrium into the superior vena cava (SVC).

However, in the absence of direct visualization, TEE is even more valuable in these procedures because of the importance of assessing bypass cannula placement and ensuring adequate ventricular de-airing. If retrograde cardioplegia is required, TEE may be used to guide a transjugular retrograde catheter into the coronary sinus.

A recent report of a large series of minimally invasive aortic valve procedures included more than 900 patients.[356] The authors reported lower mortality rates than the national average, decreased blood product use (with 53% of first-time aortic valve surgery patients receiving no blood products), an average length of hospital stay of 6.9 days, and higher rates of discharge home (including 40% of their octogenarian patients).[356]

Minimally Invasive Mitral Valve Surgery

The mitral valve can be accessed through a lower hemisternotomy, a right parasternal incision excising the cartilaginous portions of the third and fourth ribs, or a right thoracotomy. The mitral valve is then exposed through the LA or via a "transseptal" approach through the RA. Visualization of the valve for repair or replacement can be done by direct inspection and instrumentation; by "port access" under thoracoscopic guidance and video assistance, which can involve voice-activated, robotic movement of the thoracoscopic instruments; or by a more complete endoscopic technique using the DaVinci robotic system (Intuitive Surgical, Inc., Sunnyvale, CA). The DaVinci system uses robotic arms and instrumentation controlled by the surgeon sitting at a remote computer-enhanced three-dimensional imaging console to assist in completion of the surgery.

Endoscopic or minimally invasive mitral procedures usually involve CPB with aortic and venous cannulas placed via the femoral artery and vein. In addition, the surgeon may choose to use novel aortic occlusion devices that allow a bloodless operative field and delivery of cardioplegia. However, the Heartport endoaortic occlusion and cardioplegia delivery catheter is challenging to position in the aortic root and requires intraoperative fluoroscopy or echocardiography to regularly confirm the catheter's position. Known concerns and risks include migration of the catheter into the heart across the aortic valve and distal migration with occlusion of the brachiocephalic trunk. Alternatively, aortic occlusion can be applied directly with flexible cross-clamps introduced through small chest wall incisions. Cardioplegia needles may be inserted via direct visualization or under thoracoscopic guidance. Retrograde cardioplegia, although not necessarily used in all patients, can be accomplished by direct cannulation of the coronary sinus with a retrograde catheter in the operative site (right atrial approach) or through the use of a percutaneous coronary sinus catheter placed in the internal jugular vein and positioned under echocardiographic guidance.

Secondary operative considerations include the unique space/positioning required for the use of robotic instrumentation. Most minimally invasive approaches require a 30-degree "right side up" position.

In general, monitoring considerations are similar to those for standard approaches to valvular heart surgery, including a five-lead ECG, an invasive arterial catheter, and central venous access. Adequate surgical visualization often necessitates offering selective lung ventilation using a double-lumen tube or bronchial blocker. As noted with minimally invasive aortic valve surgery, the surgeon and anesthesiologist must rely heavily on TEE imaging.

Outcomes of minimally invasive mitral valve surgery have been encouraging. Reports of the Brigham experience describe mortality and morbidity rates comparable to those of full-sternotomy approaches and trends toward a reduced length of hospital stay and a higher rate of discharge home.[354,355] Although prospective trials comparing minimally invasive mitral valve surgery and standard approaches are limited, a phase II randomized multicenter trial of the DaVinci robotic system has shown the technology to be efficacious and safe while acknowledging that it entails a "learning curve."[355,357]

Other Uses of the Minimally Invasive Approach

Minimally invasive approaches can also be used to surgically treat tricuspid valve disease and atrial septal defects. Newer developments in operative treatment of ischemic heart disease have led to the consideration of "hybrid" operative and percutaneous therapies in patients with multivessel coronary artery disease. Additionally, some clinicians have attempted to combine minimally invasive valvular surgery with percutaneous catheter intervention for coexisting ischemic heart disease.[358]

Notably, early trials of Heartport technology with endoaortic occlusion catheters showed an elevated risk for intraluminal aortic injury and aortic dissection.[359,360] These reports were confirmed by the Port-Access International Registry, which showed initial trends toward higher dissection rates.[361] However, later series showed no increase in complication rates, perhaps because of increasing surgical experience.[362] At this time, the Heartport technology is still in use in some centers for port-access mitral valve surgery, and the endoaortic occlusion technology may offer an alternative when standard aortic cross-clamping is contraindicated.[363]

Heart Failure

HF has been defined as a complex clinical syndrome caused by any structural or functional cardiac disorder that impairs the ability of the ventricle or ventricles to maintain adequate cardiac output and thereby results in hemodynamic changes that perturb many neuroendocrine, humoral, and inflammatory feedback loops (Box 60-4). In the United States, more than 5 million people have HF, and its prevalence is estimated at 6.8% in people older than 65 years.

The ACC/AHA guidelines for the evaluation and management of chronic HF place patients in four classes based on the stages of the syndrome (Table 60-14).[364] Early in the course of the disease, ventricular contractility is maintained by adrenergic stimulation and activation of the renin-angiotensin-aldosterone and other neurohormonal and cytokine systems[365,366]; patients in this stage would be considered to be in ACC/AHA class B. However, these compensatory mechanisms become less effective over time, and ventricular dilation and fibrosis occur and cardiac function deteriorates. This produces a chronic state of low perfusion and refractory end-stage HF, labeled class D in the ACC/AHA classification scheme. The New York Heart Association (NYHA) functional classification system is also used to assess the severity of functional limitations and correlates fairly well with prognosis (Table 60-15).

Strategies for treating end-stage HF aim to limit disease progression, prolong life, and improve quality of life. Medical therapies, such as ACEIs, β-blockers, diuretics, inotropic agents,

and antiarrhythmics, represent the usual standard of care for HF patients. However, even multidrug regimens may not prevent progression toward class D HF. A patient who has reached this category has a 2-year mortality risk greater than 75%; surgical intervention is the only effective treatment in these patients.

Heart Transplantation

According to the ACC/AHA guidelines, the only established surgical treatment option for advanced HF is cardiac transplantation,[364] which is associated with excellent 1-year survival rates (>85%), 5-year survival rates (70%), and functional capacity.[367] Discovery of the immunosuppressive agent cyclosporine in the early 1980s made cardiac transplantation an accepted surgical option for end-stage HF.[368] Since then, techniques for detecting and grading the extent of rejection have been refined, and immunosuppressive protocols have been further improved. Furthermore, newer immunosuppressants are being evaluated.[369] Early graft failure as a result of acute rejection is now rare, but late graft failure secondary to transplant coronary artery disease remains problematic. Repeat cardiac transplantation is not rare, and even third-time transplantation may be justified.

Table 60-14 ACC/AHA Classification of Chronic Heart Failure

Stage	Description
A—High risk for heart failure	Hypertension, diabetes mellitus, CAD, family history of cardiomyopathy
B—Asymptomatic heart failure	Previous MI, LV dysfunction, valvular heart disease
C—Symptomatic heart failure	Structural heart disease, dyspnea and fatigue, impaired exercise tolerance
D—Refractory end-stage heart failure	Marked symptoms at rest despite maximal medical therapy

ACC/AHA, American College of Cardiology/American Heart Association; CAD, coronary artery disease; LV, left ventricular; MI, myocardial infarction.

A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Revise the 1995 Guidelines for the Evaluation and Management of Heart Failure): Developed in Collaboration with the International Society for Heart and Lung Transplantation; Endorsed by the Heart Failure Society of America. Circulation 104:2996-3007, 2001.

Table 60-15 New York Heart Association Heart Failure Symptom Classification System

NYHA Class	Level of Impairment
I	Ordinary physical activity not limited by symptoms
II	Ordinary physical activity somewhat limited by dyspnea
III	Exercise limited by dyspnea during a mild workload
IV	Dyspnea at rest or with very little exertion

Most candidates for cardiac transplantation have idiopathic or ischemic cardiomyopathy; less common diagnoses include viral cardiomyopathy, postpartum cardiomyopathy, refractory valvular disease, primary myocardial diseases (e.g., sarcoidosis, amyloidosis), drug-induced myocardial disease, and complex congenital heart disease (CHD) in adults. All patients on the transplant waiting list have had a recent multidisciplinary evaluation, including history taking and physical examination, routine hematologic testing, serum chemistry panels, viral serologic testing, electrocardiography, echocardiography, chest radiography, right- and left-heart catheterization, and pulmonary function tests. The goal of the evaluation is to confirm a diagnosis of class D HF that has been maximally treated but will result in death in less than 1 year.

In the United States, cardiac transplantation is performed in member centers of the United Network for Organ Sharing (UNOS), an umbrella organization responsible for coordinating organ procurement, organ allocation, and statistical information. The UNOS selection guidelines for cardiac transplantation give priority to patients with end-stage HF and a life expectancy of less than 1 year, such as patients in cardiogenic shock or a low-output state requiring mechanical or inotropic support, patients with advanced symptomatic HF and peak oxygen uptake less than 10 mL/kg/min (with achievement of an anaerobic threshold), patients with NYHA class IV HF because of advanced hypertrophic or restrictive cardiomyopathy, patients with refractory angina pectoris caused by inoperable coronary artery disease, and patients with life-threatening ventricular arrhythmias that are refractory to all appropriate medical and surgical treatment.[370] Usually, the patient's EF is less than 20%. However, patients with NYHA class III HF who are at risk for sudden death related to malignant arrhythmias are sometimes placed on the waiting list.

Assessing PVR and "reversibility" is also important. Patients with ischemic or idiopathic cardiomyopathy and increased LAP often have reversible elevated PVR, a condition that usually normalizes during the first week after heart transplantation. A pressure gradient across the vascular bed (also known as a transpulmonary gradient and calculated as the difference between mean PAP and mean PCWP) that is higher than 14 mm Hg indicates significant elevation of PVR. A reduction in PCWP to 20 mm Hg that occurs during treatment with pulmonary vasodilatory medication and is associated with persistent high PAP sug-

gests elevated PVR. A PVR that is higher than 5 dyne·sec·cm^{-5} and is unresponsive to pulmonary vasodilators indicates a major "fixed" component of vascular resistance, a condition associated with an increased risk for early mortality after orthotopic heart transplantation.[371]

The UNOS allocates donor hearts according to each patient's priority status, ABO group compatibility, body size match, and distance from the donor center. The highest priority is given to inpatients supported by mechanical circulatory assist devices for acute hemodynamic decompensation, patients maintained on assist devices who have significant device-related complications, patients requiring continuous infusion of single or multiple high-dose intravenous inotropic medications, and those with a life expectancy of less than 7 days without transplantation.

In recent years, the selection criteria have been broadened for both heart recipients and heart donors.[372] For example, HF patients in two previously excluded categories—those with diabetes and those older than 65 years—are now considered transplantation candidates in many centers.[369] In addition, although centers generally prefer donors to be younger than 35 years, these criteria have been expanded to include suitable donors (e.g., those without cardiac risk factors or evidence of coronary artery disease) who are 60 years or older.

Once a prospective donor has been identified, the accepting center must ensure that the heart is further evaluated by echocardiography and possibly by coronary angiography. Cardiac donors are accepted after careful determination of the extent of hypotension, hypoxia, and tissue trauma and after confirmation of brain death and organ viability. Echocardiography is an essential tool for donor evaluation, particularly after the patient is weaned from inotropic support. Echocardiography can be used to assess global and segmental wall motion abnormalities, RV function, valve function, the presence of a patent foramen ovale, and the presence of intracardiac air. Mild LV hypertrophy is usually acceptable. Mitral valve prolapse is common and does not contraindicate donation unless it causes severe MR.

Ideally, the donor does not have major hemodynamic or metabolic derangements requiring continuous high-dose inotropic support.[373] Frequently, the donor has been selected for multiorgan donation, and the heart procurement team must potentially coordinate with the kidney, liver, and lung procurement teams. The anesthesiologist's main concerns are to maintain hemodynamic stability and euvolemia, ideally with systemic blood pressure greater than 100 mm Hg and CVP of 8 to 12 mm Hg, and to maintain arterial blood gases within normal limits, with Pa_{O_2} greater than 100 mm Hg.

In the donor, after a median sternotomy, myocardial function is carefully evaluated, and the heart is inspected for abnormalities. The other teams are then allowed to dissect the remaining organs to be harvested. Systemic heparinization is achieved (300 U/kg), the superior vena cava is ligated, and the inferior vena cava is transected. The aorta is cross-clamped, the heart is decompressed, and cold (4°C) cardioplegia solution is infused. The heart is then removed and prepared for transport: it is placed in a sterile plastic bag that is placed inside another bag filled with ice-cold saline. This package is then carried in an ice chest. The upper time limit between harvesting and reimplantation of the heart is thought to be approximately 6 hours.[373]

Therefore, from the anesthesiologist's perspective, the preoperative period is often limited by important time constraints because induction should be timed so that CPB can commence immediately on arrival of the donor heart. Nevertheless, the preoperative evaluation should include all aspects of a routine urgent preanesthetic evaluation, including a quick inspection of the results of the most recent cardiology workup and collection of information about any recent cardiac decompensation, history of previous surgical procedures, the presence of an implantable cardioverter-defibrillator (ICD) that must be deactivated in the operating room just before or after anesthetic induction, current laboratory values, and last oral intake.

Orthotopic heart transplantation is performed via a median sternotomy. Because many recipients have had one or more previous cardiac surgical procedures, repeat sternotomy is carefully performed with an oscillating saw. The groin is prepared and draped to provide a rapid route for CPB cannulation, should it become necessary. After the pericardial incision, heparin (300 U/kg) is administered. Cannulas for CPB are placed in the ascending aorta and in the venae cavae via the RA.[369] After CPB is initiated, systemic hypothermia (28°C to 30°C) is instituted. The native heart is excised at the midlevel of the atria. The donor and recipient left atria are anastomosed first, followed by the right atria. Commonly, the superior and inferior venae cavae are anastomosed directly, and the LA is excised down to the entry of the pulmonary veins (Fig. 60-29). While systemic rewarming is begun, the PA and ascending aorta are anastomosed. Air is then aspirated from the heart, and TEE is used to ensure that the cardiac chambers are adequately de-aired before the patient is weaned from CPB. A dose of steroid (methylprednisolone) is administered as the last anastomosis is completed, before release of the aortic cross-clamp, to attenuate the immune response.[373] Lymphocyte depletion may be achieved with an infusion of polyclonal antithymocyte globulin, a preparation containing various amounts of specific antibodies directed against T-cell molecules, B-cell molecules, monocytes, macrophages, neutrophils, platelets, and endothelial cells.

If the donor heart fails to resume normal sinus rhythm, electrical cardioversion should be performed. Many patients need an infusion of an inotropic and chronotropic agent during reperfusion and weaning from bypass. If the heart rate is slow, isoproterenol or dobutamine is infused, and a temporary pacing wire is routinely placed on the right ventricle; pacing is usually set at 100 beats/min.[369] Weaning from CPB begins after ventilation is resumed and the cannula is removed from the superior vena cava. When the patient is separated from CPB, the PA catheter can be advanced into position.

Several complications can occur during the process of weaning a patient from CPB. RV failure is by far the most common cause of inability to wean from CPB and it carries a significant risk of mortality and morbidity. The donor heart is not conditioned to face such an acutely elevated RV afterload. Early signs of RV failure (RV distention and hypokinesis) may be detected with TEE, and by elevation in CVP and PAP. RV failure is thought to be caused by preexisting pulmonary hypertension, transient pulmonary vasospasm, tricuspid or pulmonary valve insufficiency, donor-recipient size mismatch, intracoronary air emboli, prolonged donor heart ischemia, or inadequate myocardial protection. Therapy for RV failure includes inotropic support, starting with isoproterenol or dobutamine. Other pharmacologic agents commonly used for pulmonary vasodilation include phosphodiesterase inhibitors (e.g., milrinone), PGE_1, B-type natriuretic peptide (i.e., nesiritide), and inhaled PGI_2 (epoprostenol) or

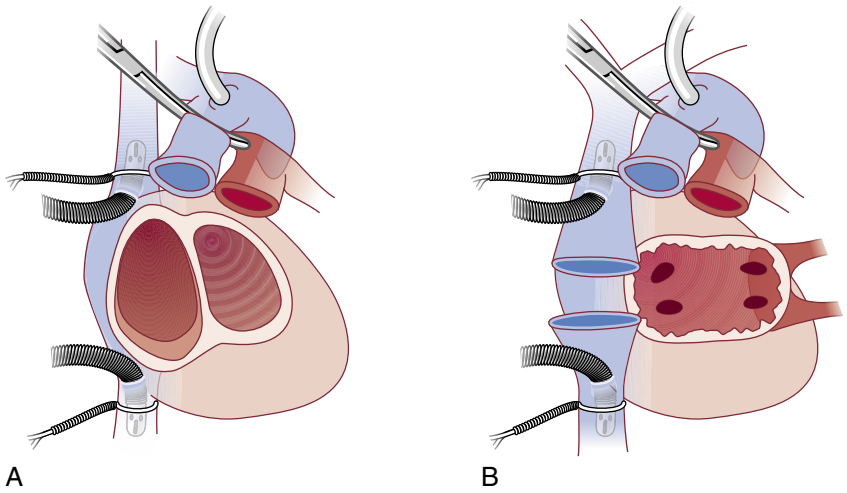

Figure 60-29 Surgical techniques for cardiac transplantation. **A,** Biatrial technique. The donor heart is anastomosed to the main bulk of the recipient's native right and left atria. **B,** Bicaval technique. The donor left atrium is anastomosed to a single left atrial cuff, including the pulmonary veins, in the recipient.

inhaled nitric oxide (Boxes 60-5 to 60-7). Vasopressin preserves SVR without causing significant changes in PVR and is often used to maintain RV perfusion pressure (Box 60-8). Rarely, patients may require support with an RV assist device.

LV dysfunction can occur as the result of prolonged donor heart ischemia, inadequate myocardial protection, coronary air embolization, or inadequate myocardial perfusion during the early post-CPB period. High-dose inotropic and vasoactive support with epinephrine, milrinone, and vasopressin may be required.

Protamine is administered after satisfactory weaning from CPB. In the postbypass period, TEE can provide additional useful information about right and left heart function and volume and can document a normal flow pattern through each anastomotic site.[373]

Box 60-5 Goals of Perioperative Management of Right-Sided Heart Failure

1. Preserving coronary perfusion by maintaining systemic blood pressure
2. Optimizing RV preload
3. Reducing RV afterload by decreasing pulmonary vascular resistance
4. Limiting pulmonary vasoconstriction through optimal ventilation
   a. High inspired oxygen concentration (100% Fio_2)
   b. Hyperventilation to a $Paco_2$ of 25 to 30 mm Hg
   c. Optimal tidal volumes
   d. Correction of acid-base abnormalities
5. Supporting RV function
   a. Pharmacologic agents
   b. Intra-aortic balloon pump
   c. RV assist devices

Fio_2, fraction of inspired oxygen; $Paco_2$, partial pressure of CO_2; RV, right ventricular.

Coagulopathy is a common complication of cardiac transplantation and is probably related to chronic hepatic congestion, preoperative anticoagulation, CPB-induced platelet dysfunction, hypothermia, and hemodilution of clotting factors. When coagulopathy occurs, it requires meticulous attention to surgical hemostasis and, possibly, administration of platelets, FFP, and cryoprecipitate or factor VII, as indicated by coagulation studies. Blood product administration should be guided by close monitoring of coagulation status. Adequate hemostasis should be achieved before the sternotomy is closed and the patient is transported to the ICU.

Even though a well-preserved transplanted heart maintains its normal contractility, it lacks the autonomic control of chronotropy and inotropy as a result of autonomic denervation. Thus, the transplanted heart responds only to direct-acting medication. Isoproterenol is often used for its chronotropic and inotropic effects. Dobutamine is routinely administered to patients with elevated PVR to increase the inotropy and chronotropy of the right ventricle. Occasionally, pacing is required to achieve faster heart rates and to reduce ventricular distention. Renal dysfunction, pulmonary dysfunction, and hyperacute allograft rejection are other possible early postoperative complications of cardiac transplantation.

Certainly, cardiac transplantation represents the definitive therapy for terminal HF. However, cardiac transplantation is not a solution for most patients with end-stage HF. More than 10,000 patients are on the heart transplant waiting list, but fewer than 2200 donor hearts are available each year.[374] In addition, these organs are usually reserved for patients younger than 65 years, even though older patients have the highest prevalence of HF. Furthermore, patients with comorbid diseases are often ineligible for transplantation. It is this mismatch between the increasing number of potential candidates for cardiac transplantation and the relatively fixed number of donors, as well as the large number of acute HF deaths, that continues to stimulate the search for alternative surgical therapies.

Ventricular Assist Devices

Mechanical circulatory support includes the use of a wide variety of devices designed to connect to the heart or to be placed within

Box 60-6 Pulmonary Vasodilator Agents

1. **Phosphodiesterase III Inhibitors**
   - Inhibition of myocardial type III phosphodiesterase leads to an increase in myocardial cAMP, which increases the influx of intracellular Ca^{2+} and has a positive inotropic effect
   - Unique mechanism of inotropic effects independent of β-receptor stimulation
   - Bypass β-adrenergic receptors in patients with preexisting heart failure
   - Additive effect with catecholamines
   - Pulmonary vasodilation
   - Coronary vasodilation
2. **B-Type Natriuretic Peptide**
   - Recombinant human B-type natriuretic peptide
   - Site of action: guanylate cyclase receptor of vascular smooth muscle and endothelial cells
   - Effect: increased intracellular cGMP and smooth muscle cell relaxation, dose-dependent reduction in PCWP and systemic arterial pressure in patients with heart failure, increased permeability of vascular endothelium, inhibition of the renin-angiotensin-aldosterone axis
   - Dose: 2-μg/kg bolus followed by a 0.01- to 0.03-μg/kg/min infusion
   - Plasma half-life: 18 minutes
3. **Prostaglandin I_2 (PGI_2)**
   - Endogenous prostaglandin
   - Synthesized by the cyclooxygenase arm of the arachidonic acid metabolic pathway
   - Potent vasodilator
   - Inhibits neutrophil activation
   - Stabilizes cell membranes
   - Enhances myocardial inotropy by activating adenylate cyclase and increasing intracellular cAMP
4. **Nitric Oxide**
   - Selective pulmonary dilator; less potent than inhaled prostacyclin
   - Activates guanylate cyclase
   - Improves ventilation-perfusion distribution
   - No effect on the cardiac or stroke index
   - Complex and expensive technology necessary for safe and effective use
   - Prolonged use can cause rebound pulmonary vasoconstriction
   - Toxic metabolites: nitrogen dioxide and methemoglobin
5. **Prostaglandin E_1 (PGE_1)**
   - Endogenous prostaglandin
   - Synthesized by the cyclooxygenase arm of the arachidonic acid metabolic pathway
   - Potent pulmonary and systemic vasodilator
   - Cleared from the circulation during its first pass through the lung

cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; PCWP, pulmonary capillary wedge pressure.

Box 60-7 Pharmacologic Agents for Inotropic Support of the RV

1. **Isoproterenol**
   - Nonselective β-adrenergic agonist
   - Positive chronotropic and inotropic agent
   - Pulmonary and systemic vasodilator
2. **Dobutamine**
   - β-Adrenergic receptor agonist with minimal α-adrenergic receptor agonist activity
   - Positive chronotropic and inotropic agent
   - Pulmonary and systemic vasodilator
3. **Epinephrine**
   - α- and β-adrenergic receptor agonist
   - β-Adrenergic receptor predominance at lower doses
   - Potent right ventricular inotrope
   - Has significant arrhythmogenic potential

the heart to assume some of its workload and permit the ventricle to rest, thereby potentially allowing reverse remodeling and recovery of some contractile function. The latest applications of mechanical circulatory support include reversing ventricular dysfunction after cardiac surgery, bridging patients to heart transplantation, and serving as destination therapy for patients who are not transplant candidates.

Studies have shown that the myocardium can repair itself during a period of unloading, after which some patients experience an improvement in quality of life.[375-381] Therefore, VADs can be used for short- or long-term support of the ventricle. The use of VADs as bridges to cardiac transplantation improves the survival rates and outcomes of patients with decompensated HF.[375-383] In addition, evidence suggests that long-term support of the left ventricle with a VAD (i.e., an LVAD) is superior to optimal medical treatment in patients with end-stage HF who are not candidates for heart transplantation.[383] Thus, mechanical circulatory support has become an important tool in the surgical management of patients with failing hearts.

Most VADs can be classified as either nonpulsatile or pulsatile (Tables 60-16 and 60-17), depending on the type of blood flow that they promote. Alternatively, when the site of the pump is taken into account, VADs can be categorized as extracorporeal

Box 60-8 Arginine Vasopressin

Endogenous peptide with osmoregulatory and vasomotor properties

End-organ effect mediated by

V_1 receptor present in vascular smooth muscle

Promotes vasoconstriction by activating G protein and phospholipase C, thereby releasing calcium from the sarcoplasmic reticulum

V_2 receptor present in the distal and collecting tubules

Promotes water resorption by increasing intracellular levels of cAMP and activating protein kinase A

cAMP, cyclic adenosine monophosphate.

Table 60-16 Pulsatile Ventricular Assist Devices

Device	Length of Support	Position	Ventricular Support	Drive Mechanism
Abiomed BVS 5000	Short term	Extracorporeal	LV, RV, BV	Pneumatically driven atrial and ventricular chambers
Thoratec VAD	Short to medium term	Extracorporeal	LV, RV, BV	Pneumatically driven sac
HeartMate IP and VE	Long term as a bridge to transplantation or recovery or as destination therapy (HeartMate VE)	Intracorporeal, abdominal (preperitoneal or intraperitoneal)	LV	Pneumatically or electrically driven, flexible, textured polyurethane diaphragm
Novacor	Long term as a bridge to transplantation or recovery	Intracorporeal, abdominal (preperitoneal or intraperitoneal)	LV	Polyurethane pump sac compressed by electrically driven pusher plates

BV, biventricular; BVS, biventricular support; IP, implantable pneumatic; LV, left ventricular; RV, right ventricular; VAD, ventricular assist device; VE, vented electric.

or intracorporeal. Most extracorporeal VADs, whether pulsatile or nonpulsatile, are used for short- or medium-term support.

Pulsatile assist devices provide a pulsatile flow and can generate a cardiac output of 6 to 9 L/min, given an adequate venous return. Currently, U.S. FDA–approved pulsatile VADs include the Abiomed BVS 5000, the Thoratec VAD System, the Novaco, and the HeartMate. The HeartMate VE (vented electric) is the only mechanical device currently approved by the FDA for destination therapy.

Nonpulsatile devices are designed with either centrifugal or axial flow patterns. These pumps generate continuous flow and have the advantage of being small, silent, valveless, and fully implantable. By working in concert with the heart, they improve the position of the left ventricle on the Frank-Starling curve. The Jarvik 2000 and the HeartMate II VADs can produce high flow rates and generate virtually all of the cardiac output. They can also operate at lower speeds, which allows the left ventricle to assume some of the workload. The Jarvik 2000 is an intraventricular device that is implanted at the LV apex, with the outflow cannula placed in the descending thoracic aorta (Fig. 60-30). The HeartMate II operates at 6000 to 15,000 rpm and provides up to 10 L/min of continuous cardiac output. An inflow graft delivers blood from the left ventricle to the pump, and an outflow graft delivers blood from the pump to the ascending aorta (Fig. 60-31). A driveline connects the pump to the external system driver. The Jarvik 2000 and the HeartMate II are used for long-term ventricular support as a bridge to heart transplantation.

Not all patients with advanced HF are good candidates for LVAD support. Contraindications to LVAD placement include active infection, irreversible renal dysfunction, severe liver impairment, stroke, severe pulmonary hypertension, incurable malignancy, and for the larger LVADs, a small body surface area (<1.5 m^2).[384] Nonetheless, the smaller size and ease of implantation of the newer axial flow LVADs make this technology potentially lifesaving for a wide range of patients, including those with a small body surface area, such as women and children.[369,385]

Because decompensated HF refractory to medical management is the principal feature of candidates for LVAD insertion, these patients may have different degrees of end-organ dysfunction caused by decreased cardiac output and perfusion pressure. Sepsis, pneumonia, ischemia, arrhythmias, and uremia secondary to renal insufficiency are common. Patients also often have reactive pulmonary hypertension caused by chronic elevation of LAP. Heart catheterization should be performed in these patients to obtain information about PVR, the pulmonary vascular response to vasodilators, cardiac output, and LV filling pressure.

Coagulopathy is common in HF patients receiving VAD support. Chronic, passive hepatic congestion may coincide with RV failure and can interfere with coagulation factor–dependent synthetic function. In addition, because prolonged or intermittent use of heparin is common in this patient population, VAD-supported patients have a higher incidence of HIT than other patients undergoing cardiac surgery do.[386,387] Testing for HIT antibodies in VAD patients, as well as implementing an alternative anticoagulation regimen, may lead to desirable outcomes.[388] In addition, VAD systems are known to activate the coagulation, thrombolytic, and inflammatory systems,[389] and platelet morphology and function are significantly altered by VAD-induced surface activation.[390]

Table 60-17 Nonpulsatile Ventricular Assist Devices

Device	Flow Type	Length of Support	Position	Ventricular Support	Drive Mechanism
Levitronix CentriMag	Centrifugal	Short term	Extracorporeal	LV, RV, BV	Electric
Tandem Heart	Centrifugal	Short term	Extracorporeal	LV	Electric
Impella	Axial	Short term	Extracorporeal	LV	Electric
Jarvik 2000	Axial	Long term	Intracorporeal	LV	Impeller electrically driven
DeBakey LVAD	Axial	Long term	Intracorporeal	LV	Electric
HeartMate II	Axial	Short term	Intracorporeal	LV	Electric

BV, biventricular; LV, left ventricular; LVAD, left ventricular assist device; RV, right ventricular.

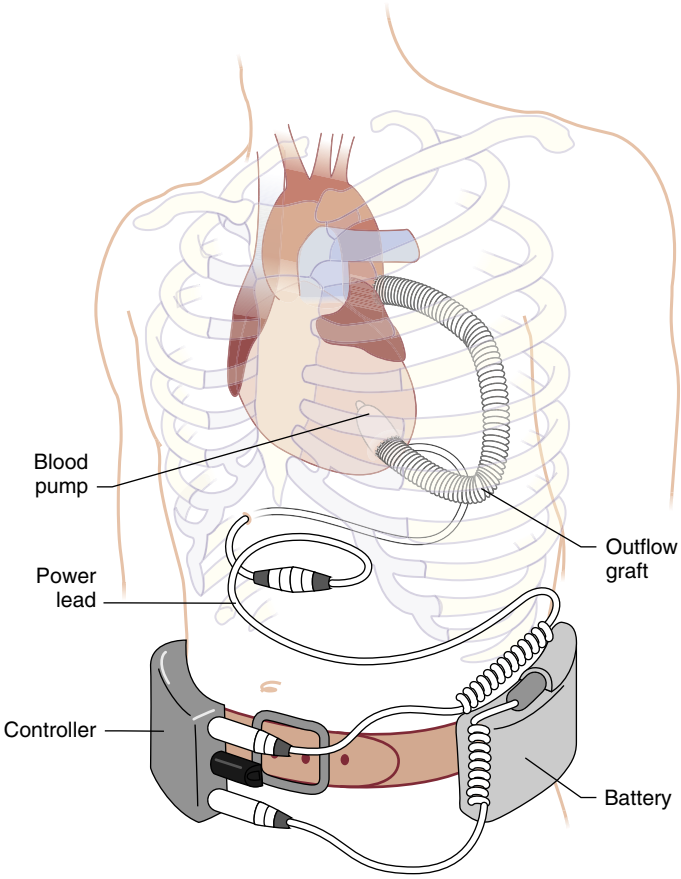

Figure 60-30 The Jarvik 2000.

Therefore, before surgery a rapid transfusion system should be prepared. Large-bore intravenous access is secured via an internal jugular or femoral vein for rapid administration of blood products. A reserve of blood and other products (e.g., FFP and platelets) is ensured. The use of antifibrinolytic agents (e.g., EACA) to minimize blood loss may be considered, although cases of fatal pulmonary embolization by microthrombi have been associated with the use of these agents.[391] In addition, the CPB circuit may be primed with FFP instead of crystalloid. Many patients have excess intravascular volume. Administering diuretics and using hemoconcentration during CPB are common methods of increasing the hemoglobin concentration in these patients.

In addition to standard monitors, a continuous cardiac output PA catheter is often inserted before or after anesthetic induction in LVAD recipients to continuously assess PAP, cardiac output, and trends in $S\bar{v}O_2$. TEE is performed before the start of CPB to identify any specific anatomic problems that could prevent the device from functioning as intended or that could cause predictable complications once LVAD support is engaged.[392] Such structural abnormalities can be categorized into those that will (1) impair effective LVAD filling (e.g., MS, poor RV function, and significant TR), (2) impair forward LVAD outflow and reduce effective decompression of the left ventricle by the device (e.g., aortic insufficiency), or (3) cause introduction problems or complications related to anatomic placement or to the physiologic changes introduced by the device (e.g., patent foramen ovale, other atrial septal defects, ventricular septal defects, ascending aortic plaques, and ventricular thrombi).

Before an LVAD is implanted, LV and RV function must be carefully evaluated, and the LA and left ventricle must be examined for thrombus, particularly at the apex of the left ventricle and in the left atrial appendage. Baseline TR should be evaluated because once the left ventricle is decompressed, the subvalvular apparatus of the tricuspid valve will be distracted to the left, which often results in failure of apposition of the tricuspid leaflets and increased TR. Thus, anything more than mild TR generally necessitates tricuspid annuloplasty. Significantly decreased RV function should prompt consideration of biventricular support because the risk of RV failure is increased when the left side of the heart is decompressed (as a result of altered RV geometry, increased preload, potential stunning during CPB, and potentially increased TR).

Aortic valve function is assessed because moderate to severe aortic valvular insufficiency will result in regurgitation of blood into the left ventricle when the LVAD is activated. This regurgitation will prevent effective decompression of the left ventricle by the LVAD; consequently, although LVAD flow will increase, effective forward systemic perfusion will be compromised. The atrial septum is inspected for a patent foramen ovale because when LVAD support is engaged, left atrial pressures will become less than right atrial pressures; this pressure differential will cause right-to-left shunting through the defect, thereby impairing systemic oxygenation. The thoracic aorta is assessed for calcification, plaques, and dilation.

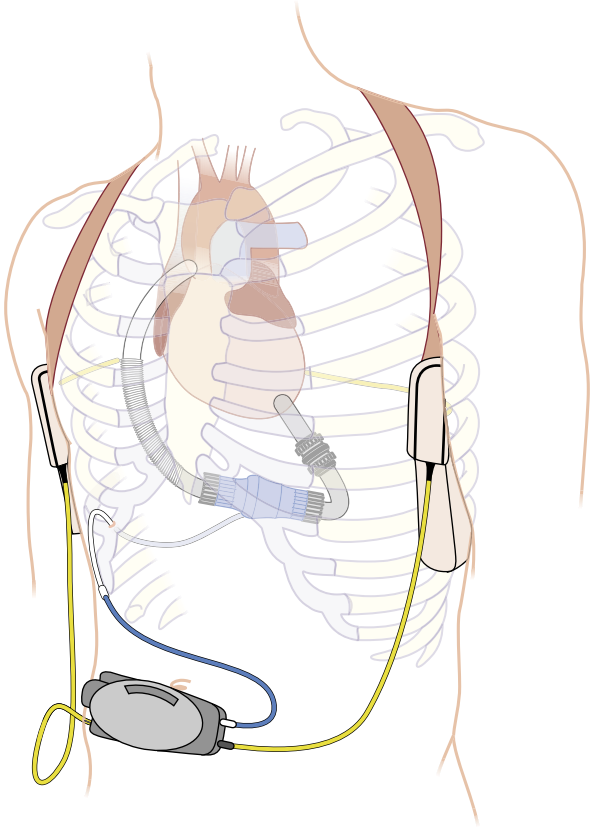

Figure 60-31 The HeartMate II continuous-flow ventricular assist device.

During CPB, TEE is used to ensure that the inflow cannula to the LVAD is centered in the left ventricle and is appropriately directed away from the LV septum or free wall (to avoid inlet occlusion) and toward the mitral valve to ensure optimal, unobstructed filling. When the LVAD is activated and the de-airing protocol is initiated near the end of CPB, TEE is used to assess the adequacy of air removal.

To function properly, LVADs must have adequate preload. The faster the LVAD fills, the faster the LVAD ejects, thereby increasing the effective LVAD output. Adequate preload depends on the ability of the right ventricle to pump a sufficient volume of blood across the pulmonary circuit and on the degree to which the pulmonary circuit permits blood flow. Therefore, successful weaning from CPB usually requires adequate RV function and reasonably low PAP.[393] Monitoring with TEE can detect early signs of RV failure (i.e., RV distention and hypokinesis), in conjunction with elevations in CVP and PAP. RV failure carries a significant risk of mortality and morbidity. Therapy for RV failure after VAD insertion is similar to therapy after heart transplantation (see the earlier section and Boxes 60-5 to 60-7), including the possible need for vasopressin (see Box 60-8). Rarely, patients may require support with an RV assist device.

After CPB is discontinued, TEE is also important for assessing the adequacy of intravascular volume, possible right-to-left shunting, the appearance (or worsening) of aortic or tricuspid valve incompetence, decompression of the left ventricle, the adequacy of inflow to the LVAD, and the absence of any residual air. If LVAD flows are less than expected, TEE is useful to rule out hypovolemia or tamponade. Moreover, TEE can be used to reassess the positions of the inflow and outflow cannulas because partial obstruction of LVAD inflow or outflow can cause hemolysis through shear stress as flow accelerates around the mouth of one or both cannulas. Such hemodynamic problems are best detected with Doppler color flow mapping.

In the postbypass period, reversing anticoagulation and achieving adequate hemostasis are the clinician's chief goals. The required volume of blood products may be high, and devices for rapid infusion of blood components are needed. Because LVAD flow is volume dependent, decreased flow usually results from a volume deficit, although RV dysfunction may also cause decreased flow. Also, even if volume loading and LVAD output are adequate, systemic perfusion pressure may be too low in the early stages after pump insertion. This problem can be caused by vasodilatory shock related to the patient's decompensated preoperative state, altered metabolism of ACEIs or amiodarone, side effects of milrinone, or deficiency of arginine vasopressin.[394] Therefore, administration of vasopressin may be necessary to maintain systemic pressure.

After LVAD implantation, primary chest closure may not be possible for 24 to 48 hours, until cardiac function has stabilized and the risk of hemorrhage has been controlled. Once sternal closure is possible, patients can be weaned from the ventilator. For successful extubation, it is often necessary to promote diuresis to alleviate residual pulmonary interstitial volume overload.

Recovery

Even though bridging to heart transplantation and destination therapy with LVADs is well studied, long-term bridging to recovery is less developed and understood. Reverse remodeling has been reported with prolonged LV unloading by an LVAD, in conjunction with the administration of clenbuterol, a β_2-adrenergic receptor agonist, to prevent myocardial atrophy.[395] Further research is needed to determine the duration of VAD support necessary for myocardial recovery, define the optimal level of ventricular unloading, and establish the sustainability of this recovery.[381,396]

Other Procedures

Surgical Ventricular Remodeling

Posterior Ventricular Excision Procedure In patients with HF, the left ventricle dilates and causes increased ventricular wall stress, myocardial cell death, and fibrosis. It has been thought that reversing ventricular dilation may prevent further myocardial cell death.[369] Therefore, procedures meant to "remodel" the left ventricle have been investigated.

Partial left ventriculectomy (LV reduction surgery) was introduced by Batista and colleagues[397] in Brazil. This procedure involves resecting a segment of the enlarged myocardium to restore normal size and function. The mitral valve is also repaired or replaced, and CABG may be performed, if necessary. Results have been variable: HF has worsened in some patients but shown stable improvement in others.[369,398]

Dor Procedure Another ventricular remodeling technique, the Dor procedure, involves placing an endoventricular patch through a ventriculotomy.[399] The procedure is meant to reduce the volume of the dilated left ventricle, thereby lessening stress on the remodeled ventricle, as well as reducing MR.[400] Restoration of a more normal elliptical shape may also improve systolic performance. One multicenter study of 1198 patients noted that the average EF improved from 30% to 40% after the Dor procedure.[401]

Extrinsic Ventricular Constraint Techniques

Cardiomyoplasty Another option that has been investigated for the surgical treatment of end-stage HF is dynamic cardiomyoplasty, in which an electrically stimulated flap of skeletal muscle, usually from the latissimus dorsi, is wrapped around the heart in an attempt to augment systolic function.[369] Dynamic cardiomyoplasty is used mainly to treat ischemic and dilated cardiomyopathy involving isolated LV failure. The main benefit of the procedure may be the mechanical "girdling" effect of wrapping the heart to prevent further LV dilation. At present, the clinical application of cardiomyoplasty remains limited.

Acorn CorCap The Acorn CorCap (for external splinting; Acorn Cardiovascular, Inc., St. Paul, MN) is a polyester-mesh cardiac support device that is surgically implanted to fit over the heart to produce passive ventricular reshaping (Fig. 60-32). It has been shown to slow the progression of HF, promote reverse remodeling, and improve functional status.[402,403] Clinical trials are being conducted to further address the safety and efficacy of the device.

Passive Ventricular Reshaping

Another innovative technique aims to preempt ventricular remodeling and address the MR that coexists with advanced HF. A novel device, the Coapsys (Myocor, Inc., Maple Grove, MN), is used to draw the mitral valve leaflets together by means of two epicardial pads connected by a flexible cord that runs beneath the valve. Early clinical results with the Coapsys have been promising in patients with moderate to severe functional mitral valve regurgitation.[404] Similarly, the use of polyester tension rods (Myosplint; Myocor, Inc., Maple Grove, MN; Fig 60-33) to draw the walls of

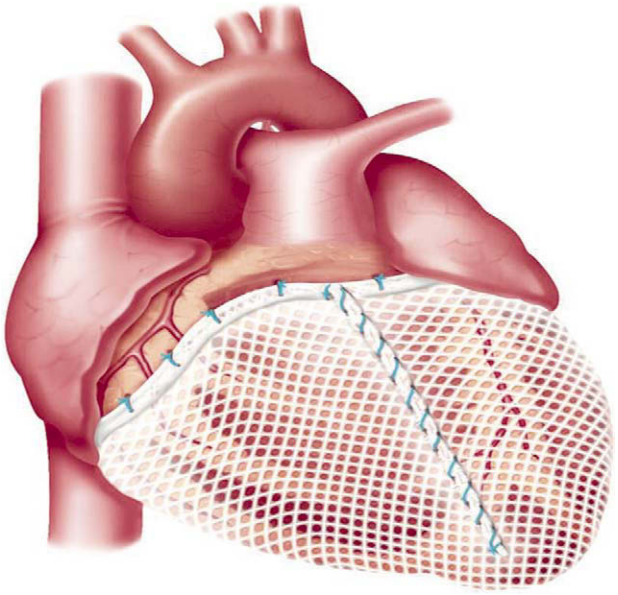

Figure 60-32 CorCap device.

the failing left ventricle together and thus alter its geometry has shown promise in patients with HF.[405]

Total Artificial Heart

The SynCardia CardioWest Total Artificial Heart (TAH) is a biventricular, orthotopic, pneumatically driven pulsatile pump. The TAH has two Medtronic-Hall inflow (27 mm) and outflow (25 mm) valves that are mounted on the housing. The ventricles fill fully and eject 70 mL per beat. Currently, the CardioWest pump is the only TAH used to bridge patients to heart transplantation.[406] In a study of this device in transplant candidates, 68% of the patients survived long term.[407] Recently, the CardioWest TAH was successfully used in a selected group of patients with irreversible cardiogenic shock. Patients recovered from all organ dysfunction and underwent successful heart transplantation.[408]

Congenital Heart Disease in Adults

Background and Current Perspective

Whereas in the 1950s only 25% of children born with CHD could be expected to reach adulthood, medical and surgical advances made since then have enabled a new and expanding clinical cohort of patients with CHD to survive to adulthood. Currently, 85% to 95% of babies born with such disease reach their adult years, and the number of adults with CHD now equals the number of children with congenital anomalies.[409,410] In fact, it is estimated that at least 800,000 adults in the United States have CHD and that 400,000 of them have moderate or complex disease.[411] Attendant adult issues, such as the long-standing effects of "corrected" or palliated CHD, acquired noncardiac disease or injury, and reproductive issues such as pregnancy, must be addressed. In addition, both females and males with CHD who reach reproductive age appear to have a greater risk for having offspring with CHD than the general population does.[412]

Given the size of the population of adults with CHD and the complexity of their original pathophysiology—complicated further by surgical repairs, palliation, or both—it seems prudent to consider this group of patients as separate and distinct within the adult surgical population. There is a misperception held by many patients and their families—and possibly by many health care professionals—that surgical treatment results in a cure. The reality is that most CHD patients face a lifetime of significant medical challenges[409] ranging from the implications of long-term antibiotic prophylaxis to the long-term sequelae of cardiac arrhythmias and ventricular dysfunction. Unlike the onset and progression of acquired adult heart disease, the progression of CHD may be slow and insidious, so CHD is often not addressed until the patient has reached adulthood, by which time the disease has caused severe, irreversible cardiac valvular and ventricular dysfunction.[409]

Preoperative Anesthetic Considerations

An appreciation of both cardiac and noncardiac pathophysiology is useful in planning an anesthetic approach to adult patients with CHD. A number of noncardiac organ systems can be involved, either as physiologic sequelae of the specific congenital heart defect or as part of a genetic/chromosomal syndrome whose manifestation includes cardiac anomalies.

Treatment of adults with CHD is conceptually facilitated by recent recommendations. The approach suggested by Perloff and Warnes[412] is based on understanding and differentiating between "residua" (anatomic or physiologic abnormalities left behind at the time of reparative surgery) and "sequelae" (new disorders or physiologic changes that are intentionally created or incurred and viewed as acceptable and necessary consequences of surgical treatment). This conceptual foundation provides a basic and much-needed framework on which anesthetic care providers may base their understanding of an adult patient with CHD.

Residua of surgery for CHD can be electrophysiologic, valvular, ventricular, vascular, or noncardiovascular.[412] Electrophysiologic residua include axis deviation on the ECG, AV block, ectopic atrial foci, and atrial tachyarrhythmias.

Valvular residua are structural and functional abnormalities of the cardiac valves. They result immediately from surgery or develop gradually as a consequence of long-standing primary pathophysiologic stress and secondary failing compensatory mechanisms.

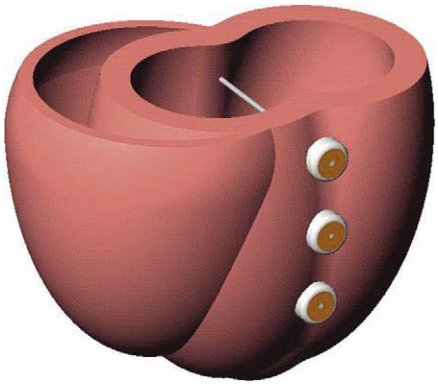

Figure 60-33 Myosplint concept.

Ventricular residua are among the most important perioperative considerations. The ventricular effects of CHD and its surgical repair or palliation include permanent structural abnormalities or dysfunction of the ventricle or ventricles and changes in ventricular function or mass that occur over time, such as the ventricular hypertrophy that develops in patients with a congenital bicuspid aortic valve that is inherently stenotic or that becomes so over a lifetime.

Vascular residua include structural abnormalities of the cerebral, coronary, and great arteries. Patients with a history of coarctation of the aorta or supravalvular AS have a diffuse inherited angiopathy that predisposes them to cerebral aneurysm formation, aortic aneurysm development, and even aortic rupture.[409] These medial aortic wall abnormalities appear to be part of a number of congenital cardiac anomalies and can involve the systemic and pulmonary arterial walls.[413] Elevated vascular pressure and resistance in the systemic or pulmonary vascular beds are other vascular residua that occur in adults with CHD. For example, postoperative residual systemic hypertension can complicate the long-term course of older patients with coarctation and is one of several syndromes that include supravalvular AS. In the pulmonary vasculature, long-standing luxuriant pulmonary blood flow can result in proliferation of pulmonary medial smooth muscle cells, which can cause elevations in PVR and possibly fixed pulmonary hypertension.

Noncardiac residua seen in adult patients with CHD are myriad. Mental retardation and somatic growth disorders complicate many congenital syndromes. Skeletal, facial, and airway abnormalities are common expressions of genetic dysmorphisms. Neurologic residua can persist as a consequence of primary cardiac disease. For example, paradoxical emboli can occur in a patient with atrial-level shunting. Furthermore, common age-associated medical problems, such as essential systemic hypertension, diabetes, and acquired coronary artery disease, may develop in adult patients with CHD.

Sequelae—new disorders or physiologic changes that develop as a consequence of correction or palliation—can be classified in a similar way. Electrophysiologic sequelae include the effects of surgical violation of atrial or ventricular muscle during intracardiac surgery and later exposure of cardiac chambers to elevated pressure and wall stress. Atrial arrhythmias, heart block, and tachyarrhythmic sudden death after ventriculotomy are known sequelae of surgical repair of CHD. Valvular sequelae can also be significant.

Furthermore, surgical repair of RV outflow tract obstruction, as performed in correction of the tetralogy of Fallot, can produce obligatory pulmonary insufficiency whereby the resultant volume overload affects the right ventricle. Sequelae of repair of inflow (mitral or tricuspid) valves are even more prevalent because of the complex nature of the inflow valvular apparatus and the functional dependence of the valve on LV or RV geometry and function.[412]

In addition, uniquely significant sequelae occur with the use of prosthetic material in the form of patches, conduits, or valves. Such material includes autografts (same individual), homografts (same species), xenografts (different species), and synthetic substances. Graft-related sequelae include accelerated fibrocalcific degeneration, thromboembolic complications, and elevated long-term risk for endocarditis.

Neurologic sequelae can include focal deficits, impaired higher cortical function, or CNS injury occurring as a consequence of brain or spinal cord malperfusion during complicated cardiac or aortic operations, especially those requiring circulatory arrest. Fortunately, advances in surgical and bypass techniques have minimized such sequelae. More subtle evidence of neurologic dysfunction includes lower than normal academic performance levels in Fontan patients or decreased motor performance and behavioral dysfunction in patients who have undergone circulatory arrest or low-flow CPB, had a prolonged stay in the ICU, or had disease involving single-ventricle pathophysiology.[414-418]

The initial assessment, history taking, and physical examination of an adult patient with CHD must be broadly systemic in nature to capture any noncardiac organ involvement. A full review of each organ system is beyond the scope of this chapter, but readers are referred to two excellent review articles by Chassot and Bettex and by Lovell.[419,420] Appropriate consultation with the patient's cardiologist (pediatric or adult), as well as access to old medical records, is optimal, especially for patients who have complex CHD or have undergone complex surgical procedures. Preoperative echocardiography is extremely helpful in understanding CHD patients' anatomy and cardiac function, both primary and compensatory.

One of the early clinical decisions to be made for an individual patient involves determining the appropriateness of surgical care in a given institution. Obviously, emergency procedures give very little latitude, but elective procedures should warrant careful assessment, especially of the abilities and experience of the anesthesiologist who will be caring for a patient with complex corrected or palliated CHD. In 2001, the 32nd Bethesda Conference on CHD advocated the creation of regional centers for the care of adults with CHD (ACHD centers), whose personnel would include a cardiac anesthesiologist with expertise in the management of patients with CHD.[411,421] The conference recommended that all adult patients with complex CHD (Boxes 60-9 and 60-10) be referred to such ACHD centers.

Intraoperative Anesthetic Considerations

In-depth discussion of the anesthetic management of particular congenital heart defects in adult patients is not the purpose of this section. However, a few basic principles are essential for all anesthesiologists to know, especially those who do not have specialized training in cardiac anesthesia or CHD but who may be faced with an older patient with CHD who needs urgent noncardiac surgery.

Principle 1: The Presence or Absence of Cyanosis

Cyanosis is usually a marker for complex CHD. Chronic cyanosis can lead to the development of abnormalities of RBC production and hemostasis. Elevated levels of erythropoietin in cyanotic patients can lead to a hyperviscosity syndrome and elevated neurologic risk. Risk factors include coexistent systemic hypertension, AF, and a history of phlebotomy and microcytosis.[422]

In any patient with cyanotic CHD, the anesthesiologist should establish intravenous fluid therapy and monitor urine output to minimize the circulatory effects of perioperative fasting, dehydration, and intraoperative hypovolemia. These conditions cause hyperviscosity, which can be associated with hemostatic abnormalities. Long-term administration of antiplatelet medications to ensure conduit patency can also cause such abnormalities.

The decision whether to measure CVP should be approached with caution and should involve consultation with a cardiologist

Box 60-9 Types of Adult Patients with Congenital Heart Diseases of Great Complexity*

Conduits, valved or nonvalved
Cyanotic congenital heart disease (all forms)
Double-outlet ventricle
Eisenmenger's syndrome
Fontan procedure
Mitral atresia
Single ventricle (also called double inlet or outlet, common or primitive)
Pulmonary atresia (all forms)
Pulmonary vascular obstructive diseases
Transposition of the great arteries
Tricuspid atresia
Truncus arteriosus/hemitruncus
Other abnormalities of atrioventricular or ventriculoarterial connection not included above (i.e., crisscross heart, isomerism, heterotaxy syndromes, ventricular inversion)

*These patients should be seen regularly at adult congenital heart disease centers.

familiar with CHD and with the patient's diagnosis. This decision also requires complete understanding of the patient's anatomy and underlying cardiac function, as well as the proposed surgical intervention. Caval-pulmonary connections, such as the bidirectional Glenn or Fontan procedures, elevate the patient's risk for thrombosis from indwelling venous catheters.

Principle 2: The Presence or Absence of Intracardiac or Extracardiac Shunts

Intracardiac shunts are classically located at the level of the atria or ventricles. The magnitude of the shunt is often expressed in terms of the ratio of pulmonary blood flow (Qp) to systemic blood flow (Qs): Qp/Qs. Balanced flow is the hallmark of normal physiology. A Qp/Qs ratio greater than 1 is generally consistent with acyanotic heart disease and luxuriant pulmonary blood flow. A Qp/Qs ratio less than 1 would be consistent with the clinical manifestation of cyanotic heart disease. Chassot and Bettex[419] remind us in their review article that there are important subcharacteristics of intracardiac shunts:

1. The direction of shunt flow is important. Shunts can be right, left, or bidirectional. Shunt flow can be influenced by changes in driving pressure across a shunt or pressure in the receiving chamber. The high intrathoracic pressure that can occur with mechanical ventilation, coughing, the Valsalva maneuver, bronchospasm, or positive end-expiratory pressure can actually reverse the direction of a left-to-right shunt or at least make it bidirectional. Therefore, paradoxical embolization by clot or air is a real risk in patients with intracardiac shunts and warrants fastidious attention to de-airing intravenous lines and careful administration of drugs via syringes through ports in intravenous lines.
2. The size of the intracardiac defect is important. Shunts are commonly labeled as restrictive or nonrestrictive according to their blood velocity or pressure characteristics measured at catheterization or by echocardiography. Large defects with associated low pressure or gradients across them have nonrestrictive flow. In addition, larger defects can be expected to have a greater effect on downstream structures and pressures. Small defects with high pressure or gradients restrict the amount of blood flow. The mainstay of anesthetic management of shunt lesions is to understand and control factors that may influence the direction and magnitude of the shunt. Shunt flow and direction are directly influenced by both PVR and SVR. Elevated SVR and decreased PVR will generally increase the magnitude and propensity for left-to-right shunting. Conversely, decreased SVR will decrease the magnitude of left-to right shunting, as will elevations in PVR. Mechanical ventilation, the inspired oxygen concentration, carbon dioxide levels, and the hemodynamic effects of anesthetic drugs are all used to accomplish certain therapeutic goals in relation to shunt management. Oxygen is a potent pulmonary vasodilator, as is a lower $Paco_2$. If the clinical problem is luxuriant pulmonary blood flow, a high Fio_2 is not optimal and

Box 60-10 Types of Adult Patients with Congenital Heart Disease of Moderate Severity*

Aortic–left ventricular fistulas
Anomalous pulmonary venous drainage, partial or total
Atrioventricular canal defects (partial or complete)
Coarctation of the aorta
Ebstein's anomaly
Infundibular right ventricular outflow obstruction of significance
Ostium primum atrial septal defect
Patent ductus arteriosus (not closed)
Pulmonary valve regurgitation (moderate to severe)
Pulmonic valve stenosis (moderate to severe)
Sinus of Valsalva fistula/aneurysm
Sinus venosus atrial septal defect
Subvalvar or supravalvar aortic stenosis (except hypertrophic obstructive cardiomyopathy)
Tetralogy of Fallot
Ventricular septal defect with
  Absent valve or valves
  Aortic regurgitation
  Coarctation of the aorta
  Mitral disease
  Right ventricular outflow tract obstruction
  Straddling tricuspid/mitral valve
  Subaortic stenosis

*These patients should be seen periodically at regional adult congenital heart disease centers.

should be avoided. Similarly, the direction and magnitude of the shunt flow determine whether one should hyperventilate a patient to achieve a low $Paco_2$ or tolerate a high-normal $Paco_2$.

3. In the presence of a shunt, the potential enlargement of receiving chambers and high downstream pressure are important. A shunt above the level of the AV valves, such as a left-to-right shunt at the atrial level, will usually cause right-sided chamber enlargement. Defects or shunts below the AV valves, such as a ventricular septal defect or patent ductus arteriosus, will initially result in left-sided chamber enlargement. Shunts at both locations increase pulmonary blood flow and, with time, can lead to potentially irreversible elevations in PVR and pulmonary pressure. Furthermore, exposure to elevated pulmonary pressure and afterload leads to RV enlargement, RV failure, bidirectional shunting, and in the most extreme cases, reversal of shunt direction and cyanosis, as in patients with Eisenmenger's syndrome.

Extracardiac shunts can be native to CHD (aberrant pulmonary venous return), surgically created (Blalock-Taussig shunt placement in some cases of cyanotic heart disease), or compensatory (aortopulmonary collateral formation with long-standing cyanotic heart disease). Special mention of aortopulmonary shunts, such as the Blalock-Taussig, Pott, and Waterson shunts, is warranted. These systemic-to-pulmonary shunts are used to palliate some forms of cyanotic heart disease. The proximal connection may be to the ascending aorta, brachiocephalic trunk, or subclavian artery. Because blood flow through this type of shunt is dependent on systemic blood pressure, systemic hypotension may lead to worsening hypoxemia. Long-term exposure to these extracardiac shunts can result in left-sided chamber enlargement and dysfunction secondary to chronic volume overload.

Principle 3: The Presence of Pulmonary Hypertension

Pulmonary arterial hypertension is defined as a mean PAP greater than 25 mm Hg or greater than 30 mm Hg with exercise. Some degree of pulmonary hypertension develops in 5% to 10% of adult patients with CHD, and the presence of pulmonary hypertension, as well as the associated exercise intolerance and decrease in functional capacity, appears to have important prognostic implications.[423] In a study of gravid patients with the tetralogy of Fallot, maternal complications were associated with pulmonary hypertension.[424]

Anesthetic management of patients with pulmonary hypertension can be problematic. Invasive monitoring and careful anesthetic titration may be required. Regional anesthesia may be used for appropriate procedures, but neuraxial blocks should be administered with caution. Patients with significant pulmonary hypertension are very sensitive to preload; therefore, hypovolemia, whether primary (blood loss) or secondary (vasodilation), should be treated immediately and aggressively. Pulmonary hypertension can be managed pharmacologically and mechanically. Factors associated with decreasing PVR and, subsequently, reductions in PAP are listed in Box 60-11.[420]

Box 60-11 Factors Associated with Decreasing Pulmonary Vascular Resistance and Reductions in Pulmonary Artery Pressure

Decrease in Pulmonary Vascular Resistance
Increasing Pao_2
Hypocapnia
Alkalemia
Minimizing intrathoracic pressure
- Spontaneous ventilation
- Normal lung volumes
- High-frequency and jet ventilation

Principle 4: The Presence of Ventricular Dysfunction

As in adult patients with heart disease that is not congenital, the presence of ventricular dysfunction is an important risk factor for morbidity and mortality, both in the perioperative period and in the long term. Regarding RV dysfunction, pulmonary hypertension, pulmonic valve incompetence, and consequent dysfunction of the subpulmonic ventricle appear to be predictors of a poor outcome.[424,425] In a study by Khairy and associates,[425] pulmonary edema complicating pregnancy was associated with subpulmonic ventricular dysfunction, severe pulmonary insufficiency, or both, independent of LV systolic function. Nevertheless, dysfunction of the systemic ventricle (the ventricle below the aortic valve) is also associated with an increased risk for morbidity and mortality.[424]

Other Cardiac Procedures

Cox-Maze Procedure

The classic Maze procedure is currently the most effective curative therapy for AF.[426] To simplify the procedure and improve its results, Cox and colleagues modified the operation twice, thus its current name, the Cox-Maze III procedure.[426,427] This procedure apparently cures AF in 99% of cases. Indications for the Cox-Maze III operation include drug intolerance, arrhythmia intolerance, and recurrent embolic events.[428]

Ablative treatments of AF involve making right and left atrial incisions and cryolesions to interrupt the multiple reentrant circuits that cause AF. Isolating the pulmonary veins and excising

Table 60-18 Energy Sources for Surgical Ablation of Atrial Fibrillation

Energy Type	Endocardial Application	Epicardial Application	Flexible Probe	Assess Transmural	No Char	Rapid
Radiofrequency*	+	+	+	+	–	+
Microwave	+	+	+	–	+	+
Cryothermy	+	+	–	–	+	–

*Radiofrequency energy may be delivered in unipolar or bipolar fashion. A commercially available bipolar instrument allows the operator to assess transmurality.

the left atrial appendage are integral parts of the Maze procedure, which requires CPB (for 45 to 60 minutes if the operation is performed by an experienced surgeon)[429-431] and cardiac arrest. This procedure can be performed through a minimally invasive chest incision, as an alternative to sternotomy, while the patient is maintained on CPB and is in cardiac arrest with cardioplegia.

A study done by Prasad and colleagues[428] found that the Cox-Maze III procedure effectively cured AF when performed alone or concomitantly with coronary or valve procedures. In patients undergoing such concomitant operations, the Cox-Maze III procedure did not significantly add to the mortality or morbidity associated with the revascularization or valve repair procedure.

New Developments in the Surgical Ablation of Atrial Fibrillation

Currently, newer technologies enable rapid creation of lines of conduction blockade, which surgeons use to ablate AF in patients undergoing concomitant cardiac surgical procedures. Such technologies include alternative energy sources such as radiofrequency (RF) and microwave energy, ultrasound, cryotherapy, and laser (Table 60-18). These technologies are also used in minimally invasive surgical ablation procedures to cure isolated AF.[426] Furthermore, the development of epicardial probes has facilitated "off-pump" ablation of AF in the beating heart.[432]

Because cardiac structures can be visualized directly during open surgery, ablation lines can be created safely, thus avoiding the complication of pulmonary vein stenosis. An epicardial approach to ablation eliminates the risk of esophageal injury.[426,433] The advantage of a surgical approach is the ease of excising the left atrial appendage, which virtually eliminates the risk of stroke. However, isolation of the pulmonary vein and excision of the left atrial appendage can now be done through the minimally invasive "keyhole approach" (Fig. 60-34) or a thoracoscopic approach.[433] Both approaches can be used without the need for CPB.[426]

Pericardial Tamponade and Constrictive Pericarditis

Pericardial Tamponade

The pericardial sac has two layers: the outer parietal pericardium and the inner visceral pericardium (epicardium), which is directly adherent to the surface of the heart. The normal amount of fluid between the two layers is 15 to 30 mL, which generates a pressure that is 5 mm Hg less than CVP and approximates pleural pressure.

Cardiac tamponade occurs when the volume of fluid trapped in the pericardial sac increases and compresses the heart, thereby compromising cardiac output.[434] In a classic tamponade scenario, the circulation adapts by increasing systemic venous and pulmonary venous pressure to equalize with pericardial pressure so that total collapse of the cardiac chambers is prevented.[435] PCWP and LV, RV, and RA diastolic pressure increase to equalize with pressure in the pericardium. As a result, atrial and ventricular diastolic transmural pressures are essentially zero, a hallmark of pericardial tamponade. Although this virtual loss of pressure

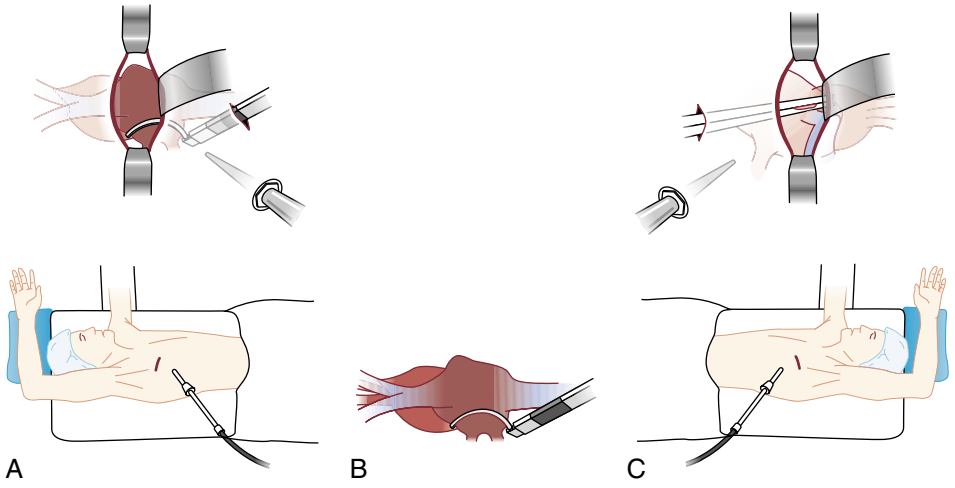

Figure 60-34 "Keyhole" approach for minimally invasive epicardial pulmonary vein isolation with excision of the left atrial appendage. **A,** Access to the right pulmonary veins is gained through a keyhole incision under endoscopic guidance. **B,** A bipolar radiofrequency clamp is used to isolate the left atrial cuff adjacent to the right pulmonary veins. **C,** Stapled excision of the left atrial appendage after the left pulmonary veins are isolated with a technique similar to that shown for the right pulmonary veins. *(From Gillinov AM, Wolf RK: Surgical ablation of atrial fibrillation. Prog Cardiovasc Dis 48:169-177, 2005.)*

reduces stroke volume, high adrenergic tone helps partially preserve cardiac output by increasing the heart rate.

If enough fluid accumulates, the pericardium reaches a stage at which it can no longer distend; therefore, the total pericardial volume no longer changes throughout the respiratory cycle.[435] This results in a phenomenon referred to as ventricular interdependence, wherein any change in the volume of one side of the heart causes the opposite change in the volume of the other side. During inspiration, increased venous return and filling of the right heart cause the interatrial and interventricular septa to bulge to the left, and opposite changes occur during expiration. Such ventricular interdependence is evident on echocardiography.

Ventricular interdependence is manifested clinically as pulsus paradoxus,[436] an exaggeration of the normal diminution of the radial pulse on inspiration (Fig. 60-35). Pulsus paradoxus is defined as a drop in systolic blood pressure exceeding 10 mm Hg during inspiration.[437] In particularly severe cases, there may be no palpable brachial or radial pulse on inspiration.[438]

Cardiac tamponade is not necessary to cause pulsus paradoxus. Wide swings in intrathoracic pressure and conditions such as pulmonary embolism or hypovolemic shock can also give rise to the phenomenon. Additionally, patients with cardiac tamponade may not have pulsus paradoxus if they have coexisting aortic insufficiency, an atrial septal defect, or preexisting elevated LVEDP secondary to LV hypertrophy or dilatation.

Figure 60-36 illustrates the pressure-volume relationship as fluid accumulates in the pericardial sac. This J-shaped curve suggests that a sudden increase in pericardial fluid volume of 100 to 200 mL can increase pericardial pressure to 30 mm Hg or more and cause severe cardiac tamponade.[435] The faster the fluid accumulation, the more severe the hemodynamic compromise. Causes of this type of acute tamponade include rupture of a thoracic aortic aneurysm, traumatic mediastinal injury, and accidental puncture of a cardiac chamber or blood vessel in the cardiac catheterization laboratory.[435]

In cases in which accumulation of pericardial fluid is slower, the compliance of the parietal pericardium is greater, and changes in volume produce smaller rises in pressure than they would if fluid accumulated more rapidly. As pericardial volume increases, so does intrapericardial pressure, with a compensatory increase in CVP to maintain a gradient to allow cardiac filling.[434] When pericardial compliance cannot increase any more, intrapericardial pressure gradually equalizes with pressure in the cardiac chambers. Cardiac output gradually declines, accompanied by a compensatory tachycardia, peripheral vasoconstriction, and increased contractility.[439]

Symptoms and Signs of Pericardial Tamponade

Patients with pericardial tamponade may have pain or feelings of fullness in the chest, dyspnea, lethargy, fever, cough, weakness, fatigue, anorexia, or palpitations.[434] The Beck triad may appear as a combination of three signs of severe tamponade: low blood pressure, increased jugular venous pressure, and distant heart sounds. However, patients whose tamponade develops secondary to a chronic medical condition (malignancy, end-stage renal disease, collagen vascular disease, etc.) may not exhibit the classic findings of the Beck triad.

Echocardiographic Features of Pericardial Tamponade Of the various echocardiographic signs of cardiac tamponade (Box 60-12), one of the most well established is diastolic

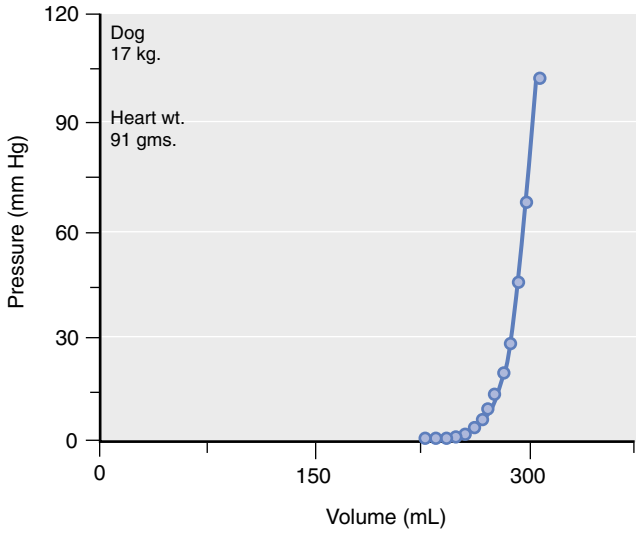

Figure 60-36 Pericardial pressure-volume curve demonstrating that a slight increase in volume can cause a significant increase in pressure. *(From Holt JP, Rhode EA, Kines H: Pericardial and ventricular pressure. Circ Res 8:1171-1181, 1960. Copyright © 1960 American Heart Association.)*

Box 60-13 Indications for Pericardiocentesis/Surgical Drainage

- Pericardiocentesis is indicated in patients with overt clinical tamponade, in those with suspicion of purulent pericarditis, and in patients with idiopathic chronic large pericardial effusion.
- Indications for surgical drainage are tamponade, either unresolved or relapsing after pericardiocentesis, and persistent active illness 3 weeks after hospital admission.
- Pericardial drainage does not seem to be warranted in the initial management of patients with large pericardial effusions without clinical tamponade because of its low diagnostic yield and poor influence on the evolution of pericardial effusion. Even the presence of echocardiographic right chamber collapse (suggesting raised intrapericardial pressure) does not by itself warrant pericardial drainage because most of these patients do not evolve to overt tamponade.

From Soler-Soler J, Sagrista-Sauleda J, Permanyer-Miralda G: Management of pericardial effusion. Heart 86:235-240, 2001.

collapse of the RA or right ventricle. Collapse of the right ventricle, seen in early diastole, appears as an invagination of the RV free wall. In contrast, right atrial collapse is seen in late diastole and early systole and appears as an invagination of the right atrial wall. The timing of collapse of the two chambers is related to the lowest intracavitary pressure in these chambers (i.e., early diastole for the right ventricle and late diastole for the RA). The presence of both RV and right atrial collapse indicates hemodynamically significant pericardial effusion (Fig. 60-37). Left heart collapse is rarely seen, because the thickness and stiffness of the left ventricle enables it to resist collapse and because the LA is located posteriorly. However, in patients with very large effusions, fluid does accumulate behind the LA and eventually collapses this chamber.[440]

Anesthetic Management of Pericardial Tamponade

Indications for pericardiocentesis (surgical drainage of pericardial effusion) are summarized by Soler-Soler and coworkers (Box 60-13).[441] Surgical intervention for pericardial disease warrants invasive monitoring, which should involve an intra-arterial catheter and possibly a central venous catheter.

In patients who are severely hemodynamically compromised, one surgical option is to perform pericardiocentesis or subxiphoid exploration under local anesthesia[442] and induce general anesthesia after the tamponade has been partially relieved. If general anesthesia is planned, watchwords in the management of cardiac tamponade are *fast*, *full*, and *strong*. It is important to administer intravenous fluids before induction to optimize preload. Increasing intravascular volume helps increase the effective filling pressure of the heart, restore the gradient between the chambers, and increase arterial pressure.

Any manipulation that can decrease venous return to the heart should be avoided, including controlled positive-pressure ventilation with large tidal volumes, which may significantly

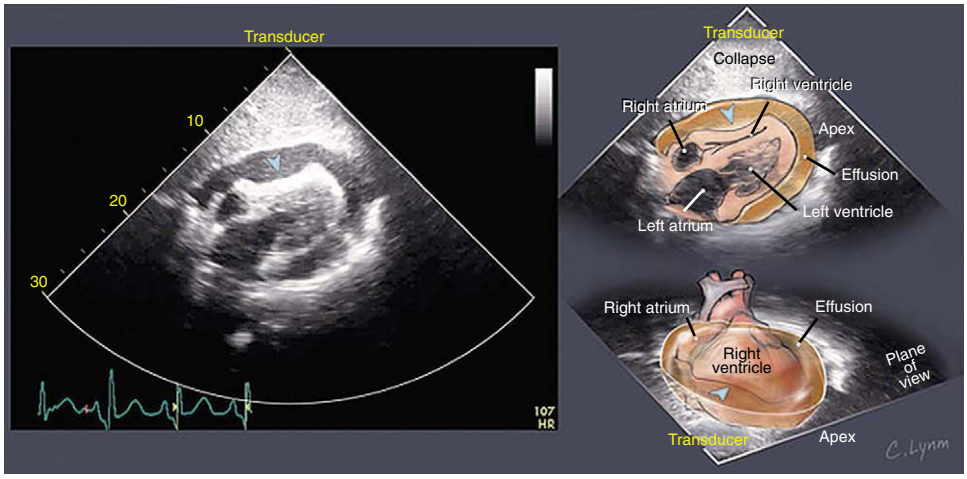

Figure 60-37 Echocardiogram showing pericardial effusion causing cardiac tamponade. A subcostal view in early diastole shows a large circumferential pericardial effusion compressing the heart, with the right ventricle completely collapsed. *(From Roy CL, Minor MA, Brookhart MA, et al: Does this patient with a pericardial effusion have cardiac tamponade? JAMA 297:1810-1818, 2007.)*

decrease preload and cardiac output.[442] Instead, if general anesthesia is required, one option is to allow the patient to breathe spontaneously until the pericardial sac is opened.[442] Alternatively, a ventilation pattern of high rate and low tidal volume can be used to minimize mean airway pressure.

Drugs that may cause myocardial depression should be avoided. Additionally, bradycardia should be avoided because tachycardia is the most important compensatory mechanism for preserving cardiac output. The use of ketamine to induce general anesthesia for creation of a pericardial window has been described.[443]

When cardiac tamponade is relieved, endogenously generated and exogenously administered catecholamines may cause sudden, severe increases in blood pressure and heart rate. This phenomenon should be anticipated and treated.

Constrictive Pericarditis

Constrictive pericarditis is said to be present when diastolic filling of the heart is restricted by a thickened and adherent pericardium. Several causes of constrictive pericarditis have been identified, including infectious processes and complications of cardiovascular surgery, and it may occur as part of Dressler's syndrome weeks or months after an MI.[444,445] However, constrictive pericarditis is most commonly idiopathic.[446]

Pathophysiology In cases of constrictive pericarditis, the thickened pericardium does not allow the heart to expand fully as it fills with blood during diastole. Instead, blood flows rapidly into the cardiac chambers during the first third of diastole and then suddenly stops as the thickened pericardium reaches its expansion limit.

Signs and Symptoms of Constrictive Pericarditis Typically, patients with constrictive pericarditis have elevated systemic venous pressure and low cardiac output.[447] Another feature of constrictive pericarditis is the diastolic equalization of pressures.[444] Because the heart is encased in a stiff pericardium, similar increases in diastolic pressure, usually within 5 mm Hg of one another, are noted in all four chambers.

Another sign seen in constrictive pericarditis is Kussmaul's sign, (an exaggeration of the x and y descent on the CVP tracing), which is elicited in response to increased blood return to the right heart on inspiration. Because the thickened pericardium no longer allows the heart to expand to accommodate all the blood flowing into it, the pressure generated by this returning volume is transmitted to the central venous system.[444]

As in pericardial tamponade, pulsus paradoxus is also usually seen in constrictive pericarditis. However, in some cases, thickening of the pericardium can shield the myocardium from the effects of the respiratory cycle, and therefore pulsus paradoxus might not be that obvious. Dyspnea and orthopnea are common in patients with constrictive pericarditis[446] because the low cardiac output caused by constrictive pericarditis severely reduces the patient's exercise tolerance and, in extremely advanced cases, causes cardiac cachexia and muscle wasting.[445] Ascites and peripheral edema may also be seen.

Anesthetic Considerations for Pericardiectomy Pericardiectomy is the treatment of choice for curing constrictive pericarditis.[444] This procedure is usually performed through a sternotomy, but it can also be performed through a left thoracotomy incision.[444,446] In patients with severe cases of the disease, pericardiectomy may involve stripping the pericardium off the heart, which may necessitate the use of CPB.

Anesthetic management of a patient undergoing pericardiectomy for constrictive pericarditis is similar to that of a patient undergoing a surgical intervention for pericardial effusion and tamponade. However, because the pericardium may need to be "peeled" from the surface of the heart, pericardiectomy carries an additional risk of arrhythmia and injury to the myocardium itself, including rupture of one of the chambers. Measures should be taken to avoid and treat arrhythmias and massive intraoperative bleeding.

Cardiac and Aortic Trauma

Penetrating Cardiac Injury

With the increase in violent crime over the last few decades, the number of cases of gunshot and stab wounds to the heart has risen.[448] Patients with penetrating cardiac injury may be critically unstable because of hemorrhage or cardiac tamponade, or they may have a benign injury to the heart.[449] An echocardiogram can detect the presence of blood around the heart[448] and can aid in making the surgical decision of whether to perform a sternotomy or to use an alternative approach.[450]

Anesthetic management of patients with penetrating cardiac injury is similar to that of other trauma patients. Unstable patients require emergency surgical intervention. The anesthesiologist must ascertain that blood is available on first knowledge of impending surgery for penetrating cardiac injury. With critically unstable patients, the anesthesiologist must secure the airway, establish intravenous access, and place the monitoring lines while the surgical incision is being made. An assistant can be very helpful in efficiently caring for such a patient. In planning induction of anesthesia and securing of the airway, the anesthesiologist should consider that the patient probably has a full stomach and volume depletion. Monitoring lines should include an arterial line and a central venous catheter. Barring any contraindications on the basis of the scant history that may be available at that time, TEE should be considered as an additional monitor. Anesthesia management involves attempting to maintain stable hemodynamics and prevent recall.

As in any trauma case, if the patient is unstable when first seen, controlled postoperative ventilation is usually preferred. The patient should be transported to the ICU with full monitoring and ventilatory support.

Traumatic Aortic Injury

Blunt aortic injury, which can result in either traumatic aortic transection (TAT) or acute rupture, is one of the most common causes of death from blunt trauma, second only to head injury. On arrival at the hospital, only 25% of patients with blunt thoracic trauma and resultant aortic injury (TAT or acute rupture) are alive.[451] Furthermore, the prognosis of patients who survive the initial injury and remain untreated is poor: 30% die within the first 6 hours, 50% die in the first 24 hours, and 90% die within the first 4 months.[452]

In blunt trauma to the chest, the mechanism of injury to the thoracic aorta is sudden traction on the relatively immobile portion of the aorta, the isthmus, as a result of sudden deceleration.[451] The isthmus is distal to the left subclavian artery, proximal to the third intercostal artery, and fixed to the left pulmonary artery by the ligamentum arteriosum.[453] This area of attachment of the ligamentum arteriosum acts as a hinge for movement of the aortic arch; thus, it receives the brunt of the shearing force during violent injury to the chest area. Hence, it is the most

common location for rupture of the aorta (50% to 70%), followed by the ascending aorta or the aortic arch in 18% and the distal thoracic aorta in 14% of cases.[451,453] The spectrum of injuries to the thoracic aorta in blunt thoracic trauma ranges from simple subintimal hemorrhage to complete aortic transection.[453]

The diagnosis of aortic injury may be made on the basis of a plain chest radiograph, computed tomography, angiography, or TEE. Smith and coworkers,[454] in a study of 93 trauma patients, concluded that TEE was a very sensitive and specific method of detecting aortic injuries in patients with blunt thoracic trauma and compared favorably with aortography. Diagnosing TAT with TEE requires recognition of a mediastinal hematoma[453]; a gap of more than 7 mm between the probe and the aorta at the level of the proximal descending thoracic aorta, plus blood between the aortic wall and the pleura, strongly suggests disruption of the aorta.[453,455] TEE can also be useful in monitoring the progression of a small intimal tear or as a screening tool for patients who have a normal mediastinum after blunt thoracic trauma.

Management of TAT focuses on the high risk of rupture that this injury entails; in-hospital rupture rates are as high as 13% in some series of TAT cases.[453,456-458] The unpredictable timing of this event adds to the concern for these patients. Aggressive management of blood pressure in the preoperative period is necessary to minimize the risk of rupture.[459] Systolic blood pressure should not exceed 100 mm Hg, and heart rate should not exceed 100 beats/min. The use of β-blockers and nitroglycerin or sodium nitroprusside infusions is recommended.

Monitoring during surgery should include an arterial catheter and central venous access. The keys to anesthetic management of patients with TAT are avoiding wide swings in systolic blood pressure and continuously monitoring the patient for end-organ ischemia. Because many operations on patients with TAT are performed on an emergency basis, aspiration precautions may be required. Additionally, some experts recommend using a modified rapid-sequence induction. Despite all precautions, marked swings in blood pressure are often seen during induction and laryngoscopy. Agents such as nitroglycerin and esmolol should be immediately available to treat any undesirable hypertension while the airway is being secured.

Intraoperatively, one major concern is the preservation of vital organs, most of all the spinal cord. In open procedures, using partial CPB (LHB) can facilitate the operation and, at the same time, preserve visceral organ perfusion and the spinal cord. This technique also prevents the aggravation of any other injuries that the patient might have sustained because this type of bypass does not require heparin.[452]

Aggressive management of blood pressure (i.e., keeping systolic blood pressure ≤100 mm Hg) and the heart rate[459] remains the cornerstone of the postoperative management of patients with traumatic thoracic aortic injuries. Another priority is maintenance of adequate perfusion of the vital organs and spinal cord.

Endovascular Aortic Repair

Endovascular repair of the aorta is a less invasive alternative to conventional open operations for aortic disease. With the endovascular technique, there is less blood loss, a reduction in the extent of hemodynamic fluctuations, and less metabolic stress on the patient. In addition, endovascular repair is often more acceptable to patients.[460] Because of the possibility of aortic rupture, preparations for emergency conversion to an open procedure should always be made in advance.[461]

General anesthesia is used during endovascular repair of TAT. As with open repair, anesthetic care of a patient undergoing endovascular repair should include an arterial catheter and central venous access.[460] TEE is valuable for locating the lesion in the thoracic aorta, positioning the guidewires, and deploying endografts.[461,462] Orihashi and associates[462] state that the sensitivity and specificity of TEE for detecting endoleaks are 100%. However, one's ability to visualize the distal ascending aorta and the proximal aortic arch with TEE is limited by the presence of the trachea and the right bronchus between the esophagus and the aorta.[463,464] Additionally, TEE can be used only when the fluoroscope is not in active use.

Ischemic Emergencies

With rapid advances in interventional cardiology, the number of patients undergoing interventional therapy in catheterization laboratories in the United States and Europe is increasing. Morris and colleagues[465] studied 5614 coronary interventions performed over a 3-year period at a single institution, 81 of which involved angiography-related accidents necessitating emergency cardiac surgery. Such emergencies included coronary artery dissection, free rupture, tamponade, foreign body embolism, and wire entrapment.

Patients may be at high risk for complications in the catheterization laboratory if they have unfavorable coronary anatomy or severe ventricular dysfunction. In some cases, cardiac surgery and cardiac anesthesia services should be consulted and placed on standby for possible emergency intervention. The rapidity of surgical intervention (e.g., revascularization or temporary mechanical support) plays a crucial role in reducing the mortality and morbidity of patients who suffer angiography-related accidents.

When ischemic complications occur during cardiac catheterization with percutaneous transcoronary angioplasty and stenting, pharmacologic intervention and possibly a device such as an IABP or VAD may be used to stabilize the patient's hemodynamic condition before being urgently or emergently transferred to the operating room for open coronary revascularization. Patients may be intubated on an emergency basis in the catheterization laboratory. In patients with coronary dissection or severe ischemia, it may be necessary to perform CPR during transport to the operating room.[466] Although the anesthesiologist, cardiologist, or both may lead these resuscitative efforts, all members of the catheterization team—physicians, nurses, and technologists—should complete a course in basic CPR; additionally, certification in advanced cardiac life support, with annual recertification, is strongly urged.[467]

If the patient is not already intubated, the choice of induction agents should be tailored to the patient's hemodynamic condition, with avoidance of hypotension and tachycardia while keeping in mind the patient's oral intake status. Perioperative monitoring of these patients should include an arterial line and central intravenous access, which should be established as soon as possible. TEE can be of immense importance in diagnosing the cardiac problem and in monitoring the patient intraoperatively.

Other procedures performed in the catheterization laboratory, notably aortic aneurysm stenting, may also require operating room backup. A dedicated surgical team should be available in the event of a life-threatening complication. Planning for the possibility of conversion to an "open" procedure is imperative, such

as when an aneurysm is leaking or a catheter has perforated a major blood vessel or cardiac chamber. If hemodynamic stability can be achieved, the patient can be urgently transported to the general operating suite. However, bringing a surgical team into the catheterization laboratory may be the most efficient strategy when circumstances are more dire, such as when a patient's aneurysm ruptures and the team is needed to directly cross-clamp the aorta.

Optimal care also depends on the ready availability of a stat laboratory. Blood gas analysis, as well as assessment of electrolytes and hemoglobin or hematocrit, is important in urgent situations. Patients undergoing procedures for coronary revascularization may be receiving platelet inhibitor drugs. Conventional coagulation tests may not be sufficient for diagnosing clinical bleeding in these patients, and tests that evaluate platelet function might be necessary.[188]

When compared with elective cardiac surgical procedures, emergency cardiac surgery carries a higher risk for mortality and morbidity, especially if the patient is in cardiogenic shock.[468] Identification of high-risk patients going to the catheterization laboratory for interventional procedures and communication among the interventional cardiologists, cardiac surgeons, and cardiac anesthesiologists about these high-risk patients are of prime importance in improving the outcome of these emergency procedures.

Procedures in the Cardiac Catheterization Laboratory and the Hybrid Operating Room

In the last 3 decades, the scope of activity in the cardiac catheterization laboratory (CCL) has greatly increased and has diverged considerably from the simple diagnosis and evaluation of valvular heart disease, coronary artery disease, and CHD.[469] In an increasing number of cases, anesthesia for patients with cardiac disease is being administered outside the standard operating suite, with the CCL being a primary site. Cardiac anesthesiologists may thus find themselves in a relatively isolated environment with bulky equipment, subdued lighting, and limited access to the patient.[469] Assistance from surgical colleagues, if required, may not be readily available. Furthermore, the services of anesthesia support personnel, the pharmacy, and the stat laboratory may not be immediately available. Finally, a recovery area suitable for patients with moderate or severe cardiac disease who have undergone heavy sedation or general anesthesia may be in a distant location.

To address some of these issues, so-called hybrid operating rooms with complete dual capability for procedures that require fluoroscopy, open surgery, or both have been designed and built within or adjacent to the regular surgical suite in some institutions. The physical location of such hybrid rooms may represent an advance in care in that key personnel are more readily available to handle unanticipated complications and emergencies.

The types of procedures that are done in the CCL or the hybrid operating room vary according to institutional preferences but may include (1) electrophysiologic assessment of rhythm disorders and management by ablation or by implantation of devices, (2) biventricular pacing for heart failure, (3) stenting of abdominal or thoracic aortic aneurysms, (4) balloon dilation and stenting for valvular and subvalvular lesions, and (5) the use of occlusion or umbrella devices to close an atrial or ventricular septal defect or a patent ductus arteriosus.

Although requirements vary depending on the nature of the procedure, sedation or anesthesia improves the efficacy and safety of many procedures.[469] Providing stable hemodynamics for organ perfusion and preservation during anesthesia is an important goal. Many CCL procedures can be performed with the aid of "monitored anesthesia care" (MAC) or regional blocks, provided that a certain patient comfort level can be achieved.[470] However, during difficult and lengthy procedures, patients may have trouble staying still. In many cases, a general anesthetic may be the best option. If indicated, general anesthesia with endotracheal intubation provides a controlled situation: patient comfort is maximized, and the airway is secured.[466] Use of a laryngeal mask or a standard mask airway is also possible, but the constant diaphragmatic movements that occur during spontaneous ventilation may interfere with fluoroscopic visualization of cardiac and vascular structures.

Radiation Safety

Because fluoroscopy is frequently used during interventional procedures in the CCL and hybrid operating rooms, it can present a significant risk of radiation exposure to patients and health care workers. Potential hazards of ionizing radiation include skin injuries and cellular mutation, which can lead to leukemia, bone cancer, and birth defects.

The radiation safety program at the Centers for Disease Control and Prevention (CDC) has developed the concept that radiation doses should be "as low as reasonably achievable" (ALARA). Exposure to radiation can be minimized by three means: distance, time, and barriers.[467] The distance between the person and the source should be maximized because the dose rate varies with the inverse square of that distance. In addition, the person's exposure time should be minimized because the dose rate and time are directly related. Finally, personal shielding and shielding of the radiation source should be maximized.

The roentgen equivalent man (rem) is the unit used to quantify radiation exposure.[466] It represents a unit of absorbed dose equal to the radiation absorbed dose (rad) multiplied by a factor weighted according to the type of radiation used. For radiographs, 1 rem is equal to 1 rad. A chest radiograph delivers a dose of 40 mrem, whereas a nuclear medicine study delivers about 14 mrem.

It is imperative that health care personnel in a radiation environment wear a dosimeter badge to track cumulative radiation exposure. The dosimeter should be worn on areas at highest risk for frequent exposure and outside any shielding garments (e.g., on the thyroid collar). Corrective action is recommended if an individual (patient or provider) receives more than 5 rem/yr to the whole body. In the case of pregnant individuals, the total radiation exposure to the fetus throughout gestation should be no more than 0.05 rem/mo or 0.5 rem total.[467]

Radiocontrast Media

Preventing allergic reactions to contrast agents is another consideration unique to procedures performed in the CCL or hybrid

suite. A complete description of any previous exposure to radiographic contrast material and whether any reaction occurred should be obtained. In many CCLs, an intravenous steroid is administered a few hours before the procedure, although there are no data to support or refute the advantages of this practice.[467] In addition, H_1 and H_2 blockers are often used to further reduce the possibility of an allergic reaction.

In patients with renal insufficiency, radiocontrast media–induced nephropathy is a concern, and diabetic patients are at particularly high risk for ARF after exposure to contrast agents.[466,467] These effects can be minimized through careful administration of contrast agents and limitation of the total dose.[466] Preprocedural and postprocedural hydration is recommended. However, in patients with severe HF, near–end-stage renal disease, or both, one must be careful to avoid volume overload.[466,467] Elevated serum creatinine levels are common after the administration of radiocontrast media, and these levels should be monitored for 72 or more hours in patients at risk. Fortunately, renal dysfunction is usually transient and rarely progresses to ARF.

Anesthesia for Electrophysiologic Procedures

Invasive cardiac electrophysiology studies are now common procedures in the CCL. Examples include electrophysiologic mapping with RF ablation or implantation and testing of an AICD. Electrophysiologic studies involve placing diagnostic catheters within various cardiac chambers to determine the origin and pathway of arrhythmias.[469] Arrhythmias are actually reproduced under controlled conditions by applying timed electrical impulses. Such arrhythmia induction, as well as any subsequently delivered "shock," is unpleasant and necessitates sedation or brief anesthesia in most patients. However, a relatively small proportion of adult patients require general anesthesia throughout the duration of the procedure. Many sedative and anesthetic agents have potential effects on cardiac rate, rhythm, or both. These effects need to be considered because the electrophysiologist must be able to induce a pathologic tachycardia to locate the pathway and successfully ablate it (or test the ability of an AICD device to terminate the arrhythmia).

Electrophysiologic Studies and Ablation

RF catheter ablation has, in many cases, replaced pharmacologic antiarrhythmic therapy for the treatment of recurrent or persistent tachyarrhythmias. Tachyarrhythmias appropriate for this treatment include those with a focal origin and, more commonly, those with a reentrant circuit. Electrophysiologic studies in the CCL usually involve inducing the tachycardia, mapping it, and performing transcatheter RF ablation.[471] Three to five electrode catheters are inserted percutaneously via venous access or via retrograde aortic catheter insertion and a transseptal approach. The catheters are positioned within the heart to allow induction of the arrhythmia and recording at key sites. Induction of the arrhythmia may be performed with pacing maneuvers that introduce critically timed ectopic beats to establish reentrant excitation. Heightened adrenergic tone, usually achieved by the administration of isoproterenol, may be necessary.

Induction of arrhythmia is unpleasant and requires some sedation. General anesthesia may be required in adults who are unable to cooperate. Many agents commonly used as part of the anesthetic technique may affect cardiac rhythm (e.g., lidocaine), and the use of such agents should be discussed with the electrophysiologist. It should be remembered that all inhaled agents affect the conduction system of the heart, whereas most intravenous induction agents have little effect on this system.[469] Once the arrhythmia's site of origin has been identified, the electrode catheter is positioned in direct contact with this site, and RF energy is delivered through the catheter. Any patient movement during ablation can result in catheter dislodgement and potential damage to normal conduction tissue.[469]

If catheter RF ablation fails, isolation of pulmonary vein foci and catheter ablation or a surgical approach may be required.[426] Further details are provided in the section "Cox-Maze Procedure."

Pacemaker/AICD Insertion, Generator Change, and Laser Lead Extraction

An AICD is a device capable of arrhythmia detection and automatic defibrillation. Such devices are often indicated for patients with advanced HF to decrease their risk of sudden death.[472] Patients require close monitoring, often including an arterial catheter, because of the potential for rapid blood pressure changes during the testing process. Central venous catheter placement should be considered in patients with poor peripheral venous access. If a technique is chosen that involves local anesthesia supplemented with sedation, administration of a small dose of propofol (in 0.25-mg/kg increments) or etomidate (0.05 to 0.1 mg/kg) in patients with preexisting hypotension may be necessary before inducing ventricular fibrillation and subsequently delivering an uncomfortable shock. It may take some time for hemodynamic variables to return to baseline after tests involving purposeful fibrillation followed by defibrillation.

Laser extraction of an AICD lead that is infected or damaged is another procedure that may be of long duration and require general anesthesia. The lead may be attached firmly to the endocardium and necessitate the use of a special coaxial laser device that slides over the lead to help burn it free. Myocardial perforation with ensuing cardiac tamponade is a rare but potentially lethal complication of this procedure.[469]

Patients with an AICD who undergo surgery (cardiac or noncardiac) should have the defibrillator disabled before anesthesia is induced and the surgical procedure begins, particularly if the use of electrocautery is planned. Preparation of an alternative method of defibrillating a potentially lethal arrhythmia, such as placement of an external defibrillator pad, must be done before the AICD is disabled. It is also important to ensure that the AICD is re-enabled immediately after the procedure is completed.

Biventricular Pacing

In many patients with advanced HF, defects in sinus or AV node function, intraventricular conduction defects (commonly left bundle branch block), or both delay the onset of LV or RV systole.[473] This lack of coordination of the left and right ventricles further reduces cardiac output and may increase the risk for mortality in these patients.[474] Cardiac resynchronization therapy is a variant of traditional AV pacing that involves placing additional pacing leads on the lateral wall of the left ventricle in a coronary

vein (accessed via the coronary sinus). Both ventricles can then be paced in a carefully timed manner to "resynchronize" RV and LV contraction, improving mechanical efficiency and cardiac output. Anesthesiologists are sometimes asked to provide sedation for these procedures, which may be somewhat lengthy. All the usual considerations for a patient with advanced HF are applicable, even if a "lighter" plane of sedation is chosen.

Problems in the Postoperative Period

Low Cardiac Output Syndrome

A combination of ischemia and reperfusion injury after cardiac surgery contributes to an energy deficit state in the myocardium that limits uptake of exogenous energy substrates from blood. Myocardial dependence on endogenous energy substrates results. Patients with preexisting cardiac failure experience a delay in myocardial recovery after cardiac surgery and require measures to relieve the workload of the heart.[475]

Criteria used to define LCOS include a CI of less than 2.4 L/min/m^2, elevated lactate levels, and urine output of less than 0.5 mL/hr for more than 1 hour.[476] $S\bar{v}O_2$ is also a good indicator of LCOS in that it reflects the balance between cardiac output and systemic oxygen demand.

Studies of patients undergoing CPB for cardiac surgery have found several preoperative risk factors for postoperative LCOS, including poor LV function, reoperation, urgency of the operation, female gender, diabetes mellitus, advanced age, left main coronary artery disease, MI within the previous 30 days, triple-vessel disease, hypertension, peripheral vascular disease, and renal dysfunction.[477,478] Furthermore, in patients undergoing cardiac surgery, preexisting diastolic dysfunction is associated with an increased risk of difficulty in separating the patient from CPB and need for vasoactive support in the ICU.[55] Therefore, evaluation of diastolic function should be part of the routine echocardiographic assessment of patients undergoing cardiac surgery. Intraoperative risk factors include myocardial ischemia during cross-clamping, reperfusion injury, cardioplegia-induced myocardial dysfunction, and activation of the inflammatory and coagulation cascades.[476]

Postoperative management of patients at high risk for LCOS requires a physiologic approach. Reducing afterload and optimizing preload help maximize cardiac function. Tachycardia should be avoided because it increases the risk for ischemia and postoperative MI. In addition, shivering should be prevented because it raises the heart rate by increasing oxygen demand.[477] Postoperative deep sedation and muscle relaxation are often used to reduce myocardial workload by reducing the body's overall metabolic demand by 25% to 30%.[475]

Pharmacologic support is sometimes needed to improve contractility as the patient is weaned from CPB and, eventually, recovering in the ICU.[476] Catecholamines and phosphodiesterase inhibitors are the main classes of pharmacologic agents used for this purpose. Table 60-19 lists the significant findings of studies of these inotropes completed by 2004. Although not yet available in the United States, a new class of drugs—calcium sensitizers, such as levosimendan—exhibit potent inodilatory properties.[199] In a study of patients with LCOS after cardiac surgery, levosimendan was found to enhance calcium sensitivity in cardiac

Table 60-19 Summary of Literature Search Findings on Therapy after Cardiac Surgery

Agent	Total Number of Studies	"Level I" Studies	"Level II" Studies	Significant Findings
Epinephrine	15	0	10	Increases CI with a biphasic effect on the SVR index. Produces a rise in serum lactate
Dopamine	22	0	14	Increased the SVR index at doses above 5.0 μg/kg/min. Less clinical efficacy than with dobutamine, dopexamine, amrinone, or enoximone. Higher incidence of adverse cardiac events than with dopexamine
Dobutamine	23	0	18	Better efficacy than dopamine and epinephrine. Decreased SVR index. Tachycardia and tachyarrythmia (especially AF) associated with its use. More ischemic complications than with amrinone
Dopexamine	20	0	12	Greater tachycardia than with dobutamine. More efficacious and fewer adverse events than with dopamine
Amrinone	27	1	13	Improved weaning from CPB. Improves CI and decreases the SVR index with minimal effects on HR. Fewer ischemic complications than with dobutamine. Reports of thrombocytopenia associated with use
Enoximone	24	0	15	Significant increase in CI without tachycardia. Decreases the SVR index. As effective as dobutamine
Milrinone	27	0	17	Significant increase in CI without tachycardia. Decreases the SVR index. As effective as dobutamine but less AF. Lusitropic. Improves IMA graft flow. As effective as 20 ppm NO in pulmonary hypertension

AF, atrial fibrillation; CI, cardiac index; CPB, cardiopulmonary bypass; HR, heart rate; IMA, internal mammary artery; NO, nitric oxide; SVR, systemic vascular resistance.
From Gillies M, Bellomo R, Doolan L, et al: Bench-to-bedside review: Inotropic drug therapy after adult cardiac surgery—a systematic literature review. Crit Care 9:266-279, 2005.

myocytes, thereby increasing stroke volume and CI while decreasing PA occlusion pressure.[479]

Arrhythmias

Cardiac arrhythmias are a common and well-recognized complication of cardiac surgery. Postoperative arrhythmias are seen in 10% to 40% of patients who undergo cardiac surgery.[480-482]

Atrial Arrhythmias

Atrial arrhythmias occur in up to 50% of patients who have undergone valve surgery[483-486] and in 17% to 33% of patients who have undergone CABG.[481,487] The most common arrhythmia after cardiac surgery is AF. Patients are at highest risk for new-onset AF in the first few days after cardiac surgery. New-onset AF can cause hemodynamic compromise, and it increases the risk for thromboembolic complications, thereby potentially prolonging a patient's hospital stay.[483-486,488]

Many potential risk factors have been studied in an effort to predict the occurrence of postoperative AF. One known preoperative risk factor is age. Age-related atrial dilatation with hypertrophy and fibrosis provides a substrate for reentrant arrhythmias.[489] This dilatation interrupts cell-to-cell electrical coupling between atrial muscle fibers.[490] Other preoperative risk factors for postoperative AF include COPD, use of digoxin within 2 weeks before surgery, low resting pulse rate, high resting systolic blood pressure, ischemia or infarction, withdrawal of β-blockers, RCA stenosis, and sinus or AV nodal artery disease.[488,491] Intraoperative risk factors for AF include cardiac venting via the right superior pulmonary vein, mitral valve repair and replacement, use of inotropic agents for more than 30 minutes after the termination of CPB, trauma from cannulation, hypomagnesemia, inflammation caused by CPB, prolonged cross-clamp times, and the type of cardioplegia used.[488,491] Pericarditis and low levels of magnesium have been proposed as possible causes of supraventricular arrhythmias in the postoperative period, but studies have not confirmed this relationship.[488]

Treatment of AF has been achieved by pharmacologic agents and electrical means. Studies have shown that β-blockers and amiodarone may be effective prophylaxis against postoperative AF.[488] In most patients, AF is self-limited, and patients usually spontaneously convert to sinus rhythm.[489] Synchronized cardioversion is reserved for patients who show signs of hemodynamic instability in the presence of AF.[488] Patients with persistent AF who do not urgently need cardioversion should be managed with the goal of controlling the ventricular rate.[488]

Ventricular Arrhythmias

Although ventricular arrhythmias occur after cardiac surgery, sustained ventricular arrhythmias are relatively uncommon. Associated factors may include hemodynamic instability, electrolyte abnormalities, hypoxia, hypovolemia, ischemia or infarction, acute graft closure reperfusion, and inotropic agents.[488]

Ventricular arrhythmias can range from simple premature ventricular complexes (PVCs) to ventricular tachycardia (VT). Simple PVCs do not pose a significant risk of life-threatening ventricular arrhythmia. On the other hand, complex ventricular arrhythmias, including both frequent PVCs (>30/hr) and nonsustained VT, may make patients prone to sudden death, especially in the long term. Sudden death is even more likely if ventricular function is also compromised. A study of 126 patients with postoperative complex ventricular ectopy reported a mortality rate of 75%.[488] During an average follow-up period of 15 months, sudden death occurred in 33% of the patients whose left ventricular ejection fraction (LVEF) was 40% or less, whereas none of the patients with a normal LVEF had sudden death.[493] Patients with sustained ventricular arrhythmias have a poor prognosis in both the short and long term.

Patients who are asymptomatic and hemodynamically stable do not usually require acute treatment of PVCs or even short runs of nonsustained VT, although any reversible causes should be corrected. On the other hand, patients with VT accompanied by hemodynamic instability need immediate synchronized cardioversion.[494] Amiodarone is reserved for hemodynamically stable patients with VT or an uncertain rhythm.[494] Ventricular fibrillation should be treated promptly with electrical defibrillation.[488] For long-term management of ventricular arrhythmias, in addition to antiarrhythmic agents, electrophysiologic studies or placement of an ICD should be considered.[488]

Bradyarrhythmias

Bradyarrhythmias are not uncommon in the immediate postoperative period. In most cases, a temporary epicardial pacemaker is sufficient. In a small percentage of patients, a permanent pacemaker may be necessary, especially in those with sinus node dysfunction or AV conduction disturbances after either CABG or valve surgery.[488]

Patients who need a permanent pacemaker may receive either a single-chamber or a dual-chamber pacemaker. Factors that influence the selection of a permanent pacemaker range from the patient's particular cardiac disease to access to technical support.[495] Both the single- and dual-chamber pacemakers have specific timing designs.

Hypertension

Immediately after cardiac surgery, the patient remains prone to hemodynamic instability, including hypertension.[496] Causes of postoperative hypertension are often multifactorial and may include withdrawal from preoperative antihypertensive medications (e.g., β-blockers and centrally acting α_2-agonists), pain, hypoxemia, hypercapnia, and hypothermia. However, arterial vasoconstriction usually plays a central role in acute postoperative hypertension.[497] Hazards of untreated postoperative hypertension include increased myocardial work and oxygen consumption, MI, rhythm disturbances, increased bleeding, and even suture line disruption. In the postoperative period, deepening sedation to control a hypertensive episode may not be the best or the only approach, particularly if "early" extubation (fast-tracking) is desirable.[496,497]

Several pharmacologic agents are available for use as antihypertensives; the ones most commonly used in clinical practice are the nitrovasodilators and the dihydropyridine-type calcium channel blockers (Box 60-14). Because of its anti-ischemic effects and familiarity, nitroglycerin is often the first agent used to treat hypertension in patients who have undergone coronary revascularization. However, nitroglycerin is not always effective in this setting because it primarily causes venodilation rather than arterial dilation. Moreover, patients tend to develop tolerance to nitroglycerin.[497]

Box 60-14 Vasodilators Available for the Treatment of Perioperative Hypertension

Adenosine
α_1-Adrenergic antagonists
α_2-Adrenergic agonists
Angiotensin-converting enzyme inhibitors (enalaprilat)
Angiotensin II antagonists
Atrial natriuretic peptide (nesiritide)
β_2-Adrenergic agonists
Dihydropyridine-type calcium channel blockers*
Dopamine agonists
Hydralazine
Nitrovasodilators*
Phosphodiesterase enzyme inhibitors
Prostaglandins

*Intravenous vasoactive therapies in widespread use to treat perioperative hypertension.
From Levy JH: Management of systemic and pulmonary hypertension. Tex Heart Inst J 32:467-471, 2005.

Because arterial vasoconstriction plays an important role in the development of hypertension after cardiac surgery, the therapeutic agent chosen should usually be one that effectively reduces hypertension. Sodium nitroprusside, a nonspecific venous and arterial vasodilator, is a common choice. However, theoretically, nitroprusside can cause coronary steal.[497] Furthermore, in patients with renal failure, elimination of sodium nitroprusside is reduced, thus making the patient vulnerable to the toxic effects of this drug's metabolites (cyanide and thiocyanate).

Fenoldopam is a short-acting dopamine agonist that causes arterial-specific vasodilation by stimulating D_1 receptors. Unlike sodium nitroprusside, fenoldopam increases renal blood flow to produce diuresis and natriuresis. Nevertheless, most clinical trials on the renal protective effects of fenoldopam are, at best, equivocal.[498] However, in one trial in cardiac surgical patients, the investigators concluded that fenoldopam did prevent acute kidney injury in a high-risk population of patients undergoing cardiac surgery.[499] Higher doses of fenoldopam may be needed for severe hypertension but may be associated with undesirable increases in heart rate.

Dihydropyridine-type calcium channel blockers, such as nicardipine and clevidipine, selectively relax arterial resistance vessels without negative inotropic or dromotropic (conduction) effects; they result in generalized vasodilation of the renal, cerebral, intestinal, and coronary vascular beds. Although cost is higher than that for the older agents (nitroglycerin or nitroprusside), nicardipine and clevidipine are recommended by some experts as first-line treatment for cardiac surgical patients with acute hypertension requiring immediate control.[497]

It is important to ensure that the patient's intra-arterial pressure is monitored adequately when any vasoactive agent is administered. Vasoconstriction or poor perfusion of the extremities may create a discrepancy between central aortic and peripheral arterial pressure. In addition, a radial arterial catheter may be "positional" if hand positioning is suboptimal, or "dampening" of the tracing may occur as a result of poor perfusion of the distal extremities. Occasionally during the perioperative period, the cardiac anesthesiologist or surgeon must replace a peripheral catheter (e.g., insert a femoral arterial catheter) to ensure that the effects of vasoactive therapy are monitored accurately.

Renal Insufficiency

Perioperative renal dysfunction, when it occurs, can have serious consequences. In a multicenter study of more than 2000 patients who underwent coronary revascularization with or without valvular surgery, Mangano and coworkers[83] found postoperative renal dysfunction in 7.7%, including 30 (1.4%) patients in whom dialysis was needed. In that study, mortality was higher in patients with ARF requiring dialysis (63%) and those with renal dysfunction (19%) than in patients who had neither (0.9%). Additionally, patients with postoperative renal failure had significantly longer hospital and ICU stays than did patients who had no renal failure or dysfunction in the postoperative period. Bove and associates,[81] in a study of more than 5000 patients who underwent cardiac surgery with CPB, found that 1.9% required postoperative dialysis and had an in-hospital mortality of 64%.

Preoperative risk factors that are commonly associated with postoperative renal dysfunction after cardiac surgery include preexisting renal insufficiency,[500,501] type 1 diabetes mellitus, age older than 65 years, major vascular surgery, arteriopathy, genetic predisposition, and recent exposure to nephrotoxic agents, such as radiocontrast dyes, bile pigments, aminoglycoside antibiotics, and nonsteroidal anti-inflammatory drugs. Also, several intraoperative factors may predispose a patient to renal dysfunction, including the need for emergency surgery,[81] CPB time exceeding 3 hours,[76] and poor cardiac function.[501] Other perioperative risk factors for renal dysfunction after cardiac surgery are hypovolemia, hypotension secondary to either hypovolemia or LCOS, and embolic phenomena.[76] Furthermore, damage to nephrons in the medullary region of the kidney is the most common cause of acute tubular necrosis, with hypoxia being a common cause of damage to nephrons in this region.[76]

Based on studies performed in patients with radiocontrast nephropathy, it has been concluded that hydration before the administration of radiocontrast media may protect the kidneys against the occurrence of postoperative renal dysfunction.[76] Because the mechanism of renal injury after CPB appears to be similar to that after the administration of radiocontrast dyes, it is thought that adequate hydration and maintenance of normovolemia can help in the prevention of postoperative renal dysfunction in cardiac surgical patients.[76] Furthermore, in patients at high risk for ARF, perioperative care should optimize cardiac output and, if possible, reduce the duration of CPB.[81]

Although the definition of ARF varies between studies, three useful criteria include (1) a serum creatinine level greater than 44 mmol/L (>0.5 mg/dL) above its preoperative value, (2) a serum creatinine level greater than 50% above its preoperative value, and (3) a serum creatinine level higher than 177 mmol/L (>2.0 mg/dL).[76] Another definition of ARF involves a classification scheme (Table 60-20) that uses the acronym "RIFLE."[502] A study performed by Kuitunen and colleagues[502] concluded that 90-day mortality is high in patients with a severe RIFLE classification.

Certainly, postoperative ARF in cardiac surgical patients is associated with longer ICU stay, longer overall hospital stay, and

Table 60-20 The RIFLE* Classification Scheme for Acute Renal Failure

	GFR Criteria	Urine Output Criteria
Risk	Plasma creatinine increased 1.5× or GFR decrease >25%	<0.5 mL/ kg/h × 6 hr
Injury	Plasma creatinine increased 2× or GFR decrease >50%	<0.5 mL/kg/hr × 12 hr
Failure	Plasma creatinine increased 3×, acute plasma creatinine ≥350 µmol/L, or acute rise ≥44 µmol/L	<0.3 mL/kg/hr × 24 hr or anuria × 12 hr
Loss	Persistent acute renal failure = complete loss of kidney function >4 wk	
ESKD	End-stage kidney disease (>3 mo)	

*Acronym for risk, injury, failure, loss, and end-stage kidney disease (ESKD).
GFR, glomerular filtration rate.
From Kuitunen A, Vento A, Suojaranta-Ylinen R, Pettilä V: Acute renal failure after cardiac surgery: Evaluation of the RIFLE classification. Ann Thorac Surg 81:542-546, 2006.

increased mortality[76,83]; thus, it should be prevented whenever possible. Several treatment modalities have been suggested to prevent or ameliorate postoperative renal dysfunction (Box 60-15).[76] Unproven pharmacologic therapies include dopamine, dopexamine, the loop diuretics, mannitol, calcium channel entry blockers, ACEIs, and atrial natriuretic peptide.

Central Nervous System Dysfunction

CNS dysfunction is a common and potentially catastrophic complication of cardiac surgery and CPB. Rates of CNS injury vary between studies, but a large multicenter study found an overall 6.1% incidence of adverse cerebral outcomes.[56] Other studies, examining only neurocognitive dysfunction, have reported incidences approaching 60%.[62] A large European study involving more than 16,000 patients reported the following injury rates: OPCAB, 1.9%; CABG, 3.8%; aortic valve operations, 4.8%; CABG combined with valve procedures, 7.4%; mitral valve operations, 8.8%; and multiple-valve procedures, 9.7%.[61]

The impact of surgery-related CNS injury is profound. In a single-institution database study of 10,860 cardiac surgical patients, those who had overt perioperative strokes had survival rates of 64% at 1 year and 44% at 5 years, whereas patients who did not have perioperative strokes had survival rates of 94% at 1 year and 81% at 5 years.[503] The impact of stroke on health care resource utilization is also a cause for concern. Roach and colleagues[56] found that 47% of patients who had a type I neurologic event (stroke or transient ischemic attack) were discharged from the hospital to a skilled nursing facility or rehabilitation center. Furthermore, 30% of patients with more subtle neurocognitive dysfunction (type II event) after cardiac surgery were discharged to such facilities versus 8% without type I or type II events. Given that the clinical manifestation of cerebral injury is primarily a postoperative diagnosis, often with potentially irreversible neurologic sequelae and significant consequences for resource utilization, preoperative risk stratification and intraoperative management are important focal points for efforts to ameliorate and reduce CNS dysfunction and injury within the cardiac surgical population.

Neuroprotection Strategies

Numerous strategies have been tried in an attempt to decrease the incidence and severity of neurologic injury in cardiac surgical patients. A recent review of the literature by Hogue and associates,[234] using methods promoted by the AHA for making evidence-based recommendations, yielded only four management strategies with current evidence, albeit of a low to intermediate level, to support their use: epiaortic scanning leading to alterations in bypass or surgical technique, maintaining higher mean arterial pressure during CPB, using pulsatile perfusion, and using α-stat pH management during CPB. Each strategy received only a class IIb rating, which Hogue and colleagues define as follows:

> "*Class IIb: interventions are acceptable, safe, and useful. Considered 'within' the standard of care: reasonable prudent physicians can choose. Considered optional or alternative intervention by a majority of experts.*"

Many therapies and strategies received an indeterminate classification in Hogue and colleagues' review because there is not yet adequate evidence that they produce any improvement in neurologic outcome. Most pharmacologic strategies, such as the use of thiopental, propofol, nimodipine, and other drugs, received a class III rating, which means that the existing literature did not provide evidence of their efficacy. Table 60-21 lists the evidence-based ratings for various neuroprotective strategies.

Postoperative Management of Central Nervous System Injury or Dysfunction

Stroke after surgery may be indicated by the patient's inability to follow commands or move all extremities shortly after surgery. Neurologic consultation should be obtained, including diagnostic imaging. Diffusion-weighted magnetic resonance imaging is the most sensitive and accurate imaging technique for postoperative cardiac surgical patients.[504] It detects more microembolic lesions than conventional magnetic resonance imaging does and is better able to find multiple, "watershed" lesions.[505]

Box 60-15 Aims of and Treatment Modalities to Reduce or Prevent the Development of Postoperative Renal Dysfunction

1. Maintain adequate oxygen delivery—by ensuring adequate cardiac output, adequate oxygen-carrying capacity, and proper hemoglobin saturation
2. Suppression of renovascular constriction—by ensuring adequate volume preload and use of infusions of mannitol, calcium entry blockers, and angiotensin-converting enzyme inhibitors
3. Renal vasodilation—by dopaminergic agents, prostaglandins, and atrial natriuretic peptide
4. Maintain renal tubular flow—by loop diuretics and mannitol (which may act to prevent tubular obstruction, which can cause cellular swelling, ischemia, and death)
5. Decrease oxygen demand—by the use of loop diuretics and mild cooling
6. Attenuate ischemic reperfusion injury—as a result of the release of oxygen free radicals and calcium ions

Table 60-21 Evidence-Based Ratings for Pharmacologic and Nonpharmacologic Neuroprotection during Cardiopulmonary Bypass

Intervention	Rating
Heparin-bonded CPB circuits	Class indeterminate
Epiaortic ultrasound–guided changes in the surgical approach	Class IIb
Modified aortic cannula	Class indeterminate
Leukocyte-depleting filters	Class indeterminate
Cell-saver processing of pericardial aspirate	Class indeterminate
CO_2 wound insufflation	Class indeterminate
Maintaining "higher" MAP targets (i.e., greater than than the lower target of 50 mm Hg)	Class IIb for patients at high risk for neurologic injury
Nonpulsatile (versus pulsatile) perfusion	Class IIb (class indeterminate for patients at high risk for neurologic injury)
α-stat (versus pH-stat) acid base management	Class IIb (class indeterminate for patients at high risk for neurologic injury)
Minimal hematocrit target during CPB of >27%*	Class indeterminate
Thiopental, propofol, nimodipine, prostacylin, GM_1 ganglioside, pegorgotein, clomethiazole	Class III
Remacemide, lidocaine, aprotinin, pexelizumab	Class indeterminate
"Tight" intraoperative glucose control	Class indeterminate
Hypothermia	Class indeterminate

*The optimal hematocrit during CPB is not defined by available data. A hematocrit of greater than 27% is chosen as being indicative of "high" hematocrit based on its use in available randomized trials.
CPB, cardiopulmonary bypass; MAP, mean arterial blood pressure.
From Hogue CW Jr, Palin CA, Arrowsmith JE: Cardiopulmonary bypass management and neurologic outcomes: An evidence-based appraisal of current practices. Anesth Analg 103:21-37, 2006.

Management of CNS injury or dysfunction after cardiac surgery consists of general supportive measures. Hypotension should be avoided, and consideration should be given to using volume expansion, inotropic augmentation (pharmacologic or mechanical), or vasoactive medications (vasopressin or phenylephrine) to support blood pressure and brain perfusion. The brain oxygen supply-demand balance should be optimized through adequate oxygenation, sedation, and temperature control (because fever increases oxygen extraction). As mentioned in the section on glucose control, hyperglycemia should be avoided. Lytic therapy is of little use in cardiac surgery because it poses a risk for postoperative surgical bleeding.

Encephalopathic neurologic dysfunction can include neurocognitive decline, delirium, and seizure activity. Neurocognitive dysfunction, as mentioned previously,[62] has been reported to occur frequently after cardiac surgery requiring bypass. Neurocognitive decline can be manifested subtly, diagnosable only with complicated psychometric testing, or at the other extreme, it can be manifested as postoperative delirium. Delirium is characterized by disturbed consciousness and altered cognition that develops acutely. In one series of more than 16,000 cardiac surgical patients, delirium was reported to occur in 8.4% of cases.[506] Independent predictors of postoperative delirium included a history of cerebrovascular disease, peripheral vascular disease, AF, diabetes, LV dysfunction, preoperative cardiogenic shock, hemofiltration, elevated transfusion load, and operative times longer than 3 hours.

Recognition is a key element in the management of delirium, which is often multifactorial. Medications are a common cause. Clinical factors that may be important but cannot be mitigated in the postoperative period include advanced age, exposure to extended periods of CPB, the effects of microemboli, inflammatory mediators, preexisting dementia, and a history of CNS disease. Treatment revolves around delineating any treatable medical conditions that may be the precipitating cause of the delirium, such as drug or chemical toxicity or withdrawal, metabolic disorders such as hypoglycemia/hyperglycemia and uremia, fluid and electrolyte disturbances, inadequate cerebral perfusion because of a low–cardiac output or low-perfusion state, and infection or sepsis.

Peripheral Neuropathy

Peripheral nerve injury frequently follows cardiac surgery. In a review article, Sharma and coauthors[507] reported injury rates of 1.5% to 24% for the brachial plexus and 10% to 60% for the phrenic nerve. Phrenic nerve injury can occur as a result of the use of slushed ice in the pericardial well to provide surface cooling for the heart. Numbness, weakness, pain, decreased reflexes, and diminished coordination in an extremity are suggestive of peripheral nerve injury. Sensory findings in the fourth and fifth fingers, consistent with ulnar neuropathy, are most common.[508,509] The mechanisms of injury are most often related to the use of a sternal retractor and compression of the brachial plexus, although upper extremity neuropathy can occur as a consequence of arm positioning as well. Symptoms are usually self-limited and improve with time and, if needed, with physical therapy.

Respiratory Insufficiency

Even after uncomplicated cardiac surgery, a midline sternotomy (or thoracotomy) causes significant reductions in total lung capacity, vital capacity (VC), forced expiratory volume in 1 second (FEV_1), and functional residual capacity.[510] These changes may result in postoperative atelectasis and, frequently, at least mild hypoxemia. More severe postoperative respiratory insufficiency causing difficulty weaning may be due to intrinsic pulmonary problems (e.g., COPD, atelectasis, pneumonia, or surgical trauma to the lungs), ARDS related to CPB or transfusion (transfusion-related acute lung injury [TRALI]), pulmonary embolism, or cardiogenic pulmonary edema secondary to low cardiac output.

Preoperative efforts to minimize pulmonary complications after cardiac surgery include optimizing pulmonary function for patients undergoing elective surgery. With regard to the surgical approach, it has been theorized that off-pump surgery causes fewer changes in pulmonary mechanics than on-pump surgery does, but studies have shown little difference between the techniques.[511-513] Likewise, ministernotomy techniques have not been shown to improve pulmonary mechanics or arterial blood gases.[514,515] However, in some studies, off-pump MIDCAB per-

formed through an anterior thoracotomy resulted in less impairment of VC and FEV_1 than on-pump[516] or off-pump[517] CABG performed through a median sternotomy did.

Pain management should be included in postoperative efforts to minimize pulmonary complications. Sternotomy pain may limit the patient's ability to cough and perform deep-breathing exercises, and incisional leg pain from harvesting of saphenous veins may prevent early ambulation, thereby increasing the risk for pulmonary complications. Gust and colleagues[518] noted less atelectasis when patient-controlled analgesia rather than nurse-controlled analgesia was used after CABG. However, it is unclear whether the reduced atelectasis translates into less pulmonary morbidity.[519] The reader is referred to the section on pain at the end of this chapter for other options for improving postoperative pain control and thereby minimizing "splinting" and complications such as lobar collapse, pneumonia, and increased duration of hospitalization.

After cardiac surgery, traditional management has included overnight mechanical ventilation. Certainly, it is clinically important to have a period of controlled ventilation to allow rewarming and emergence from anesthesia, optimize cardiac function, and ensure hemodynamic stability and the absence of unacceptable bleeding. However, currently many patients are extubated within 3 to 6 hours of arriving in the postoperative care unit (so-called "fast-tracking"). In planning for fast-tracking, one should avoid using high-dose narcotic anesthetic techniques, and postoperative doses and the timing of analgesic and sedative administration must be appropriate.[520]

Fortunately, only a small percentage of patients require prolonged mechanical ventilation after cardiac surgery. Data from the STS National Adult Cardiac Surgery Database[521] and the Cardiothoracic Centre–Liverpool[522] show that 5.5% of patients who undergo CABG require mechanical ventilation for more than 48 hours afterward. Independent risk factors for prolonged ventilation include advanced age, preoperative ventilation, elevated serum creatinine, EF less than 30%, valve surgery, previous cardiac surgery, urgent or emergency surgery, recent MI, peripheral vascular disease, use of CPB, current smoking, and an FEV_1 less than 70% of the predicted value.[522]

Prolonged ventilation is most commonly due to cardiac dysfunction and cardiogenic pulmonary edema. Patients with marginal cardiac function may require diuresis, afterload reduction, or inotropy. Pulmonary-related reasons for inability to wean from mechanical ventilation include noncardiogenic pulmonary edema, pneumonia, severe COPD, ARDS, and pulmonary embolism. Finally, nonpulmonary complications such as persistent postoperative bleeding, neurologic complications (including stroke and delirium), renal insufficiency/failure, gastrointestinal complications, and sepsis may also result in a need for prolonged mechanical ventilation. Not surprisingly, poor in-hospital survival and poor long-term outcome have been associated with nonpulmonary complications that result in prolonged mechanical ventilation.[523]

Bleeding/Coagulopathy

Definition, Incidence, and Mechanisms

In cases of documented coagulopathy, transfusion often seems inevitable, but it carries a cost in terms of health care resources and patient outcomes. A study of more than 1900 cardiac surgical patients found that those receiving transfusions had a 70% increased risk for death and a doubling of their 5-year mortality rate, after adjustment for comorbid conditions, when compared with patients not receiving transfusion.[524] In addition, in a retrospective database study of more than 8000 patients who underwent cardiac operations at New England institutions, RBC transfusion was an independent predictor of LCOS requiring IABP counterpulsation, return to CPB, and persistent inotropic support.[525] Long-term reductions in quality of life have also been associated with a high RBC transfusion load in cardiac patients.[107] Furthermore, a multinational observational study found that differences between countries in perioperative outcome of patients undergoing CABG were related to intraoperative transfusion of FFP or platelets, among other hematologic factors.[526]

Efforts to Attenuate Perioperative Bleeding in Cardiac Surgery

In 2007, the STS and the Society of Cardiovascular Anesthesiologists (SCA) published a joint statement on practice guidelines for transfusion and blood conservation in cardiac surgery.[527] They reviewed all the available literature on blood conservation and transfusion practices in cardiac surgery and found six factors that appear to be important predictors of blood product transfusion in cardiac surgery.

- Advanced age
- Low preoperative red cell volume (i.e., preoperative anemia or low body surface area)
- Preoperative antiplatelet or antithrombotic medications
- Complex or redo operation
- Emergency operation
- Noncardiac comorbidity

Having identified a population of patients (as just listed) who are most likely to require blood products during cardiac procedures, this task force gave specific recommendations on blood conservation that include the following five points[527]:

- Consideration should be given to the use of drugs that either increase preoperative blood volume (e.g., erythropoietin) or decrease postoperative bleeding (e.g., antifibrinolytics).
- Techniques of conserving blood, including cell-saver sequestration and retrograde priming of the pump, should be included in the operative plan.
- To spare the patient's blood from the insult of CPB, autologous predonation and normovolemic hemodilution should be considered.
- Institutions should implement transfusion algorithms supported with POC testing.
- Multimodal application of all the aforementioned guidelines is the best way to conserve blood.

Correcting Existing Coagulopathies

Preoperative coagulopathy can result from congenital or acquired abnormalities. Hereditary coagulopathies include clotting factor deficiencies and platelet defect diseases such as von Willebrand's, Hermansky-Pudlak, Bernard-Soulier, Scott's, Werlhof's, and Glanzmann's syndromes.[527]

Acquired coagulopathy is usually drug induced. Patients receiving warfarin will require 2 to 5 days without warfarin for

normalization of the prothrombin time and the international normalized ratio.[109] Patients whose operations cannot be deferred until laboratory normalization will need treatment with FFP. Patients receiving aspirin have irreversible thromboxane receptor inhibition; 7 to 10 days without aspirin is necessary for new, uninhibited platelets to regenerate. Treatment of bleeding thought to be associated with aspirin has traditionally included platelet transfusion, desmopressin (DDAVP), or both. However, DDAVP may not be effective for managing bleeding in CABG patients treated with aspirin.[528]

New antithrombotic medications have added to the breadth and complexity of coagulopathic manifestations of patients undergoing cardiac surgery. Such agents include LMWH, platelet receptor antagonists, direct thrombin inhibitors, t-PA, and streptokinase. The STS/SCA blood conservation and transfusion guidelines recommend that clopidogrel and related thienopyridine antiplatelet medications be discontinued 5 to 7 days before surgery to limit blood loss.[527] Patients requiring platelet inhibition to manage their acute coronary syndromes can be changed to shorter-acting GP IIb/IIIa receptor inhibitors, such as tirofiban or eptifibatide.[527] Because clopidogrel's binding to platelets is irreversible, platelet transfusion is the only therapeutic option for patients who are taking clopidogrel, although routine platelet transfusion is not advocated.[527] Because of individual variability in the degree of platelet inhibition with clopidogrel,[529,530] POC monitoring is recommended to assess platelet function and the need for platelet transfusion.[527]

The GP IIb/IIIa receptor inhibitors have similar considerations. Bleeding associated with noncompetitive inhibition of abciximab must be reversed with platelet transfusion. Although short-acting inhibitors may be associated with bleeding,[527] some studies show that they provide a measure of platelet protection and better patient outcomes.[178,179] Like clopidogrel, drugs that inhibit the GP IIb/IIIa receptor exhibit individual variability,[531] thus supporting recommendations for POC, data-driven transfusion guidelines.

LMWH has little association with an increased bleeding risk.[527] There is no effective antidote for the anti–factor Xa inhibition caused by LMWH. Bleeding caused by t-PA or streptokinase is treated with antifibrinolytic therapy (EACA or TA).[129]

Pharmacologic Attenuation of Bleeding

Pharmacologic attenuation of cardiac surgical bleeding revolves around the use of a few specific medications: synthetic antifibrinolytics, aprotinin, DDAVP, and recombinant factor VII. The STS/SCA guidelines provide the strongest support for their evidence-based recommendations regarding the efficacy of synthetic antifibrinolytics and aprotinin in reducing perioperative bleeding in cardiac operations.[527] However, aprotinin marketing has been suspended because of ongoing concerns regarding patient outcomes.[532]

In structural terms, the synthetic antifibrinolytics are lysine analogs. They bind to plasminogen and plasmin, which inhibits their ability to bind to lysine residues on fibrin and thereby impedes fibrinolysis. The two synthetic antifibrinolytics that are used clinically are EACA (Amicar) and TA. They differ primarily in potency and elimination half-life: TA is 6 to 10 times more potent and has a longer half-life than EACA does.[533]

Standard dosing of EACA consists of a 50-mg/kg load followed by an infusion of 25 mg/kg/hr; standard dosing of TA consists of a 10-mg/kg load followed by an infusion of 1 mg/kg/hr. However, many other dosing strategies are described in the literature.[534-539] Interested readers might consider examining the work of Dowd and coworkers[540] on the pharmacokinetics of TA and their recommendations for higher continuous infusions of TA on-pump to maintain stable blood concentrations.

A recent meta-analysis of the literature on antifibrinolytics came to the following conclusions[541]:

- Both TA and EACA significantly reduce blood loss when compared with placebo.
- EACA reduces packed RBC transfusion rates by approximately 37%, and TA reduces these rates by approximately 25%.
- Both drugs may reduce rates of surgical re-exploration; in the meta-analysis, these reductions were not statistically significant, but there was a trend that seemed to indicate that these reductions did occur.
- Neither TA nor EACA seems to produce any adverse outcomes.

Both drugs are renally excreted, so they should not be given to patients with upper urinary tract bleeding because the concentration of the drug in the renal collection system could cause thrombosis and obstructive nephropathy.[129]

Antifibrinolytic therapy—specifically, the use of aprotinin—became controversial in 2006.[542] Aprotinin is a powerful serine protease inhibitor that is extracted from bovine lung tissue. Other serine proteases include plasmin, kallikrein, and factor XIIa. Royston and coauthors[543] originally published findings of reduced bleeding in cardiac surgical patients in 1987. Numerous subsequent studies have demonstrated a reduction in bleeding associated with cardiac surgery and CPB.[527] Traditional dosing of aprotinin is based on its ascribed kallikrein inhibitory potential and consists of a loading dose of 2 million KIU (kallikrein inhibitory units) intravenously and in the pump prime, followed by an infusion of 500,000 KIU/hr. Monitoring of ACT must use a kaolin-based activator because aprotinin prolongs celite-based ACTs, thereby potentially leading to heparin underdosing.

Aprotinin is a bovine source protein, and anaphylaxis has been reported.[544-546] The risk of anaphylaxis with re-exposure is reported to be approximately 2.8%.[547] The risk appears greatest for those re-exposed to aprotinin within a 6-month window. To minimize this risk, dosing recommendations include delaying the bolus injection until the surgeon is prepared to initiate bypass, administering a 1-mL (10,000 KIU) test dose to all patients, considering the use of H_1/H_2 receptor blockade before re-exposure, and avoiding re-exposure to aprotinin within 6 months of a previous exposure.[548]

Controversy surrounding aprotinin has existed for some time. Given aprotinin's powerful antifibrinolytic activity, there has been clinical concern regarding increased risk for perioperative MI and early graft closure, stroke, and renal dysfunction.[549] An initial clinical report from the Cleveland Clinic noted a statistical trend toward increased MI and graft closure; this trend was eventually explained by heparin underdosing related to the use of celite ACTs.[550] Subsequently, more liberal trends in the use of aprotinin in cardiac surgery developed, and some clinicians advocated its use in both first-time and redo operations.[551] Furthermore, Mora Mangano and colleagues[552] reported no association between aprotinin use and postoperative renal dysfunction in 853 patients undergoing deep hypothermia and circulatory arrest.

Royston and coauthors[553] reported that aprotinin was associated with a lower overall risk of adverse outcomes. However, in 2006, Mangano and associates,[554] in an observational study of 4374 patients undergoing cardiac surgery, reported that aprotinin use was associated with a doubling of the risk of dialysis-dependent renal failure, as well as a 55% increase in the risk for MI or HF and a 181% increase in the risk for stroke or encephalopathy. Subsequently, in 2007, Mangano and colleagues[542] reported that aprotinin use was an independent predictor of 5-year mortality. Furthermore, a meta-analysis of 138 trials comparing aprotinin, TA, and EACA showed that all three agents were efficacious in reducing blood loss and transfusion rates but that high-dose aprotinin was associated with an increased risk for renal dysfunction.[541] Finally, in November 2007, the FDA announced that at the agency's request, Bayer Pharmaceuticals had agreed to a marketing suspension of aprotinin based on preliminary results from a randomized, double-blind Canadian study comparing the safety and efficacy of EACA, TA, and aprotinin. Findings from this study suggested that when compared with EACA and TA, aprotinin increased the risk for death.[532]

The STS/SCA task force gave its weakest categorical support to the use of desmopressin and recombinant factor VIIa (rVIIa) to treat bleeding associated with cardiac surgery.[527] Use of desmopressin was classified as "not unreasonable" in patients with characteristics known to be responsive to desmopressin (von Willebrand factor or factor VIII deficiencies, cirrhosis, aspirin use, and uremic platelet dysfunction).[527] Desmopressin is administered in doses of 0.3 to 0.4 μg/kg, which are usually given slowly over a period of 20 to 30 minutes to reduce the drug's propensity to cause hypotension. Use of rVIIa is classified as "not unreasonable" for treating intractable life-threatening hemorrhage unresponsive to traditional therapies.[527]

rVIIa increases the amount of thrombin needed to promote hemostasis. It was initially developed as therapy for patients with hemophilia and has since been used "off-label" to treat cardiac surgical patients with intractable bleeding after surgery and bypass. Factor VII may serve as an activator of factors IX and X and may also bind directly to platelets, thereby leading to localized activation of factor X and subsequent generation of thrombin on the surface of platelets.[555]

A few observational studies have associated rVIIa administration with reductions in bleeding in patients with significant perioperative hemorrhage during cardiac surgery.[102,556-558] A recent literature review[559] identified six comparative studies[560-565] and concluded that rVIIa at doses of 40 to 100 μg/kg is recommended to treat intractable hemorrhage in cardiac surgical patients when standard hemostatic therapies have failed.[527,559] Redosing may be considered if hemorrhage is refractory 30 to 60 minutes after the initial dose. Prophylactic use of rVIIa is not currently indicated in cardiac surgery. Questions about the risk of thromboembolic complications remain unanswered and will require larger, adequately powered prospective and randomized studies.

Transfusion Triggers

An impediment to the development of uniform guidelines in transfusion medicine for cardiac surgical patients has been the lack of scientific and clinical consensus on what level of anemia requires intervention. The increasing surgical complexity, patient age, and number of comorbid conditions seen in current cardiac surgical practice have promoted the idea that raising hemoglobin levels may be warranted. However, blood products should be used cautiously in cardiac operations.[107,524-526] Although the transfusion of blood products is associated with well-known clinical complications, such as pathogen transmission and TRALI, as well as system issues, such as supply/demand issues and cost,[566] absolute indicator values for transfusion remain elusive. Randomized, double-blind, and placebo-controlled studies designed to answer transfusion outcome questions are ethically challenging and are not found in the literature.[566] Furthermore, clinical data that indicate a need to transfuse based on tissue or organ oxygen debt are often unavailable.[567]

Data-Driven Transfusion Guidelines

In summary, the clinical practice guidelines published by the STS/SCA task force in 2007 strongly encourage multimodal efforts to reduce transfusion rates and conserve blood products. Studies using transfusion algorithms paired with POC data to guide therapy have found these measures to be both efficacious and cost-effective.[527] An example of a standard laboratory test–based algorithm is shown in Figure 60-38. Algorithms can be constructed to incorporate any particular dynamic POC monitor or monitors.[205-208,568-570] In one prospective study with three treatment arms using three different POC monitors, all treatments were equally efficacious in reducing transfusion rates and amounts when compared with the control condition, in which transfusions were performed according to the surgeon's judgment.[205] Another study of 100 consecutive CABG operations in which strict transfusion guidelines and an algorithmic approach were used reported no transfusions in any patient.[568] For a clinical initiative regarding blood product utilization and blood salvage to be effective, it must involve all care providers at each level of clinical intervention and care. Data-driven management of coagulopathies conserves a somewhat limited resource (blood products), and it produces better clinical outcomes.

Pain

Pain after cardiac surgery can have many sources, including the sternotomy incision, chest tubes, and leg incisions. Some of the deleterious effects of postoperative pain after cardiac surgery are due to the stress response and enhanced sympathetic tone,[571,572] which can increase the heart rate, PVR, myocardial work, and myocardial oxygen consumption. In addition, α-receptors in the coronary vasculature may respond to sympathetic stimulation by producing coronary vasoconstriction, which may further aggravate postoperative myocardial ischemia. Thus, pain can contribute significantly to postoperative cardiac morbidity after cardiac surgery.

Post-cardiac surgical pain can also negatively affect the respiratory system. Typically, a restrictive defect occurs that is characterized by loss of lung volumes, with 30% to 35% reductions in tidal volume, VC, and functional residual capacity, thereby potentially contributing to atelectasis.[518,519,573] Moreover, the patient's pain may cause voluntary reduction of muscular movement in the thorax and abdomen, a phenomenon often described as "splinting." Such splinting interferes with the patient's ability to cough effectively and clear secretions. Ultimately, this problem can lead to lobar collapse, pneumonia, and increased duration of hospitalization.[518,519,573]

Unrelieved pain also has psychological effects. Pain-related anxiety, depression, and sleep deprivation may contribute to delirium in patients in the intensive care setting.

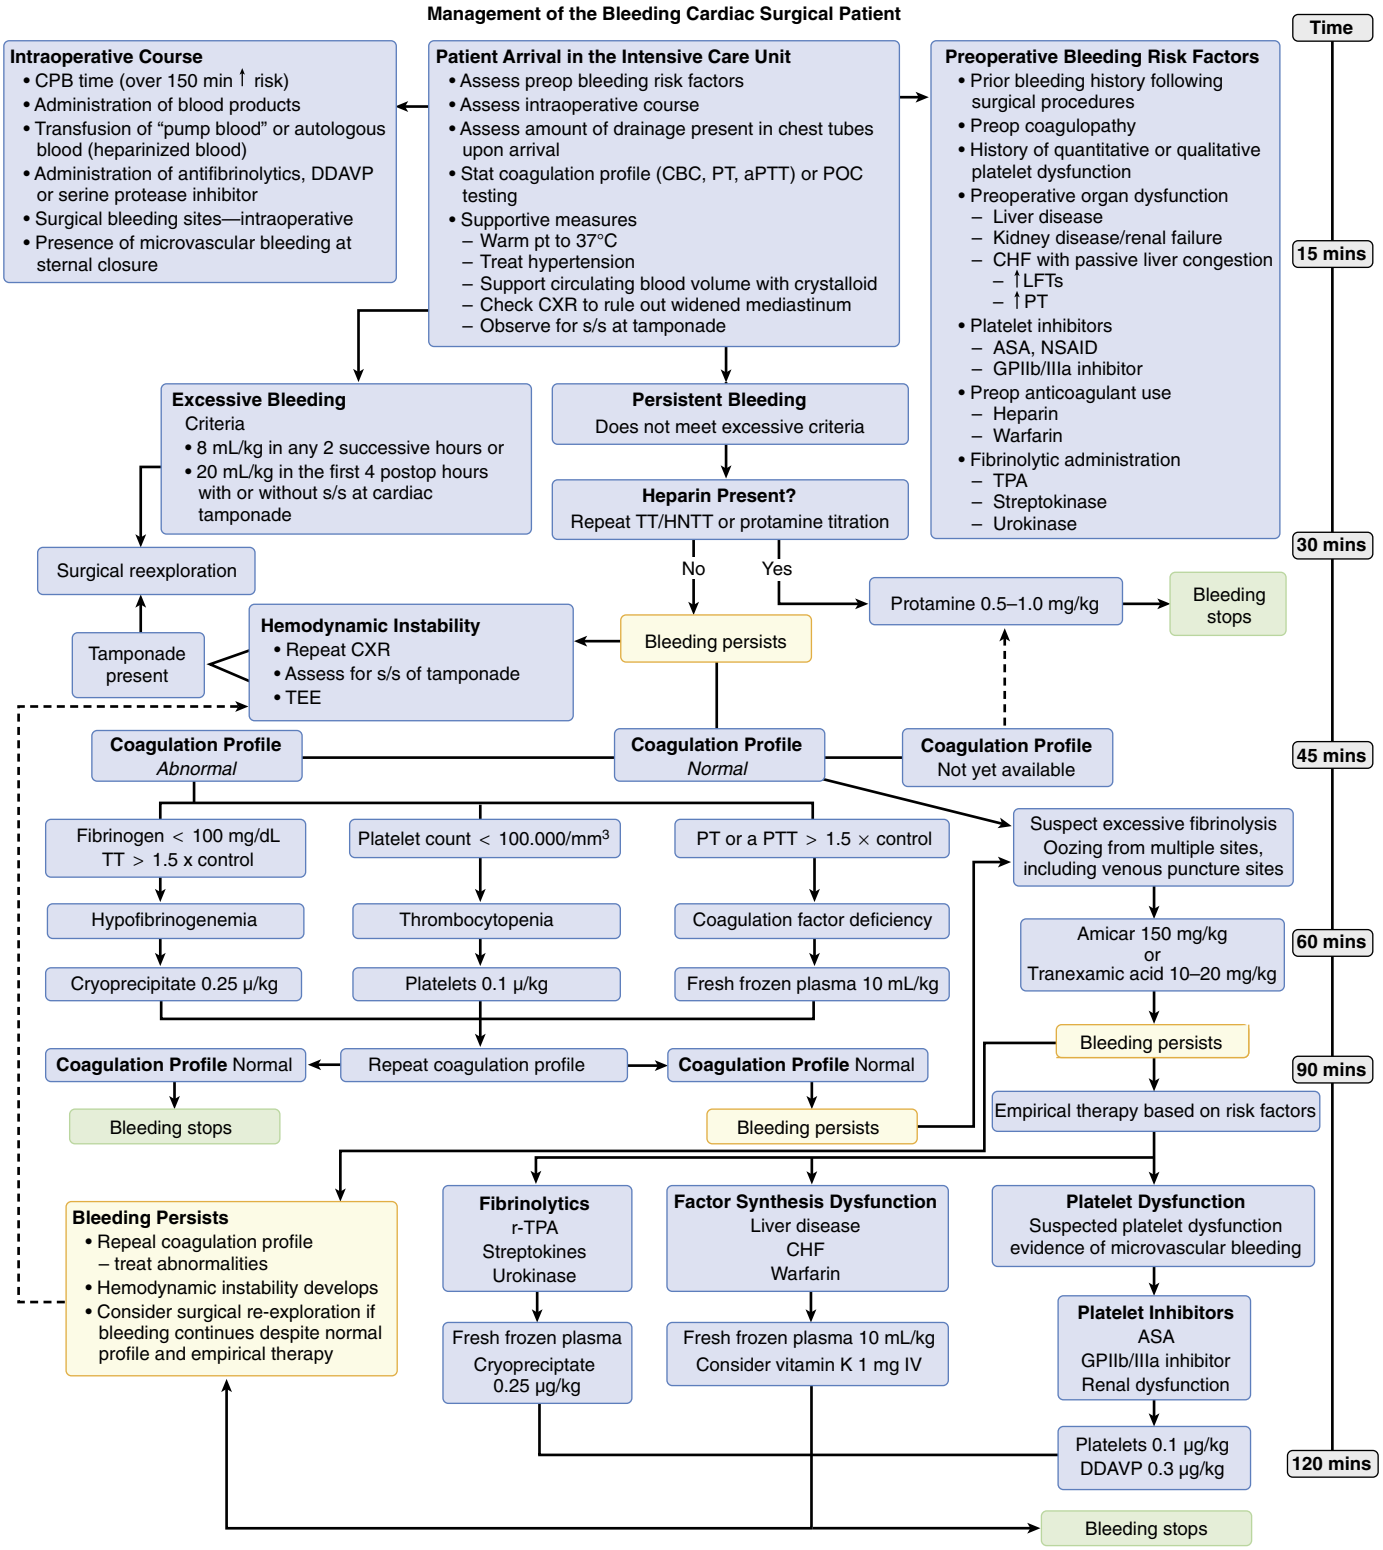

Figure 60-38 Example of a scheme for treating excessive bleeding. *(From Milas B, Johes D, Gorman R: Management of bleeding and coagulopathy after heart surgery. Semin Thorac Cardiovasc Surg 12:326, 2000.)*

In recent years, so-called fast-track anesthesia, entailing earlier extubation, a relatively brief stay in the ICU, faster discharge from the hospital, and lower overall cost, has become a standard of care for the cardiac anesthesiologist. Effective pain control helps achieve these goals.

Opioids remain the "gold standard" for pain control but they have side effects that include nausea, vomiting, urinary retention, decreased gastric motility, pruritus, sedation, and respiratory depression. Interest has emerged in the use of intrathecal and epidural local anesthetics and narcotics to improve analgesia

in patients undergoing cardiac surgery. Two meta-analyses of anesthetic techniques used in cardiac surgical patients have found that neither thoracic epidural analgesia nor intrathecal analgesia had a significant effect on MI or mortality, nor did they shorten patients' hospital stays.[574,575] However, in many studies, thoracic epidural analgesia did significantly reduce pain and the risk for dysrhythmias, pulmonary complications, and time to tracheal extubation, and it reduced analog pain scores at rest and with activity. Intrathecal analgesia modestly decreased systemic morphine use and pain scores but significantly increased the incidence of itching. Although a major concern surrounding the use of intrathecal and particularly epidural analgesia in cardiac surgery is the use of anticoagulation during the operation and consequent fear of spinal cord damage from a possible epidural hematoma, this complication is rare.[575]

Other techniques include the use of bilateral single-shot paravertebral blocks[576] or intercostal nerve blocks followed by a subcutaneous continuous infusion of local anesthetics.[577] Additionally, because all analgesics have side effects, some authors have suggested that it is better to use combinations of drugs or techniques, or so-called multimodal analgesia. Theoretically, multimodal analgesia may allow the use of lower doses of all agents and thus reduce the severity of the dose-related side effects of any single agent used.[578] Despite the appeal of the idea of multimodal analgesic techniques, cyclooxygenase-2–selective inhibitors and probably all nonsteroidal anti-inflammatory drugs are contraindicated after cardiac surgery with CPB.[579,580]

Additional studies will be required to solidify the link between pain relief and decreased morbidity, shorter hospital stay, and reduced cost.[581]

61 Anesthesia for Correction of Cardiac Arrhythmias

Key Points

1. Cardiac arrhythmias are caused by disorders of impulse formation or disorders of impulse conduction, or both. Cardiac arrhythmia may be life-threatening because of a reduction in cardiac output, reduction in myocardial blood flow, or precipitation of a more serious arrhythmia.
2. Radiofrequency ablation is the therapy of choice for many types of cardiac arrhythmias.
3. Electrophysiologic studies are used to map out normal and abnormal intracardiac structures. In this process, the mechanism of arrhythmia is delineated, and ablation can be performed at the same time.
4. Pacing technologies have been developed to treat heart failure resulting in increases in pulse pressure, left ventricular stroke volume, cardiac index, and wedge pressure.
5. Implantable pacemakers are placed for treatment of symptomatic bradycardia with the ability to respond to changing hemodynamic demands.
6. The development of implantable cardioverter-defibrillators (ICDs) to terminate ventricular tachyarrhythmias by delivering high-voltage shocks to the ventricle has revolutionized therapy for cardiac arrhythmias.
7. The main purpose of ICD placement is to prevent sudden cardiac death resulting from hemodynamically unstable ventricular arrhythmias.
8. An ICD also can be placed for cardiac resynchronization. Cardiac resynchronization therapy has been shown to improve heart failure symptoms, quality of life, exercise capacity, and electrocardiographic variables.
9. Anesthetic management of patients for correction of cardiac arrhythmias depends on associated comorbid illness and the procedure that is planned.

Cardiac arrhythmias are caused by disorders of impulse formation or disorders of impulse conduction, or both. Disorders of impulse formation include enhancement or depression of automaticity, parasystolic activity, and triggered activity. Disorders of conduction include decremental conduction, re-entry, entry block, exit block, concealed conduction, and supernormal conduction.[1]

At the present time, radiofrequency catheter ablation has replaced antiarrhythmic drug therapy as the treatment of choice for many types of cardiac arrhythmias. Before the 1980s, cardiac electrophysiology was primarily used to confirm mechanisms of arrhythmias, with management mainly by pharmacologic means. As a result of shortcomings in antiarrhythmic drug therapy (including the results of randomized trials), radiofrequency ablation and implantable cardioverter-defibrillators (ICDs) were developed.[2,3]

Historical Perspectives

The treatment of cardiac arrhythmias with device-based therapy may have begun in 1899, when Prevost and Batteli[4] noted almost as an afterthought that direct electric shock could terminate ventricular fibrillation in dogs. Hooker and colleagues[5] showed 3 decades later that the passage of electric current across the heart can initiate and terminate ventricular fibrillation. In 1947, Beck saved the first human life by the successful use of cardiac defibrillation in a 14-year-old boy, who developed ventricular fibrillation during a thoracic procedure and went on to achieve full recovery.[6] These early achievements provided the foundation for the landmark work of Mirowski and Mower,[6a] which ultimately led to the development of ICDs in humans in 1980.

Scope of Cardiac Arrhythmias

Cardiac arrhythmias are common (see Chapters 42 and 43). Some cardiac arrhythmias are life-threatening, and others are merely a nuisance. Cardiac arrhythmias are caused by abnormalities in impulse formation or conduction that lead to slow or fast, regular or irregular heart rhythms. At the present time, it is not difficult to treat slow rhythms because available pacemakers are able to adapt slow function to the needs of the body.[7] The situation is different, however, for patients with rapid rhythms. Rapid rhythms may originate anywhere in the heart and result from various mechanisms. These mechanisms may be focal, meaning that the abnormal impulse formation is confined to a small area, or they may be the result of an impulse running in a circuit composed of several interconnected cardiac cells. Such a circuit may be small or large, as in atrial flutter and in arrhythmias in which the normal atrioventricular conduction system and an extra connection between the atrium and the ventricle are incorporated into the circuit of the arrhythmia.[8]

Pharmacologic interventions originally were used in attempts to terminate and prevent rapid rhythms. It has become clear in the past several decades, however, that antiarrhythmic drugs may have serious side effects and sometimes may even facilitate the occurrence of life-threatening arrhythmias and sudden death.[9] As a result of these effects, techniques were developed for localizing the site of origin or pathway of an arrhythmia and then isolating or destroying the tissue that is responsible. By employing an intracardiac catheter, it is now possible to determine the site of origin or pathway of an arrhythmia and cure the rhythm disturbance by applying through the catheter radiofrequency, laser, ultrasound, or microwave energy or freezing temperatures to the tissue causing the arrhythmia.

Heart failure is a major problem in elderly patients (see Chapter 71). Although pharmacologic treatment of heart failure has improved, outcome generally remains poor. New pacing technologies may now be used to treat selected patients with heart failure. For many years, permanent pacing has been used to treat symptomatic bradycardia, and pacing may alleviate heart failure when associated with heart block. Several studies have examined the use of conventional dual-chamber atrioventricular–right ventricular pacing for treatment of heart failure in the absence of symptomatic bradycardia or heart block.[3,10] Biventricular pacing aims to restore synchronous cardiac contraction. Studies have shown that when ventricular desynchrony is reduced, the heart is able to contract more efficiently and increase left ventricular ejection fraction and cardiac output, while working less and consuming less oxygen.[11] In addition, re-establishment of left ventricular synchrony can increase left ventricular filling times, decrease pulmonary capillary wedge pressure, and reduce mitral regurgitation.

Normal Cardiac Rhythm

In the normal heart, the dominant impulse arises in the sinus node with a rate of 60 to 100 beats/min. During sleep, the rate may decrease to 30 to 50 beats/min.[12] Episodes of sinus pauses up to 3 seconds, sinoatrial block, junctional rhythms, and first-degree and second-degree atrioventricular nodal block that occur often enough (especially in trained athletes) are considered to be normal variants.[7]

The impulses generated from the sinoatrial node propagate along three intra-atrial conduction pathways: the anterior, middle, and posterior internodal tracts. These tracts are not discrete pathways, but groups of cells that conduct slightly faster than the atrial myocardium.[13] The internodal tracts give rise to interatrial fibers. The electric impulse, whether propagated in the atrial myocardium or along the internodal tracts, converges on the atrioventricular junction. The atrioventricular node located in the atrioventricular junction ultimately receives the impulses generated from the sinoatrial node. The impulses are delayed in the atrioventricular node before they are finally distributed to the ventricular myocardium via the His-Purkinje system.

Normally, the heart rate increases with exercise to at least 85% of the age-predicted maximum of 220 minus age in years; failure to do so is termed *chronotropic incompetence*. Sinus arrhythmia is defined as sinus rhythm with P-to-P variations of more than 10%. Sinus arrhythmia is due to cyclic variations in vagal tone commonly related to respiration (the rate is faster with inspiration and slower with expiration).[14] Sinus arrhythmia disappears with exercise, breath-holding, and atropine, and is more likely to be seen in individuals who do not have heart disease.[15]

Cardiac Arrhythmias

Cardiac arrhythmia is caused by a disorder of impulse generation, impulse conduction, or a combination of both. Cardiac arrhythmia may be life-threatening because of a reduction in cardiac output, reduction in myocardial blood flow, or precipitation of a more serious arrhythmia.[16] Arrhythmias may be described based on (1) rate (bradycardia or tachycardia); (2) rhythm (regular or irregular); (3) origin of impulse (supraventricular, ventricular, or artificial pacemaker); (4) impulse conduction (atrioventricular, ventriculoatrial, or block); (5) ventricular rate; or (6) special phenomena (e.g., pre-excitation).

Re-entry is a common electrophysiologic mechanism that predisposes to most ventricular arrhythmias and to most supraventricular tachyarrhythmias. The most common mechanism of re-entry is based on the model originally proposed by Erlanger and Schmitt and later modified by Wit.[1] This model postulates the presence of a ring or loop of cardiac tissue that is functionally separate from neighboring tissue and the presence of transient or permanent unidirectional block in a portion of the loop. Unidirectional block may be anatomic in origin (e.g., bundle branches, fibrosis, dual pathways, atrioventricular node plus accessory pathway) or functional (e.g., ischemia, drug effect).

Atrial flutter is a macro-re-entrant arrhythmia identified by flutter waves, often best seen in the inferior leads at 250 to 350 beats/min. Patients often present with a 2:1 atrioventricular conduction with a ventricular rate of 150 beats/min, although the atrioventricular conduction ratio can change abruptly.

Atrial fibrillation is a narrow-complex tachyarrhythmia and is the most common in the general population. The prevalence of atrial fibrillation in the general population increases exponentially with age, from 0.9% in individuals age 40 to 5.9% in individuals older than age 65. The most important risk factors for development of atrial fibrillation in the general population are

structural heart disease, valvular heart disease, and left ventricular hypertrophy.[17]

Ventricular tachyarrhythmia is defined as three or more consecutive ectopic beats at a rate greater than 100 beats/min.[18] Ventricular tachyarrhythmia is traditionally classified as nonsustained or sustained. Sustained ventricular tachyarrhythmia is defined as ventricular tachyarrhythmia lasting more than 30 seconds. Nonsustained ventricular tachyarrhythmia is defined as ventricular tachyarrhythmia that terminates spontaneously within 30 seconds. Sustained ventricular tachyarrhythmia also is traditionally classified as monomorphic (one site of origin) or polymorphic (two or more sites of origin).[18] Monomorphic ventricular tachyarrhythmia usually results from re-entry, and the site of re-entry depends in part on the type of heart disease. In patients with coronary artery disease, the re-entry circuit is usually located in ventricular myocardium, whereas in dilated cardiomyopathy with left bundle branch block, bundle branch re-entry is common.[19] Monomorphic ventricular tachyarrhythmia may occur in individuals with an otherwise normal heart, whereas polymorphic ventricular tachyarrhythmia may occur in acquired states that produce a marked prolongation of the Q–T interval. Nonsustained ventricular tachyarrhythmia is frequently asymptomatic, but may produce palpitations, weakness, and presyncope.[19]

Torsades de pointes is a French term translated as "twisting of the points." It is a syndrome composed of polymorphic ventricular tachyarrhythmia. It may be due to various medications or electrolyte imbalances. Torsades de pointes is usually paroxysmal, but is frequently symptomatic and often produces loss of consciousness. It occasionally degenerates to ventricular fibrillation.

Ventricular fibrillation accounts for 80% to 85% of sudden cardiac deaths.[19] Ventricular fibrillation is usually preceded by ventricular tachyarrhythmia, but also may occur as a primary arrhythmia. More recent studies suggest that ventricular fibrillation results from multiple wavelengths that disperse randomly, using the leading circle form of re-entry.[19] The most common cause of ventricular fibrillation is acute myocardial infarction. It also is observed in patients with chronic ischemic heart disease, hypoxia resulting from any cause, acidosis, hypokalemia, and massive hemorrhage.

Indications for Correction of Cardiac Arrhythmias

Intracardiac electrophysiologic studies can give valuable information about normal and abnormal electrophysiology of intracardiac structures (see Chapters 42, 43, and 97). These studies are used to confirm the mechanism of an arrhythmia, to delineate its anatomic substrate, and to ablate it. The electric stability of the ventricles also can be assessed, as can the effects of an antiarrhythmic regimen.

In addition, pacing technologies have been developed to treat heart failure with promising results, leading to improvement in morbidity and mortality in these patients. Hemodynamic responses to biventricular pacing include an increase in the rate of elevation of left ventricular pressure and increases in pulse pressure, left ventricular stroke work, cardiac index, and wedge pressure.[20] Cardiac resynchronization therapy improves ventricular function without increasing myocardial energy consumption, in contrast to the effect of inotropic agents, such as dobutamine.[11] In addition, cardiac resynchronization therapy may reverse left ventricular remodeling over time.[21]

Permanent Pacing

Indications for pacemaker therapy have increased in recent years and now include the treatment of bradyarrhythmias and heart failure according to the American College of Cardiology and American Heart Association guidelines.[22] These guidelines discuss indications for pacing in patients with sinus node dysfunction, acquired atrioventricular block, chronic bifascicular and trifascicular block, hypersensitive carotid sinus, and neurally mediated syndromes. The guidelines serve to direct the treating physician in selecting which patients would benefit from device therapy.

A Swedish team led by Sennings and Elmqvist implanted the first pacemaker in 1958.[23] A thoracotomy was required, and pacing was done through electrodes sutured to the epicardium. In these early systems, significant problems with changes in pacing threshold, lead infection, and lead breakage were common. Transvenous lead implantation subsequently developed by Furman would resolve many of these issues.[24] In 1958, Furman successfully paced an elderly patient with a catheter electrode inserted transvenously. Other investigators took on the challenge of solving various technical problems, such as device miniaturization, longer life batteries, and stable, reliable lead material.[25]

As the indication for implantation expanded from atrioventricular conduction disturbances to management of sinus node dysfunction, the need for implantable pacemakers grew in proportion.[25] Technology evolved rapidly with the development of lithium-iodide batteries that had greater longevity. Electronic advances then led to major miniaturization using integrated circuits as opposed to discrete components. Lead materials used in today's pacemaker rely on silicone and polyurethane, which are more biocompatible and reliable than earlier materials. With all these technical refinements, present-day pacemakers are small and can pace reliably for 8 to 10 years before generator replacement is needed.

The primary functional challenge for contemporary pacemakers is to maintain the heart rate based on circulatory needs, pacing in a manner that mimics the natural physiology of excitation and conduction. In a healthy heart, the sinus node is modulated by the autonomic nervous system, and its rate is determined by a multiplicity of factors, such as physical activity, emotion, and blood pressure. Not only the rate, but also the activation sequence and atrioventricular conduction time vary with demand; these requirements also must be considered. Rate is controlled by pacemaker discharge, and the excitation and conduction sequence depend on the placement of pacing electrodes.

Approximately 120,000 pacemakers are implanted each year in the United States. Indication for implantation for most of these cases is sick sinus syndrome. Other indications include atrioventricular block, carotid sinus hypersensitivity, malignant vasodepressor syndrome, and hypertrophic cardiomyopathy.[26]

The primary purpose of implantable pacemakers is to treat symptomatic bradycardia. With the extraordinary developments that have occurred in pacemaker therapy for the traditional indi-

cation, bradycardia, new uses are now beginning to be explored. Pacemakers have progressed from large, fixed-rate, single-chamber devices to multiprogrammable, multichamber devices with the ability to respond to changing hemodynamic demands. As technology advances, other possible uses are likely to be conceived.

Resynchronization Therapy

Cardiac resynchronization therapy has been shown to improve heart failure symptoms, quality of life, exercise capacity, hospitalization, and echocardiographic variables.[27] Based on the available data, cardiac resynchronization therapy is indicated in patients with drug-refractory, symptomatic New York Heart Association functional class III and IV heart failure of either ischemic or nonischemic origin.[28] In addition, these patients are protected from associated risk of sudden cardiac death when combined with an ICD system.[29]

The development of an automatic internal defibrillator or ICD began in the 1960s. External cardiac defibrillation was increasingly being used in coronary care units for the treatment of ventricular fibrillation and sudden cardiac death. Although the idea of automatic external defibrillation had been discussed initially by Zycoto, Mirowski and colleagues[30] were the first to champion and begin practical development of an automatic internal device. In 1969, Mirowski and Mower developed the prototype of today's automatic internal defibrillator.[31]

The primary goal of all defibrillators is to terminate ventricular tachyarrhythmias by delivering high-voltage shocks to the ventricle. As with implantable pacemakers, defibrillating devices need to be small and reliable, and to have adequate longevity. ICDs have evolved not only to perform this function, but also to take on additional tasks, such as antitachycardia pacing of the ventricle, dual-chamber pacing, and termination of atrial tachyarrhythmias.

A key difference between pacing and defibrillation of the heart is that for pacing; only a very small mass of myocardium needs to be stimulated, whereas for defibrillation, most, if not all, of the myocardium must be stimulated. Because the myocardium is easily excitable throughout diastole, a small wave of depolarization during pacing can readily propagate throughout the whole heart. In contrast, during ventricular fibrillation, there are usually multiple re-entrant wave fronts that are continuously changing in location and size that must be quelled. To defibrillate successfully, most of these wavefronts have to be interrupted simultaneously; to achieve this, one needs to capture most of the tissue that is in a state of relative refractoriness.[32] One unique property of defibrillation success is that it is probabilistic.[33] The same energy that can defibrillate the heart on one occasion may be unsuccessful at another time.

The main purpose of ICD placement is to prevent death from hemodynamically unstable ventricular tachyarrhythmias. Although advances in technology have made these devices much more flexible in terms of arrhythmia detection and electric therapy potions, their main purpose is to reduce sudden cardiac death, which claims approximately 300,000 lives in the United States annually. Secondary prevention of sudden cardiac death in patients who have survived cardiac arrest is another major indication for ICD placement. In such patients and especially in patients of this group for whom no reversible or curable cause can be found, ICD implantation has been repeatedly documented to provide a major mortality benefit.[34] Interest in managing atrial tachyarrhythmias also has grown significantly in recent years. It is now recognized that about 30% of patients with ventricular tachyarrhythmia also have atrial tachyarrhythmias.[35] Such atrially initiated tachyarrhythmias can worsen patient symptoms, can result in inappropriate ventricular shocks, and may be responsible for initiating ventricular tachyarrhythmias that can exacerbate other pathologies, such as heart failure. New strategies for treatment and prevention of atrial tachyarrhythmias are incorporated into devices that are capable of defibrillation and antitachycardia pacing in the atrium and the ventricle, in addition to combined dual-chamber pacing.[36]

The relative ease of ICD implantation and longevity of current defibrillators have made them a valuable tool in primary prevention. Patients no longer must survive a cardiac arrest to justify the risk of ICD implantation.

Preoperative Evaluation

Most patients who require pacemaker or ICD placement have significant cardiovascular disease. In addition, correction of cardiac arrhythmia may require radiofrequency catheter ablation. Radiofrequency catheter ablation has proved highly effective in the treatment of atrioventricular nodal re-entrant and accessory pathway tachycardias. Indications for pacemaker and ICD placement continue to evolve as the utility of these devices continues to increase. Although most pacemaker placement is done with local anesthetic infiltration, ICD placement may require monitored anesthesia care or in some cases general anesthesia. The modern ICD unit is capable of delivering the full spectrum of therapy for ventricular tachyarrhythmias and for bradycardia therapy with dual-chamber pacing/sensing, rate modulation, and mode-switching features.

As mentioned earlier, there are two common indications for ICD placement. One is continued ventricular tachyarrhythmias despite adequate drug therapy. Another indication is history of sudden cardiac arrest that is not associated with myocardial infarction.

Preoperative evaluation processes necessary for placement of an ICD should be complete by the time the decision is made to place the device (see Chapters 34 and 35). These patients need a thorough preoperative evaluation. This evaluation includes electrophysiologic testing to determine the inducibility of ventricular tachycardia and electrophysiologically guided drug therapy. Preoperative pulmonary function tests may be necessary in patients on amiodarone to evaluate possible toxicity of this drug, which can result in chronic obstructive pulmonary disease or interstitial lung disease. In some instances, the underlying pathophysiology of malignant ventricular arrhythmias is related to ischemic or idiopathic cardiomyopathy.[37] These patients often present with poor left ventricular function and higher incidence of congestive heart failure. Patients with a history of congestive heart failure should be in optimal condition before surgery.

Generally, all patients who present for correction of cardiac arrhythmia require preoperative evaluations including electrocardiogram, chest radiograph, hemoglobin, and electrolytes. Patients should be NPO (have nothing by mouth) at least 8 hours before the procedure. In addition, patients who require device and lead extractions because of malfunction or infection may require blood product transfusions during the procedure. Consequently,

type and crossmatch of blood products is frequently necessary for these procedures.

Anesthetic Considerations

Pacemakers

Permanent implantable pacemakers have been the standard modality of treatment for patients with all types of bradyarrhythmias. A significant number of these patients present with sick sinus syndrome and are older. Consequently, devices are placed under general anesthesia in these patients. As a result of more recent advances in pacemaker technology, these devices now can be placed as a therapeutic modality to alter hemodynamic states. Surgeons used to be primarily responsible for device insertion. Now the task falls under the services of cardiologists. Device placement is commonly performed in the cardiac catheterization suite under local anesthesia on an outpatient basis. Complicated high-risk patients now present for pacemaker insertion, however, in addition to more recent indications by the American College of Cardiology/American Heart Association for these devices. In light of these increased indications, the expertise of anesthesiologists is needed for monitoring and perioperative care of these patients.

Monitored Anesthesia Care

Currently, most pacemaker insertions are performed by cardiologists. Most of these cases are performed under local anesthesia with sedation. Depending on the level of training, administration of sedatives and analgesics can be provided by nurses.

In instances that require deeper sedation for a patient's comfort or for critically ill patients with hemodynamic instability, monitored anesthesia care by an anesthesiologist may be required (see Chapter 78). Adequate monitoring and resuscitation equipment is required in such situations. The goal of monitored anesthesia care is to provide analgesia, sedation, and anxiolysis, while ensuring rapid recovery with minimal or no side effects. Any sedative-hypnotic medication may be used during monitored anesthesia care with a wide variety of delivery systems.[38] Subanesthetic concentrations of inhaled agents also have been used to supplement local anesthetics. Newer drugs, such as centrally mediated α_2-agonists, have been shown to produce anxiolysis, sedation, and reduced requirements for supplemental analgesic medications during monitored anesthesia care.

General Anesthesia

Patients requiring pacemaker placement rarely require general anesthesia for placement. If general anesthesia is required, it should be directed toward underlying cardiac pathophysiology, indications, complications, and hemodynamic goals. Immediate access to life-support equipment, such as a cardiac defibrillator and a transcutaneous pacemaker, is necessary if the device is being placed under general anesthesia.

Implantable Cardioverter-Defibrillator

Since the 1980s, indications for use and implantation of ICDs have steadily increased. Over the past 2 decades, ICDs have undergone a significant evolution. In the 1970s and 1980s, ICD placement usually required thoracotomy for placement of epicardial patches.

Preoperative Evaluation

As mentioned earlier, common indications for ICD implantation include continued ventricular tachyarrhythmias unresponsive to adequate pharmacotherapy and history of sudden cardiac arrest unassociated with myocardial infarction. Newer indications include patients with various forms of the congenital long QT syndrome.[39] Patients with long QT syndrome who have already survived an episode of cardiac arrest or documented polymorphic ventricular tachyarrhythmia, especially if on pharmacotherapy at the time, are increasingly being evaluated as ICD candidates. In addition, patients with hypertrophic cardiomyopathies and without a history of sudden death are usually evaluated for ICD placement.[40] In these patients, sustained ventricular arrhythmias, nonexertional syncope, or a strong family history of sudden death with early age of presentation strongly indicates ICD implantation.

In all instances, the evaluation that is necessary for ICD implantation is completed by the time the decision is made to place the device (see Chapters 34 and 35). Electrophysiologic studies may have been done to determine the forms of arrhythmias present. When the pathophysiology of ventricular arrhythmias is related to idiopathic or ischemic cardiomyopathy,[41] these patients may present with poor left ventricular function and a high incidence of congestive heart failure. Consequently, they should be optimized as much as possible preoperatively.

Anesthetic Considerations

In the 1980s, ICD implantation was done with epicardial leads via thoracotomy under general anesthesia with one-lung ventilation. The technologic development of implantable ICDs with transvenous lead systems has simplified their implantation. Consequently, it was reasoned that ICDs can be placed under deep sedation with little or no intervention by the anesthesiologist analogous to what is needed for pacemaker placement.[42] Placement of an ICD under general anesthesia may be safer and more comfortable for the patient, however. Patients who present for ICD placement are often critically ill with cardiopulmonary comorbidity. It is not unusual for these patients to present with ejection fractions less than 30% and to require vasopressors to support hemodynamics during the procedure. In addition, some form of general anesthesia is necessary for intraoperative testing of defibrillating thresholds.

Monitored Anesthesia Care

Small, new-generation devices and transvenous lead systems lend themselves to the use of local anesthesia and intravenous sedation for ICD implantation. Midazolam and fentanyl are usually the drugs of choice when an ICD is placed under monitored anesthesia care (see Chapter 78). Monitoring includes pulse oximetry, five-lead electrocardiogram, and noninvasive blood pressure. Depth of anesthesia is monitored clinically. One of the major aspects of ICD placement is testing the device. Testing the device may require deep sedation or general anesthesia because the shocks that are associated with this procedure can be very painful.

The presence of an anesthesiology team may be necessary for ICD placement under monitored anesthesia care.

General Anesthesia

Most patients who present for ICD placement typically have comorbidities such as ventricular tachycardia, congestive heart failure with ejection fraction less than 30%, coronary artery disease, pulmonary hypertension, chronic renal insufficiency, or valvular heart disease. These patients may be unable to lie flat for the prolonged period necessary for placement of the ICD. In addition, they may require close hemodynamic monitoring during the testing of the device. General anesthesia should be considered in these patients. When general anesthesia is chosen, in addition to standard monitoring, an arterial line may be added. External cardioverter-defibrillator pads are required for all ICD placements. These are employed in cases where an implanted defibrillator fails. General anesthesia also may be requested for anxious and extremely nervous patients. Because pacemakers and ICDs are placed percutaneously, anesthesiologists must be vigilant to possible complications, such as myocardial infarction, stroke, possible cardiac injury (perforation/tamponade), and pneumothorax from subclavian vascular access.

Extraction of Devices

As a result of continued growth and expanding indications for pacemakers and ICD placement, leads may require extraction because of mechanical dysfunction, the need to upgrade to more complex devices, or local or systemic infection. Lead extractions are probably one of the most challenging procedures that a cardiac electrophysiologist has to face today.

Indications for lead extractions can be divided into two categories—patient-related and lead-related. Patient-related indications include infection, ineffective therapy (high defibrillation threshold), perforation, migration, embolization, induction of arrhythmias, venous thrombosis, unrelenting pain, device interactions, and device upgrades.[43] Lead-related indications include lead recalls, lead failure, and lead interactions.[44]

Lead extraction is performed via powered sheaths through which energy is delivered to the tip in the form of excimer laser light or electrocautery. These systems burn through scar tissue adherent to the wall of the lead throughout its course. The potential for life-threatening complications, such as lead fracture, venous or myocardial rupture, and tamponade, makes general anesthesia with invasive monitors a prudent choice for lead extractions.

Postoperative Care

Postoperative care of patients with pacemaker or ICD implantation depends on various factors surrounding the implantation of the device (see Chapter 85). As mentioned earlier, most of these patients are quite ill with significant comorbidities. It is not unusual for patients to have congestive hart failure with an ejection fraction less than 30% as a result of poor left ventricular function. Consequently, it is imperative to have these patients monitored in the postanesthesia care unit, especially if the device is placed or extracted under general anesthesia. The spectrum of recovery sites after these procedures may vary from postprocedure units to a coronary intensive care unit. Most of these procedures are done on an outpatient basis; anesthesia is tailored to ensure rapid recovery after implantation.

Correction of Cardiac Arrhythmias with Ablation Therapy

Catheter ablation is a safe and curative option for most cardiac arrhythmias, with 85% to 98% cure rates among the arrhythmias treated most frequently.[45] The rate of major complications is less than 3%.[45] Cardiac ablation therapy involves the delivery of energy through a catheter that is usually placed in the endocardial position in the heart, destroying myocardial tissue that is responsible for the tachyarrhythmia. Multiple electrodes are inserted to locate the arrhythmia and ablate it. Usually the diagnostic portions of the ablation study are done during the same procedure.[46] The efficacy of catheter ablation depends on the accurate identification of the site of origin of the arrhythmia. When the site is identified, the electrode catheter is positioned in direct contact with the site of the arrhythmia, and radiofrequency energy is delivered through the catheter to destroy it.

The current that is generated by radiofrequency is alternating current, and is delivered at cycle lengths of 300 to 750 kHz when used for catheter ablation.[47] It causes resistive heating of the tissue in contact with the electrode. The degree of tissue heating is inversely proportional to the radius to the fourth power.[48] Consequently, the lesions created by radiofrequency energy are small. Although electric injury may be a contributing factor, the primary mechanism of tissue destruction by radiofrequency current is thermal injury. Acute lesions created by a radiofrequency current consist of a central zone of coagulation necrosis surrounded by a zone of hemorrhage and inflammation.[49]

Cardiac arrhythmias that can be treated with radiofrequency ablation include paroxysmal supraventricular tachycardia, Wolff-Parkinson-White syndrome, atrial flutter, atrial fibrillation, and idiopathic ventricular tachycardia. Most cardiac arrhythmias that are treated with radiofrequency ablation are not life-threatening, but have a significant impact on a patient's quality of life.[50] Advantages of radiofrequency ablation of cardiac arrhythmias include relief of symptoms, improvement in functional capacity and quality of life, and elimination of the need for lifelong antiarrhythmic drug therapy. The principal disadvantage is the risk of complications, which varies depending on the type of ablation procedure and skill of the operator.

Anesthetic Considerations

Catheter ablation was introduced into clinical practice in 1982. Initially, ablation was performed with direct electric shocks.[51] As a result of several advantages over direct current, radiofrequency ablation has replaced direct current ablation. These advantages include the absence of skeletal and cardiac muscle stimulation, minimal discomfort during delivery of energy, the possibility of performing the procedure in conscious patients, and the discrete nature of resulting lesions.[49]

Most cardiac ablation therapy for correction of arrhythmias can be performed under moderate sedation or monitored

anesthesia care. In some of these cases, deep sedation may be required as the case progresses. In a few cases, general anesthesia may be required if the patient is anxious or cannot tolerate lying in the supine position for an extended period. General anesthesia may be implemented for these patients with standard American Society of Anesthesiologists monitors with adequate vascular access. Catheter ablation is the first-choice treatment for most cardiac arrhythmias. It is a safe treatment and is usually effective as a single procedure. Because it is curative in many patients, it is offered to all patients who would otherwise be committed to long-term drug therapy.

Future Trends

Correction of cardiac tachyarrhythmias has improved dramatically in the past 2 decades. Emphasis has shifted from pharmacologic therapy to nonpharmacologic therapy of tachyarrhythmias; this has led to a significant increase in the numbers of radiofrequency catheter ablations and defibrillator implantations. These developments were triggered by technologic advances that showed superiority of these procedures over the use of antiarrhythmic drugs.[52] As a result, treatment of supraventricular tachycardias and tachycardias involving accessory atrioventricular pathways will probably remain the domain of catheter ablation. The cure rates of patients treated with catheter ablation is very high. In addition, treatment of life-threatening ventricular tachyarrhythmia will remain in the domain of ICDs for the foreseeable future. The role of ICD therapy has been clearly defined with respect to prolongation of life and has been expanded to include primary prophylaxis of sudden death in high-risk populations.[53]

As a result of these developments, the presence of an anesthesiology team will continue to grow in cardiology suites. Patients who are being cared for in these areas are sicker with significant comorbidities. The role of conscious sedation will continue to diminish in the performance of these procedures. These patients will require full monitoring and care under the direction of an anesthesiologist.

62 Anesthesia for Vascular Surgery

Key Points

1. Recent advances in our understanding of the biology of atherogenesis suggest that endothelial dysfunction is a critical element in the pathogenesis of atherosclerotic cardiovascular disease and its complications. Inflammation in the artery wall probably plays a fundamental role as well.
2. Major vascular surgery is particularly challenging to the anesthesiologist because these are high-risk operations in a patient population with a high prevalence of either overt or occult coronary artery disease, which is the leading cause of perioperative and long-term mortality after vascular surgery.
3. Accurate clinical assessment of the pretest probability of significant coronary artery disease is necessary for prudent use and rational interpretation of preoperative cardiac testing.
4. Guidelines on perioperative cardiovascular evaluation and care suggest that coronary intervention is rarely necessary to simply lower the risk of surgery unless such intervention is indicated irrespective of the preoperative context. Current evidence does not support the role of prophylactic coronary revascularization as a means to reduce perioperative or long-term morbidity after major vascular surgery.
5. Perioperative management of patients undergoing vascular surgery requires an understanding of the underlying pathophysiology of the specific vascular lesion.
6. Patients should be maintained on their usual cardiovascular medications throughout the perioperative period. Antiplatelet therapy requires special consideration and must be individualized to each patient.
7. Prevention and treatment of perioperative myocardial ischemia require careful control of the determinants of myocardial oxygen supply and demand. ST-segment monitoring, particularly with computerized ST-segment analysis, should be used to detect myocardial ischemia during the perioperative period.
8. Clinical trial data suggest that initiation of perioperative β-blocker therapy has potential benefits and risks.
9. The clinical usefulness of any intraoperative monitoring technique ultimately depends on patient selection, accurate interpretation of data, and appropriate therapeutic intervention.
10. Evidence suggests that maintenance of vital organ perfusion and function by the provision of stable perioperative hemodynamics is more important to overall outcome after aortic surgery than is the choice of anesthetic agent or technique.
11. The pathophysiology of aortic cross-clamping and unclamping is complex and depends on many factors, including the level of the cross-clamp, the extent of coronary artery disease and myocardial dysfunction, blood volume and distribution, activation of the sympathetic nervous system, and the anesthetic agents and techniques.
12. The degree of preoperative renal insufficiency is the strongest predictor of postoperative renal dysfunction.
13. Endovascular aortic surgery has recently emerged as a less invasive alternative to conventional open aortic repair. Endoleak, or the inability to obtain or maintain complete exclusion of the aneurysm sac from arterial blood flow, is a complication specific to endovascular aortic repair.
14. The primary clinical utility of cerebral monitoring during carotid endarterectomy is to identify patients in need of carotid artery shunting; secondarily, such monitoring is used to identify patients who may benefit from blood pressure augmentation or change in surgical technique.
15. Postoperative hypothermia is associated with many undesirable physiologic effects and may contribute to adverse cardiac outcome.

Perioperative management of patients undergoing vascular surgery is challenging because of the frequent occurrence of coexisting disease in elderly patients, the hemodynamic and metabolic stress associated with arterial cross-clamping and unclamping, and the ischemic insults to vital organs, including the brain, heart, kidneys, and spinal cord. As a result, perioperative morbidity and mortality are more frequent with vascular surgery than with most other surgical procedures. Anesthesia care must focus on preservation of vital organ function, with a strong emphasis on the heart, which is the single most important cause of morbidity after vascular surgery. The clinical controversies associated with vascular surgery are diverse and involve aspects of preoperative, surgical, anesthetic, and postoperative management. The controversy associated with routine preoperative screening for coronary artery disease (CAD), as well as appropriate treatment if detected, has particular importance (see Chapters 34 and 35). Ongoing debate continues over anesthetic technique and outcome because vascular procedures often lend themselves to local, regional, general, or combined regional and general anesthesia.

In the 1970s, vascular surgery was recognized as a risk factor for perioperative cardiac morbidity. In the 1980s, the focus shifted to risk stratification in an effort to identify patients who were at greatest risk for morbid outcomes. In the 1990s, intensive clinical investigation involving anesthetic technique, sympatholytic drugs, hemodynamic control, and analgesic technique was undertaken and provided important insight into the prevention, treatment, and mechanisms of cardiac and other morbidity. During this time, a guideline-based approach to health care was initiated, primarily in the United States (see Chapter 92). More recently, there has been a paradigm shift away from routine preoperative screening for CAD with a focus on risk stratification and treatment of CAD to an intensive strategy of perioperative cardiac risk reduction using medications and risk factor modification (see Chapters 34 and 35). Additionally, over the last decade the multidisciplinary field of endovascular surgery has provided less invasive approaches or alternatives to conventional vascular reconstruction. These less invasive procedures, initially offered to patients traditionally considered unfit for open surgery, are being widely applied to the larger cohort of patients undergoing vascular surgery.

The goal of this chapter is to review issues related to the perioperative care of vascular surgery patients and to address the underlying controversies. For simplicity, the five major categories of vascular surgical procedures are discussed separately: abdominal aortic surgery, thoracoabdominal aortic surgery, endovascular aortic surgery, lower extremity vascular surgery, and carotid surgery.

Atherosclerosis

Atherosclerosis is a progressive disease process that compromises the arterial blood supply to any or all of the vital organs or the extremities. Atherosclerotic cardiovascular diseases are the leading cause of death and disability in the United States. Established risk factors are male gender, age, family history of premature cardiovascular disease, high levels of low-density lipoprotein (LDL) cholesterol, low levels of high-density lipoprotein (HDL) cholesterol, diabetes, obesity, hypertension, and smoking. More recently identified risk factors include homocysteine, fibrinogen, lipoprotein(a), apolipoproteins B and A-I, and C-reactive protein (CRP). Because atherosclerosis usually has no early warning signs, prevention is difficult and risk modification is often delayed until the patient has progressed to an advanced stage of disease. The lesions of atherosclerosis occur primarily in large- and medium-sized arteries and may be present throughout one's lifetime. Although atherosclerotic lesions result from a variety of pathogenetic processes, progression of atherosclerosis occurs in three general stages. The initial lesion of atherosclerosis, the fatty streak, starts in early childhood and forms beneath the normal endothelium. These lesions consist of lipid-laden macrophages (i.e., foam cells), smooth muscle cells, and elastic and collagen fibers. The fatty streak progresses to a fibrous plaque consisting of degenerated foam cells covered by a layer of proliferated smooth muscle cells. Unlike the fatty streak, these lesions may compromise blood flow through a vascular bed and cause ischemia or thrombosis to the vital organs or extremities and subsequent infarction. The advanced lesions of atherosclerosis represent a progression of the fibrous plaque, with an expanded lipid-rich core, accumulation of calcium, and disruption of endothelial integrity. Physical disruption of the plaque's protective cap permits contact between flowing blood and the highly thrombogenic material located in the lesion's lipid core (e.g., tissue factor), which results in thrombus formation (i.e., atherothrombosis). Thrombosis may lead to complete occlusion and clinically important complications (e.g., acute myocardial infarction [MI]) or, in the case of intraplaque hemorrhage, to plaque progression.

The American Heart Association Committee on Vascular Lesions has provided a numerical classification of histologically defined atherosclerotic lesion types.[1] Figure 62-1 outlines the most updated classification.[2] Lesion types I, II, and III are always small and clinically silent. With the development of type IV lesions, the pathways to clinical disease vary (see Fig. 62-1). Although lesions IV through VI may progress such that they obstruct the lumen of a medium- or large-size artery and produce a clinical event (i.e., MI, stroke, or extremity ischemia), the clinical manifestations of atherosclerotic disease are most often associated with type VI lesions. The criteria for type VI histology are often interrelated and include one or more of the following: surface defect, hematoma, and thrombosis. Regression of lipid from lesion types IV, V, and VI may result in lesion morphology similar to that of type VII and VIII lesions.

Inflammation in the artery wall plays a fundamental role in the initiation and progression of atherosclerosis.[3,4] As a result of this new understanding, inflammation has become a therapeutic target in the prevention and treatment of atherosclerosis and its complications. Established pharmacologic strategies, such as those for preventing recurrent MI and death, may have unexpected anti-inflammatory effects. For example, inhibitors of hydroxymethylglutaryl coenzyme A (i.e., statins) reduce LDL cholesterol levels but also have anti-inflammatory actions such as a reduction in leukocyte adhesion and macrophage activation.[5] Serum markers of inflammation are now being used as markers of atherosclerosis risk. Elevated plasma levels of CRP, an acute-phase reactant produced in response to inflammatory cytokines (primarily interleukin-6), are being used in cardiovascular risk stratification.[6,7] CRP levels are correlated with risk of death and MI[8] and with the development of peripheral vascular disease.[9] Aspirin's ability to reduce MI probably relates to both its antiplatelet and anti-inflammatory (i.e., reduces CRP levels) actions.[10]

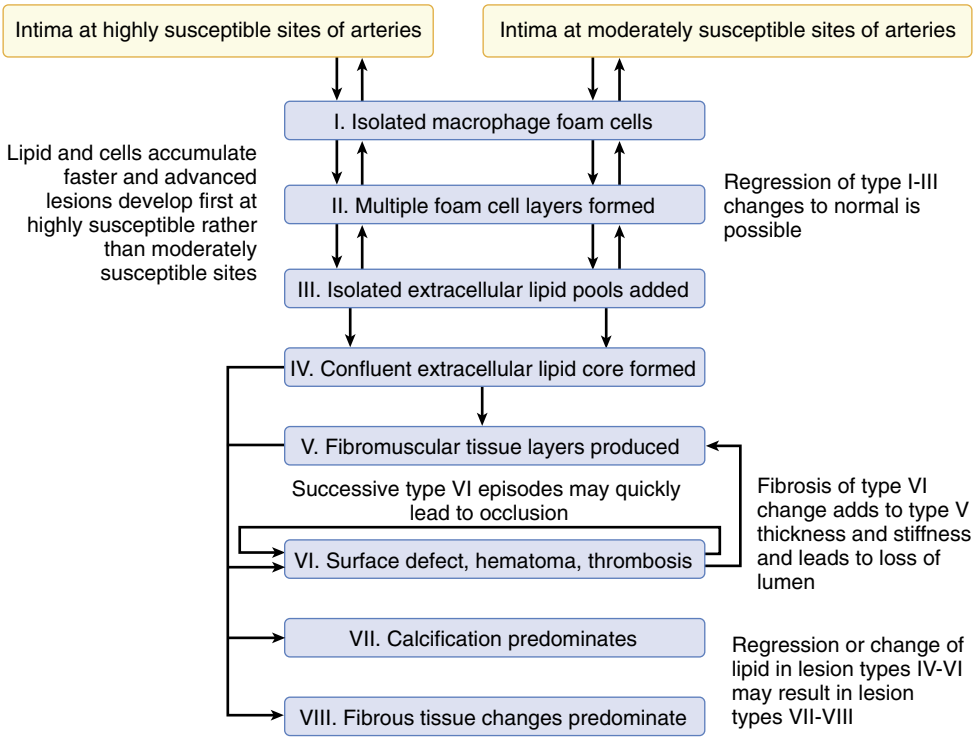

Figure 62-1 Outline of the sequence in the evolution of atherosclerotic lesions from type I to type IV and of the various possible subsequent pathways of progression to lesion types beyond type IV. The diagram lists the main histologic characteristics of each sequential step (lesion type). *Thick* or *thin arrows* differentiate between the relative ease with which lesions develop at specific sites, or they indicate the relative frequency and importance of a pathway section. *(From Stary HC: Natural history and histological classification of atherosclerotic lesions: An update. Arterioscler Thromb Vasc Biol 20:1177-1178, 2000.)*

The anatomic distribution of atherosclerotic lesions is shown in Fig. 62-2. The most common sites are the coronary arteries, the carotid bifurcation, the abdominal aorta, and the iliac and femoral arteries. Atherosclerotic lesions tend to develop near arterial branch points and along the outer surfaces of arterial curves. Their development may be related to increased shear stress and injury to the endothelial surface. Increased cholesterol blood levels are related to atherosclerosis.[11] Statins are the lipid-modifying drugs of choice for the treatment and prevention of atherosclerosis. The efficacy of statins in reducing cholesterol levels and cardiovascular events is well established in large outcome-based clinical trials.[12-14] When the cholesterol level is less than 150 mg/dL, lipids are mobilized from atherosclerotic lesions.[15] Estrogens protect against atherosclerosis in part by increasing HDL and decreasing LDL. Some evidence supports the role of antioxidants in preventing atherosclerotic lesions.[16] Vitamins C and E, carotenoids, and folic acid may be beneficial in this regard. Aspirin, by means of its anti-inflammatory and antiplatelet effects, is effective in preventing stroke and MI.

Preoperative Evaluation

Coexisting Disease

Patients undergoing vascular surgery have a high incidence of coexisting disease, including diabetes mellitus, hypertension, renal impairment, and pulmonary disease, all of which should be assessed and, if possible, optimized before surgery (see Chapters 34 and 35). Because of the systemic nature of atherosclerotic disease, vascular patients frequently have arterial disease affecting multiple vascular territories. CAD is the leading cause of perioperative mortality at the time of vascular surgery, and long-term survival after vascular procedures is significantly limited by the frequent occurrence of morbid cardiac events.[17] Less than 10% of patients who undergo vascular surgery have normal coronary arteries, and more than 50% have advanced or severe CAD. Unrecognized MI (determined by wall motion abnormalities at rest in the absence of a history of MI) and silent myocardial ischemia (determined by stress-induced wall motion abnormalities in the absence of angina) often occur in vascular surgery patients (23% and 28%, respectively) and are associated with increased long-term mortality and adverse cardiac events.[18] Left ventricular systolic dysfunction is five times more common in patients with vascular disease than in matched controls.[19] It is not clear whether any specific category of vascular disease is associated with a greater likelihood of coexisting CAD. Some investigators have shown a similar incidence and severity of CAD in patients with aortic, lower extremity, and carotid disease.[20] Others have shown that patients with lower extremity vascular disease are more likely to have significant CAD and to experience perioperative morbidity.[21-23] Medical therapy is the cornerstone of the management of CAD.

Perioperative and Long-Term Cardiac Outcomes

Preoperatively, the potential for MI and death in patients undergoing vascular surgery must be considered (Table 62-1). Nonfatal

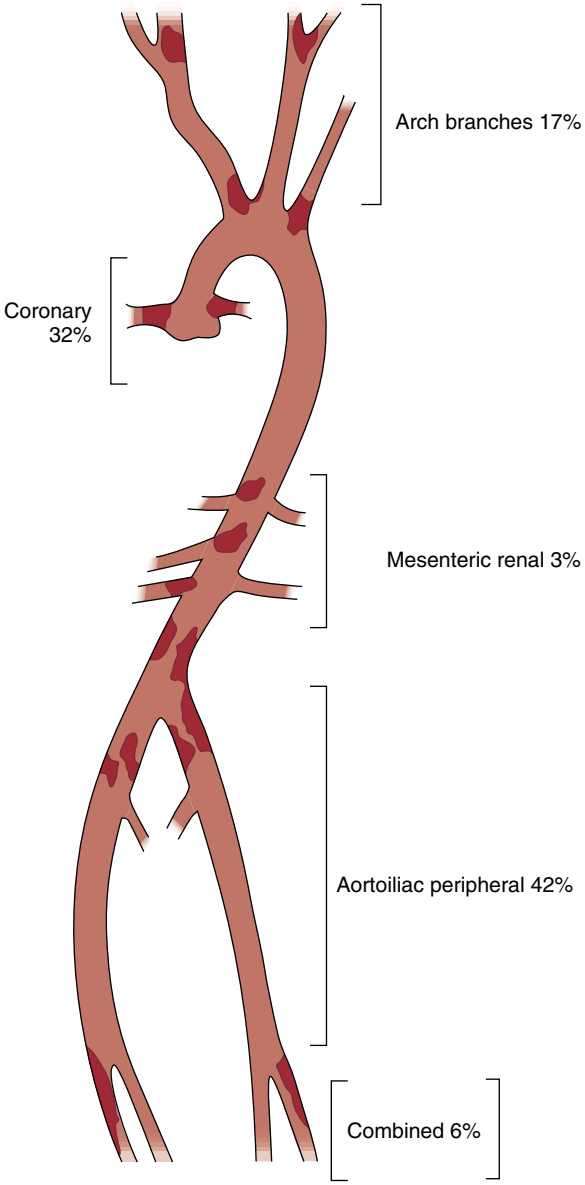

Figure 62-2 Distribution of atherosclerotic lesions. Plaques occur at the origins of large vessels and at bifurcations. Distribution and relative severity differ according to risk factors. *(From Zwolak RM, Cronenwett JL: Pathophysiology of vascular disease.* In *Yeager MP, Glass DD* [*eds*]*: Anesthesiology and Vascular Surgery. East Norwalk, CT, Appleton & Lange, 1990, pp 3-29.)*

and fatal MIs are the most important and specific outcomes that determine perioperative cardiac morbidity. When multiple recent studies are pooled, the overall prevalence of perioperative MI and death is 4.9% and 2.4%, respectively. When outcomes are assessed over the long term (2 to 3 years), the prevalence of MI and death is 8.9% and 11.2%, respectively. This perioperative and long-term morbidity and mortality persist despite aggressive medical and surgical therapy.[35]

Guideline-Based Approach

A guideline-based approach to health care is relatively new and originated primarily in the United States. The American College of Cardiology (ACC) Foundation and the American Heart Association (AHA) have jointly produced guidelines in the area of cardiovascular disease for more than 2 decades. The ACC/AHA Task Force on Practice Guidelines published "Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery" in 1996.[38] This evidence-based approach to perioperative evaluation and management was updated in 2002[39] and most recently in 2007.[40,41] A stepwise approach (simplified from the 2007 guidelines) to perioperative cardiac evaluation and care for noncardiac surgery is provided in Chapter 34. The authors emphasize that the purpose of the preoperative evaluation is not to give medical clearance but rather to perform an evaluation of the patient's current medical status; make recommendations concerning the evaluation, management, and risk of cardiac problems; and provide a clinical risk profile that the patient and caregivers can use in making treatment decisions that may influence perioperative and longer-term cardiac outcomes. The overriding theme of the perioperative guidelines is that intervention is rarely neces-

*For short-term follow-up, outcomes are reported for the duration of the hospital stay or 30 days, and death from MI was classified as both MI and Death. For long-term follow-up, MI was not included as a subset of Death because the cause of death was often unknown. The incidence of MI is underestimated in the long-term part of the table.

sary to simply lower the risk associated with surgery unless such intervention is indicated irrespective of the preoperative context. Thus, preoperative testing should not be performed unless it is likely to influence patient care. The particular challenge that the vascular surgery patient presents is emphasized throughout the document. Aspects of the updated guidelines and its evidence-based approach will be discussed throughout this chapter.

Cardiac Risk Assessment

The preoperative cardiac assessment presents an opportunity to initiate and optimize pharmacologic management, perform appropriate diagnostic and therapeutic interventions, and adjust overall care to decrease not only perioperative risk but also long-term risks from cardiovascular events. The ACC/AHA stepwise approach considers vascular surgery distinct from other noncardiac surgical procedures and is reviewed in detail in Chapter 34. Only issues specific to vascular surgery are reviewed in this chapter.

After assessment of cardiac risk, there is the additional challenge of modifying perioperative management to reduce risk by adjusting or adding cardiac medications (e.g., β-adrenergic blocker), direct coronary intervention (e.g., percutaneous coronary intervention [PCI] or coronary artery bypass grafting [CABG]), modifying or intensifying perioperative management (e.g., invasive hemodynamic monitoring), or changing preoperative plans (e.g., performing endovascular aortic repair rather than open aortic repair). Coordination is essential between surgeons, anesthesiologists, and cardiologists, each of whom may have different criteria for risk assessment and different objectives for risk modification.

Clinical Risk Indices

Assessing cardiac risk in patients before vascular surgery is a controversial and difficult task (see Chapters 33 and 34). Although risk indices are a cost-effective screening method for determining which patients require further cardiac evaluation (i.e., additional risk stratification with noninvasive technologies), the high pretest probability of CAD in vascular surgery patients makes the risk index somewhat less useful. Risk indices do not provide specific risk prediction for individuals, but rather place patients in general risk categories, most commonly designated as low (cardiac risk generally <1%), intermediate (cardiac risk of 1% to 5%), or high (cardiac risk often >5%). As discussed later, clinical risk variables identified by logistic regression in vascular surgery cohorts can be used along with noninvasive cardiac testing to optimize preoperative assessment of cardiac risk before vascular surgery.[42,43] From the registry of the Coronary Artery Revascularization Prophylaxis (CARP) trial, the absence of multiple preoperative cardiac risk variables identifies patients with the best long-term surival after elective vascular surgery.[44]

Previous Coronary Artery Bypass Surgery

Previous coronary revascularization may not provide the same level of protection against MI and death after major vascular surgery.[45] Results from the randomized, prospective CARP trial demonstrated that an aggressive strategy of prophylactic coronary artery revascularization before vascular surgery in patients with stable cardiac symptoms does not improve short-term outcome or long-term survival.[35] At 2.7 years after randomization, mortality was 22% and 23% in patients with and without revascularization, respectively. Postoperative MI, defined by elevated troponin levels, occurred in 12% and 14% of patients with and without revascularization, respectively. Among those randomized to revascularization, patients undergoing CABG had fewer perioperative (6.6% versus 16.8%) and late postoperative (9.9% versus 23.7%) MIs than did patients undergoing PCI despite more diseased vessels in the CABG group (3.0 versus 2.2).[46] Completeness of the revascularization procedure (CABG > PCI) was the predominant variable accounting for this difference. The DECREASE (Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echo)-V pilot study investigated in a randomized fashion the role of prophylactic coronary revascularization in high-risk (three or more clinical risk variables and extensive stress-induced ischemia on noninvasive cardiac testing) patients undergoing major vascular surgery.[47] Preoperative coronary revascularization was not associated with improved short- or long-term outcome. There was no significant difference in the composite end point of all-cause death or nonfatal MI at 30 days

(43% versus 33%) or during 1-year follow-up (49% versus 44%) between patients randomized to revascularization or no revascularization. No difference was observed in the incidence of perioperative cardiac events between patients treated with CABG or PCI. The results of these two randomized trials are congruent with the current ACC/AHA guidelines on perioperative management[40] and CABG,[48] in which preoperative revascularization is reserved for patients with unstable cardiac conditions or advanced coronary disease, for whom a survival benefit with CABG has been proved. Of note, periprocedural complications after CABG are substantially higher in patients with peripheral arterial disease than in those without such disease.[49] These complications may preclude or alter the timing of subsequent vascular surgery.

Previous Percutaneous Coronary Intervention

The role of prophylactic percutaneous coronary revascularization in the preoperative management of vascular surgery patients is controversial.[35,47] Current evidence appears to limit PCI to patients with unstable active CAD.[41] Patients with peripheral vascular disease are often not ideal candidates for PCI. These interventions require placement of a large-diameter introducer sheath in the femoral artery, which predisposes to pseudoaneurysm and compromised blood flow to the lower extremities.[50] PCI can be performed through the brachial artery, but it is technically difficult. PCI in patients with peripheral arterial disease, as opposed to those without peripheral arterial disease, is associated with lower procedural success, higher in-hospital cardiovascular complications, and higher mortality on follow-up.[51] Thus, current guidelines indicate that PCI before noncardiac surgery, including vascular surgery, is of no value in preventing perioperative cardiac events, except in patients in whom PCI is independently indicated for unstable active cardiac conditions.[41]

Noninvasive Diagnostic Cardiac Testing

Accurate clinical assessment of the pretest probability of significant CAD is necessary for the prudent use and rational interpretation of preoperative cardiac testing. In general, noninvasive cardiac testing prior to vascular surgery is best directed at patients considered to be at intermediate clinical risk. Such testing should not be undertaken if it is unlikely to alter patient management and should not be considered as a preliminary step leading to coronary revascularization, as it is rarely necessary to perform a revascularization procedure solely for the purpose of getting a patient through the perioperative period. Extensive cardiac evaluation prior to vascular operations can result in morbidity, delays, and patient refusal to undergo vascular surgery. A complete review of this subject is found in Chapters 34 and 42.

Cardiac Catheterization and Prophylactic Revascularization

The largest series on outcome in vascular surgery patients is that of Hertzer and colleagues[20] from the Cleveland Clinic. These investigators performed cardiac catheterization in 1000 consecutive patients scheduled to undergo peripheral vascular surgery (aortic aneurysm resection, carotid endarterectomy, and lower extremity revascularization). The incidence and severity of CAD were assessed according to the following classification: normal coronary arteries; mild to moderate CAD with no lesion exceeding 70% stenosis; advanced, compensated CAD with one or more lesions exceeding 70% stenosis but with adequate collateral circulation; severe, correctable CAD with greater than 70% stenosis in one or more coronary arteries; and severe inoperable CAD with greater than 70% stenosis in one or more coronary arteries and severe distal disease or poor ventricular function. The most remarkable findings were that only 8.5% of patients had normal coronary arteries and 60% had advanced or severe coronary lesions (>70% stenosis).[20] Even when CAD was not suspected by the clinical history, more than a third of patients had advanced or severe coronary lesions. The results are shown in Table 62-2.

Combined mortality rates over the immediate- and long-term (4.6-year follow-up) postoperative period are shown in Table 62-3. Of the 216 patients who underwent coronary revascularization (CABG), 12 (5.5%) died after this surgery. This mortality rate is greater than that reported for patients undergoing CABG surgery without peripheral vascular disease (1% to 2%), which suggests that the risks associated with CABG should be seriously considered as part of the preoperative evaluation of these patients. When overall early and late mortality (>5 years) is considered, death occurred in 12% versus 26% of patients who did or did not undergo CABG, respectively. Although these data appear to support the beneficial effect of CABG on outcome, the mortality from CABG itself (5.5%) reduces its apparent benefits.

Two randomized clinical trials have been performed to determine the impact of prophylactic coronary artery revascularization on outcome after vascular surgery.[35,47] Of the 5859 patients screened in the CARP trial,[35] 1190 underwent coronary angiography based on a combination of clinical risk factors and noninvasive stress imaging data.[42] The incidence and severity of CAD on these angiograms were reported as follows: 43% of patients had one or more major coronary arteries with at least a 70% stenosis suitable for revascularization (and were randomized to either revascularization or no revascularization before vascular surgery), 31% had nonobstructed coronary arteries, 18% had coronary stenosis considered unsuitable for revascularization, and 5% had left main coronary artery stenosis of 50% or greater. The CARP trial showed that prophylactic revascularization (by CABG or PCI) was generally safe but did not improve long-term outcome after vascular surgery. Long-term mortality (2.7 years) was 22% in the revascularization group and 23% in the no-revascularization group (Fig. 62-3). Although the trial was not designed to test the short-term benefit of prophylactic revascularization, there was no reduction in perioperative outcomes,

Table 62-2 Results of Coronary Angiography in 1000 Patients with Peripheral Vascular Disease

	Clinical CAD

including death (3.1% versus 3.4%) and MI (12% versus 14%). The CARP trial results can be applied to a large percentage of the vascular surgery population; however, they cannot be extrapolated to patients with unstable cardiac symptoms, left main coronary artery disease, aortic stenosis, or severe left ventricular dysfunction because these conditions excluded patients from study participation. The DECREASE-V trial[47] screened 1880 vascular surgery patients, 430 of whom with three or more clinical risk factors underwent noninvasive stress testing using stress-echo or perfusion imaging. Patients with extensive stress-induced ischemia (26%) were randomly assigned to revascularization or no revascularization. Coronary angiography showed two-vessel disease in 24%, three-vessel disease in 67%, and left main coronary artery disease in 8%. Prophylactic coronary revascularization (CABG or PCI) did not improve perioperative or long-term outcome (Table 62-4). The incidence of all-cause death or nonfatal MI at 30 days in patients who underwent revascularization or did not was 43% versus 33%, respectively. The incidence of the composite end point at 1 year was similar, 49% versus 44%, respectively.

The lack of benefit of prophylactic coronary revascularization in the CARP and DECREASE-V trials is difficult to reconcile

with the more favorable data from Hertzer and coworkers[20] and other studies (Coronary Artery Surgery Study [CASS][52] and Bypass Angioplasty Revascularization Investigation [BARI][53]), but it is consistent with current guideline recommendations.[40] Clearly, issues are at play that go beyond critical coronary lesions, which suggests that current understanding of the coronary anatomy predisposing to cardiac risk is lacking. There is emerging evidence that perioperative MI may be caused by culprit lesions (i.e., vulnerable plaques) often located in coronary vessels without critical stenosis.[54] Strategies aimed at reducing the perioperative stress response and potential triggers of coronary plaque rupture may be more appropriate than those leading to coronary revascularization.

Assessment of Pulmonary Function

Postoperative pulmonary complications are potentially serious in patients undergoing vascular surgery, with the most significant morbidity seen in patients undergoing open aortic procedures (see Chapter 93). The most important pulmonary complications are atelectasis, pneumonia, respiratory failure, and exacerbation of underlying chronic disease. Given the prevalence of cigarette smoking in this population, chronic obstructive pulmonary disease and chronic bronchitis are common and, when present, place the patient at increased risk for postoperative pulmonary complications. When clinical assessment suggests severe pulmonary compromise, pulmonary function tests may be useful in evaluating and optimizing respiratory function (see Chapter 44). Preoperative blood gas determination can be used to establish a baseline for postoperative comparison. Baseline hypercapnia (partial pressure of arterial carbon dioxide >45 mm Hg) indicates a higher risk for postoperative morbidity. Bronchodilator therapy may be indicated on the basis of results of pulmonary function tests, although the risk of β-agonist–induced arrhythmia or myocardial ischemia must also be considered. Preoperative treatment with a short course of glucocorticoids (prednisone, 40 mg/day for 2 days) may be helpful for patients with significant chronic obstructive pulmonary disease or asthma.[55] Evidence of pulmonary infection requires treatment with appropriate antibiotics. Although there is limited evidence for improved pulmonary outcome with regional anesthesia,[56] patients with significant pulmonary disease may benefit from epidural techniques that are maintained into the postoperative period because the use of local anesthetics helps avoid respiratory depression from systemic opiates. Effective strategies to prevent pulmonary complications in the postoperative period are limited. Incentive spirometry and continuous positive airway pressure are the only modalities of proven benefit.[57] Given proper pulmonary care, even patients with severe pulmonary insufficiency, however, may undergo aortic surgery with acceptable morbidity and mortality.[58]

Assessment of Renal Function

Chronic renal disease is common in vascular surgery patients and is associated with an increased risk for death and cardiovascular disease (see Chapters 33 and 45).[59] Chronic renal disease strongly predicts long-term mortality in patients with symptomatic lower extremity arterial occlusive disease irrespective of disease severity, cardiovascular risk, and concomitant treatment.[60] Cardiovascular disease, itself, is independently associated with a decline in renal function and the development of kidney disease.[61] Serum creatinine and creatinine clearance are commonly used to assess renal function perioperatively. A preoperative serum creatinine level higher than 2 mg/dL is an independent risk factor for cardiac complications after major noncardiac surgery.[62] Preoperative creatinine clearance less than 60 mL/min is an independent predictor of both short- and long-term mortality after elective vascular surgery.[63] Perioperative β-blocker[63] use and perioperative statin[63] use are associated with a lower risk of death in vascular surgery patients with renal impairment. Atherosclerotic disease in the abdominal aorta or renal arteries may compromise renal blood flow and renal function. Conversely, renal artery stenosis causes hypertension through renin- and angiotensin-induced vasoconstriction. Hypertension itself may cause renal insufficiency or

failure. Diabetic nephropathy is also common. Superimposed on baseline abnormalities in renal function are the preoperatively and intraoperatively administered angiographic dyes, which are directly nephrotoxic. Renal ischemia occurs with interruption of renal blood flow from aortic cross-clamping. Even with infrarenal aortic cross-clamps, there can be a significant reduction in renal blood flow despite normal systemic arterial blood pressure and cardiac output. Embolic plaque can be showered into the renal arteries, especially when suprarenal aortic cross-clamps are applied and released. Fluctuations in intravascular volume and cardiac output can compromise renal perfusion during the intraoperative and postoperative periods. In one series of more than 500 patients, the prevalence of acute renal failure was 7% after abdominal aortic reconstruction.

Perioperative Myocardial Ischemia

Etiology and Prevention

Ischemic cardiac morbidity is the most common cause of perioperative (and overall) death in the United States.[17] Table 62-5 summarizes eight studies showing the relative incidence of preoperative, intraoperative, and postoperative myocardial ischemia. The two studies[28,33] with the lowest rates of intraoperative myocardial ischemia both rigorously controlled intraoperative heart rate and blood pressure by protocol. Norris and associates[33] continued this "tight" hemodynamic control into the postoperative period and reported the lowest rate (15%) of postoperative myocardial ischemia. These studies suggest that good control of perioperative hemodynamics, with an emphasis on heart rate control (<85 beats/min), probably plays an important role in reducing myocardial ischemia. Despite evidence supporting the potential benefit of even tighter heart rate control (<70 beats/min) in reducing myocardial ischemia after vascular surgery,[67] there is strong evidence, suggesting potential harm.[68] There is little information available regarding the importance of blood pressure control. A rational approach that appropriately addresses patients with hypertension or hypotension is described in Figure 62-4.

Several clinical studies have increased our understanding of the clinical variables that may precipitate myocardial ischemia, such as heart rate. After vascular surgery, unlike CABG, patients leave the operating room with the same coronary disease that they came in with, only to experience the stress of the postoperative period. Some vascular patients exhibit heart rate–related myocardial ischemia at "subtachycardic" heart rates.[69] In certain high-risk patients, heart rates of about 85 beats/min consistently trigger ischemic ST-segment changes. The primary role of the anesthesiologist is not merely to control the heart rate but also to diagnose and treat the underlying cause of heart rate changes.

The optimal hematocrit value for vascular surgery patients is unknown. An increased incidence of myocardial ischemia and cardiac morbidity appears to occur if hemoglobin concentrations are less than 9.0 g/dL in the early postoperative period.[70] Therefore, the practice of maintaining hemoglobin concentrations above 9.0 g/dL in vascular patients, especially those at significant risk for ischemic cardiac morbidity, makes sense (see Chapter 55).

Monitoring for Myocardial Ischemia

Three methods are used to detect myocardial ischemia during the perioperative period: surface ECG, transesophageal echocardiography (TEE), and pulmonary artery catheterization (see Chapters 40 to 42). The sensitivity and specificity for detection of ischemia, the level of training required, and the cost of these methods differ and are important considerations. Monitoring for ischemia is important during and after vascular surgery. Ischemia may lead to infarction,[26,71] especially when the ischemia is sustained over time (>2 hours).[72,73] Although no controlled clinical trials have demonstrated a reduction in perioperative morbidity with ischemia monitoring and treatment, the clinical determinants of myocardial oxygen supply and demand should be optimized in an attempt to resolve the ischemic condition.

Table 62-5 Incidence of Myocardial Ischemia* during the Preoperative, Intraoperative, and Postoperative Periods in Vascular Surgery Patients

Study	Preoperative	Intraoperative	Postoperative	Overall
Pasternack et al.[31]

*Percentage of patients with myocardial ischemia as detected by continuous Holter monitoring and ST-segment analysis.
†Unpublished data.

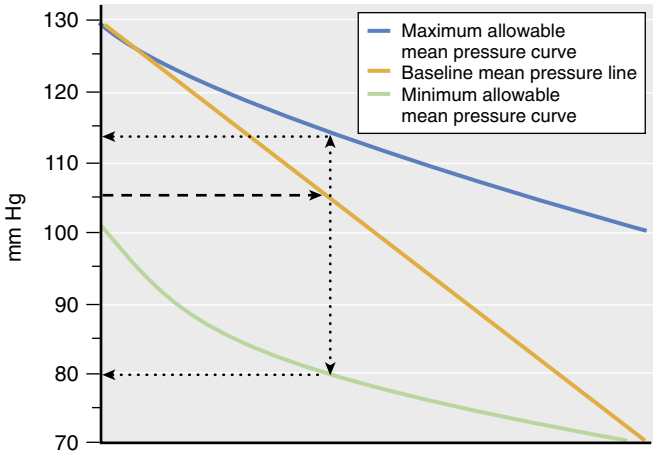

Figure 62-4 Nomogram used to determine minimum and maximum mean blood pressure limits. The nomogram is used by reading the baseline mean arterial pressure (MAP) from the left-hand axis horizontally onto the diagonal baseline mean pressure line. The point of intersection on this line is then extended vertically to intersect with the minimum and maximum allowable mean pressure curves. A patient with a baseline MAP of 105 mm Hg, shown in the figure, would have an allowable MAP range of 80 to 114 mm Hg. *(From Norris EJ, Beattie C, Perler BA, et al: Double-masked randomized trial comparing alternate combinations of intraoperative anesthesia and postoperative analgesia in abdominal aortic surgery. Anesthesiology 95:1054-1067, 2001.)*

Perioperative β-Blocker Therapy

Perioperative β-blocker therapy is an important and controversial topic, particularly in patients undergoing vascular surgery, and is reviewed more fully in Chapters 34 and 35. Patients maintained on chronic β-blocker therapy should continue taking β-blockers throughout the perioperative period. β-Blockers should not be used as the initial or primary treatment of tachycardia caused by perioperative events, such as hypovolemia, anemia, pain, or infection, because these conditions require prompt treatment of the underlying cause. Treatment of tachycardia caused by the sympathetic stimulation associated with surgical stress should be considered in high-risk patients, particularly those with known ischemic potential (i.e., ischemia on preoperative testing). Caution must be taken to avoid hypotension and bradycardia. Acute initiation of high-dose β-blockade in the perioperative period should be avoided. If a decision is made to initiate β-blocker treatment in the perioperative period in an effort to reduce cardiac risk, the safest approach may be to initiate therapy with a low dose and titrate to effect over a 7- to 10-day period before the planned surgery. Although perioperative β-blocker therapy may decrease the number of patients referred for preoperative cardiac testing, such testing will not probably be eliminated, and careful consideration must be given to this approach in terms of its risk-to-benefit ratio.

Hemodynamic Monitoring

The appropriate level of invasive hemodynamic monitoring (see Chapter 40) in patients undergoing vascular surgery is a controversial issue. Multiple considerations determine the need for monitoring, and it is difficult to generalize for all vascular patients. Given the frequency of coexisting disease, the potential for fluid shifts and blood loss, and the physiologic changes associated with cross-clamping and unclamping, virtually all patients undergoing major vascular surgery should be monitored with an intra-arterial catheter. This allows beat-to-beat blood pressure monitoring, accurate determination of diastolic pressure, and sampling of arterial blood for diagnostic purposes. The radial artery is most commonly selected for cannulation because of its superficial location and the presence of collateral circulation. The need to verify collateral blood flow is questionable. The Allen test[74] can be used to assess collateral flow in the palmar arch, but there is evidence that ischemic injury can occur in patients with a normal Allen test result and that no injury occurs in patients with an abnormal Allen test result when the radial artery is cannulated.[75] When the radial artery is difficult to cannulate, the ulnar or axillary arteries are alternative sites. The axillary artery can be cannulated by use of the Seldinger technique, but extreme care should be taken to avoid injecting air when flushing an axillary catheter because the tip may lie close to or inside the aortic arch and thus allow air to enter the cerebral circulation. Whenever possible, the femoral arteries should be avoided in patients with peripheral vascular disease.

Vascular surgery patients often have a large discrepancy in arterial blood pressure between the right and left arms as a result of atherosclerotic lesions in the subclavian or axillary arteries; such discrepancy results in a falsely low pressure in the ipsilateral arm.[76] Patients scheduled for carotid surgery have the highest incidence of right/left arm blood pressure differences.[76] To avoid "pseudohypotension," arterial blood pressure should be verified in both arms, and the arm with the higher pressure should be monitored during surgery. Both arms may have falsely low blood pressure as a result of bilateral disease. In this case, the femoral artery may be the best option for monitoring.

There is significant controversy over the utility of central venous and pulmonary artery catheters for hemodynamic monitoring of patients during vascular surgery. The surgical procedure often determines the degree of fluid shifting and blood loss and thus the usefulness of invasive monitoring. The patient's underlying cardiac, pulmonary, and renal status also needs to be considered. Although cardiovascular function is highly dependent on adequate ventricular filling (i.e., the heart cannot pump out more

blood than it receives), values of central venous pressure and pulmonary artery occlusion pressure do not correlate with values of measured circulating blood volume.[77] Additional information, such as stroke volume and cardiac output, are often important when extreme stress is placed on an already impaired heart. The indications for central venous pressure and pulmonary artery catheter monitoring are discussed in further detail in the subsequent sections.

The role of TEE (see Chapter 41) in the perioperative period has expanded rapidly over the last decade. TEE is useful in identifying anatomic and functional cardiac abnormalities and is a sensitive monitor for detection of myocardial ischemia. During complex aortic reconstruction, TEE provides important real-time information on cardiac filling and function and is particularly useful when unexplained hemodynamic instability is encountered.

Abdominal Aortic Reconstruction

Anesthesia for conventional abdominal aortic reconstruction requires an understanding of the pathophysiology, extensive knowledge of the surgical procedure, the ability to interpret sophisticated hemodynamic data, and skillful pharmacologic control and manipulation of hemodynamics. Preoperative and intraoperative communication with the surgical team is essential. All open operative procedures on the abdominal aorta and its major branches require large incisions and extensive dissection, clamping and unclamping of the aorta or its major branches, varying duration of organ ischemia-reperfusion, significant fluid shifts and temperature fluctuations, and activation of neurohumoral and inflammatory responses. The major objectives of surgical treatment of the aorta are to relieve symptoms, reduce the frequency of associated complications, and in the case of aortic aneurysm, prevent rupture. Over the last decade, the growth and development of catheter-based technology for the treatment of peripheral arterial disease have generated tremendous interest for less invasive methods to treat aortic disease. Endovascular aortic surgery (discussed later) has emerged as a less invasive alternative to conventional surgical repair. The endovascular field is evolving rapidly with new devices, innovations, and indications for aortic disease.

Natural History and Surgical Mortality

Abdominal Aortic Aneurysm

Abdominal aortic aneurysms occur frequently in elderly men, with an incidence approaching 8%. Age, smoking, family history of abdominal aortic aneurysm, and atherosclerotic disease are risk factors for abdominal aortic aneurysm. Although the prevalence is much lower in women, the risk factors for abdominal aortic aneurysm are similar to those in men. More than 8000 deaths result from rupture of abdominal aortic aneurysms each year in the United States.[78] The number of hospital discharges each year with the first diagnosis of aortic aneurysm is nearly 70,000.[78] Approximately 40,000 patients undergo open repair of abdominal aortic aneurysm each year in the United States, at a cost likely to exceed a billion dollars. The incidence of abdominal aortic aneurysm appears to be rising and is age and sex dependent.

Abdominal aortic aneurysm is a multifactorial disease associated with aortic aging and atherosclerosis. Although no unified concept of pathogenesis exists, there are genetic, biochemical, metabolic, infectious, mechanical, and hemodynamic factors that may contribute to the development of abdominal aortic aneurysmal disease.[79,80] Adventitial elastin degradation (elastolysis), a hallmark of abdominal aortic aneurysm formation, may be the primary event.[81] Chronic inflammation is a prominent feature of abdominal aortic aneurysms and probably plays a fundamental role in the destruction of connective tissue in the aortic wall.[82] Concomitant aortoiliac occlusive disease is present in approximately 20% to 25% of patients with abdominal aortic aneurysms. Approximately 5% of patients undergoing abdominal aortic resection have inflammatory aneurysms. Rare causes of abdominal aortic aneurysm disease include trauma, mycotic infection, syphilis, and Marfan's syndrome.

The natural history of abdominal aortic aneurysmal disease is one of progressive enlargement and ultimate rupture and death. Perioperative mortality from elective resection of infrarenal aortic aneurysms has progressively declined from 18% to 20% during the 1950s, to 6% to 8% in the mid-1960s, to 5% to 6% in the early 1970s, to 2% to 4% in the 1980s, at which time it plateaued. A publication of 1000 consecutive elective infrarenal aneurysm repairs over a 15-year period reported a perioperative mortality rate of 2.4%.[83] Hertzer and coworkers[84] reported a mortality rate of 1.2% for 1135 consecutive elective abdominal aortic repairs at the Cleveland Clinic. This single-center mortality rate is considerably lower than the mortality rates of 5.6% to 8.4% reported from large national data sets.[85,86] These higher mortality rates on the national level have prompted some to suggest that all of the technologic and treatment advances over the last 2 decades have not had an impact on outcomes of patients with abdominal aortic aneurysms.[86] Regionalization of care and endovascular treatments currently hold the most promise for improvement in operative mortality.

For ruptured abdominal aortic aneurysms, perioperative mortality has not changed significantly over the last 4 decades and remains nearly 50%, with few exceptions. If one takes into consideration patients with rupture who die before reaching a hospital, the overall mortality rate after rupture may very well exceed 90%.[87]

The diameter and rate of expansion of abdominal aortic aneurysms are currently the best predictors of the risk for rupture. The Joint Council of the American Association for Vascular Surgery and Society for Vascular Surgery have published guidelines for the treatment of abdominal aortic aneurysms.[88] These guidelines emphasize that it is not possible or appropriate to recommend a single threshold diameter for operative intervention that can be generalized to all patients. There is nearly uniform agreement that elective repair should be undertaken in all patients with abdominal aortic aneurysms 6 cm or greater in diameter. Although some controversy exists regarding elective abdominal aortic aneurysm repair when its diameter is in the 5.5- to 5.9-cm range,[89] it is currently accepted that the risk for rupture of a 5.5-cm aneurysm (per year) is equal to or greater than the risk for perioperative mortality, and thus surgical repair is indicated. The 1-year incidence of probable rupture in patients refusing or unfit for elective repair has recently been reported as 9.4%, 10.2%, and

32.5% for aneurysms 5.5 to 5.9 cm, 6.0 to 6.9 cm, and 7.0 cm or greater, respectively.[90]

The natural history of abdominal aortic aneurysms 4.0 to 5.5 cm in diameter is not well defined, and significant controversy exists regarding surgical repair.[91-93] Two prospective randomized clinical trials conducted in the United Kingdom (United Kingdom Small Aneurysm Trial[94]) and the United States (Aneurysm Detection and Management Study[95]) concluded that surveillance of abdominal aortic aneurysms 4.0 to 5.5 cm in diameter is a safe management option and that early surgical repair did not result in any long-term survival advantage. However, surgical repair is often recommended if such aneurysms become symptomatic or expand more than 0.5 cm in a 6-month period. Aneurysms less than 4 cm in diameter are thought to be relatively benign in terms of rupture and expansion.

The long-term durability of open infrarenal abdominal aortic aneurysm repair is excellent and well established. The incidence of late graft complications is very low (0.4% to 2.3%).[84] Late survival rates after repair of nonruptured abdominal aortic aneurysms are 92% at 1 year and 67% at 5 years.[87]

Aortoiliac Occlusive Disease

As noted earlier, the infrarenal aorta and the iliac arteries are two of the most common sites of chronic atherosclerosis. Because of the diffuse and progressive nature of aortoiliac atherosclerosis, plaque enlargement may reduce blood flow to the lower extremities below a critical level and result in symptoms of ischemia. Unlike patients with aortic aneurysmal disease, patients undergo surgery for aortoiliac occlusive disease only if they are symptomatic. Surgical intervention is indicated for disabling intermittent claudication and limb-threatening ischemia. Intervention is directed toward restoring peripheral pulsatile circulation to relieve claudication and toward preventing amputation. Patients with localized aortoiliac occlusive disease typically have claudication because collateral circulation adequate to prevent critical lower extremity ischemia usually exists. Perioperative mortality is lower in patients undergoing aortoiliac reconstruction than in those undergoing abdominal aortic surgery.[96]

Therapeutic options for managing aortoiliac occlusive disease include anatomic or direct reconstruction (i.e., aortobifemoral bypass), extra-anatomic or indirect bypass grafts (i.e., axillofemoral bypass), and catheter-based endoluminal techniques (i.e., percutaneous transluminal angioplasty with or without stent insertion). Aortobifemoral bypass is viewed as the "gold standard" in treating aortoiliac occlusive disease.[96] Extra-anatomic bypass grafts are generally reserved for specific indications, usually patients with infection, failure of previous reconstruction, or prohibitive risk. Reduced long-term patency and inferior functional results are frequently the trade-off for lower perioperative morbidity and mortality. Catheter-based endoluminal techniques, such as percutaneous transluminal angioplasty, are used for relatively localized disease and may be reasonable alternatives to aortobifemoral bypass in 10% to 15% of patients with aortoiliac occlusive disease.[96]

Renal and Visceral Arterial Insufficiency

Atherosclerosis is the most common cause of renal artery stenosis. Occlusive lesions are located almost exclusively in the proximal segment and orifice of the renal artery and are usually an extension of aortic atherosclerosis. Fibromuscular dysplasia is an important, but less common cause of renal artery stenosis and most frequently involves the distal two thirds of the renal arteries. Hemodynamically significant renal artery stenosis may cause hypertension by activation of the renin-angiotensin-aldosterone system, and bilateral involvement may result in renal failure. Patients with renovascular hypertension frequently have poorly controlled hypertension despite maximal medical therapy. These patients often have severe bilateral renal artery stenosis and may have recurrent congestive heart failure or flash pulmonary edema. Indications for intervention include control of hypertension and salvage of renal function. Operative interventions include aorto-renal bypass, extra-anatomic bypass (hepatorenal or splenorenal bypass), or transaortic endarterectomy. Suprarenal or supraceliac aortic cross-clamping is frequently required for open operative interventions. Percutaneous transluminal angioplasty with stenting of the renal artery is used as the first-line treatment in selected patients.

Stenosis at the origin of the celiac and mesenteric arteries occurs as a result of extension of aortic atherosclerosis. The inferior mesenteric artery is by far the most commonly involved, followed by the superior mesenteric artery and the celiac artery. Occlusion of a single vessel rarely causes ischemic symptoms because of the extensive nature of visceral collateralization. However, occlusion or significant stenosis of any two vessels may compromise collateral flow sufficiently to give rise to chronic visceral ischemia. Operative repair of visceral artery stenosis is reserved for symptomatic patients. Operative interventions include transaortic endarterectomy and bypass grafts, which frequently require supraceliac aortic cross-clamping. Mortality rates for such procedures range from 7% to 18%. To avoid the high mortality associated with open repair, percutaneous transluminal angioplasty with stenting has increasingly been applied in patients with chronic visceral ischemia. Acute visceral artery occlusion can be caused by an embolus or, less commonly, by thrombosis. To avoid the extremely high mortality associated with acute visceral ischemia, diagnosis and surgical intervention must occur before gangrene of the bowel develops.

Aortic Cross-Clamping

The pathophysiology of aortic cross-clamping is complex and depends on many factors, including level of the cross-clamp, status of the left ventricle, degree of periaortic collateralization, blood volume and distribution, activation of the sympathetic nervous system, and anesthetic agents and techniques. Most abdominal aortic reconstructions require clamping at the infrarenal level. However, clamping at the suprarenal and supraceliac levels is required for suprarenal aneurysms and renal or visceral reconstructions and is frequently necessary for juxtarenal aneurysms, inflammatory aneurysms, and aortoiliac occlusive disease with proximal extension. These higher levels of aortic occlusion have a significant impact on the cardiovascular system, as well as on other vital organs rendered ischemic or hypoperfused. Ischemic complications may result in renal failure, hepatic ischemia and coagulopathy, bowel infarction, and paraplegia. As endovascular repair becomes more common, an increasing proportion of patients undergoing open repair will have anatomically complex aneurysms, many of which will require suprarenal cross-clamping.

Hemodynamic and Metabolic Changes

The hemodynamic and metabolic changes associated with aortic cross-clamping are summarized in Box 62-1. It is critically impor-

tant to understand that the magnitude as well as direction of these changes is complex and dynamic, not consistent across experimental and clinical studies, and highly dependent on a number of important factors (Box 62-2). The systemic cardiovascular consequences of aortic cross-clamping can be dramatic, depending primarily on the level at which the cross-clamp is applied. Arterial hypertension above the clamp and arterial hypotension below the clamp are the most consistent components of the hemodynamic response to aortic cross-clamping at any level. The increase in arterial blood pressure above the clamp is primarily due to the sudden increase in impedance to aortic blood flow and the resultant increase in systolic ventricular wall tension or afterload. However, factors such as myocardial contractility, preload, blood volume, and activation of the sympathetic nervous system may also be important.[97] Cross-clamping of the aorta at or above the diaphragm results in the most profound increases in arterial blood pressure unless diverting circulatory support or intravenous vasodilators are used.

Changes in cardiac output and filling pressure with aortic cross-clamping are not consistent and require an *integrated approach* in an attempt to understand the direction and magnitude of such changes (Fig. 62-5). Cross-clamping of the proximal descending thoracic aorta increases mean arterial, central venous, mean pulmonary arterial, and pulmonary capillary wedge pressure by 35%, 56%, 43%, and 90%, respectively, and decreases the cardiac index by 29%. Heart rate and left ventricular stroke work are not significantly changed. Supraceliac aortic cross-clamping increases mean arterial pressure by 54% and pulmonary capillary wedge pressure by 38%.[98] Ejection fraction, as determined by two-dimensional echocardiography, decreases by 38%. Despite normalization of systemic and pulmonary capillary wedge pressure with anesthetic agents and vasodilator therapy, supraceliac aortic cross-clamping causes significant increases in left ventricular end-systolic and end-diastolic area (69% and 28%, respectively), as well as wall motion abnormalities indicative of ischemia in 11 of 12 patients (Table 62-6). Aortic cross-clamping at the suprarenal level causes similar but smaller cardiovascular changes, and clamping at the infrarenal level is associated with only minimal changes and no wall motion abnormalities.

The marked increases in ventricular filling pressure (preload) reported with high aortic cross-clamping have been attributed to blood volume redistribution and increased afterload. The most substantial body of evidence supports the hypothesis of *blood volume redistribution* during thoracic aortic cross-clamping. The splanchnic circulation, an important source of functional blood volume reserve, is central to this hypothesis. The splanchnic organs contain nearly 25% of the total blood volume, nearly two thirds (>800 mL) of which can be autotransfused from the

highly compliant venous vasculature into the systemic circulation within seconds.[99] Primarily because of lower splanchnic venous capacitance, blood volume is redistributed from vascular beds distal to the clamp to the relatively noncompliant vascular beds proximal to the clamp (Fig. 62-5). Both passive and active mechanisms lower splanchnic venous capacitance with thoracic aortic cross-clamping. Cross-clamping the aorta above the splanchnic system dramatically reduces splanchnic arterial flow, which produces a significant reduction in pressure within the splanchnic capacitance vessels.[77] This reduction in pressure allows the splanchnic veins to *passively* recoil and increase venous return to the heart and blood volume proximal to the clamp. Thoracic aortic cross-clamping also results in significant increases in plasma epinephrine and norepinephrine, which may enhance venomotor tone both above and below the clamp. The splanchnic veins are highly sensitive to adrenergic stimulation. The major effect of catecholamines on the splanchnic capacitance vessels is venoconstriction, which *actively* forces out splanchnic blood, reduces splanchnic venous capacitance, and increases venous return to the heart.[77]

Several animal studies that support the blood volume redistribution hypothesis merit mention. Cross-clamping the thoracic aorta in dogs results in marked increases in mean arterial pressure and end-diastolic left ventricular pressure (84% and

188%, respectively) and no significant change in stroke volume. In this same experimental model, simultaneous cross-clamping of the thoracic aorta and the inferior vena cava resulted in no significant change in mean arterial pressure or preload (Fig. 62-6). Stroke volume was reduced by 74%. By transfusing blood (above the clamps) during this period of simultaneous clamping, the authors reproduced the hemodynamic effect of thoracic aortic cross-clamping alone. This study also demonstrated that thoracic aortic cross-clamping is associated with a significant and dramatic increase (155%) in blood flow above the level of the clamp whereas no change in blood flow occurred with simultaneous aortic and inferior vena cava clamping. In other animal models, the proximal aortic hypertension and increased central venous pressure occurring after thoracic aortic cross-clamping were completely reversed by phlebotomy.[100] Aortic cross-clamping at the thoracic and suprarenal levels in dogs both resulted in proximal aortic hypertension, but only occlusion at the thoracic level increased central venous pressure.[101] In this study, thoracic aortic occlusion increased blood volume in organs and tissues proximal to the clamp, whereas no such increase occurred with suprarenal aortic cross-clamping. These experimental data strongly support the hypothesis of blood volume redistribution during aortic cross-clamping and help explain the marked differences in hemodynamic responses observed after aortic cross-clamping at different levels.[98]

Afterload-dependent increases in preload also occur with aortic cross-clamping, usually in the setting of impaired myocardial contractility and reduced coronary reserve. The impaired left ventricle may respond to increased afterload with an increase in end-systolic volume and a concomitant reduction in stroke volume (afterload mismatch). The reduction in stroke volume may be due to limited preload reserve, myocardial ischemia, or inability of the heart to generate a pressure-induced increase in contractility (the Anrep effect). If right ventricular function remains normal, the preclamp right ventricular stroke volume added to the elevated left ventricular end-systolic volume results in left ventricular dilation and elevated end-diastolic volume. If corrective measures are not undertaken, overt left ventricular overload may result, with severe peripheral organ dysfunction and pulmonary edema.

Most clinical studies indicate that cardiac output decreases with thoracic aortic cross-clamping (without vasodilator therapy or diverting circulatory support), whereas most animal studies show no significant change or an increase in cardiac output. Although this inconsistency is complex and not easily reconciled, the status of the left ventricle probably plays a major role. Whereas a normal intact heart can withstand large increases in loading conditions without significant ventricular distention or dysfunction, an impaired heart with reduced myocardial contractility and coronary reserve may respond to such loading conditions with marked ventricular distention as a result of acute left ventricular dysfunction and myocardial ischemia. Although impaired myocardial contractility and reduced coronary reserve are rare in animal experiments, such disorders are frequent in the elderly population undergoing aortic reconstruction. The increase in ventricular loading conditions seen with thoracic and supraceliac cross-clamping in the clinical setting[98] may increase left ventricular wall stress (afterload), with resultant acute deterioration of left ventricular function and myocardial ischemia. Impaired subendocardial perfusion caused by high intramyocardial pressure may be the cause of wall motion abnormalities and changes in ejection fraction. Reflex mechanisms causing immediate feedback inhibition may also explain the reduction in cardiac output with aortic cross-clamping. For example, baroreceptor activation resulting from increased aortic pressure should depress the heart rate, contractility, and vascular tone. Thoracic aortic cross-clamping with

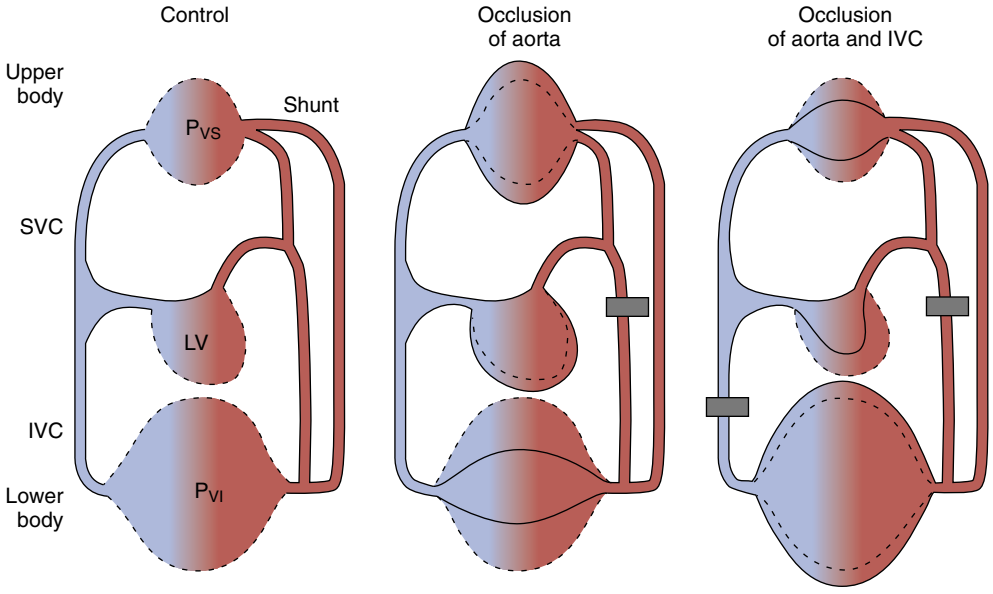

Figure 62-6 Schematic drawing of the circulation. Compliant regions (*dashed lines*) of the upper and lower part of the body and end-diastolic volumes of the left ventricle in the control state (*left panel*) are shown after occlusion of the aorta alone (*middle panel*) and combined occlusion of the aorta and inferior vena cava (*right panel*). the use of vasodilator therapy to normalize ventricular loading conditions maintains or increases cardiac output.[102,103]

The metabolic effects of aortic cross-clamping are summarized in Box 62-1. Cross-clamping of the thoracic aorta decreases total-body oxygen consumption by approximately 50%.[102,104] For reasons that are unclear, oxygen consumption decreases in tissues above the clamp.[104] In clinical studies, increased mixed venous oxygen saturation occurs with aortic cross-clamping above the celiac axis.[105,106] This increase in mixed venous oxygen saturation may be explained by a reduction in oxygen consumption that exceeds the reduction in cardiac output, thus decreasing total-body oxygen extraction.[106] Central hypervolemia and increased arteriovenous shunting in tissues proximal to the aortic clamp may play a role in reducing total-body oxygen extraction.

Arterial blood pressure, blood flow, and oxygen consumption distal to a thoracic aortic cross-clamp decrease by 78% to 88%,[107] 79% to 88%,[104] and 62%,[104] respectively, from baseline values before clamping. Blood flow through tissues and organs below the level of aortic occlusion is dependent on perfusion pressure and is independent of cardiac output. Administration of sodium nitroprusside to maintain proximal aortic pressure above the cross-clamp at preclamp levels has been shown to further reduce arterial pressure distal to the clamp by 53%. As discussed later, these data have significant implications regarding vital organ protection during aortic cross-clamping.

The cardiovascular response to infrarenal aortic cross-clamping is less significant than with high aortic cross-clamping (see Table 62-6). Although several clinical reports have noted no significant hemodynamic response to infrarenal cross-clamping,[108] the hemodynamic response generally consists of increases in arterial pressure (7% to 10%) and systemic vascular resistance (20% to 32%) with no significant change in heart rate. Cardiac output is most consistently decreased by 9% to 33%.[108,109] Reported changes in ventricular filling pressure have been inconsistent.[98,108,109] Blood volume redistribution may affect preload with infrarenal aortic cross-clamping (see Fig. 62-5). In this situation, blood volume below the clamp shifts to the compliant venous segments of the splanchnic circulation above the clamp, thereby dampening the expected increase in preload. The preload changes with infrarenal aortic cross-clamping may also be dependent on the status of the coronary circulation. An early report found that patients with severe ischemic heart disease responded to infrarenal aortic cross-clamping with significantly increased central venous (35%) and pulmonary capillary (50%) pressure whereas patients without CAD had decreased filling pressure. Echocardiographically detected segmental wall motion abnormalities occur in up to 30% of patients during infrarenal aortic reconstruction,[110] with 66% occurring at the time of aortic cross-clamping.[110,111] Clinical studies imply that patients with aortoiliac occlusive disease have less hemodynamic response to infrarenal aortic cross-clamping than do patients with abdominal aortic aneurysmal disease,[112] perhaps as a result of more extensive periaortic collateral vascularization.[113]

Renal Function and Protection

Preservation of renal function is of significant importance during aortic reconstructive surgery. Acute renal failure occurs in approximately 3% of patients undergoing elective infrarenal aortic reconstruction, and mortality resulting from postoperative acute renal failure is greater than 40%.[97] Despite significant improvements in the perioperative care of patients undergoing aortic reconstruction, the high morbidity and mortality resulting from acute renal failure are largely unchanged over the last several decades. Much of the morbidity associated with significant postoperative renal dysfunction is *nonrenal* in nature.

Although urine output is closely monitored and often augmented during aortic surgery, intraoperative urine output does not predict postoperative renal function.[114,115] Thus, adequacy of renal perfusion cannot be assumed by urine output. Procedures requiring aortic cross-clamping above the renal arteries dramatically reduce renal blood flow. Experimental studies report an 83% to 90% reduction in renal blood flow during thoracic aortic cross-clamping. Infrarenal aortic cross-clamping in humans is associated with a 75% increase in renal vascular resistance, a 38% decrease in renal blood flow, and a redistribution of intrarenal blood flow toward the renal cortex.[108] These rather profound alterations in renal hemodynamics occurred despite no significant change in systemic hemodynamics, and they persisted after unclamping. The sustained deterioration in renal perfusion and function during and after infrarenal aortic cross-clamping has been attributed to renal vasoconstriction, but the specific pathophysiology remains unknown.[108] Renal sympathetic blockade with epidural anesthesia to a T6 level does not prevent or modify the severe impairment in renal perfusion and function that occurs during and after infrarenal aortic cross-clamping. Although plasma renin activity is increased during aortic cross-clamping,[116] pretreatment with converting enzyme inhibitors before infrarenal aortic cross-clamping does not attenuate the decreased renal blood flow and glomerular filtration rate. Other mediators, such as plasma endothelin, myoglobin, and prostaglandins, may contribute to the decreased renal perfusion and function after aortic cross-clamping.

Acute tubular necrosis accounts for nearly all the renal dysfunction and failure after aortic reconstruction. The degree of preoperative renal insufficiency remains the strongest predictor of postoperative renal dysfunction. In addition to aortic cross-clamping–induced reductions in renal blood flow, ischemic reperfusion injury, intravascular volume depletion, embolization of atherosclerotic debris to the kidneys, and surgical trauma to the renal arteries all contribute to renal dysfunction.

Mannitol, loop diuretics, and dopamine are used clinically in an attempt to preserve renal function during aortic surgery. Significant controversy exists regarding the use of these agents, as well as the mechanisms by which they may offer a protective effect. Despite studies demonstrating little or no benefit,[117-119] it is widely believed that renal protection before aortic cross-clamping is beneficial, and therefore many clinicians administer these drugs. The use of mannitol to induce osmotic diuresis before aortic cross-clamping is ubiquitous in clinical practice. Mannitol improves renal cortical blood flow during infrarenal aortic cross-clamping and reduces ischemia-induced renal vascular endothelial cell edema and vascular congestion. Other mechanisms by which mannitol may be beneficial include acting as a scavenger of free radicals, decreasing renin secretion, and increasing renal prostaglandin synthesis.[120]

Loop diuretics and low-dose dopamine (1 to 3 μg/kg/min) have been advocated to protect the kidneys from aortic cross-clamp–induced injury by increasing renal blood flow and urine output intraoperatively. Some clinicians advocate the routine use of these agents for patients with preoperative renal insufficiency and for procedures requiring suprarenal aortic cross-clamping. Intraoperative use of these agents requires increased surveillance of intravascular volume and electrolytes during the postoperative period. Therapy with these agents could actually be harmful

because of hypovolemia and resultant renal hypoperfusion. In addition, dopamine's positive inotropic and chronotropic activity may cause tachycardia and increase myocardial oxygen consumption in patients with limited coronary reserve. Although I have virtually abandoned the prophylactic use of dopamine, I often administer diuretics to patients with low urine output after aortic unclamping, particularly those maintained on chronic diuretic therapy.

Fenoldopam mesylate, a selective dopamine type 1 agonist that preferentially dilates the renal and splanchnic vascular beds, has shown some early promise as a renoprotective drug.[121,122] However, its role in the prevention of renal dysfunction after aortic surgery is not known.[123] Statin use is associated with preserved renal function after aortic surgery requiring suprarenal aortic cross-clamping.[124] Remote ischemic preconditioning reduces the incidence of renal impairment after open aortic surgery.[125]

Optimal systemic hemodynamics, including maintenance of intravascular volume, is the most effective means of renal protection during and after aortic cross-clamping.[126,127] The goal is to achieve a preload adequate to allow the left ventricle to cope with cross-clamping–induced changes in contractility and afterload while maintaining cardiac output. However, in providing such therapy, excessive intravascular volume should be avoided, which may lead to inappropriate increases in preload or pulmonary edema in patients with decreased myocardial reserve.

Therapeutic Strategies

Patients with preexisting impaired ventricular function and reduced coronary reserve are most vulnerable to the stress imposed on the cardiovascular system by aortic cross-clamping. Rational therapeutic strategies to prevent the deleterious effect of aortic cross-clamping primarily include measures to reduce afterload, normalize preload, and maintain cardiac output. Vasodilators, positive and negative inotropes, and controlled volume depletion (i.e., phlebotomy) may be used selectively.

Patients with impaired ventricular function requiring supraceliac aortic cross-clamping are the most challenging. Myocardial ischemia, reflecting an unfavorable balance between myocardial oxygen supply and demand, may result from the hemodynamic consequences of aortic cross-clamping. Controlled (i.e., slow clamp application) supraceliac aortic cross-clamping is important to avoid abrupt and extreme stress on the heart. Both afterload and preload reduction is often required. Afterload reduction, most commonly accomplished with the use of sodium nitroprusside (predominantly an arteriolar dilator), is necessary to "unload" the heart and reduce ventricular wall tension. In a large series of patients requiring cross-clamping of the descending thoracic aorta, stable left ventricular function was maintained with sodium nitroprusside during cross-clamping. Sodium nitroprusside allowed adequate intravascular volume before unclamping, which resulted in stable unclamping hemodynamics, although isoflurane can provide hemodynamics comparable to that provided by sodium nitroprusside during thoracic aortic cross-clamping,[102] Though not widely used, amrinone provides hemodynamic control equivalent to that of sodium nitroprusside during abdominal aortic surgery.[128] A normal preload is equally important and involves careful fluid titration and vasodilator administration. Nitroglycerin is commonly used in this setting because it increases venous capacity to a greater extent than sodium nitroprusside does. Infusion of nitroglycerin during abdominal aortic surgery maintains ventricular function during the cross-clamp period.

In patients without evidence of left ventricular decompensation or myocardial ischemia during supraceliac aortic cross-clamping, a proximal aortic mean arterial pressure of up to 120 mm Hg may be acceptable. The surgeon may request lower proximal arterial pressure if friable aortic tissue is encountered. Blood flow below the aortic clamp is dependent on pressure and decreases further during therapy with vasodilators.[104] In this setting, vital organs and tissues distal to the clamp are exposed to reduced perfusion pressure and blood flow. Though infrequent, maintenance of adequate cardiac output may require active intervention with inotropic agents. In general, anesthetic agents that significantly depress myocardial function are avoided during aortic procedures.

Aortic Unclamping

The hemodynamic and metabolic effects of aortic unclamping are listed in Box 62-3. The hemodynamic response to unclamping depends on a number of factors, including the level of aortic occlusion, total occlusion time, the use of diverting support, and intravascular volume. Hypotension, the most consistent hemodynamic response to aortic unclamping, can be profound, particularly after removal of a supraceliac cross-clamp (Fig. 62-7). Reactive hyperemia in tissues and organs distal to the clamp and

*These changes are of greater significance with longer duration of cross-clamping and with more proximal cross-clamping.

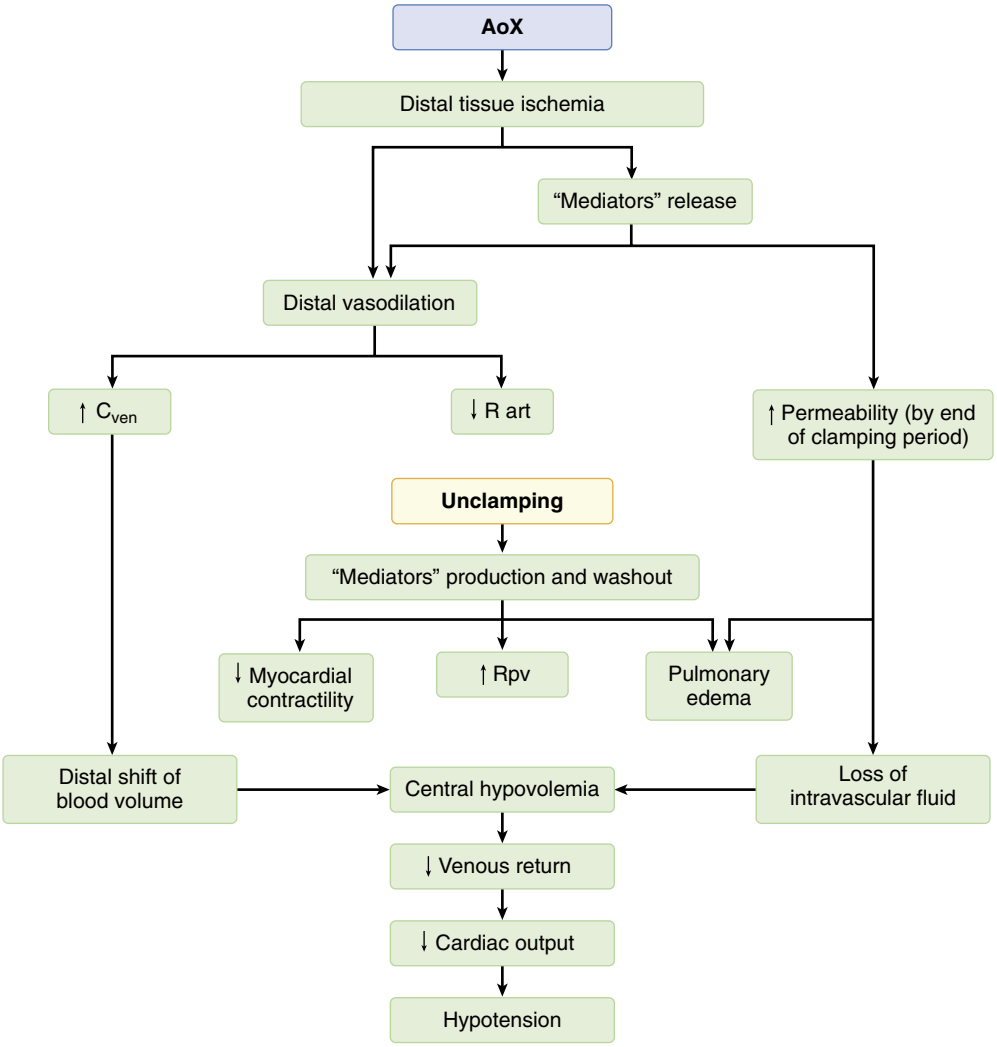

Figure 62-7 Systemic hemodynamic response to aortic unclamping. AoX, aortic cross-clamping; C_{ven}, venous capacitance; R art, arterial resistance; Rpv, pulmonary vascular resistance. *(From Gelman S: The pathophysiology of aortic cross-clamping and unclamping. Anesthesiology 82:1026-1060, 1995.)*

the resultant relative central hypovolemia are the dominant mechanisms of the hypotension. Washout of vasoactive and cardiodepressant mediators from ischemic tissues, as well as humoral factors, may also contribute to the hemodynamic responses after unclamping the aorta. These humoral factors and mediators, which may also play a role in organ dysfunction after aortic occlusion, include lactic acid, renin-angiotensin, oxygen free radicals, prostaglandins, neutrophils, activated complement, cytokines, and myocardial-depressant factors.[97]

Avoidance of significant hypotension with unclamping requires close communication with the surgical team, awareness of the technical aspect of the surgical procedure, and appropriate administration of fluids and vasoactive agents. It is essential that preoperative fluid deficits, intraoperative maintenance requirements, and replacement of blood loss be accomplished before unclamping. Vasodilators, if used, should be gradually reduced and discontinued before unclamping. Potent inhaled agents should be decreased. Moderate intravascular volume loading (approximately 500 mL) during the immediate prerelease period is indicated for infrarenal unclamping. More aggressive intravascular fluid administration is required in the period immediately preceding supraceliac unclamping. Maintaining increased central venous or pulmonary capillary wedge pressure *during* the cross-clamp period is not indicated and may result in significant overtransfusion of fluids and blood products. Gradual release of the aortic clamp and reapplication or digital compression if significant hypotension results are important measures in maintaining hemodynamic stability during unclamping. Although vasopressor requirements are minimal after release of the infrarenal clamp, significant support is often needed after the removal of supraceliac clamps. Caution must be observed when vasopressor support is used in this setting because profound proximal hypertension may occur if reapplication of the cross-clamp is required above the celiac axis. In addition, hypertension should be avoided to prevent damage to or bleeding from the vascular anastomoses.

Anesthetic Management

Intraoperative Monitoring

The potential for significant and rapid blood loss cannot be underestimated. I most commonly use one 8.5 Fr internal jugular

catheter and one or two large-bore peripheral catheters. A hemostatic valve with a side port is placed on the 8.5-Fr catheter to accept either a central venous or a pulmonary artery catheter. Placement of an arterial catheter should be routine in all patients undergoing aortic reconstruction. As with other vascular procedures, the radial artery is most commonly selected for cannulation because of its superficial location, easy accessibility, and low complication rate. A noninvasive blood pressure cuff should be placed on the arm contralateral to the arterial catheter in the event of catheter malfunction.

A central venous catheter should be used for all open aortic procedures. It allows monitoring of central venous pressure and administration of drugs directly into the central circulation. The routine, nonselective use of pulmonary artery catheter monitoring is not recommended for patients undergoing infrarenal abdominal aortic reconstruction.[129,130] For these procedures, pulmonary artery catheters should be considered for patients with significant left ventricular dysfunction (ejection fraction <30%), a history of congestive heart failure, significant renal impairment (preoperative creatinine >2.0 mg/dL), or cor pulmonale. In patients with good left ventricular and pulmonary function, central venous pressure correlates well with left ventricular filling pressure.[131] I routinely insert a pulmonary artery catheter for all patients requiring supraceliac aortic cross-clamping. The invasive monitoring catheters can be placed before or after induction of general anesthesia. The advantage of preinduction catheter placement is assessment of the patient's awake (i.e., baseline) cardiovascular status, which allows correction of severe abnormalities in cardiac filling and function before induction.

With selective use, accurate interpretation of data, and rational treatment strategies, pulmonary artery catheter monitoring may be beneficial in high-risk patients undergoing complex aortic reconstruction. However, the clinical value of pulmonary artery catheter monitoring in high-risk patients has not been established. Clinical studies over the last 2 decades have yielded quite conflicting results. Some studies have reported a decrease in mortality, some no effect,[132,133] and others an increase in mortality.[134] Consensus statements have been published,[135,136] most recently by the National Heart, Lung and Blood Institute and the Food and Drug Administration (FDA).[136] A large prospective, randomized trial compared goal-directed therapy guided by a pulmonary artery catheter with standard care without the use of a pulmonary artery catheter in high-risk surgical patients and reported no benefit of treatment guided by a pulmonary artery catheter.[137] This study did not find an increase in mortality with insertion and use of a pulmonary artery catheter.

Two-dimensional TEE has been used intraoperatively to assess global ventricular function, guide fluid therapy, and monitor for myocardial ischemia. Continuous monitoring of ventricular function is commonly obtained with a single short-axis view at the level of the midpapillary muscle. Using this same view, visualization of the left ventricle at end-diastole allows rapid assessment of ventricular filling (preload). Ejection fraction area can be calculated by use of the left ventricular end-diastolic and end-systolic area. In patients undergoing abdominal aortic reconstruction, echocardiographic short-axis left ventricular end-diastolic area, end-systolic area, and ejection fraction area correlate closely with changes in corresponding left ventricular volume and ejection fraction obtained by radionuclide angiography.[138,139] Patients requiring supraceliac aortic cross-clamping have significant increases in end-diastolic area and significant decreases in ejection fraction on echocardiography that are not completely normalized with vasodilators and frequently are not detected by pulmonary artery catheter monitoring.[98]

TEE can also reveal abnormalities in left ventricular wall motion and wall thickening. The relationship between these abnormalities and coronary perfusion has been established experimentally and clinically,[140] and such abnormalities may precede ECG evidence of ischemia.[141] The short-axis view at the level of the midpapillary muscles allows assessment of all three major coronary distributions. TEE-detected segmental wall motion abnormalities may occur in up to 37% of patients during infrarenal aortic reconstruction[142] and in more than 90% of patients requiring supraceliac aortic cross-clamping.[98,110] The natural history of echocardiographic segmental wall motion abnormalities was studied in 156 patients undergoing noncardiac surgery who were at risk for cardiac morbidity.[142] The 24 patients undergoing aortic surgery had the highest incidence of new segmental wall motion abnormalities (38%). Surprisingly, the incidence of new segmental wall motion abnormalities did not differ in patients with known CAD and those with cardiac risk factors only. Ischemic episodes detected by TEE correlated poorly with postoperative cardiac complications. The authors also reported a discordant relationship between new segmental wall motion abnormalities and ischemic changes on the ECG. In a subsequent report, a subset of 285 patients who were at high risk for cardiac complications and were undergoing noncardiac surgery were studied with continuous intraoperative use of a two-lead ECG, 12-lead ECG, and TEE for the detection of ischemia.[143] A lack of concordance was found between the three different ischemia monitors. When compared with preoperative clinical data and intraoperative monitoring in which a two-lead ECG was used, routine monitoring for myocardial ischemia with TEE or a 12-lead ECG during noncardiac surgery had little incremental clinical value in identifying patients at high risk for perioperative ischemic outcomes. Thus, the sensitivity and specificity of segmental wall motion abnormalities cannot be used as a marker for myocardial ischemia or as a predictor of perioperative ischemic outcomes.

The optimal intraoperative monitoring techniques for patients undergoing abdominal aortic reconstruction have not been established. Existing clinical studies offer insufficient data to conclusively answer the question of whether pulmonary artery catheter or TEE monitoring improves outcome. The clinical usefulness of any monitoring technique ultimately depends on patient selection, accurate interpretation of data, and appropriate therapeutic intervention.

Autologous Blood Procurement

Elective abdominal aortic reconstruction may result in substantial blood loss and warrants the routine crossmatching of 4 to 6 units of packed red blood cells. Suprarenal aneurysms and other more complex aortic reconstructions often demand even greater allogeneic blood availability. Over the last 2 decades, concerns regarding the safety, availability, and acceptability of allogeneic blood have led to greater use of autologous blood procurement (see Chapters 55 and 57). Preoperative autologous donation, intraoperative cell salvage, and acute normovolemic hemodilution have all been used during aortic surgery to reduce or eliminate exposure to allogeneic blood and the associated risks of transfusion-related complications.

Intraoperative cell salvage is the most widely used technique and in some centers is considered routine. The equipment is expensive and requires significant training and expertise. An early, nonrandomized study reported a 75% reduction in the number of allogeneic red cell units transfused during elective aortic surgery with the use of cell salvage.[144] Later randomized studies have reported conflicting results.[145,146] The routine use of cell salvage during aortic surgery may not be cost-effective ($250 to $350 per case), and thus it may best be reserved for a select group of patients with high expected blood loss.[147] The equivalent of at least 2 units of washed blood needs to be recovered for this technique to be cost-effective.[148] A cost-effective option is to use the cell salvage reservoir for blood collection and activate the full salvage process only if large blood loss occurs.

Acute normovolemic hemodilution is often used in conjunction with intraoperative cell salvage during aortic surgery. Two randomized studies reported that the combined use of hemodilution and cell salvage reduced the allogeneic blood requirement in patients undergoing aortic surgery.[149,150] As with cell salvage alone, this benefit is probably greater with procedures involving higher blood loss. Another randomized study found that the combined use of the two techniques during aortic surgery was cost neutral in comparison to standard allogeneic transfusion.[151] Hemodilution does not worsen myocardial ischemia and may improve hemodynamic tolerance to aortic cross-clamping in patient with CAD.[152]

Anesthetic Drugs and Techniques

A variety of anesthetic techniques, including general anesthesia, regional (epidural) anesthesia, and combined techniques, have been used successfully for abdominal aortic reconstruction. Combined techniques most commonly use a lumbar or low thoracic epidural catheter in addition to a "light" general anesthetic. Local anesthetics, opioids, or more commonly, a combination of the two may be administered by bolus or continuous epidural infusion. Evidence suggests that maintenance of vital organ perfusion and function by the provision of stable perioperative hemodynamics is more important to overall outcome than the choice of anesthetic agent or technique is.[33] Therefore, the specific anesthetic technique for patients undergoing abdominal aortic reconstruction is important insofar as it allows rapid and precise control of hemodynamic parameters. Given the high incidence of cardiac morbidity and mortality in patients undergoing aortic reconstruction, special emphasis must be placed on factors that influence ventricular work and myocardial perfusion.

Induction of general anesthesia should proceed in a controlled fashion such that stable hemodynamics is maintained during loss of consciousness, laryngoscopy and intubation, and the immediate postinduction period. A variety of intravenous anesthetics (thiopental, etomidate, propofol) are suitable. The addition of a short-acting, potent opioid such as fentanyl (3 to 5 μg/kg) usually provides stable hemodynamics during and after induction. Volatile anesthetics may be administered in low concentration before intubation during assisted ventilation as an adjunct to blunt the hyperdynamic response to laryngoscopy and endotracheal intubation. Esmolol (10 to 25 mg), sodium nitroprusside (5 to 25 μg), nitroglycerin (50 to 100 μg), and phenylephrine (50 to 100 μg) should be available for bolus administration during induction if needed to maintain appropriate hemodynamics.

Maintenance of anesthesia may be accomplished with a combination of a potent opioid (fentanyl or sufentanil) and an inhaled anesthetic (sevoflurane, desflurane, or isoflurane) (i.e., balanced anesthesia). Patients with severe left ventricular dysfunction may benefit from a pure opioid technique, but a balanced anesthetic technique allows the clinician to take advantage of the most desirable characteristics of potent opioids and inhaled agents while minimizing their undesirable side effects.

Nitrous oxide can be used to supplement either an opioid or an inhaled anesthetic. In general, nitrous oxide decreases cardiac output and arterial pressure while increasing systemic vascular resistance.

Various regional anesthetic and analgesic techniques have been used effectively during and after aortic reconstruction. Does the use of regional anesthetic and analgesic techniques reduce the incidence of perioperative morbidity in patients undergoing aortic reconstruction? The benefits of combined general-epidural anesthesia intraoperatively, with or without epidural analgesia continued into the postoperative period, remain controversial.[32,33,153-156] Moreover, if outcome is improved, are the benefits from the intraoperative anesthetic technique or the postoperative pain regimen, or both, contributors? In a randomized trial using epidural morphine in patients undergoing aortic surgery, Breslow and associates[157] found attenuation of the adrenergic response and a lower incidence of hypertension in the postoperative period. A large randomized trial reported no reduction in nonsurgical complications with the use of intrathecal opioid.[34] The effects of the anesthetic or analgesic technique on the incidence of perioperative myocardial ischemia have received considerable attention. Four randomized trials, with nearly 450 combined patients undergoing aortic reconstruction, failed to demonstrate a reduction in the incidence of perioperative,[33,158] intraoperative,[111] or postoperative[155] myocardial ischemia when epidural techniques were used. Additionally, randomized trials have not demonstrated a reduction in the incidence of cardiovascular, pulmonary, or renal complications after aortic surgery with the use of epidural techniques.[32,33,66,154,155]

The duration and intensity of postoperative care after aortic surgery are critically dependent on the physiologic derangements incurred during the perioperative period (i.e., depression of consciousness, hypothermia, fluid overload, incisional pain, ileus, and respiratory depression), as well as on the development of certain less common, but more severe postoperative complications (i.e., MI, pneumonia, sepsis, renal failure, and decreased tissue perfusion). Length of hospital stay may therefore be considered the outcome variable most directly proportional to an integrated final negative effect of all significant perioperative morbidity (excluding in-hospital death) and the variable most likely to be altered by the anesthetic or analgesic technique. Randomized trials have not demonstrated any reduction in length of hospital stay after aortic surgery with the use of regional techniques.[32-34,66,154,155] Norris and colleagues reported the results of a randomized clinical trial comparing alternative combinations of intraoperative anesthesia (i.e., general or combined epidural-general) and postoperative analgesia (i.e., intravenous patient-controlled analgesia or epidural patient-controlled analgesia) with respect to length of stay after abdominal aortic surgery.[33] Two unique features of the trial included a factorial design (Fig. 62-8), which allowed the inclusion of all four combinations of intraoperative anesthesia and postoperative analgesia and the ability to separate the influence of time period and technique, and a double-blind design, which helped eliminate investigator and treating physician bias. The study rigorously protocolized perioperative management, standardized postoperative surgical care,

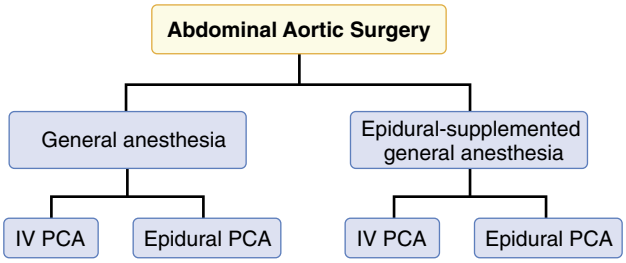

Figure 62-8 Outline of factorial study design. This design allows the inclusion of all four possible combinations of intraoperative anesthesia and postoperative analgesia and the ability to separate the influences of time period and technique. Data analysis by treatment group, intraoperative treatment, postoperative treatment, and any epidural activation, as well as simultaneous consideration of both intraoperative and postoperative treatment in the same model (factorial analysis), is possible and allows improvement in outcome to be attributed to intraoperative anesthesia, postoperative analgesia, the combination of the two, or unrelated factors. PCA, patient-controlled analgesia. *(From Norris EJ, Beattie C, Perler B, et al: Double-masked randomized trial comparing alternate combinations of intraoperative anesthesia and postoperative analgesia in abdominal aortic surgery. Anesthesiology 95:1054-1067, 2001.)*

and optimized postoperative pain management. Although the overall length of stay was much shorter (median, 7.0 days) than that reported in other studies,[32,66,154,155] we were not able to demonstrate a reduction in length of stay or direct medical costs based on anesthetic or analgesic technique (Table 62-7). The overall incidence of postoperative complications in the trial was low and not different based on anesthetic or analgesic technique. Postoperative pain was well controlled overall, with similar pain scores in both analgesic treatment groups. Thus, if perioperative care and pain relief are optimized, epidural anesthetic and analgesic techniques for aortic surgery offer no major advantage or disadvantage over general anesthesia and intravenous patient-controlled analgesia.

Clinical studies have identified several disadvantages in the use of epidural local anesthetics in combination with general anesthesia during aortic reconstruction, including hypotension at the time of aortic unclamping and increased intravascular fluid and vasopressor requirements. Supraceliac aortic cross-clamping may significantly exaggerate these disadvantages, and as a result, some clinicians avoid epidural local anesthetics for such procedures. Epidural opioids without local anesthetics can be used for procedures requiring supraceliac aortic cross-clamping. Epidural local anesthetic can be given later, after aortic unclamping, when hemodynamics and intravascular volume have stabilized. For low thoracic or high lumbar epidural catheters, the initial bolus should be limited to 6 to 8 mL of local anesthetic. Additional local anesthetic is administered by continuous infusion at 4 to 6 mL/hr with adjustments based on hemodynamics and inhaled anesthetic requirements during surgery. Although elective aortic reconstruction via the retroperitoneal approach using straight epidural anesthesia (no general anesthetic) has been reported,[159,160] this technique is not recommended for routine use.

Emergence from anesthesia should be conducted after restoration of circulation and establishment of adequate organ perfusion. Hemodynamic, metabolic, and temperature homeostasis must be achieved before skin closure; otherwise, patients are transported to the intensive care unit (ICU) with their trachea intubated and their ventilation controlled. Extubation of the trachea is not generally attempted in patients with supraceliac aortic cross-clamp times longer than 30 minutes, patients with poor baseline pulmonary function, or patients requiring large volumes of blood or crystalloid during surgery. At the start of skin closure, inhaled anesthetics are discontinued, nitrous oxide is increased to 70%, and any residual neuromuscular blockade is reversed. A large nasal airway can be inserted after induction but before systemic heparinization in all patients for whom extubation is planned in the operating room. Hypertension and tachycardia are aggressively controlled during emergence by the use of short-acting agents such as esmolol, nitroglycerin, and sodium nitroprusside. Patients are placed in a recumbent, head-up posi-

tion, and nitrous oxide is discontinued. If spontaneous ventilation is adequate, the trachea is extubated. Some centers advocate extubation of all patients in the ICU after a period of stability has been established. In these cases, mild sedation with a benzodiazepine such as midazolam is appropriate.

Temperature Control

Postoperative hypothermia is associated with many undesirable physiologic effects[161-163] and may contribute to adverse outcomes (see Chapter 48).[164-167] Normothermia should be maintained before skin incision by increasing ambient temperature in the operating room, applying warm cotton blankets, and warming intravenous fluids. If significant hypothermia occurs early in the procedure, normothermia is extremely difficult to achieve, and emergence and tracheal extubation may be delayed. During surgery, all fluids and blood products should be warmed before administration. A forced-air warming blanket should be applied over the upper part of the body. The lower part of the body should not be warmed because doing so can increase injury to ischemic tissue distal to the cross-clamp by increasing metabolic demands.

Thoracoabdominal Aortic Surgery

Open repair of the thoracoabdominal aorta is widely regarded as the most challenging surgical procedure in terms of overall anesthetic and perioperative management. Surgical repair is required for a spectrum of disease, including degenerative aneurysm, acute and chronic dissection, intramural hematoma, mycotic aneurysm, pseudoaneurysm, penetrating aortic ulcer, coarctation, and traumatic aortic tear. Since the first thoracoabdominal aortic aneurysm (TAA) repair in 1955, tremendous advances have been made in the field. These advances have led to significant reductions in operative mortality and perioperative complications. However, even in centers where numerous procedures are performed, morbidity and mortality are high, especially in patients with dissecting or ruptured aneurysms. To successfully care for these patients, the anesthesiologist must be knowledgeable in the areas of one-lung ventilation; extracorporeal circulatory support, including circulatory arrest; renal and spinal cord protection; induced hypothermia; invasive hemodynamic monitoring, including TEE; massive transfusion; and management of coagulopathy. Intraoperative management requires a team effort with intimate cooperation between surgeons, anesthesiologists, perfusionists, nurses, and electrophysiologic monitoring staff. Endovascular stent-graft repair of lesions that affect the descending thoracic and thoracoabdominal aorta is evolving rapidly. As discussed later, accumulating experience with stent-graft repair of thoracic aortic aneurysm, dissection, and traumatic tear has demonstrated this modality to be an effective alternative to open repair for select patients.

Etiology and Classification

Aneurysms of the thoracoabdominal aorta occur primarily because of atherosclerotic degenerative disease (80%) and chronic aortic dissection (17%).[168] The remainder are caused by either trauma or connective tissue diseases involving the aortic wall from conditions such as Marfan's syndrome, cystic medial degeneration, Takayasu's arteritis, or syphilitic aortitis.[169] The true incidence of TAA is unknown, but population studies suggest a prevalence much less than that of infrarenal abdominal aortic aneurysm. Degenerative and dissecting TAAs differ in their associated risk factors, extent of aortic involvement, and natural history.[170,171] Thus, complete characterization of each TAA is required to formulate a comprehensive treatment plan. Development of both degenerative and dissecting TAAs is ultimately related to weakening of the aortic wall. Although the natural history of TAA without surgery is uncertain, enlargement tends to be progressive and nonoperative management is generally associated with a poor prognosis. With progressive enlargement, nutritional blood flow to the aorta is compromised. The increasing diameter is associated with increased wall tension, even when arterial pressure is constant (law of Laplace). The high incidence of associated systemic hypertension enhances aneurysm enlargement.

Degenerative and dissecting TAAs are symptomatic at initial evaluation in 57% and 85% of patients, respectively.[170,171] The most common initial complaint is back pain. Additional symptoms can be caused by compression of organs or structures adjacent to the aneurysm. Aortic rupture, as a manifestation of TAA, occurs with equal frequency (9%) in both degenerative and dissecting aneurysms.[170,171] Rupture of the thoracic and abdominal segments occurs with equal frequency and primarily in patients with aneurysms larger than 5 cm. Surgical repair is usually recommended when aneurysm diameter exceeds 6 cm,[172] but earlier repair may be offered to patients with Marfan's syndrome and those with a strong family history of an aortic aneurysm.

In addition to cause, aneurysms of the thoracoabdominal aorta may be classified according to their anatomic location. In 1986, Crawford and colleagues,[168] recognizing the correlation between aneurysm extent and clinical outcome, proposed a classification based on the extent of aortic involvement (Fig. 62-9). The Crawford classification defines aneurysms as types I, II, III, and IV and is appropriately applied to aneurysms of all causes (degenerative and dissecting). Type I aneurysms involve all or most of the descending thoracic aorta and the upper abdominal aorta. Type II aneurysms involve all or most of the descending thoracic aorta and all or most of the abdominal aorta. Type III aneurysms involve the lower portion of the descending thoracic aorta and most of the abdominal aorta. Type IV aneurysms involve all or most of the abdominal aorta, including the visceral segment. Types II and III are most difficult to repair because they involve both the thoracic and the abdominal segments of the aorta. Patients with Crawford type II aneurysms are at greatest risk for paraplegia and renal failure from spinal cord and kidney ischemia during cross-clamping. Even with extracorporeal circulatory support, there is an obligatory period when blood flow to these organs is interrupted because the origin of the blood flow is between the cross-clamps. For this reason, protective measures to prevent ischemic injury are important in reducing morbidity.

Aortic dissection, with or without aneurysm formation, has likewise been classified according to the extent of aortic involvement. The most widely used classification, proposed by DeBakey and colleagues, defines aortic dissection as types I, II, and III (Fig. 62-10). Type I aneurysms begin in the ascending aorta and extend throughout the entire aorta. These lesions are usually repaired via a two-stage approach, with the first procedure

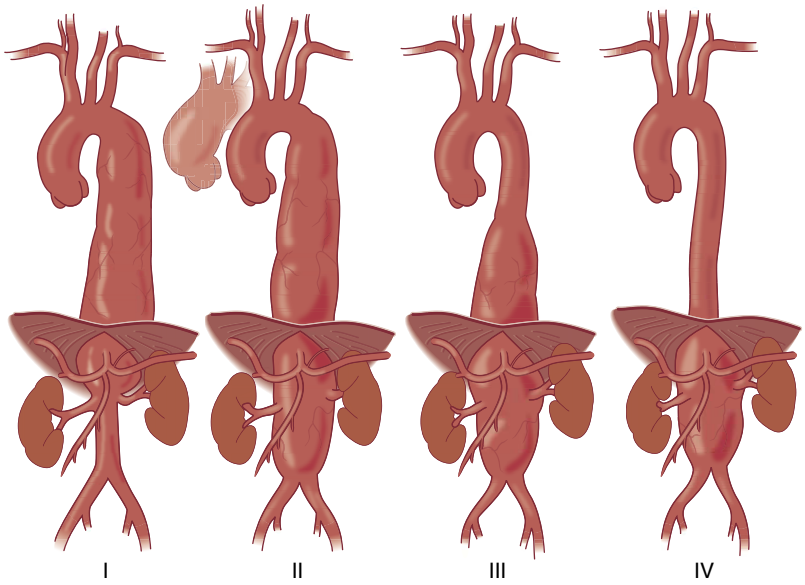

Figure 62-9 The Crawford classification of thoracoabdominal aortic aneurysms is defined by anatomic location and extent of involvement. Type I aneurysms involve all or most of the descending thoracic aorta and the upper abdominal aorta; type II aneurysms involve all or most of the descending thoracic aorta and all or most of the abdominal aorta; type III aneurysms involve the lower portion of the descending thoracic aorta and most of the abdominal aorta; and type IV aneurysms involve all or most of the abdominal aorta, including the visceral segment. *(Adapted from Crawford ES: Thoracoabdominal and supra-renal abdominal aortic aneurysm.* In *Ernst CB, Stanley JC* [*eds*]*: Current Therapy in Vascular Surgery. Philadelphia, BC Decker, 1987, pp 96-98.)*

on the ascending aorta and aortic arch and the second procedure on the descending thoracic aorta. Type II aneurysms are confined to the ascending aorta. Both types I and II often involve the aortic valve and cause aortic regurgitation, and sometimes they involve the ostia of the coronary arteries. Type III aneurysms begin just distal to the left subclavian artery and extend either to the diaphragm (type IIIA) or to the aortoiliac bifurcation (type IIIb). Another commonly used classification of aortic dissection is the Stanford classification. This more simplified classification divides aortic dissection into those that involve the ascending aorta (Stanford type A) and those that do not involve the ascending aorta (Stanford type B). Aortic dissection is also classified by duration, with those less than 2 weeks classified as acute and those greater than 2 weeks classified as chronic. This classification has

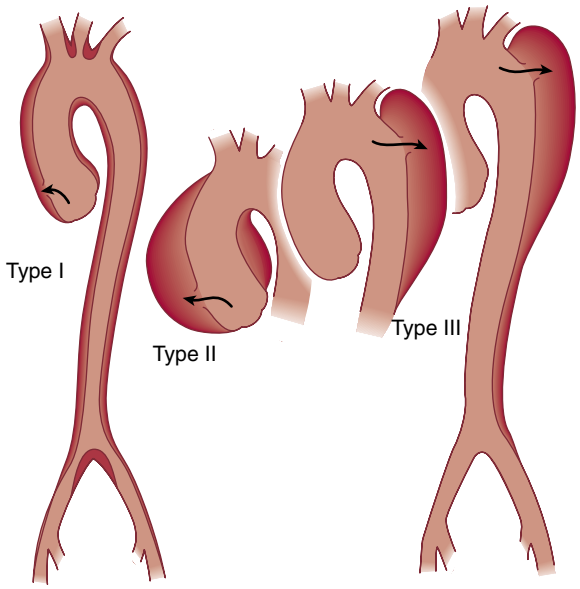

Figure 62-10 The DeBakey classification of dissecting aneurysms of the aorta. Type I has an intimal tear in the ascending aorta with dissection extending down the entire aorta. Type II has an intimal tear in the ascending aorta with dissection limited to the ascending aorta. Type III has an intimal tear in the proximal descending thoracic aorta with dissection either limited to the thoracic aorta (type IIIA) or extending distally to the abdominal aorta or aortoiliac bifurcation (type IIIB). *(Adapted from DeBakey ME, Beall AC Jr, Cooley DA, et al: Dissecting aneurysms of the aorta. Surg Clin North Am 46:1045-1055, 1966.)*

very significant mortality implications, with much higher mortality in the acute phase.

Acute aortic dissection involving the ascending aorta (DeBakey types I and II, Stanford type A) is a surgical emergency that requires immediate cardiac surgical repair (see Chapter 60).[173] Acute dissections involving the descending aorta (DeBakey type III, Stanford type B) are most often treated conservatively (i.e., blood pressure, heart rate, and pain control) because surgical repair has no proven benefit over medical or interventional treatment in stable patients.[174] Early surgical intervention may be required for a variety of reasons, including aneurysmal formation, impending rupture, organ or leg ischemia, and inadequate response to medical therapy. In approximately 20% to 40% of patients with chronic aortic dissection, significant aneurysmal dilatation of the descending thoracic or thoracoabdominal aorta will develop.[175]

Morbidity and Mortality

Despite tremendous development in surgical and anesthetic technique, mortality and complication rates remain high for open surgical repair of TAA. Patients who undergo replacement of the entire thoracoabdominal aorta (Crawford extent type II) have the highest perioperative risk.[176] Contemporary mortality rates reported from large institutional series range from 5% to 14%.[176-179] Statewide and nationwide mortality rates may be considerably higher (approximately 20%).[180,181] The perioperative mortality rate may significantly underestimate the risk associated with TAA repair. In a large statewide series, the mortality with elective TAA repair was 19% at 30 days and 31% at 365 days.[181]

The incidence of paraplegia or paraparesis in patients undergoing surgical repair of TAA is reported to be 3.8% to 40%, depending on factors such as anatomic location, the duration of cross-clamping, the use of protective measures, the degree of dissection, and whether the aneurysm has ruptured.[168,176-179,182] Extensive dissecting TAA repair carries the highest risk of neurologic deficit. A contemporary report of 210 consecutive open TAA repairs reported three patients with paraplegia and two with temporary paraparesis for an overall rate of neurologic deficit of 2.4% (1.4% permanent).[183] Renal failure occurs in 3% to 30% of patients, depending on similar factors noted earlier.[176,184,185] Overall, approximately 6% of patients need postoperative dialysis after TAA repair, which is associated with high mortality (30% to 60%).[185,186] Gastrointestinal complications occur in approximately 7% of patients[187,188] and are associated with a mortality approaching 40%.[178] Not surprisingly, pulmonary complications are the most common problem associated with TAA repair. The incidence of postoperative pulmonary insufficiency approaches 50%,[183,189] with 8% to 14% of patient requiring tracheostomy.[179,189] As with all other vascular surgical procedures, cardiac complications are common and a leading cause of perioperative mortality. In general, perioperative mortality and major complication rates after open isolated descending thoracic aortic replacement are lower than those described for TAA repair.[190]

Preoperative Preparation and Monitoring

Open surgical TAA repair requires extensive preoperative evaluation and planning. The evaluation and management of coexisting cardiac and pulmonary disease are discussed earlier in this chapter. Before the day of surgery, the anesthesiologist and vascular surgeon should discuss, at a minimum, the following issues: extent of the aneurysm and technique of surgical repair, plans for distal aortic perfusion, monitoring for spinal cord ischemia, renal and spinal cord protection, hemodynamic monitoring, and ventilation strategy.

Blood loss during TAA repair can be profound, and the need for massive transfusion must not be underestimated. I routinely have 15 units of packed red blood cells and 15 units of thawed fresh frozen plasma immediately available in the operating room, and additional units must be readily obtainable. I use a large cooler to store blood products on ice in the operating room so that they can be returned to the blood bank if not used. Platelets should be readily available as well. A dedicated critical care technician is helpful in assisting with laboratory testing and retrieving products from the blood bank.

Large-bore intravenous access is obviously important, especially if partial bypass (in contrast to full bypass) is planned because it is difficult or impossible for the perfusionist to administer fluid or blood products into the closed partial bypass circuit. Three 8.5-Fr catheters can be inserted into the internal jugular and antecubital veins. One of these accepts a pulmonary artery catheter, and the other two are connected to a rapid infuser system (RIS, Haemonetics, Braintree, MA). This system allows the delivery of up to 1500 mL/min of blood products at a temperature of 37°C to 38°C. A right radial arterial catheter is used for aneurysms involving the proximal descending thoracic aorta because occasionally the cross-clamp is placed proximal to the left subclavian artery, thus occluding flow to the left upper extremity. When distal aortic perfusion techniques are used, I monitor arterial blood pressure distal to the cross-clamps. This can be accomplished with the placement of a right femoral arterial catheter, or the surgical team can place a catheter directly into the femoral artery or distal aorta. This catheter monitors perfusion pressure to the kidneys, spinal cord, and mesenteric circulation during the time when the cross-clamps are high on the descending aorta and the lower body region is perfused by a shunt or bypass circuit. Radial and femoral arterial pressure should be simultaneously displayed on the anesthesiologist's monitor and a monitor visible to the surgeons and the perfusionists. TEE is used routinely during TAA repair (see Chapter 41). When used by a properly trained individual, assessment of left ventricular end-diastolic volume, myocardial ischemia, and valvular function is possible. It is also possible to determine the size and the extent of the aneurysm.

A double-lumen endobronchial tube should be inserted for the purpose of one-lung ventilation (see Chapter 59). One-lung ventilation provides optimal visualization of the surgical field and reduces retraction related trauma to the left lung. A left-sided endobronchial tube is optimal because it is more easily positioned and less likely to become malpositioned. Additionally, there is risk of occluding the right upper lobe bronchus with a right-sided tube. I position all double-lumen tubes under direct vision using a fiberoptic bronchoscope because it facilitates quick and definitive placement and allows direct visualization of the distal trachea and mainstem bronchi. Occasionally, when the left mainstem bronchus is compressed by a large aneurysm,[191] the lumen does not accommodate an endobronchial tube. In this situation, a right-sided endobronchial tube might be necessary. Rarely, the right mainstem bronchus may be compressed by a large aneurysm.[192] The double-lumen tube is usually changed, if possible, to a single-lumen tube at the completion of surgery. This facilitates

ICU management of pulmonary hygiene and reduces resistance to breathing during weaning in the postoperative period. The airway is often edematous after surgery, and it may be difficult or impossible to change the double-lumen tube without tube-changing catheters.

Many centers use electrophysiologic monitoring with somatosensory evoked potentials (SSEPs) or motor evoked potentials (MEPs) to monitor for spinal cord ischemia (see Chapter 46). These monitoring techniques may be helpful in both identifying the important intercostal arteries that perfuse the spinal cord and confirming successful reimplantation into the aortic graft.[193] If spinal cord ischemia is identified, cross-clamps can often be repositioned, upper or lower body blood pressure can be increased to augment perfusion through collateral channels, or other measures may be taken to protect the spinal cord (i.e., cerebrospinal fluid [CSF] drainage, induced hypothermia, or intrathecal pharmacologic agents). These techniques are discussed later. There are three general problems with SSEP monitoring when used during TAA repair. First, sensory monitoring is more likely to detect lateral and posterior sensory column ischemia and is a poor monitor for the anterior motor column. As a result, paraplegia can occur despite normal SSEP signals.[194] Second, inhaled anesthetics and hypothermia can significantly interfere with SSEP signals. Third, ischemia affects peripheral nerves, and ischemia in the lower extremities delays conduction from the usual stimulation sites (e.g., posterior tibial nerve).[195] To eliminate the peripheral nerves as a confounding factor, spinal stimulation via a lumbar epidural electrode can be used, which may be more specific for ischemic injury than peripheral monitoring is.[195] Lower extremity and peripheral nerve ischemia can be avoided with the use of distal aortic perfusion techniques. To avoid lower extremity ischemia from occlusion of the left femoral artery at the insertion site of the retrograde perfusion cannula, some surgeons suture a small-caliber graft onto the femoral artery (end to side) for insertion of the cannula, which allows both antegrade and retrograde perfusion. These limitations of SSEP monitoring just outlined probably accounted for the lack of improvement in neurologic outcome in a large prospective series of TAA repairs.[196] In this same series, the incidence of false-negative responses was 13% and that of false-positive responses was 67%, thus making identification of critical spinal arteries impossible.

The transcranial MEP technique has been used successfully to monitor the anterior columns of the spinal cord. The technique is relatively simple and can be viewed as a "train-of-four" for the brain and spinal cord. Electrical stimulation over the motor cortex activates α-motor neurons, and evoked electromyographic responses are obtained in lower extremity muscle. Only electromyogenic responses are specific for the status of the motor neurons in the anterior horn gray matter. Bilateral recording needles should be placed in the popliteal fossae (i.e., popliteal nerve) and bilateral surface electrodes over the gastrocnemius and tibialis anterior muscles. Bilateral stimulating needles are routinely placed in the popliteal fossae to monitor direct muscle responses and the level of neuromuscular blockade. During aortic cross-clamping, MEPs are monitored every minute. A reduction in MEP amplitude to less than 25% of baseline is considered an indication of spinal cord ischemia and requires corrective measures. Because signal averaging is not required and the anterior horn cells react with an almost immediate functional loss after the onset of ischemia, the technique can be used to rapidly identify intercostal arteries supplying the spinal cord. Additionally, the technique can be used to evaluate the adequacy of distal aortic perfusion and the patency of reimplanted critical intercostal arteries. Careful titration of a short-acting neuromuscular blocker is required to maintain a stable level of neuromuscular blockade. Complete neuromuscular blockade makes MEP monitoring impossible. A continuous infusion technique should be used to maintain electrical muscle amplitude at approximately 50% of baseline. Isoflurane, desflurane, sevoflurane, and nitrous oxide all depress synaptic conduction and significantly decrease the amplitude of myogenic MEPs. Although modifications of the stimulating technique have improved monitoring with inhaled anesthetics somewhat, a total intravenous anesthetic technique may be optimal. Fentanyl and ketamine have little effect on myogeneic MEPs and have been used successfully as a combined anesthetic in a large series of patients undergoing TAA repair with MEP monitoring.[183] This series of 210 consecutive patients had the lowest rate of neurologic deficit (2.4%) and permanent paraplegia (1.4%) reported.[183]

Body temperature should be monitored at two sites (core and peripheral) to assess cooling and warming when bypass techniques are used. There is an important difference, however, between full and partial bypass with regard to temperature monitoring. With full bypass, perfusion is usually into the ascending aorta, and typically the upper body core temperature (i.e., nasopharynx or esophagus) cools and warms fastest, whereas the lower body temperature changes more slowly. With partial bypass, the opposite is true. The blood from bypass is returned into the femoral artery, and the lower part of the body (i.e., rectum or bladder) changes before the upper part changes. This difference is important to recognize in order to achieve complete cooling and warming because the lagging temperature should be the end point for cooling and warming.

Anesthetic Management

Simple Aortic Cross-Clamping

Descending thoracic and thoracoabdominal aortic surgery can be performed without extracorporeal support (i.e., left heart bypass or cardiopulmonary bypass). Large series of the "clamp-and-sew" technique have been published with relatively favorable outcomes, but these cases are from institutions with the greatest clinical experience and the shortest cross-clamp times. Advocates of this technique favor its surgical simplicity. However, the benefits of avoiding the complexity and complications of bypass must be weighed against the risk of vital organ ischemia and complications such as renal failure and paraplegia.

Other than the location and extent of the aneurysm, the duration of cross-clamping on the aorta is the single most important determinant of paraplegia and renal failure with the clamp-and-sew technique. Clamp times of less than 20 to 30 minutes are associated with almost no paraplegia.[168,197] When clamp times are between 30 and 60 minutes (the vulnerable interval), the incidence of paraplegia increases from approximately 10% to 90% as time progresses. Because clamp times are typically in this range or longer, specific adjuncts directed against end-organ ischemic complications are often used.[198] Such adjuncts include epidural cooling for spinal cord protection, regional hypothermia for renal protection, and in-line mesenteric shunting to reduce visceral ischemia.[178]

When the simple clamp-and-sew technique is used, application of the aortic cross-clamp results in significant proximal hypertension, which requires active pharmacologic intervention.

Management strategies have been discussed previously in the section on abdominal aortic reconstruction. Briefly, both sodium nitroprusside and isoflurane[102] have been used successfully to control the proximal hypertension associated with high aortic cross-clamping. Isoflurane is best reserved for patients with good myocardial function. Vasodilators, such as sodium nitroprusside, must be used with caution because they can result in significant overperfusion of the body proximal to the clamp and very low pressures distally. Nitroglycerin can be used to normalize preload and cardiac filling and thus reduce ventricular wall tension. Although nitroglycerin does not control proximal hypertension well as a single agent, it is very helpful when used in combination with sodium nitroprusside. Management of aortic unclamping has been discussed earlier.

Left Heart Bypass

Maintaining lower body perfusion with the use of retrograde distal aortic perfusion reduces ischemic injury and improves outcome, provided that the pressure is high enough to perfuse the organs. The simplest method of providing distal aortic perfusion is a passive conduit or shunt. The heparin-bonded Gott shunt was developed to avoid the need for systemic heparinization and is used to divert flow passively from the left ventricle or proximal descending thoracic aorta to the distal aorta. Some centers place a temporary axillary-to-femoral artery graft to function as a shunt during aortic cross-clamping.

Partial bypass, also referred to as left heart bypass or left atrial-to-femoral bypass, is the most commonly used distal aortic perfusion technique (Fig. 62-11). This technique allows adjustment of blood flow and usually draws blood from the left atrium and returns blood to the left femoral artery. A centrifugal pump is used (Biomedicus, Eden Prarie, MN), and there is no need for full-dose systemic heparin because the circuit is coated with heparin. The typical heparin dose for partial bypass is 100 U/kg. With this technique, an oxygenator is unnecessary because only the left side of the heart is bypassed. Insertion of a heat exchanger into the circuit allows cooling and warming, which is beneficial but not absolutely essential. Variations of left heart bypass include cannulating the aortic arch or proximal descending thoracic aorta instead of the left atrium. With this circuit, the left ventricle is relieved of the increased afterload during aortic cross-clamping. With left atrial cannulation, the left ventricle is relieved of preload and cardiac output is reduced. Either way, proximal hypertension is controlled, the work of the ventricle is decreased, and perfusion is provided to the distal aorta. My colleagues and I have had even greater success with cannulation of a pulmonary vein instead of the left atrium. This method accomplishes the same effect as with atrial cannulation but is associated with less atrial irritability. When hypothermia (30°C) is combined with atrial cannulation, approximately 15% of patients experience new atrial fibrillation.[199] Although most patients revert to sinus rhythm on rewarming, direct cardioversion may be required.

During left heart bypass, it is essential that arterial blood pressure be monitored above and below the aortic cross-clamps. I simultaneously display radial and femoral artery pressure and aim for a mean arterial pressure of 80 to 100 mm Hg above the cross-clamp and at least 60 mm Hg below the cross-clamp. Careful control of intravascular volume, bypass pump flow, and vasoactive drugs is required to achieve the target blood pressures. Management of left heart bypass requires continuous communication and cooperation between the surgeon, anesthesiologist, and perfusionist. We typically set the initial pump flow to approximately

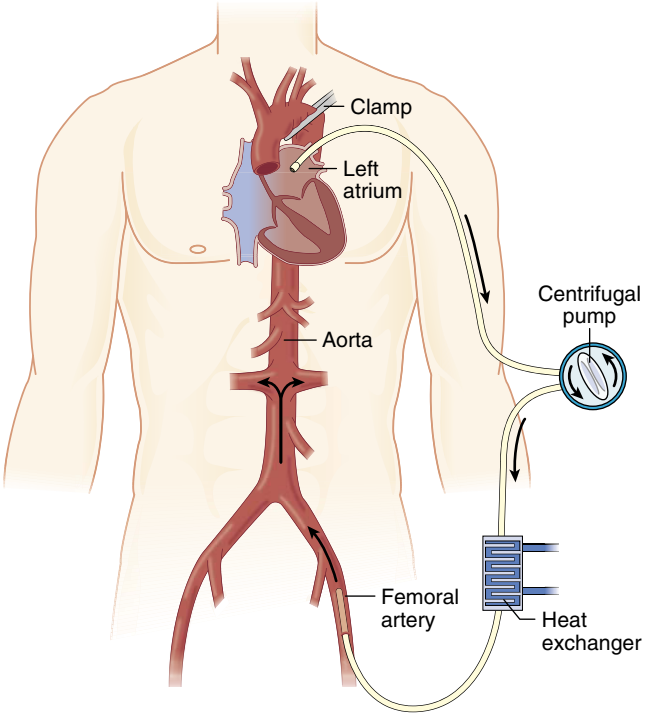

Figure 62-11 Diagram of left atrial-femoral bypass. The left atrium and the left femoral artery are cannulated, and a centrifugal pump is used with heparin-coated tubing. A heat exchanger may be added to the circuit for cooling and rewarming.

50% of the patient's cardiac output with application of the proximal aortic clamp. Flow is then adjusted to maintain target proximal and distal pressures. Administration of vasodilators is very infrequently required at this stage. With no vital organ ischemia, the surgeon can complete the proximal anastomoses in an unhurried fashion. With sequential aortic clamping, intercostal arteries can be reimplanted with minimal adjustments of pump flow. Pump flow is eventually reduced significantly during reimplantation of the visceral and renal arteries. At this time, distal perfusion is only to the lower extremities. We routinely use moderate hypothermia (32°C) during bypass to protect the vital organs during obligate periods of ischemia. After completion of the distal anastomoses, pump flow is increased and the patient is actively warmed to 37°C.

Deep Hypothermic Circulatory Arrest

Complex aneurysms involving the aortic arch often require elective cardiopulmonary bypass with an interval of deep hypothermic (15°C) circulatory arrest (DHCA) because cerebral blood flow is transiently interrupted during surgery (see Chapter 60). Bypass can be accomplished by cannulation of the femoral artery and the femoral vein (i.e., femoral-femoral bypass). During the interval of DHCA, some centers also use anterograde (i.e., innominate artery) or retrograde (i.e., internal jugular vein) selective cerebral perfusion with cold oxygenated blood to extend the safe maximum duration of circulatory arrest.[200] Without this technique, 45 to 60 minutes is thought to be the safe limit of DHCA, but 90 minutes has been reported with selective cerebral perfusion.[201]

DHCA may also be necessary whenever the location, extent, or severity of aortic disease precludes placement of a proximal aortic clamp during thoracic or thoracoabdominal aortic repair.[202] This is often the case in patients with previous aortic arch repair, where adhesions and scarring make application of the proximal aortic cross-clamp difficult or impossible during TAA repair.[203] DHCA eliminates the need for proximal aortic clamping and allows a bloodless field for the proximal aortic anastomosis. Some centers advocate the use of DHCA during complex aortic reconstruction because deep hypothermia may provide better end-organ and spinal cord function.[204,205] This potential benefit must be carefully weighed against the risks associated with prolonged cardiopulmonary bypass and circulatory arrest. After completion of the proximal anastomosis and intercostal artery–to-graft anastomoses under DHCA, the aortic graft is cannulated and bypass flow is reestablished to the upper part of the body. During a period of hypothermic low bypass flow, the distal anastomoses are completed and then rewarming is initiated.

Anesthetic Technique

There is no single best anesthetic technique for TAA repair. Usually, balanced anesthesia is provided with a combination of an opioid, a low-dose potent volatile anesthetic, a benzodiazepine, and a long-acting muscle relaxant. A total intravenous technique may be optimal if transcranial MEP monitoring is used. Induction of general anesthesia should be slow and controlled. Hypertension should be avoided because acute stress on the aneurysm can cause rupture. The heart rate should be maintained at or below baseline because myocardial ischemia is often related to the heart rate. Extubation should always take place in the ICU and only after a significant period of hemodynamic and metabolic stability. The postoperative analgesic regimen should focus on pain control and stable hemodynamics.

Spinal Cord Ischemia and Protection

Paraplegia is a devastating complication of aortic surgery. The incidence of paraplegia is reported to be 0.5% to 1.5% for coarctation repair, 0% to 10% for thoracic aneurysm repair, 10% to 20% for thoracoabdominal repair, and as high as 40% for extensive dissecting TAA repair.[206-210]

The spinal cord receives its blood supply from two posterior arteries (≈25%) and one anterior spinal artery (≈75%) (Fig. 62-12). The posterior spinal arteries, which supply the sensory tracts in the spinal cord, receive flow from the posterior and inferior cerebellar arteries, the vertebral arteries, and the posterior radicular arteries. The anterior spinal artery, which supplies the motor tracts in the spinal cord, is formed by two branches of the intracranial portion of the vertebral arteries. The upper cervical segment of the spinal cord receives most of its blood flow from the vertebrals. The thoracic portion of the anterior spinal artery is supplied by the anterior radicular arteries (one or two cervical, two or three thoracic, and one or two lumbar). The largest of the radicular arteries is called the great radicular artery (GRA) or the artery of Adamkiewicz. The GRA is the major blood supply to the lower two thirds of the spinal cord. The segmental supplier of the GRA is variable (T5-L5) but is located between T9 and T12 in approximately 75% of cases. The variation in origin of the GRA explains why even infrarenal aortic aneurysm repair is associated with a 0.25% incidence of paraplegia. The specific impact of extensive segmental artery sacrifice on spinal cord perfusion during TAA repair is poorly understood.

Various methods have been used to prevent ischemic injury to the spinal cord. Distal aortic perfusion with extracorporeal support has been shown to reduce the incidence of paraplegia.[211] Any of the various methods of distal bypass are likely to be beneficial when the anticipated cross-clamp time is longer than 30 minutes, but they are probably not beneficial when cross-clamp time is less than 20 minutes. CSF drainage is frequently used to improve spinal cord perfusion during TAA repair and is often used in combination with distal aortic perfusion.[177,212] Spinal cord perfusion pressure is defined as distal mean aortic pressure minus CSF pressure or central venous pressure, whichever is greatest. Autoregulation of spinal cord blood flow is similar to cerebral autoregulation, and blood flow is relatively constant over the range of 50 to 125 mm Hg. During hypoxia or hypercapnia, autoregulation is lost, and flow becomes linearly related to perfusion pressure. Thus, significant flow may remain even at very low perfusion pressure. Drainage of CSF is thought to be important because CSF pressure often increases (by 10 to 15 mm Hg) with cross-clamping of the descending thoracic aorta. The increase in CSF pressure reduces spinal cord perfusion pressure and increases the likelihood of ischemic spinal cord injury.

Despite evidence from animal studies that CSF drainage protects the spinal cord, clinical use of this technique is controversial. One randomized trial reported a reduced incidence of paraplegia,[213] but another reported no benefit.[214] The majority of the evidence in support of CSF drainage comes from nonrandomized historical cohort studies in which the technique is used in combination with other adjuncts, such as intrathecal papaverine[213,215] and hypothermic partial bypass.[177,182,199,212] Coselli and colleagues[216] offered the strongest evidence supporting the efficacy of CSF drainage. They conducted a prospective, randomized

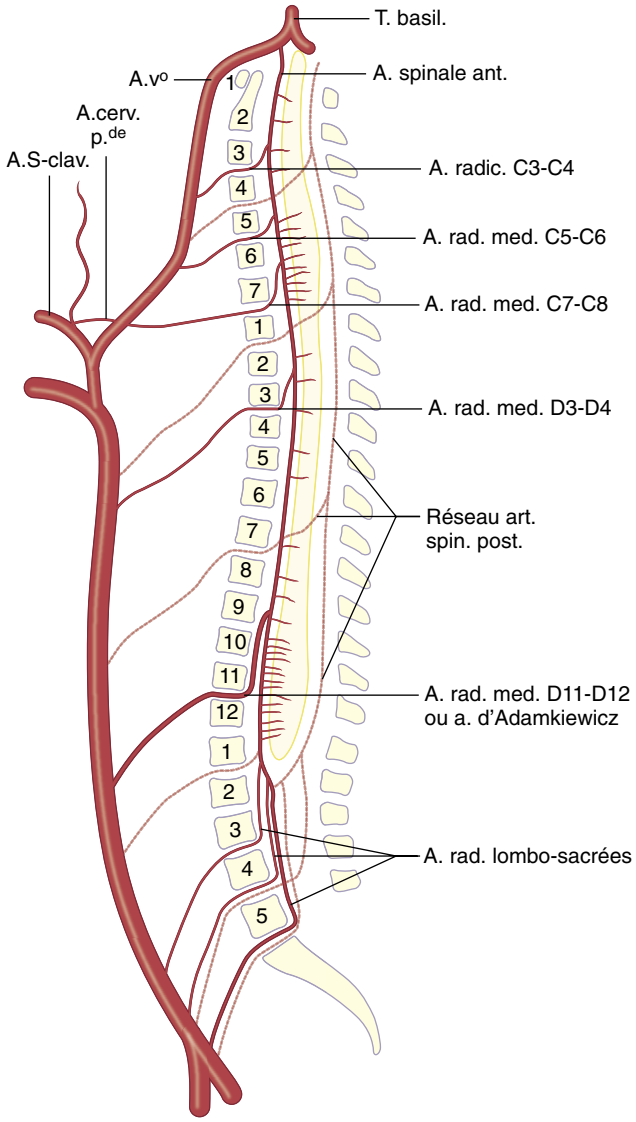

Figure 62-12 Diagram of the blood supply to the spinal cord showing the anterior and posterior radiculomedullary branches seen in a lateral view. The primary blood supply to the thoracolumbar portion of the spinal cord is derived from the artery of Adamkiewicz; its origin varies but it usually branches off the aorta in the T9 to T12 region. *(From Djindjian R: Arteriography of the spinal cord. Am J Roentgenol Radium Ther Nucl Med 107:461-478, 1969.)*

clinical trial to evaluate the impact of CSF drainage on the incidence of spinal cord injury after Crawford type I and II TAA repair. CSF drainage resulted in an 80% reduction in the relative risk for a postoperative deficit. Nine patients in the control group (13%) had paraplegia or paraparesis versus only two patients in the CSF drainage group (2.6%). Left heart bypass, moderate heparinization, permissive mild hypothermia, and reimplantation of patent intercostal and lumbar arteries were performed in both treatment groups. The target CSF pressure was 10 mm Hg. CSF drainage has also been shown (in case reports) to reverse delayed-onset neurologic deficit after open[217] and endovascular[218] TAA repair.

Although CSF drainage is widely used during TAA repair, the technique is not without risks. Potential complications include headache, meningitis, chronic CSF leakage, spinal or epidural hematoma, and subdural hematoma. The possibility of intraspinal pathology should be considered in any patient with a postoperative lower extremity neurologic deficit.[219] A recent retrospective review of 230 patients who underwent TAA repair with CSF drainage at the Johns Hopkins Hospital reported eight subdural hematomas (3.5%).[220] High-volume CSF drainage was identified as a risk factor for its occurrence. Six patients had subdural hematomas detected during hospitalization, with an associated mortality of 67%. Two patients were seen in a delayed fashion, and both required an epidural blood patch to control chronic CSF leakage.

Hypothermia is probably the most reliable method of neuroprotection from ischemic injury. By reducing oxygen requirements by approximately 5% for each degree centigrade, a twofold prolongation of tolerated cross-clamp time is achieved by cooling even to mild hypothermia (34°C). Because the reduction in metabolic rate is linearly related to temperature, moderate or profound hypothermia provides even greater protection. Both systemic and regional spinal cord cooling is beneficial. Systemic hypothermia can been achieved with either full cardiopulmonary bypass (with or without DHCA)[221] or partial bypass.[199,222] Cooling to 30°C to

32°C with left atrial-to-femoral bypass in conjunction with CSF drainage was associated with no permanent neurologic sequelae in a series of 20 patients despite a relatively long average cross-clamp time (≈70 minutes).[199] My colleagues and I have since used this technique in more than 250 patients cooled to 32°C, with a 5% incidence of paraplegia. Although some risk is incurred when a beating heart is subjected to moderate hypothermia, the benefits appear to outweigh the risks. Supraventricular and ventricular dysrhythmias respond well to cardioversion or mild warming to 33°C to 34°C. Regional cooling of the spinal cord by cold perfusion of the GRA with blood[223] or crystalloid provides significant protection during spinal ischemia in animal models. Regional cooling is beneficial in humans who received epidural infusions of 4°C saline.[224] Even if active cooling is not used, it is advantageous to allow patients to passively cool to 33°C to 34°C during TAA repair. With passive cooling, the challenge is rewarming after the surgical repair. This is most easily accomplished with the use of a forced-air blanket over the upper part of the body. The lower body region should not be actively warmed because warming ischemic tissue increases metabolic requirements, acidosis, and ischemic injury.

A variety of drugs have been studied in an attempt to reduce the incidence of ischemic spinal cord injury. Barbiturates have been shown to provide significant protection.[225] Corticosteroids provide protection in dogs[226] but were beneficial in humans only when they were combined with CSF drainage.[227] Calcium channel blockers were protective against spinal cord ischemia in some studies[228,229] but not in others.[230,231] *N*-methyl-D-aspartate receptor antagonists have been investigated because ischemic injury appears to be related to increased levels of excitatory amino acids (particularly glutamate), which allow increased permeability to calcium ions and high intracellular calcium concentrations. Dextrorphan (a noncompetitive *N*-methyl-D-aspartate receptor antagonist) shows promise during spinal cord ischemia.[232] Magnesium, another *N*-methyl-D-aspartate receptor antagonist, improves recovery from spinal cord ischemia in rat and dog models when administered intrathecally.[233,234] Naloxone is protective in patients with traumatic spinal cord injuries and in a rabbit model of spinal ischemia. Naloxone also shows promise when combined with CSF drainage in patients undergoing TAA repair.[235] Intrathecal papaverine appears to be protective,[215] especially when combined with CSF drainage.[213,236] Other agents under investigation include levosimendan, allopurinol, adenosine, ziconotide, activated protein C, and desferrioxamine. Other than the use of corticosteroids and naloxone at a few centers, most of these agents are considered investigational.

Preoperative spinal cord angiography in patients with TAA has been reported by several groups. The rationale for this highly invasive angiographic procedure is that precise identification of intercostal arteries giving rise to the GRA will allow focused reimplantation of these vessels during surgical repair and help prevent spinal cord injury. Selective intercostal angiography identifies the GRA when an intercostal branch is found making a cephalad hairpin turn to enter the spinal canal and supply a midline longitudinal artery (i.e., the anterior spinal artery) (Fig. 62-13). The GRA can be identified in 43% to 86% of patients studied with traditional angiography.[237,238] Higher detection rates for GRA localization have been reported with computed tomographic angiography and magnetic resonance angiography, with the latter achieving rates of nearly 100%.[239]

The importance of reimplanting the intercostal arteries identified as supplying the GRA is not universally accepted. Clinical reports have demonstrated that even in patients with an identified and reimplanted GRA, spinal cord injury could not always be prevented.[240] Some investigators have concluded that preoperative localization of the GRA has little impact on neurologic outcome after TAA repair. A report from my institution[237] found no improvement in overall neurologic outcome with preoperative spinal cord angiography, but it offered important insight regarding the type of aneurysm, identification of the GRA, and neurologic outcome. In patients undergoing TAA repair for extensive degenerative aneurysms, spinal cord injury occurred in 0 of 45 patients versus 10 (12%) of 81 patients with and without an identified GRA, respectively. In contrast, identification of the GRA was not helpful in the case of chronic expanding aortic dissection, with 3 (15%) of 20 patients versus 3 (6%) of 49 patients suffering spinal cord injury with and without an identified GRA, respectively. The investigators hypothesized that mural thrombus in degenerative aneurysms results in the occlusion of many intercostal arteries and favors the development of extensive paravertebral collateral channels (see Fig. 62-13). Identification of a GRA allows focused reimplantation with uniform success. In patients with chronic dissection, most intercostal arteries are patent, collateralization is minimal, and reimplantation of one or two intercostal arteries may be insufficient to supply blood flow to the spinal cord. This collateral blood supply concept is further supported by clinical studies demonstrating that clamping the segmental supplier to the GRA during TAA repair does not produce critical spinal cord ischemia in the majority of patients.[241] Sufficient collateral blood supply, independent of the GRA, must therefore exist to maintain spinal cord integrity.

Delayed-onset neurologic deficits are common after TAA repair.[242] In a large series of 2368 TAA repairs, 93 (3.9%) patients had postoperative paraplegia or paraparesis, 34 (37%) of whom initially had intact spinal cord function but a deficit developed later.[243] Preoperative renal dysfunction, acute dissection, and extent type II TAA are significant predictors of delayed neurologic deficit.[244] Postoperative hypotension and CSF drain malfunction may play an important role in the development of these deficits.[245] In one report, 57% of patients recovered neurologic function with optimization of blood pressure and CSF drainage.[244]

Renal Ischemia and Protection

Renal failure after TAA repair results from preexisting renal dysfunction, ischemia during cross-clamping, thrombotic or embolic interruption of renal blood flow, and hypovolemia and hypotension. Approximately 6% of patients require postoperative dialysis, even in centers with the most clinical experience.[185,186] The associated mortality can be high.[185] The primary predictor of postoperative renal failure is preoperative renal dysfunction.[246] The duration of cross-clamp time is very important with the clamp-and-sew technique.

Retrograde distal aortic perfusion techniques are widely used to preserve renal function during the cross-clamp period. Adequate bypass flow and arterial blood pressure are essential for maintaining renal function. Systemic and regional hypothermia, by reducing oxygen requirements, protects the kidneys during ischemia. Some centers advocate the use of DHCA in the treatment of distal TAAs (i.e., extent type III and IV) to preserve renal function.[247]

The role of pharmacologic protection is somewhat controversial. Mannitol (12.5 to 25.0 g/70 kg) is often given before cross-clamping. Mannitol improves renal cortical blood flow and the

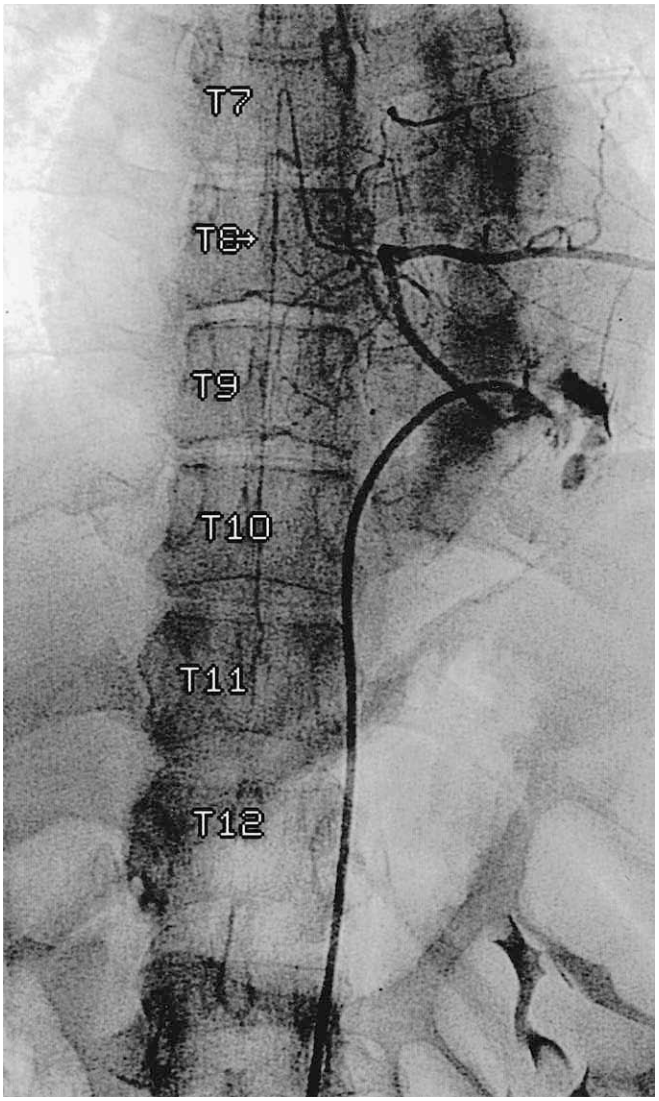

Figure 62-13 Spinal cord angiogram of an extensive degenerative thoracoabdominal aortic aneurysm. Selective injection of the intercostal artery at T8 (*arrow*) demonstrates the great radicular artery and the extensive paravertebral collateralization.

glomerular filtration rate in animal models of ischemia. Endothelial cell swelling is decreased, and an osmotic diuresis occurs. There is evidence of free radical scavenging with mannitol and subsequent protection from ischemia in animals.[120] Loop diuretics are sometimes given, but these drugs have been less effective than mannitol in experimental models. In clinical studies, the prophylactic use of loop diuretics has not been shown to improve outcome or to reduce the need for dialysis for patients with acute renal failure. Dopamine given in low doses (3 μg/kg/min) dilates renal blood vessels and increases renal blood flow and urine output. Despite these beneficial effects, there is no clear evidence from clinical trials that dopamine provides renal protection during ischemia. Fenoldopam mesylate, a selective dopamine type 1 agonist that preferentially dilates the renal and splanchnic vascular beds, has shown some early promise as a renoprotective agent.[121,122]

At the present time, optimal renal protection during TAA surgery should rely on hypothermia, mannitol, and prevention of hypotension and hypoperfusion of the kidneys.

Coagulation and Metabolic Management

Coagulopathy is a frequent complication during TAA repair. A dilutional coagulopathy in which platelets become deficient after approximately one blood volume of replacement develops during massive transfusion (see Chapter 55). At somewhere between one and two blood volumes of replacement, coagulation factors are diluted to levels low enough to increase bleeding. Other contributing factors are residual heparin; ischemia of the liver, where most coagulations factors are produced; and persistent hypothermia after weaning from bypass. With the early use of fresh frozen plasma and platelets, severe coagulopathy can often be avoided. The prothrombin time, partial thromboplastin time, fibrinogen level, and platelet count should be measured frequently. Cryoprecipitate may be necessary to correct coagulopathy, especially when the prothrombin time and partial thromboplastin time are prolonged and hypervolemia prevents the administration of significant volumes of fresh frozen plasma. When coagulopathy persists despite these efforts, ε-aminocaproic acid is beneficial as antifibrinolytic therapy, and desmopressin can be given to increase

circulating levels of von Willebrand factor and factor VIII. Normothermia should be achieved by complete rewarming before separation from bypass, by increasing ambient temperature after separation from bypass, and by forced-air warming over the upper body skin surface.

Arterial blood gases and electrolyte levels should be measured frequently. Sodium bicarbonate should be given to treat the metabolic acidosis that occurs during and after cross-clamping. Hyperkalemia should be treated aggressively, especially in oliguric or anuric patients. Calcium chloride and sodium bicarbonate are the primary acute treatments of hyperkalemia.

Endovascular Aortic Repair

Endovascular surgery is one of the most exciting developments in the treatment of vascular disease and is revolutionizing current treatment modalities for aortic disease, including aneurysm, dissection, rupture, and traumatic injury. The endovascular approach was developed as a less invasive alternative to open abdominal aortic aneurysm repair and to provide a treatment option for patients considered to be poor surgical candidates. The use of endoluminal grafts to treat peripheral arterial disease began experimentally in the late 1960s. The feasibility of this technique for the treatment of abdominal aortic aneurysm was established experimentally some 2 decades later. In 1991, Parodi and colleagues[248] reported the first clinical use of the technique in five patients with abdominal aortic aneurysms. They described the placement of an endoluminal, stent-anchored, Dacron tube graft via retrograde cannulation of the common femoral artery under local or regional anesthesia. Balloon expansion of the stents fixed the ends of the graft to the aortic wall and excluded the aneurysm from the systemic circulation. The technique was satisfactory in three of the five patients. Since these early reports, there has been an explosive increase in the use of endoluminal devices to treat aortic disease. These devices accounted for nearly 50% (29,542 of 61,598) of elective repairs of abdominal aortic aneurysm in Medicare beneficiaries during the period 2001 to 2004.[249]

Interest in endoluminal aortic grafting has expanded to include disease of the thoracic and thoracoabdominal aorta. Endovascular grafting has also emerged as a viable alternative to open repair of aortic rupture and complex aortoiliac occlusive disease. As experience with endoluminal stent-graft systems and endoluminal techniques increases, along with continued refinement of devices, the endovascular approach will be applied to more patients with increasingly complex aortic disease.[250]

Stent-Graft Devices and Approval

The FDA approved the use of two endovascular stent-graft devices for repair of infrarenal abdominal aortic aneurysms in the United States in 1999, with a 5-year surveillance requirement. This surveillance requirement has been extended to lifelong because of reported cases of aneurysm rupture and death. FDA approval of these devices was granted without the usual requirement for a randomized controlled trial. Instead, the FDA allowed a concurrent "matched" group of patients treated by open repair to serve as a control group. One of the two devices approved for use in 1991 was withdrawn from clinical use because of difficulty in delivery and deployment. Three additional stent-graft devices have received regulatory approval in the United States, and more will probably be approved in the near future. Several other stent-grafts are approved for use by other governments around the world. Stent-grafts are often used "off-label" or under physician Investigation Device Exemption studies for indications other than infrarenal abdominal aortic aneurysm repair. Since regulatory device approval, a rapid increase in endovascular abdominal aortic aneurysm repair has occurred nationwide. The stent-grafts used for infrarenal abdominal aortic aneurysm repair are Y-shaped devices. The stent-graft is often modular in design and made of synthetic fabric with reinforcing stent struts. The larger main trunk is designed for the distal aorta and the two smaller branches are for the iliac arteries.

Since the initial report by Dake and coworkers in 1994,[251] tremendous progress has been made in the endovascular treatment of thoracic aortic disease. In 2005, the FDA approved the use of a thoracic stent-graft device for the treatment of descending thoracic aortic aneurysms.[252] Two additional devices are awaiting FDA approval. Several thoracic stent-grafts are commercially available around the world and have been used extensively for a spectrum of aortic disease, including dissection, penetrating ulcer, rupture, and traumatic transection.

Procedures on the thoracoabdominal aorta require novel (i.e., multibranched or fenestrated) endovascular grafting systems or staged hybrid approachs. Tubular aortic stent-graft devices can be modified to incorporate a combination of fenestrations and branches based on the anatomy of the visceral aortic segment. These complex devices are currently in use in Europe and await FDA approval in the United States pending completion of ongoing clinical trials. Hybrid approachs often require open visceral and renal bypass followed by stent-graft implantation over the "debranched" visceral segment. Similar approaches are being used to treat complex aneurysms that encroach on the distal aortic arch. In patients with aneurysmal disease of the entire aortic arch, the traditional "elephant trunk" procedure has been combined with a second-stage stent-graft procedure of the descending thoracic aorta. The distal end of the elephant trunk serves as the proximal attachment site for the stent graft.

Endovascular Technique

The endovascular approach can be undertaken without the large incisions, extensive dissections, prolonged aortic cross-clamp times, and significant blood loss and fluid shifts associated with open repair. The arterial access site for endovascular stent-graft placement is selected on the basis of vessel size and degree of obstructing atherosclerotic disease. The technique most commonly requires bilateral transverse groin incisions to expose the common femoral arteries. In patients with severely diseased femoral or iliac arteries, balloon angioplasty or local endarterectomy can be performed to allow passage of the delivery system. Adjunctive retroperitoneal procedures may be necessary in up to 20% of patients during endovascular abdominal aortic aneurysm repair.[253] Indications include small external iliac arteries that limit femoral access and a concomitant iliac artery aneurysm that precludes distal fixation of the stent-graft in the common iliac artery. In these cases, a transverse lower abdominal incision with retroperitoneal dissection exposes the iliac artery, and a synthetic conduit is sutured (end to side or end to end) onto the common

iliac artery. The delivery system is endoluminally placed into the aorta through this iliac conduit. At the termination of the procedure, the conduit can be ligated, attached to the external iliac artery (interposition graft), or attached to the common femoral artery (iliofemoral bypass graft). Although adjunctive retroperitoneal procedures may allow a larger number of patients to undergo endovascular aortic repair, such procedures are associated with an increased risk for complications, greater blood loss, longer procedure time, and longer hospital length of stay than endovascular repair with standard femoral access is.[253] Obviously, the advantage of endovascular techniques being less invasive than open repair is reduced when adjunctive procedures are required. Adjunctive procedures may also be needed with endovascular repair of the thoracic aorta. One series involving patients with a spectrum of aortic disease reported that 25% of patients needed open surgical access to the aorta and 21% needed left subclavian–carotid transposition to provide an adequate proximal fixation site.[254]

Although adjunctive surgical procedures may be needed, the technical skill required for endovascular aortic surgery is primarily catheter based. Thus, appropriately trained cardiologists, radiologists, and vascular surgeons can all deliver endovascular treatment of aortic disease. A multispecialty approach is commonly used and offers patients the expertise of both surgical and catheter-based specialists. Even though no standard has been set, the requirements for endovascular aortic surgery are the same wherever it is performed. The standard operating room environment is ideal from the surgical and anesthesia standpoint, particularly when conversion to an open repair is required. The operating room must be equipped with endovascular supplies, portable radiologic imaging tools, and an angiographic table. Angiographic suites often have superior radiographic imaging tools and angiographic tables and are better equipped to deal with ionizing radiation. The superior imaging may reduce radiation exposure and decrease contrast dye loads. In an effort to provide an optimized environment for multispecialty endovascular intervention, many centers are constructing sophisticated operative angiographic suites in or adjacent to the operating room.

Endovascular stent-grafting of the aorta requires preoperative diagnostic imaging to precisely evaluate and delineate the aortic anatomy. For abdominal aortic aneurysms, length and diameter of the proximal neck, location of important aortic and iliac side branches (accessory renal arteries, inferior mesenteric artery, and hypogastric arteries), and distal fixation site characteristics must be determined. Significant aneurysm neck angulation, short neck length, large neck diameter, and severe aortic calcification currently exclude many patients from endovascular repair. TEE and intravascular ultrasonography are often used to locate the entry and exit sites of dissections and to confirm precise stent-graft placement.

Endovascular stent-grafts are often custom-made for each patient based on aortic anatomy. Each endovascular stent-graft delivery device has a unique method of deployment, and many individual variations in technique are possible. First-generation endografts were not fully stented and required balloon expansion of the proximal portion at the time of deployment. Metal hooks in the proximal portion were embedded into the aortic wall with balloon inflation, which resulted in complete aortic occlusion, not unlike aortic cross-clamping. These unsupported endografts were prone to complications such as migration and kinking. Distal migration during proximal endograft deployment was particularly troublesome with intrathoracic endograft placement. Induced hypotension,[255] adenosine-induced asystole,[256] and induced ventricular fibrillation[257] have all been used successfully to reduce endograft migration during deployment. Current-generation endografts are fully stented (i.e., stent-grafts) and self-expanding. Balloon expansion is not required at the time of deployment. Stent-graft migration at the time of deployment is largely prevented and associated complications are reduced. A unique trilobed aortic balloon can be used to expand the stent-graft for aortic apposition after deployment without complete aortic occlusion.[258] Though no longer a requirement, mild induced hypotension (with nitroglycerin or sodium nitroprusside) can be used selectively during stent-graft deployment.

Anesthetic Management

Local,[259] regional,[260] and general anesthesia[261] techniques have all been described for endovascular aortic repair shortly after its introduction. A variety of regional techniques have been used, including paravertebral, spinal, continuous spinal, epidural, and combined spinal/epidural. General anesthesia was commonly used with early-generation devices because procedure times were often long. As centers have gained experience with newer-generation devices, procedure times have been reduced and local and regional techniques are used more often, most commonly with intravenous sedation. A sedation technique using dexmedetomidine with local anesthesia has been reported.[262] Despite procedural advances and the established feasibility of local and regional anesthesia, these techniques have not become accepted on a large scale. An analysis of anesthesia type based on data from the EUROSTAR registry (5557 endovascular repairs of infrarenal aortic aneurysm) reported the use of local, regional, and general anesthesia in 6%, 25%, and 69% of patients, respectively.[263] The influence of anesthesia type on outcome based on the EUROSTAR data indicates that the use of local or regional anesthesia may reduce ICU admission, hospital length of stay, and early complications.[263] Further analysis of high-risk patients from this registry suggests that a mortality benefit may exist when local or regional anesthesia is used.[264] A retrospective analysis of 229 endovascular abdominal aortic aneurysm repairs using local anesthesia with intravenous sedation or general anesthesia reported similar rates of cardiac and pulmonary morbidity.[261] Reduced intraoperative fluid requirements[261,265] and less vasopressor support[265] have been reported with the use of local anesthesia. Given the retrospective nature of these reports and the significant selection bias regarding assignment of anesthetic technique, specific recommendations regarding the use of local, regional, and general anesthesia are premature. As with open aortic repair, maintenance of vital organ perfusion and function by the provision of stable perioperative hemodynamics is probably more important to overall outcome than the choice of anesthetic technique is.

I commonly use a general anesthetic technique for endovascular aortic repair in patients requiring extensive groin dissection or any retroperitoneal dissection and those requiring complex repairs, where conversion to open repair may be more likely. A balanced technique using relatively short-acting agents maximizes management flexibility. Opioid requirements are usually minimal (2 to 4 μg/kg fentanyl), and postoperative pain is easily managed. Esmolol, sodium nitroprusside, nitroglycerin, and phe-

nylephrine should be available and used to maintain appropriate hemodynamics. Epidural and spinal anesthesia is used selectively based primarily on patient and surgeon preference.

Placement of a radial artery catheter should be routine for all endovascular aortic repairs. It should be placed on the right side because a catheter may be placed percutaneously in the left brachial artery for aortic angiography. Central venous and pulmonary artery catheter monitoring is not routine. Two large-bore peripheral intravenous catheters are recommended. Although blood loss and fluid requirements are not usually excessive, the potential for rapid blood loss is real. The possibility of acute aortic rupture necessitates the availability of fluids, blood, and a rapid infusion device. Catheterization of the bladder is required for most procedures. Monitoring of urine output can help guide fluid management, particularly when high volumes of heparinized flush solution and radiographic contrast material are used and when diuretics (i.e., mannitol or furosemide) are administered. Fluid management is directed primarily at maintaining normovolemia. Isotonic bicarbonate infusion is often used in patients with renal dysfunction to reduce the incidence of contrast-induced nephropathy.[266] Active patient warming is frequently necessary to prevent hypothermia, particularly with longer procedures.

Endovascular repairs involving the descending thoracic aorta require additional preparation and monitoring. These procedures are often performed in the operating room under general anesthesia. Although current-generation devices are much less prone to graft migration during deployment, pharmacologically (i.e., sodium nitroprusside or nitroglycerin) induced hypotension (i.e., systolic blood pressure <100 mm Hg) is commonly used during deployment. TEE monitoring is frequently used and can be extremely helpful in identifying proximal and distal stent-graft landing zones, entry and exit points of dissections, true and false lumens, and aneurysm exclusion. Although published reports of endovascular repairs involving the descending thoracic aorta are limited, neurologic deficits consistent with spinal cord ischemia have been reported.[267,268] Concomitant or previous abdominal aortic repair and long-segment thoracic aortic exclusion appear to be important risk factors.[267-269] Postoperative hypotension may play a role as well.[268] Delayed paraplegia 10 months after endovascular repair of thoracic aortic aneurysms has been reported.[270] CSF drainage has been shown to reverse delayed-onset neurologic deficit after endovascular TAA repair,[217,218,268] thus prompting some centers to use perioperative CSF drainage in all high-risk patients.[268] Intraoperative spinal evoked potential monitoring plus temporary (15 minutes) balloon occlusion of the thoracic aorta before stent-graft deployment has been reported as a means to evaluate the patient's risk for spinal cord ischemia.[271]

Endoleak

The inability to obtain or maintain complete exclusion of the aneurysm sac from arterial blood flow, termed *endoleak*, is a complication specific to endovascular aortic repair. The concern is that any pressurization of the aneurysm sac (i.e., endotension) can lead to aneurysm enlargement and rupture. Endoleaks can be detected by arteriography, computed tomographic scanning, magnetic resonance imaging, and duplex ultrasound scanning. A classification system developed for endoleak describes four distinct types.[272] Type I endoleak occurs when there is an inadequate seal between the stent-graft and the aortic wall at the proximal or distal attachment sites. Type II endoleak occurs when there is retrograde filling of the aneurysm sac from patent intercostal, lumbar, inferior mesenteric, or testicular arteries. Type III endoleak is due to structural failure of the stent-graft that allows blood to flow directly into the aneurysm sac. The structural failure may be due to tears in the graft fabric or separation of individual components of a modular endograft. Type IV endoleak relates directly to the porosity of the graft material. Endoleaks are also classified as primary (after deployment) or secondary (after initial seal). A "type V" endoleak has appeared in the literature and refers to persistent pressurization of the aneurysm sac after endovascular repair *without* an identified leak on imaging studies.

The rate of occurrence of endoleak depends on many factors, including the endograft device, the method of deployment, vascular anatomy, and progression of disease. Management of endoleak after endograft placement is quite controversial and ranges from observation with periodic imaging surveillance to immediate endovascular or surgical correction. Type I and III endoleaks are associated with an increased risk of rupture[273] and are almost uniformly treated aggressively. Although type II endoleaks do not often require urgent treatment and many spontaneously thrombose, they are associated with aneurysm enlargement.[273] Type IV endoleaks are usually self-limited and rarely require specific treatment. Type V endoleaks require intervention if aneurysm growth is detected.

Endovascular extension grafts, coil embolization, and conversion to open repair have been used successfully to repair endoleaks.[274]

Morbidity and Mortality

A meta-analysis of 39 studies reported on perioperative (30-day, 2387 patients) and postoperative (>30-day, 1645 patients) complications after endovascular abdominal aortic repair.[275] Mean follow-up was 13.9 months. The perioperative mortality rate was 3.7%, and the annual mortality rate was 5.0% per year. Rates of both endoleak (13.1%) and conversion to open repair (5.0%) were higher in the perioperative period than postoperatively (5.4% and 1.4% per year, respectively). The EUROSTAR registry was established in 1996 to collect data on the outcome of endovascular repair of abdominal aortic aneurysms in Europe. In a publication from the EUROSTAR database involving 3222 patients who received a variety of endografts, operative mortality was 2.0%.[276] Mean follow-up was 13.7 months. Early conversion to open repair occurred in 1.5% of patients, and secondary interventions occurred at a rate of 10% per year (1% per year conversion to open repair and 9% per year revision). The risk of rupture was 0.46% per year with an associated mortality rate of 56%. This database has confirmed the importance of endoleak, stent-graft failure, and stent-graft migration in the causation of aneurysm rupture.[277]

The Cleveland Clinic group reported their experience involving 703 patients who underwent endovascular repair of abdominal aortic aneurysms with several devices.[278] As with other reports, the average follow-up was just over 12 months. Overall, secondary procedures were required in 15% of patients, with a cumulative risk of 12% at 1 year, 24% at 2 years, and 35% at 3 years. The mortality associated with these secondary proce-

dures was 8% overall and 18% in patients who required conversion to open repair. In another report from this same group, outcome after endovascular repair was significantly worse with larger (>5.5 cm) aneurysms. At 24 months, patients with larger aneurysm had more type I endoleaks, device migration, and conversion to open repair. Of even greater importance, survival was diminished (71% versus 86%), and risk for aneurysm-related death was increased (6.1% versus 1.5%) at 24 months in patients with large aneurysms. The midterm (4 years) outcome results from the EUROSTAR database (4392 patients) also found large aneurysms to be associated with increased rates of aneurysm-related death, non–aneurysm-related death, and rupture.[279]

Limited information is available regarding endovascular repair involving the descending thoracic aorta. Although short-term results from small to moderate-sized retrospective series are encouraging,[258,280,281] severe complications, including paraplegia, aortic rupture, stroke, renal failure, and respiratory failure, have been reported.[282] Additionally, major procedure- or device-related complications occur in up to 38% of patients.[283] A mortality rate of 6.2% has been reported for 642 patients treated worldwide.[284] The long-term durability of endovascular repair of the descending thoracic aorta is unknown. Long-term endograft surveillance is required to detect device failure.

Randomized Clinical Trials

Endovascular repair of abdominal aortic aneurysms was originally developed to provide a treatment option for patients considered to be poor surgical candidates. Early controlled clinical trials reported greater hemodynamic stability,[285] reduced stress response,[286] shorter postoperative length of stay,[287] and better analgesic control[288] than with open aortic repair. These nonrandomized trials demonstrated that endovascular aortic aneurysm repair is feasible and safe and may reduce perioperative morbidity when compared with open repair.[289-291] Based on these early reports and without the benefit of long-term outcome data or randomized clinical trials, endovascular aneurysm repair has been applied to a large proportion of patients with abdominal aortic aneurysms. Randomized clinical trials have been conducted in Europe and are currently in progress in the United States to answer several critical questions related to the broad application of endovascular technology in patients fit and unfit for open repair.

Dutch Randomized Endovascular Aneurysm Management (DREAM) Trial

The DREAM trial randomized 351 patients (from the Netherlands and Belgium) with abdominal aortic aneurysms greater than 4.9 cm who were considered suitable candidates for both open and endovascular options to either open repair or endovascular repair. Operative mortality (30 day) was 1.2% in the endovascular repair group and 4.6% in the open repair group.[292] The combined rate of operative mortality and severe complications was 4.7% in the endovascular repair group and 9.8% in the open repair group.[292] However, 2 years after randomization, the cumulative survival rates did not differ between treatment groups (90%).[293] Cumulative rates of aneurysm-related death were 2.1% for endovascular repair and 5.7% for open repair.[293] The rates of survival free of complications were also similar in the two groups (66%).[293] The authors concluded that the perioperative survival advantage with endovascular repair versus open repair is not sustained after the first postoperative year.[293] Quality of life in the first postoperative year was evaluated in a subset of DREAM trial participants. Although endovascular repair had a quality-of-life advantage in the early postoperative period, at 6 months and beyond, patients reported better quality of life after open repair.[294] In a follow-up report on cost-effectiveness, endovascular repair (in patients fit for open repair) did not result in a quality-adjusted life-year gain at 1 year after surgery, provided only marginal survival benefit, and was associated with a substantial increase in cost.[295] The outcome results of endovascular repair in the DREAM trial are comparable to observations from a large common practice–derived database (EUROSTAR registry) and appear to be generalizable to common clinical practice.[296]

EVAR-1 Trial

The EVAR-1 trial randomized 1082 patients (United Kingdom) with abdominal aortic aneurysms greater than 5.5 cm, older than 60 years, and judged fit for open repair to either endovascular repair or open repair. The primary end point was all-cause mortality. Secondary end points were aneurysm-related mortality, postoperative complications, health-related quality of life, and hospital costs. Operative mortality (30 day) was 1.7% in the endovascular repair group and 4.7% in the open repair group,[297] closely matching the DREAM trial results.[292] Secondary interventions (30 day) were more common in patients undergoing endovascular repair (9.8% versus 5.8%).[297] After a follow-up of 4 years, all-cause mortality did not differ between groups (26% for endovascular versus 29% for open)[298] despite an initial postoperative benefit of endovascular repair.[297] Aneurysm-related mortality at 4 years was lower in the endovascular repair group (4% versus 7%)[298] and in accord with the operative mortality benefit. Overall rates of complications (41% versus 9%) and reinterventions (20% versus 6%) were lower in the open repair group. Of patients undergoing endovascular repair, 2.7% required conversion to open repair during the follow-up period. There were no clinically significant differences in health-related quality of life. Hospital costs were approximately a third higher for endovascular repair.

EVAR-2 Trial

The EVAR-2 trial was designed to compare endovascular repair versus no intervention in patients deemed unfit for open abdominal aortic aneurysm repair. A total of 338 patients (from the United Kingdom) with abdominal aortic aneurysms greater than 5.5 cm, older than 60 years, and deemed unfit for open repair because of comorbid conditions were randomized to undergo endovascular repair or no intervention. All patients received best medical treatment for their comorbid conditions. Primary and secondary end points were the same as for the EVAR-1 trial. Operative mortality (30 day) for the endovascular group was 9%,[299] considerably higher than that reported in EVAR-1. The overall mortality rate at 4 years was 64%, and there was no difference between the endovascular group and the no-intervention group in aneurysm-related mortality or all-cause mortality.[299] Although there were more deaths from aneurysm rupture in the no-intervention group, the initial high mortality in the endovascular group resulted in no late differences in mortality. The authors concluded that endovascular repair did not improve survival over no intervention, had little effect on health-related

quality of life, and was associated with a need for continued monitoring and reintervention, at substantially increased cost.[299] In-hospital mortality for the highest-risk patients undergoing endovascular aortic aneurysm repair in the United States may be lower than that reported in EVAR-2, suggesting that these high-risk patients should not be denied endovascular repair.[300]

These completed European trials, as well as those currently under way in the United States, will aid understanding and improve the application of both endovascular and open repair for abdominal aortic aneurysm.

Lower Extremity Revascularization

Lower extremity arterial insufficiency, or peripheral arterial disease, is a common condition that affects as many as 10 million people in the United States, and its incidence is increasing annually.[301] Because individuals with lower extremity peripheral arterial disease are most often asymptomatic or have symptoms other than classic intermittent claudication, the true prevalence of the disease is unknown. In a population-based study of individuals 55 years and older, the prevalence of peripheral arterial disease was 19.1% (16.9% in men and 20.5% in women).[302] The prevalence of peripheral arterial disease in primary care practices in the United States is high (29%), and the condition is often unrecognized (44%).[303] Arterial disease of the upper extremity does occur but is much less common than lower extremity involvement.

Atherosclerosis is the most common cause of peripheral arterial disease. Risk factors for atherosclerosis of the lower extremity are the same as for other vascular areas and include advanced age, male sex, hypertension, smoking, hyperlipidemia, and diabetes. Infrainguinal atherosclerosis may involve the femoral artery, popliteal artery, and any of the infrapopliteal arteries. The superficial femoral artery is the most common site of major atherosclerotic involvement below the inguinal ligament. Nonatherosclerotic causes of peripheral arterial disease include embolism, thromboangiitis obliterans (Buerger's disease), immune arteritis, radiation arteritis, giant cell arteritis, adventitial cystic disease, fibromuscular dysplasia, and homocysteinemia.

As previously noted, peripheral arterial disease is a very strong indicator of generalized atherosclerosis and is a risk marker for other vascular conditions, including CAD, cerebrovascular disease, and aneurysmal disease. For example, patients with concomitant CAD and peripheral arterial disease have a higher prevalence of triple-vessel coronary disease than patients with CAD alone do.[304] Additionally, over 20% of patients with peripheral arterial disease have a 70% or greater carotid artery stenosis.[305] It is well documented that patients with peripheral arterial disease are at higher risk for cardiovascular morbidity and mortality than individuals without peripheral arterial disease are.[306-310] The increased cardiovascular risk may not be entirely due to atherosclerosis because these patients may have an enhanced prothrombotic state secondary to platelet activation[311] and a high prevalence of diverse hypercoagulable states.[312] The natural history of atherosclerotic lower extremity peripheral arterial disease is illustrated in Figure 62-14.

Acute Arterial Occlusion

Acute peripheral arterial occlusion occurs primarily as a result of embolism and thrombosis. Pseudoaneurysm after invasive procedures in which the femoral artery is cannulated is a much less common cause of acute ischemia. The vast majority of emboli to the lower extremity originate in the heart, with intermittent atrial fibrillation and myocardial infarction being the most common causes of emboli. Although rheumatic heart disease is now a rare cause of embolic occlusion, prosthetic heart valves may be a source of emboli. Other causes of embolization include bacterial endocarditis, atrial myxoma, paradoxical venous emboli, and atheromatous debris from proximal aneurysms. Arterial emboli often lodge at vessel bifurcations. Common sites in the lower extremity include the femoral artery bifurcation, iliac artery bifurcation, and popliteal artery.

Thrombotic occlusions probably outnumber embolic occlusions by a ratio as high as 6:1.[313] Acute arterial thrombosis of native vessels almost always occurs in the setting of severe and long-standing atherosclerosis. It can be viewed as the terminal event in the progression of atherosclerosis. Thrombosis of vascular bypass grafts is common and may result in acute ischemia. The high prevalence of diverse hypercoagulable states in patients with peripheral arterial disease may predispose such patients to thrombosis.[312]

The clinical manifestation of acute arterial occlusion will vary depending on the location of the obstruction and the extent of collateral circulation. In patients with a sudden onset of acute extremity ischemia, the occlusion often occurs abruptly and without the preexisting development of collateral pathways. Although ischemic symptoms are often more severe in patients with embolic occlusion than in patients with thrombotic occlusion, differentiation between embolic and thrombotic occlusion may be difficult. Acute occlusion of a previously patent extremity artery is a dramatic event characterized by pulselessness, pain, pallor, paresthesia, and paralysis (the "five P's"). Absence of pulses and pallor are early manifestations. The sudden onset of pain is very common, and it may be intense. Motor weakness and paresthesia are usually late manifestations of severe ischemia.

Acute ischemia needs to be evaluated rapidly because irreversible tissue injury can occur within 4 to 6 hours.[314] Initial management usually involves immediate anticoagulation to prevent propagation of thrombus, stabilization and control of coexisting medical conditions, and arteriography. Immediate surgical revascularization is generally indicated in the profoundly ischemic extremity. Patients with embolization to a nonatherosclerotic extremity are frequently managed with femoral thromboembolectomy under local anesthesia. Management of patients with peripheral arterial disease who are suspected of having thrombotic occlusion requires arteriography to determine the severity and anatomic location of the occlusion. Angioplasty or thrombolytic therapy may be performed in conjunction with arteriography. Intra-arterial thrombolysis is often used as an initial intervention in an effort to unmask the culprit lesion responsible for the occlusive event. Patients are frequently scheduled for lower extremity bypass surgery the following day, pending evaluation of lower extremity blood flow. The frequent use of heparin anticoagulation and thrombolytics has significant implications for the anesthesiologist because regional anesthesia is not

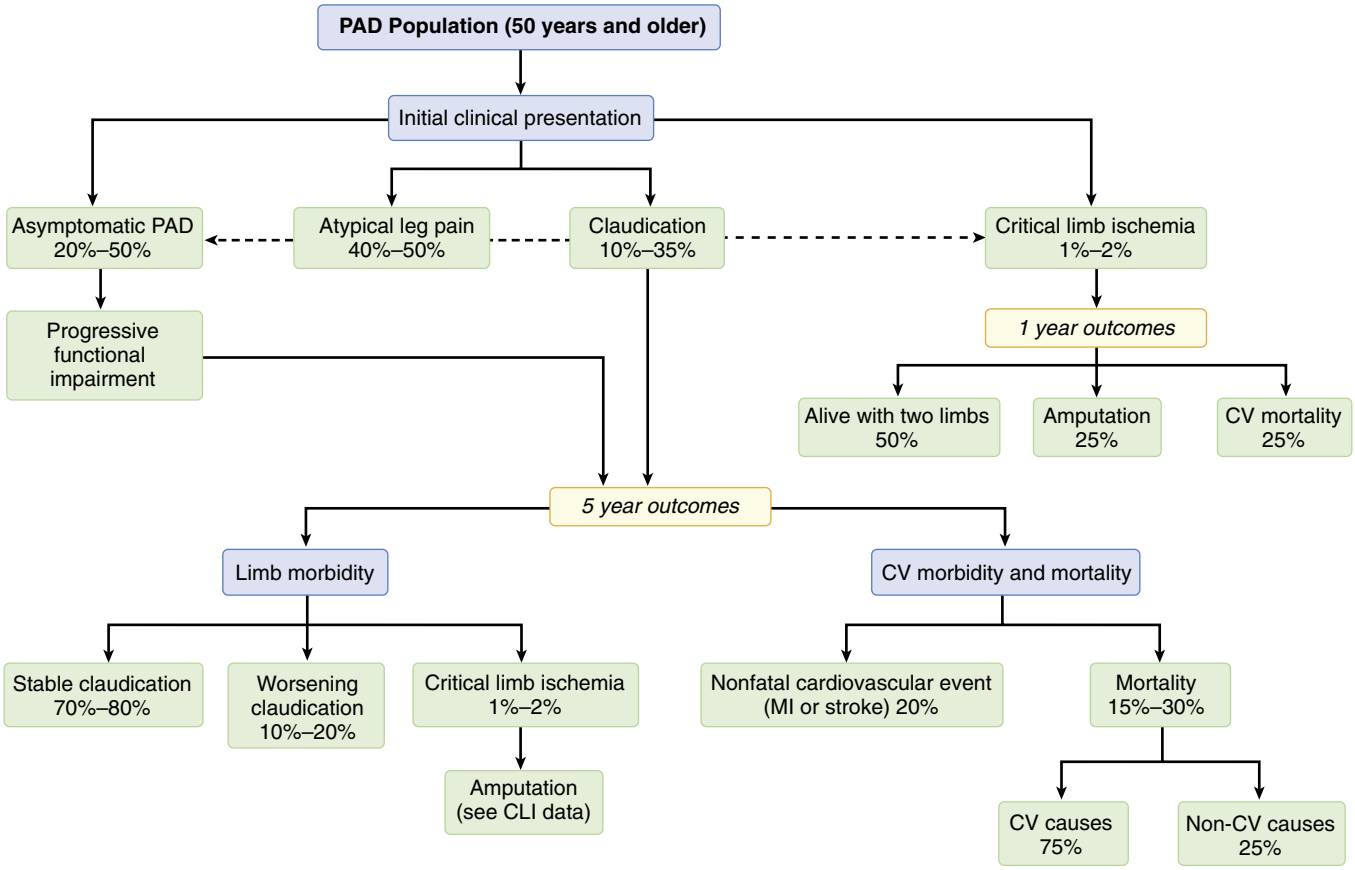

Figure 62-14 Natural history of atherosclerotic lower extremity peripheral arterial disease (PAD). Individuals with atherosclerotic lower extremity PAD may be asymptomatic (without identified ischemic leg symptoms, albeit with a functional impairment) or have leg symptoms (classic claudication or typical leg symptoms) or critical limb ischemia (CLI). All individuals with PAD face a risk of progressive limb ischemic symptoms, as well as a high short-term cardiovascular ischemic event rate and increased mortality. These event rates are most clearly defined for individuals with claudication or CLI and less well defined for individuals with asymptomatic PAD. CV, cardiovascular; MI, myocardial infarction. *(From Hirsch AT, Haskal ZJ, Hertzer NR, et al: ACC/AHA 2005 guidelines for the management of patients with peripheral arterial disease [lower extremity, renal, mesenteric, and abdominal aortic]: Executive summary. A collaborative report from the American Association for Vascular Surgery/Society for Vascular Surgery, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, Society of Interventional Radiology, and the ACC/AHA Task Force on Practice Guidelines [Writing Committee to Develop Guidelines for the Management of Patients with Peripheral Arterial Disease] endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation; National Heart, Lung, and Blood Institute; Society for Vascular Nursing; TransAtlantic Inter-Society Consensus; and Vascular Disease Foundation. J Am Coll Cardiol 47:1239-1312, 2006.)*

an option in an anticoagulated patient. Morbidity and mortality rates in this patient population are high, particularly in patients requiring significant operative intervention.[315-317]

Chronic Arterial Occlusion

Chronic arterial insufficiency is most often secondary to long-standing atherosclerosis in which the arterial lumen of the lower extremity becomes progressively stenosed by atherosclerotic plaque. When the stenosis approaches total occlusion, the marked reduction in blood flow leads to thrombotic occlusion. Hemodynamically significant stenosis and total-vessel occlusion commonly exist in the lower extremity with no or very minimal symptoms. The development of collateral vessels around a stenosed or occluded arterial segment often prevents clinical symptoms until multiple occlusions exist in major vessels. Thus, the majority of patients with peripheral arterial disease are asymptomatic. Patients with symptoms most commonly have mild intermittent claudication—pain or fatigue in the muscles of the lower extremity caused by exertion and relieved with rest. The pain usually occurs in the muscle group distal to the site of arterial insufficiency. With disease progression, severe disabling intermittent claudication or rest pain, so-called critical limb ischemia, can develop.

Noninvasive testing with the ankle-brachial index (ABI) is the clinical standard for documenting the presence and severity of peripheral arterial disease. The ABI is determined by dividing ankle systolic pressure by brachial systolic pressure. Normally, the ABI is between 1.0 and 1.1; a value less than 0.9 indicates arterial disease proximal to the point of measurement. The ABI approximates the degree of arterial insufficiency; claudication occurs with indexes ranging from 0.3 to 0.9, disabling claudication or rest pain with indexes less than 0.5, and gangrenous extremities with indexes less than 0.2.[318]

One of the most important aspects of peripheral arterial disease is that it is a very strong marker for early mortality. In patients with peripheral arterial disease the risk of amputation is much less than the risk of death.[319] A low ABI is a strong predictor for disease progression,[320,321] but it is also one of the strongest risk

factors for all-cause mortality.[310] Claudication is associated with a high rate of mortality[309] but is relatively benign in terms of lower extremity outcome.[310,320]

Surgical Management

Accepted treatments of lower extremity arterial disease include both nonoperative and operative modalities. Nonoperative options include lifestyle and risk factor modification, exercise programs, and pharmacologic therapy. Operative options include percutaneous endovascular modalities and surgical reconstruction. Endovascular techniques include more established therapies such as intra-arterial thrombolytic therapy, balloon catheter embolectomy, transluminal balloon angioplasty, and angioplasty and stent placement, as well as new technologies such as novel angioplasty balloons, atherectomy and laser angioplasty systems, cryotherapy, and placement of nitinol and drug-eluting stents.[322] Surgical procedures include endarterectomy, bypass grafting (primary or revision), and amputation.

Lower extremity arterial reconstruction is performed both for severe disabling claudication and for critical limb ischemia (limb salvage). The choice of operative approach depends primarily on the location and distribution of arterial occlusions. There are several surgical approaches to patients with lower extremity arterial insufficiency. For occlusion distal to the inguinal ligament, a femoral-popliteal bypass with an autologous great saphenous vein (reversed) graft is most often the procedure of choice. Graft patency rates with this approach are reported to be 59% at 5 years and 38% at 10 years. The saphenous vein may be used in situ (not reversed), but this technique is more demanding and requires excision of the valves to allow adequate flow. Human umbilical vein and polytetrafluoroethylene grafts can be used when an autologous saphenous vein is unavailable, which is often the case when patients have previously undergone coronary artery bypass or lower extremity bypass. The cephalic and basilic veins from the upper extremities are sometimes used as a graft. Harvesting vein from the upper extremities has obvious implications with regard to intravenous catheter placement and the use of regional anesthesia.

In patients with aortoiliac disease who are not candidates for aortobifemoral bypass because of coexisting medical diseases, an extra-anatomic procedure (axillofemoral or femorofemoral bypass) is an alternative approach that is thought to be a less stressful procedure. Distal arterial reconstruction with a bypass to the tibial, peroneal, or pedal vessels is almost exclusively performed for limb salvage. Prosthetic grafts have very high failure rates, and every attempt is made to harvest adequate autologous vein.

Preoperative Preparation and Monitoring

Preoperative assessment and optimization of cardiac risk were discussed previously (also see Chapters 34 and 35). It is extremely important that long-term cardiac and respiratory medications be given the morning of surgery. Continuing chronic β-blocker therapy is particularly important because acute withdrawal can be associated with significant morbidity. Current, recent, and anticipated use of hemostasis-altering drugs should be established and discussed with the surgical team. In most instances, antiplatelet therapy with aspirin should be continued. Preoperative termination of other antiplatelet therapy, such as thienopyridine derivatives, should be made on an individual basis.

Monitoring for lower extremity arterial revascularization should include an intra-arterial catheter that permits continuous blood pressure monitoring to optimize coronary artery and lower extremity graft perfusion, as well as blood sampling for diagnostic laboratory testing. A urinary bladder catheter is usually indicated because the duration of the procedure may be long and urine output may be useful for assessing intravascular volume and cardiac output. Although central venous catheters are not necessarily helpful in routine cases, central venous pressure monitoring should be considered for patients with significant renal dysfunction, in whom intravascular volume should be carefully monitored, and for patients with significantly impaired ventricular dysfunction or congestive heart failure. In these patients, pulmonary artery catheter monitoring may be helpful, but given the relatively low potential for blood loss and third-space fluid loss with lower extremity vascular procedures, the pulmonary artery catheter is usually reserved for patients with active congestive heart failure or unstable angina. Our criteria for using invasive hemodynamic monitoring have been described previously.[28] As discussed earlier, computerized ST-segment monitoring is helpful in monitoring for myocardial ischemia.

Regional versus General Anesthesia

The most appropriate regimen of intraoperative anesthesia and postoperative analgesia for high-risk patients undergoing vascular surgery remains controversial. Competing concerns regarding both the quality and escalating costs of perioperative care have challenged clinicians to establish practice standards that are both safe and efficient. Postoperative complications after vascular surgery are common and have an adverse impact on both clinical outcome and resource use. Improvement in clinical outcome and reduced use of medical resources in patients undergoing vascular surgery may result from the use of one particular regimen of anesthesia and analgesia over another.[56,323] If such improvement can be achieved, selection of the most appropriate anesthetic and analgesic regimen would then be of great benefit to patients, providers, payers, and society.

The question of whether regional or general anesthesia is preferable for vascular surgery has been debated for years, but only in the past decade have well-designed prospective randomized trials been completed. Earlier nonrandomized trials were prone to significant bias because many clinicians had the unfounded belief that regional anesthesia was safer for patients with advanced cardiac or pulmonary disease. Even the prospective studies must be interpreted cautiously because many suffer from deficiencies in design and methodology, including nonuniform patient populations,[56,156,323] lack of standardization or control of perioperative treatments,[27,32,56,66,154,156,158,323] use of nonequivalent modalities for postoperative pain relief,[27,32,56,156,158,323] and possible investigator bias.[27,28,32,56,66,154-156,158,323] It should be recognized that many clinical trials have attempted to optimize the delivery and management of anesthetic techniques, which may mask the true risks associated with the anesthetic. An example is the strict hemodynamic control, transfusion thresholds, and postoperative analgesia regimens that have been used in clinical trials.[28,33] The physician must also appreciate that the overall complication rates

reported in clinical trials may seem high, but this may be explained by the aggressive surveillance commonly used in clinical trials. In general, it is often best to choose the anesthetic and analgesic techniques that are most familiar to a particular institution because, for example, unfamiliarity and mismanagement of epidural catheters can cause serious complications. It is my personal hypothesis that overall optimization of perioperative care, rather than anesthetic or analgesic selection, is the most important factor in improving outcome after vascular surgery.

Occasionally, surgical procedures such as embolectomy and femoral pseudoaneurysm repair can be completed with the patient under local anesthesia with intravenous sedation. Because these procedures may progress to more invasive arterial reconstruction, a regional or general anesthetic should be considered before the procedure begins to avoid an unplanned conversion to general anesthesia.

In some situations, one anesthetic technique (regional or general) is preferable to the other. The patient may have a preference for one technique over another based on a number of factors. Regional techniques should be avoided in patients who are uncooperative, demented, or unable to lie flat. Needle or catheter placement can be difficult in patients with severe spine deformity or previous spinal instrumentation. Local infection, neurologic disease affecting the lower part of the body, and hemostasis-altering drugs are all considered, to varying degree, a contraindication to regional anesthesia. Anticoagulant and antiplatelet therapy is common in the vascular surgery population and often precludes the use of spinal or epidural techniques.[324] Symptomatic bleeding within the neuraxis (spinal or epidural hematoma) is a potentially devastating complication of neuraxial anesthesia that can lead to permanent neurologic injury. I view preoperative anticoagulation with heparin or warfarin and any active thrombolytic therapy as a contraindication to the use of spinal and epidural anesthesia. In patients in whom such agents have recently been discontinued, very careful consideration should be given on an individual basis before performing neuraxial techniques. The anesthesiologist must take into consideration the agent used, the duration of discontinuance, current coagulation status, and concomitant administration of medications affecting hemostasis. The use of regional techniques during intraoperative systemic heparinization does not appear to represent a significant risk.[325] Although it has been recommended that surgery be canceled when blood is obtained through the neuraxial needle, support for this recommendation is lacking.[326] Much more importantly, it has also been recommended that epidural catheters not be removed until anticoagulants have been discontinued in the postoperative period.[324] The use of and indications for low-molecular-weight heparin continue to increase, and there is evidence to suggest a significant risk of spinal/epidural hematoma when regional techniques are used in conjunction with these drugs.[327] Current recommendations suggest that regional techniques be delayed at least 12 to 24 hours after the last dose of low-molecular-weight heparin.[324] The use of antiplatelet agents is a complex topic, and it is important to note the pharmacologic differences among the drugs when regional techniques are desired.[324,328] Although some centers routinely check a bleeding time in patients who have taken aspirin in the 7 days before a planned regional anesthetic technique, there is no evidence that a bleeding time is useful in this setting.[329,330] In general, when a regional technique is desired for a patient with any question of a coagulation abnormality, spinal anesthesia with the smallest-diameter needle is preferable to epidural anesthesia.[327] A comprehensive consensus report on neuraxial anesthesia and anticoagulation is available and should be read by all clinicians.[324]

Given the relative risks associated with neuraxial anesthesia in patients receiving anticoagulant or antithrombolytic therapy, some clinicians advocate the broader use of peripheral nerve blocks, such as sciatic, femoral, popliteal, and ankle (see Chapter 52). Continuous catheter techniques can be used to provide both anesthesia and postoperative analgesia. High-resolution ultrasound imaging of neural structures, percutaneous electrode guidance, and the use of stimulating catheters have recently been introduced into clinical practice. Peripheral nerve blocks are probably associated with fewer systemic and neuraxial side effects, but little clinical information is available in the vascular surgical population. Because of the high volume of local anesthetics frequently used for peripheral nerve blocks, the issue of systemic toxicity must be considered. Caution should be considered with the use of peripheral nerve block in an anticoagulated patient, particularly when the neural structures are deep or located in close proximity to vascular structures.

Because regional anesthesia does not require airway instrumentation, neuromuscular blocking agents, or volatile agents, it has traditionally been a prevailing belief that regional anesthesia is preferable in patients with significant pulmonary disease. Although it is true that instrumentation of the airway may precipitate bronchospasm or increase the risk for nosocomial infection, general anesthesia with endotracheal intubation does allow complete airway and ventilation control, the ability to effectively administer inhaled bronchodilators, and the ability to easily suction airway secretions. A reduction in time to extubation after aortic surgery is a fairly consistent theme with regional anesthesia and analgesia, but this does not appear to have any impact on clinically relevant pulmonary outcomes.[32,23,66,156]

Epidural analgesia has been championed over parenteral opioid analgesia as a means of optimizing postoperative pulmonary function by improving pain control and respiratory muscle function. Although epidural analgesia can provide excellent postoperative pain control and may improve postoperative lung function (i.e., increased tidal volume and vital capacity), clinical studies do not support a consistent finding of improved pulmonary outcomes.[331] Overall, there is little evidence from well-designed clinical studies to demonstrate improved pulmonary outcome with regional anesthesia and analgesia.[332] Because postoperative maneuvers to increase mean lung volumes are of proven benefit in preventing postoperative pulmonary complications, it has been recommended that maneuvers to encourage deep breathing, such as deep-breathing exercises, incentive spirometry, and chest physiotherapy, should be the focus of preventive efforts.[332]

Cardiac morbidity is the most common cause of death in patients undergoing surgery, and the incidence of perioperative cardiac morbidity is 10 times greater in vascular surgery patients than in nonvascular surgery patients.[17] Eleven prospective randomized trials evaluating the effects of regional versus nonregional anesthesia or analgesia in vascular surgical patients have reported on cardiac outcomes and death. Three studies (Cook and colleagues,[333] Christopherson and coworkers,[28] and Bode and associates[27]) compared pure regional (spinal or epidural) versus general anesthetic techniques in lower extremity vascular patients. Tuman and colleagues[323] compared combined epidural/general versus general anesthetics in aortic and lower extremity surgical patients. Six studies (Baron and coworkers,[32] Davies and associates,[154] Garnett and colleagues,[158] Bois and coworkers,[155] Boylan and

associates,[66] and Norris and colleagues[33]) compared epidural and nonepidural anesthetic or analgesic techniques (or both) in aortic surgical patients. Fleron and coworkers[34] compared intrathecal opioid versus intravenous analgesia in aortic surgical patients. Of note, only the report by Norris and associates[33] had a double-blinded design. The results of these studies, involving more than 1500 patients, are shown in Table 62-8.

In summary, no study demonstrated any difference in outcome with regard to mortality, MI, myocardial ischemia, or congestive heart failure. Only the study by Tuman and colleagues[323] reported a difference in cardiac outcome. Outcome was significantly improved by epidural anesthesia and analgesia, but only when more subtle outcomes (i.e., dysrhythmias) were included. Christopherson and coworkers[28] (i.e., the Perioperative Ischemia Randomized Anesthesia Trial [PIRAT]) and Norris and associates[33] (i.e., PIRAT II) found no difference in cardiac events or myocardial ischemia as detected by continuous Holter monitoring over a 3-day postoperative period. In these studies from my institution, strict intraoperative and postoperative protocols were used to guide and optimize perioperative management and postoperative analgesia. Bode and colleagues[27] reported on the largest randomized trial, which included a spinal anesthesia group in addition to general and epidural groups. There were no differences in cardiac events in any of the three groups. Of note, a failed spinal or epidural technique in this trial was associated with 9% mortality, as opposed to 2% for all successful general and regional anesthetics.[27]

One of the most interesting and clinically significant finding in these randomized trials is the beneficial effect of regional anesthesia on lower extremity graft patency in the postoperative period. Two of the studies (Tuman and colleagues[323] and Christopherson and coworkers[28]) reported a fivefold greater incidence of graft occlusion after general (relative to regional) anesthesia. Most graft occlusions occurred in the first 1 to 3 days after surgery, after which the established difference in the incidence of graft occlusion between anesthetic techniques was maintained over time (6 weeks and beyond) (Fig. 62-15). This time course suggests that anesthetic technique may have played a role in graft occlusion. Bode's group[334] reported an overall very low incidence of graft occlusion, but differences in hemodynamic management, surgical technique, and the patient population may explain these findings. For example, intraoperative intravascular angioscopy was used to inspect the grafts to confirm patency before completion of surgery, and all patients were cared for in an intensive care setting for 48 hours after surgery. Thus, optimization of care with respect to graft patency may negate any beneficial effect of regional techniques. It is also important to keep in mind that none of these studies were specifically designed to evaluate surgical outcome (i.e., graft patency) in a prospective manner. A retrospective review of more than 300 primary femoropopliteal-tibial bypass procedures reported no differences in graft thrombosis rates for epidural (14%) or general anesthesia (9.4%).[335]

The proposed mechanism for the benefit of regional anesthesia is the effect of the anesthetic technique on coagulation. General anesthesia is associated with a hypercoagulable state in the early postoperative period, whereas regional anesthesia attenuates this effect.[336] Tuman and colleagues[323] demonstrated this by thromboelastography and Rosenfeld and coworkers[336] by increased plasminogen activator inhibitor (Fig. 62-16) and fibrinogen levels. It appears that fibrinolysis is decreased after general anesthesia and is normal after regional anesthesia. These findings may be related to attenuation of the surgical stress response with regional anesthesia because there appears to be a link between stress, catecholamines, and acute-phase reactants, such as plasminogen activator inhibitor and fibrinogen.[337,338] Platelet reactivity is also enhanced in the presence of a stress response.[338] Another important mechanism for the increased lower extremity graft patency with regional anesthesia may be the increased lower extremity blood flow associated with sympathectomy.

In the postoperative period, Breslow and associates[339] demonstrated differences in the adrenergic response with general versus regional anesthesia (Fig. 62-17). Epinephrine and norepinephrine are increased after general anesthesia relative to regional anesthesia. The cortisol response after general anesthesia is also greater than that after regional anesthesia.[339] This "stress response" is associated with increased blood pressure and hemo-

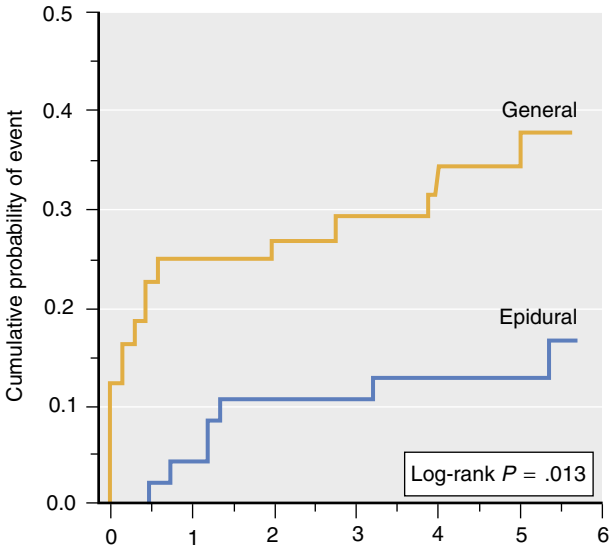

Figure 62-15 Cumulative probability of reoperation for regrafting, thrombectomy, or amputation over a 6-week follow-up period. Reoperation was significantly more frequent after general than after epidural anesthesia. *(From Christopherson R, Beattie C, Norris EJ, et al: Perioperative morbidity in patients randomized to epidural or general anesthesia for lower extremity vascular surgery. Perioperative Ischemia Randomized Anesthesia Trial Study Group. Anesthesiology 79:422-434, 1993.)*

dynamic liability during the intraoperative and early postoperative periods after general anesthesia as compared with regional anesthesia.[28,340] When the hemodynamic parameters are controlled pharmacologically, however, there is no difference related to anesthetic technique in myocardial ischemia or cardiac morbidity.[27,28,33]

Postoperative pain is recognized as one of the many factors contributing to the surgical stress response. In studies comparing epidural analgesia with parenteral opioid analgesia for control of postoperative pain after major surgery, improved pain control with epidural techniques is often reported. A recent meta-analysis review supports the view that epidural analgesia provides better postoperative analgesia than parenteral opioids do.[341] However, the historical studies that form the basis of the meta-analysis review have often neglected to control, specify, and, most importantly, optimize treatment in the nonepidural arms of their studies. Unfortunately, this issue remains a significant limitation in more recent trials.[156,342] Epidural analgesic techniques will probably continue to outperform "suboptimal" nonepidural analgesic techniques. I believe that intravenous patient-controlled analgesia is the optimal mode of delivery for opioid analgesia and should be used as the nonepidural arm of all postoperative pain studies. Postoperative epidural analgesia does not consistently outperform intravenous patient-controlled opioid analgesia.[343] Of particular note, patient-controlled epidural analgesia outperforms both intermittent-bolus and continuous-infusion epidural

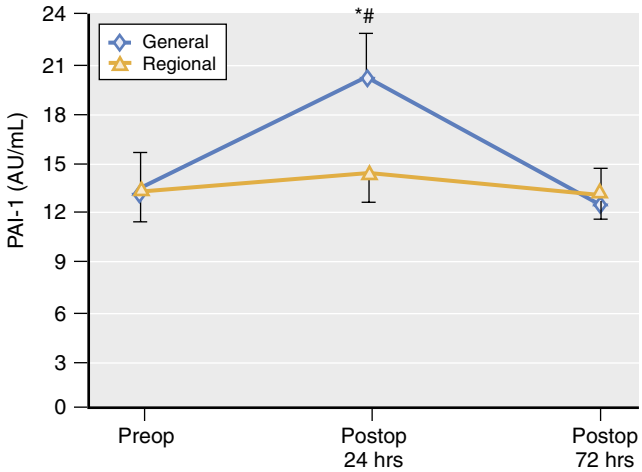

Figure 62-16 Plasminogen activator inhibitor-1 (PAI-1) levels in activity units (AU) per milliliter measured preoperatively and at 24 and 72 hours postoperatively after lower extremity revascularization. PAI-1 levels in the general anesthesia group increased from 13.6 ± 2.1 AU/mL to 20.2 ± 2.6 AU/mL at 24 hours and returned to baseline at 72 hours. In contrast, PAI-1 levels in the regional anesthesia group remained unchanged over time. *(Adapted from Rosenfeld BA, Beattie C, Christopherson R, et al: The effects of different anesthetics regimens on fibrinolysis and the development of postoperative arterial thrombosis. Perioperative Ischemia Randomized Anesthesia Trial Study Group. Anesthesiology 79:435-443, 1993.)*

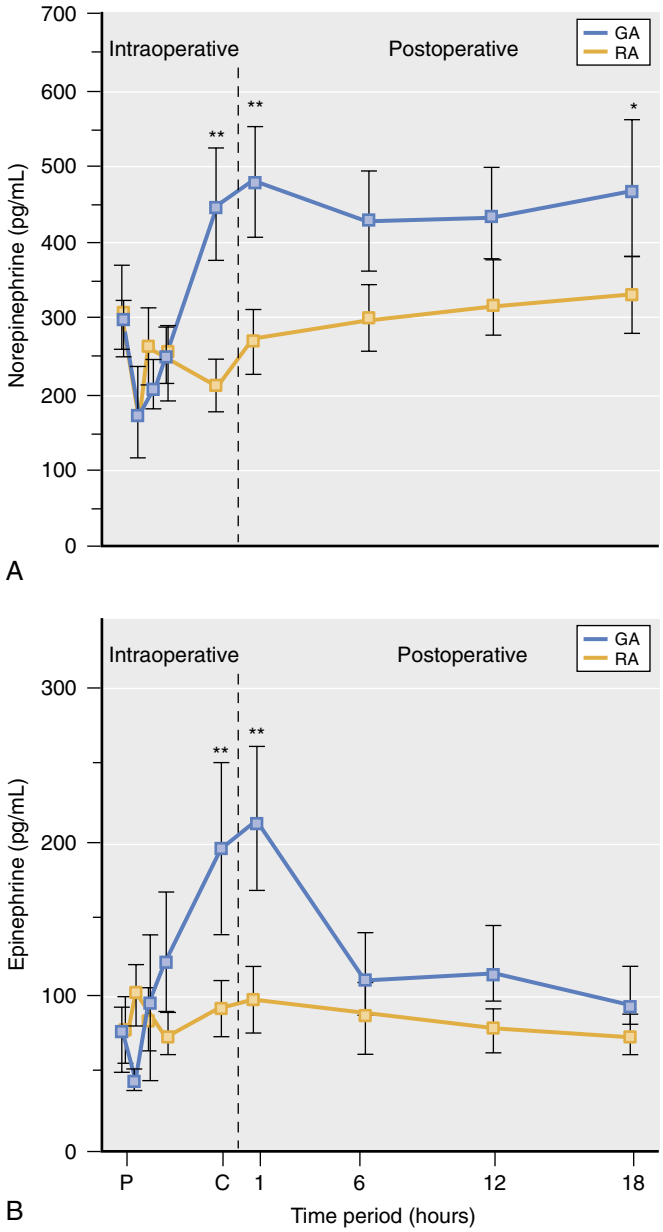

Figure 62-17 Plasma norepinephrine (**A**) and epinephrine (**B**) concentrations before induction of anesthesia (P), at skin closure (C), and at 1, 6, 12, and 18 hours after lower extremity revascularization. GA, general anesthesia with postoperative parenteral morphine by patient-controlled analgesia; RA, regional (epidural) anesthesia with postoperative epidural analgesia by patient-controlled analgesia. *(Adapted from Breslow MJ, Parker SD, Frank SM, et al: Determinants of catecholamine and cortisol responses to lower extremity revascularization. The PIRAT Study Group. Anesthesiology 79:1202-1209, 1993.)*

analgesia. Thus, the mode of delivery is an important factor with both epidural and parenteral opioid analgesia. The clinician also needs to keep in mind that the superior pain control reported with epidural techniques is relative, with adequate pain control consistently reported for parenteral analgesia.[344] In the only double-blinded trial in vascular surgery patients, Norris and colleagues[33] reported no difference in postoperative pain scores in patients randomized to either patient-controlled epidural analgesia or patient-controlled intravenous analgesia after aortic surgery. In this trial, postoperative pain management (i.e., epidural and intravenous) was optimized, continued for 72 hours, and managed by an acute pain service. Postoperative epidural catheter failure may occur in up to 6.3% of patients.[345]

Anesthetic Management

A variety of anesthesia techniques, including general anesthesia, regional (i.e., epidural or spinal) anesthesia, and combined techniques, have been used successfully for lower extremity reconstruction. General anesthesia is usually delivered with use of a balanced technique consisting of opioids, potent inhaled anesthetics, nitrous oxide, and neuromuscular blockade. Induction of anesthesia should proceed in a controlled fashion such that a stable hemodynamic profile is maintained. Maintenance of anesthesia may be accomplished with a low-dose inhaled anesthetic (i.e., isoflurane, desflurane, or sevoflurane) in 50% nitrous

oxide and opioid (3 to 5 μg/kg of fentanyl). Because virtually all patients are extubated in the operating room, high doses of opioid are generally avoided. The goal is to maintain stable hemodynamics and to prevent myocardial ischemia during the intraoperative and postoperative periods. Judicious use of β-blockers and vasoactive drugs is often necessary.

Regional anesthesia can be accomplished with spinal or epidural techniques. Disadvantages of spinal anesthesia include the limited duration of action in the setting of a surgical procedure that is somewhat unpredictable in length and complexity. The level of sympathetic block is somewhat less controllable than with the epidural technique. Hypotension can occur with either technique and should be treated promptly with judicious use of fluids and vasopressors. An advantage of an epidural technique is the ability to continue drug delivery into the postoperative period for analgesia and attenuation of the stress response. A lumbar epidural catheter is ideal for lower extremity vascular procedures. The dermatomes that need to be anesthetized are innervated at the same level where the catheter is inserted because the incision is usually in the L1 to L4 region. Small volumes of local anesthetic are recommended because a T10 block is generally sufficient. Usually, 9 to 12 mL (including the test dose) is sufficient for the initial dose, and more drug is given as needed. Because vascular surgery patients are generally advanced in age and thus prone to higher block levels, larger doses may result in high sympathetic blockade with significant hypotension.[346] A high sympathetic block is problematic because of decreased coronary perfusion and excessive fluid and vasopressor requirements. Congestive heart failure may result in the postoperative period when the sympathectomy resolves and the intravascular space contracts. When administering an epidural test dose, careful attention should be directed to both the heart rate and blood pressure. Blood pressure may be a more reliable indicator of an intravascular injection because vascular surgery patients may have little or no increase in heart rate as a result of β-blocker therapy and decreased β-adrenergic responsiveness secondary to aging.[347] When hypotension results from sympathectomy, a low-dose phenylephrine infusion is helpful in reducing intravenous fluid requirements. I believe that this approach is more physiologic than administration of large fluid volumes.

Postoperative Considerations

Pain and anxiety should be carefully controlled in the postoperative period because the stress response and myocardial ischemia are of greatest concern at this time. Intravascular volume should be optimized, significant anemia avoided (hemoglobin maintained at >9.0 g/dL), and heart rate and blood pressure carefully controlled. Computerized ST-segment analysis is helpful in identifying ischemic changes. Peripheral pulses should be checked frequently to verify lower extremity graft patency. Blood pressure augmentation and anticoagulants may be necessary when peripheral perfusion is limited. Urgent surgery may be required to reopen clotted or stenotic grafts.

Postoperative analgesia can be provided by intravenous or epidural opioids delivered by patient-controlled analgesia or epidural opioids with local anesthetics delivered by continuous infusion or patient-controlled analgesia. For epidural patient-controlled analgesia, a dilute concentration of local anesthetic should be used to allow neurologic evaluation of the lower extremities to rule out spinal/epidural hematoma. Bupivacaine (0.0625%) is ideal in this regard. Fentanyl (5 μg/mL) can be added and the solution infused at 2 mL/hr, with an on-demand (patient-controlled analgesia) bolus of 2 to 4 mL and a lockout interval of 10 minutes.

Carotid Endarterectomy

The strong association between stroke and carotid artery occlusive disease is well known. The principal cause of carotid artery occlusive disease is atherosclerosis, which most commonly involves the bifurcation of the common carotid artery with frequent extension into both the internal and external carotid arteries. The clinical manifestations of carotid artery disease represent a spectrum of conditions, with fatal or debilitating stroke secondary to cerebral infarction at one end of the spectrum and ranging successively through nondebilitating stroke, transient ischemic attack, and amaurosis fugax (transient attack of monocular blindness) to an asymptomatic bruit. Cerebrovascular sequelae of carotid atherosclerosis may result either from embolization of thrombus or atheromatous debris or from a reduction in flow (hypoperfusion) secondary to stenosis. The latter probably accounts for less than 10% of the cerebrovascular sequelae of carotid atherosclerosis. Although much is known about the genesis and evolution of atherosclerosis, significantly less is known about the circumstances that lead to plaque instability and rupture. Regardless of the mechanism, the degree of cerebral injury depends on such factors as plaque morphology, characteristics of the embolus, duration of hypoperfusion, cerebrovascular vasoreactivity, integrity of the circle of Willis, and cerebral collateral circulation.

Stroke is a major public health burden worldwide. It is the third leading cause of death and the leading cause of serious, long-term disability in the United States. Stroke is also a major contributor to health care costs. The direct and indirect costs of stroke in the United States in 2008 are estimated at $65.5 billion.[348] Approximately 780,000 people experience a new (≈600,000) or recurrent (≈180,000) stroke each year in the United States.[348] Annually, there are more than 950,000 hospitalizations and 165,000 deaths from stroke. There are well-defined risk factors in patients with stroke, the most important of which is hypertension. Approximately 83% of strokes are ischemic (i.e., cerebral thrombosis or embolism) in nature, and 7.6% of ischemic strokes result in death within 30 days of initial evaluation.[349] Less than 20% of strokes are preceded by a transient ischemic attack. Despite a well-documented decline in stroke mortality, the annual incidence rate of stroke may be increasing.[350] This increase is probably due to growth in high-risk populations. Indeed, if recent trends continue, increases in stroke death will outpace the overall population growth, with a doubling in deaths over the next 30 years.[351] The incidence of perioperative stroke in unselected patients,[352] patients with asymptomatic carotid bruit, and patients with at least 50% carotid stenosis[353] undergoing general anesthesia and surgery is approximately 0.1%, 1.0%, and 3.6%, respectively.

Although treatment options to reverse the effect of acute ischemic stroke are limited, outcomes may be improved with appropriate therapy.[354] The only approved therapy is intravenous recombinant tissue plasminogen activator.[355] Given the narrow 3-hour treatment window from the onset of symptoms, prompt

evaluation and diagnosis of ischemic stroke are critical. With the exception of acute stroke after carotid endarterectomy, surgical treatment of patients with acute ischemic stroke is controversial and not generally recommended because of limited data and perceived high risk. Endovascular treatment of patients with acute ischemic stroke is undergoing intense investigation. Emergency angioplasty and stenting, mechanical disruption of arterial clot, and mechanical extraction of thrombi are interventions currently being evaluated.[356] The AHA/American Stroke Association has recently published revised guidelines for the early management of patients with ischemic stroke.[357]

Indications

Endarterectomy of the carotid bifurcation reduces symptoms and prevents stroke for more than 40 years. The efficacy of carotid endarterectomy for prevention of ipsilateral stroke in patients with and without symptoms has been demonstrated in large-scale randomized clinical trials.[358,359] In centers of excellence, it is a low-risk procedure with excellent long-term durability.[360] The first successful carotid endarterectomy was performed by DeBakey in 1953 and later reported with a 19-year follow-up.[361] Carotid endarterectomy is the most common peripheral vascular surgical procedure performed in the United States, with an estimated 130,000 procedures performed annually.[362] The AHA[363] and others[364] have published guidelines for carotid endarterectomy. The rate and number of carotid endarterectomies have fluctuated significantly since the early 1970s. With marked growth in the specialty of vascular surgery and an expanding list of surgical indications, the number of carotid endarterectomies performed in nonfederal hospitals increased from 15,000 in 1971 to 107,000 in 1985[365] and then declined substantially over the next 5 to 6 years.[366] The decline was probably due to publications questioning the indications for the procedures and isolated reports citing excessively high rates of operative morbidity and mortality.[367]

In 1992, a marked increase in the number of carotid endarterectomies occurred after the results of two large-scale, prospective randomized trials were published.[366] The North American Symptomatic Carotid Endarterectomy Trial and the European Carotid Surgery Trial both reported definitive results for symptomatic patients with high-grade carotid stenosis (70% to 99%).[358,368] In the North American Symptomatic Carotid Endarterectomy Trial, at 2 years' follow-up the stroke rate for surgical patients was 9% versus 26% for medical patients.[358] This benefit of carotid endarterectomy has persisted at 8 years of follow-up.[369] In the European Carotid Surgery Trial, the long-term stroke rate was 2.8% for surgical patients, excluding a perioperative stroke and death rate of 7.5%, and 16.8% for medically managed patients.[368]

The efficacy of carotid endarterectomy in asymptomatic patients with carotid stenosis has been evaluated in five randomized trials.[359,370-373] The Carotid Artery Surgery Asymptomatic Narrowing Operation Versus Aspirin trial, the first to publish its results, concluded that carotid endarterectomy was not indicated for asymptomatic patients with 50% to 90% carotid stenosis.[370] Unfortunately, this study was seriously flawed and the results questioned. The Mayo Asymptomatic Carotid Endarterectomy Study was terminated early because of a significantly increased number of MIs and transient cerebral ischemic events in the surgical group.[371] Most of these events were not related to the surgery itself but rather to the absence of aspirin in the surgical group. The Department of Veterans Affairs trial was designed to compare the effects of carotid endarterectomy plus aspirin versus medical treatment (i.e., aspirin) in asymptomatic male patients with 50% or greater carotid stenosis.[372] This trial demonstrated a significant reduction in ipsilateral neurologic events in the surgical group (8%) versus the medical group (20.6%). However, the combined incidence of stroke and death was not different between study groups. The Asymptomatic Carotid Atherosclerosis Study demonstrated that patients with asymptomatic carotid stenosis (≥60%) who were treated with carotid endarterectomy and aspirin have a reduced 5-year risk of ipsilateral stroke when compared with patients treated with aspirin alone (5.1% versus 11.0%).[359] These results reflect only a 5.9% absolute risk reduction in 5 years, which is just above 1% per year. Of note, improvement in outcome for patients randomized to undergo endarterectomy in this trial did not reach significance until 3 years after surgery. The European Asymptomatic Carotid Surgery Trial, the largest trial to date, largely replicated the results of the Asymptomatic Carotid Atherosclerosis Study, but in a somewhat more pragmatic setting.[373] This trial demonstrated that patients with asymptomatic carotid stenosis (≈70%) on ultrasound who were treated by immediate carotid endarterectomy plus medical treatment have a reduced 5-year risk of stroke when compared with patients treated with medical therapy alone (6.4% versus 11.8%). Of note, half of this 5-year benefit involved disabling or fatal strokes.

Although landmark randomized clinical trials have clearly defined individuals who are likely to benefit from carotid endarterectomy (and set the standard for developing evidence-based practice guidelines throughout the world), it has been suggested that the significant increase in the number of carotid endarterectomies performed over the last decade may be due in part to the extrapolation of trial results to patients and settings not directly supported by the trials.[362,374] For example, both the North American Symptomatic Carotid Endarterectomy Trial and the Asymptomatic Carotid Atherosclerosis Study restricted enrollment to patients younger than 80 years, and both trials carefully selected institutions and surgeons to optimize the results of surgery. Additionally, the Asymptomatic Carotid Atherosclerosis Study, in subgroup analysis, could not demonstrate a significant benefit for women.[359] With the advent of a second interventional treatment modality, percutaneous carotid angioplasty and stenting (discussed later), this issue has become more complex.

Perioperative Morbidity and Mortality

Although the randomized trials just noted have demonstrated a protective effect of carotid endarterectomy on ipsilateral stroke, the critical determinants of benefit for any given patient must include the perioperative event rate and expected long-term survival. The perioperative complication rate for carotid endarterectomy needs to be very low (≈3% or less) to maintain the beneficial effects of surgery over medical therapy.[363] A systematic review of 51 studies (1980 to 1995) reported an overall mortality of 1.6% and a risk of stroke or death of 5.6% after carotid endarterectomy for symptomatic carotid stenosis.[375] Another systematic review of 25 studies (1980 to 1995) reported a 30-day mortality of 1.3% for asymptomatic stenosis and 1.8% for symptomatic stenosis.[376] The overall risk of stroke or death was 3.4% for asymptomatic stenosis and 5.2% for symptomatic stenosis.[376] The incidence of periopera-

tive stroke is highest in patients in whom stroke is diagnosed, lower in patients with transient ischemic attack, and lowest in asymptomatic patients. Neurologic deficits occur most commonly in patients with poorly controlled preoperative hypertension or in those with hypertension or hypotension postoperatively. More than half of these deficits occur more than 4 hours postoperatively. The incidence of perioperative MI in patients undergoing carotid endarterectomy ranges from 0% to 4%.[377,378] MI is the leading cause of both perioperative and late mortality after carotid endarterectomy. Recent reports suggest that carotid endarterectomy can be performed safely in the very elderly and those deemed high risk, with combined stroke or death rates being comparable to those found in randomized trials (North American Symptomatic Carotid Endarterectomy Trial and Asymptomatic Carotid Artery Study).[379-381]

Preoperative Evaluation

As discussed previously, successful evaluation of patients with arterial occlusive disease must address the systemic and progressive nature of atherosclerosis. CAD is common in patients undergoing carotid endarterectomy and is the leading cause of both early and late mortality.[382-384] Hertzer and coworkers performed coronary angiograms in 506 patients scheduled for carotid endarterectomy and found severe correctable CAD in 28%. Despite the known high incidence of CAD in patients undergoing carotid endarterectomy, preoperative studies are rarely needed for the evaluation of myocardial function or ischemic potential. Exceptions to this practice are patients with unstable angina, recent MI with evidence of ongoing ischemia, decompensated congestive heart failure, and significant valvular disease. Unless the surgical plan can be altered, perioperative management improved, or mortality reduced, specialized studies are not appropriate in most patients scheduled for carotid endarterectomy. This approach is based on the following rationale. First, randomized trials have definitively established that carotid endarterectomy can prevent stroke in appropriately selected patients.[278,283,358,359] Second, although percutaneous angioplasty plus stenting of the carotid artery is evolving into an appropriate alternative for some high-risk patients,[385] at the present time carotid endarterectomy remains the gold standard.[386,387] Third, based on the previous two reasons, it would be unlikely that the results of specialized testing would cause the procedure to be canceled. Fourth, because careful intraoperative and postoperative monitoring and medical management are standard for all patients undergoing carotid endarterectomy, specialized testing has little potential to alter perioperative management. Finally, there is no good evidence to suggest that preoperative strategies leading to coronary angiography and ultimately coronary revascularization are appropriate in patients undergoing carotid endarterectomy given the low overall rates of perioperative cardiac morbidity and mortality. Reduction in short-term mortality has not been shown with prophylactic coronary revascularization before aortic or lower extremity vascular surgery.[35,47] Thus, in patients with asymptomatic or stable CAD, I believe that the best strategy is to proceed with carotid endarterectomy without additional studies. This approach does not take into consideration the potential long-term benefits from aggressive preoperative cardiac assessment and ultimate coronary revascularization. However, there is no convincing evidence that such benefit exists.

Patients with both severe CAD and severe carotid artery occlusive disease represent somewhat of a management dilemma[388] because it is often unclear which disease should be treated first.[389] The severity of cerebrovascular and coronary disease must be evaluated in terms of clinical symptoms and anatomic lesions, and a decision must be made to perform either a combined or a staged procedure. A meta-analysis of 16 studies with 844 combined patients and 920 staged patients reported that the combined approach may be associated with a higher risk for stroke or death.[390] A staged approach with carotid endarterectomy as the first procedure may result in significant morbidity from cardiac causes. Conversely, performing coronary revascularization first may result in a high incidence of stroke. For patients with both unstable CAD and symptomatic carotid artery disease, a combined procedure has been advocated.[391] Numerous reports from centers of excellence support a combined approach, which has demonstrated both low morbidity and low mortality.[388,392-394] However, these reports may not reflect community-wide outcomes of the combined approach.[395] To date, no randomized trials have been performed to assess the benefit of combined versus staged procedures. Given this lack of objective data, management of an individual patient should be guided by careful assessment of the relative severity of the coronary and carotid disease with particular emphasis on both surgeon- and institution-specific results in these patient populations. Carotid artery angioplasty plus stenting has recently been introduced as an alternative revascularization modality before staged CABG. However, data are limited, and the role of carotid artery angioplasty and stenting in this setting is unproven.[396]

Anesthetic Management

Anesthetic management goals for carotid endarterectomy include protection of the heart and brain from ischemic injury, control of the heart rate and blood pressure, and ablation of the surgical pain and stress responses. These goals must be achieved with another important goal in mind—to have an awake patient at the end of surgery for the purpose of neurologic examination.

The preoperative visit is particularly important in patients undergoing carotid surgery. During this visit, a series of blood pressure and heart rate measurements are obtained from which acceptable ranges for perioperative management can be determined. Patients are instructed to continue all long-term cardiac medications up to and including the morning of surgery. Unless contraindications exist, aspirin therapy should be continued throughout the perioperative period. As noted earlier, discontinuation of aspirin therapy may be related to an increased rate of MI and transient ischemic events in patients undergoing carotid endarterectomy.[281] When patients arrive at the hospital on the day of surgery, they are queried regarding any new cardiovascular or cerebrovascular symptoms. Long-term cardiovascular medications not taken at home should be administered in the preoperative holding area whenever possible. Patient reassurance is particularly important at this time because anxiety is associated with increases in heart rate, systemic vascular resistance, and myocardial oxygen consumption, which in this patient population could precipitate significant cardiac morbidity.[397]

I routinely monitor leads II and V_5 for detection of rhythm disturbances and ST-segment changes. On-line ST-segment analysis is particularly helpful and is used routinely. An intra-arterial catheter for beat-to-beat blood pressure monitoring is placed in

all patients. Central venous and pulmonary artery catheters are usually unnecessary for carotid surgery. If such monitors are used, the subclavian or femoral insertion sites are most practical because inadvertent carotid puncture could compromise blood flow as a result of hematoma. In my experience, the most common reason for central access is difficult or inadequate peripheral access. Intravenous access for fluid and drug administration can be accomplished with a single, secure, medium-bore (16-gauge) catheter. Because both arms will be tucked to the patient's sides, the intravenous catheter must run well after patient positioning.

General Anesthesia

Any of the commonly used induction agents, maintenance anesthetics, and short- to intermediate-acting nondepolarizing muscle relaxants can be used safely during carotid endarterectomy, given that stable hemodynamics are maintained and the patient is awake at the end of the procedure. My induction technique with sufentanil is as follows. After placement of routine monitors and administration of oxygen by facemask, a sufentanil infusion (0.5 to 1.0 μg/kg) is initiated. If the patient becomes at all sedated during the planned 10- to 15-minute infusion period, as evidenced by slowed speech or delayed response to questioning, the infusion is discontinued. No additional opioids are administered intraoperatively. Induction of anesthesia is accomplished with incremental doses of thiopental (≤8 mg/kg) followed by succinylcholine, unless contraindications exist. Etomidate or propofol may also be used. Esmolol is particularly effective in blunting the increases in heart rate and blood pressure during laryngoscopy and intubation and is used liberally during the induction period.[398] Blood pressure responses during and after endotracheal intubation are unpredictable in this patient population, and the clinician must be prepared for immediate treatment of extremes in blood pressure. My preference is to use short-acting drugs, such as phenylephrine (50 to 100 μg) for hypotension and sodium nitroprusside (5 to 25 μg) for hypertension. Patients with poorly controlled hypertension (diastolic blood pressure >100 mm Hg) require special care. These patients are often intravascularly volume depleted and may have significant hypotension with induction. Administration of fluids intravenously (5 mL/kg), careful titration of anesthetics, and immediate treatment of hypotension are especially important.

Anesthesia is maintained with 50% nitrous oxide in oxygen and low-dose (i.e., less than half the minimum alveolar concentration) potent inhaled anesthetics. Isoflurane is preferred because fewer ischemic electroencephalographic (EEG) changes occur during carotid occlusion than with halothane[399,400] or enflurane.[399-401] In addition, studies using EEG and regional cerebral blood flow (rCBF) measurements suggest that the critical rCBF (the rCBF below which EEG changes of cerebral ischemia occur) is lower for isoflurane than for halothane or enflurane.[399,400] Sevoflurane may be a good alternative because its critical rCBF in patients undergoing endarterectomy is similar to that determined with isoflurane[402] and it may facilitate more rapid emergence.[403] I typically use vecuronium for muscle relaxation because the procedure rarely lasts longer than 90 minutes. I do not use a cervical plexus block or request local anesthetic infiltration for skin incisions because the surgical stimulation is minimal and it is frequently necessary to support blood pressure. A combined remifentanil and propofol anesthetic technique has been reported but offered little advantage over inhaled anesthetics.[404]

Despite only modest surgical stimulation, hemodynamic fluctuations are common during carotid endarterectomy. Blood pressure and heart rate are controlled within predetermined and individualized ranges during the surgical procedure with short-acting agents whenever possible (esmolol, phenylephrine, nitroglycerin, and sodium nitroprusside). Arterial blood pressure should be maintained in the high-normal range throughout the procedure and particularly during the period of carotid clamping in an attempt to increase collateral flow and prevent cerebral ischemia. In patients with contralateral internal carotid artery occlusion or severe stenosis, induced hypertension to approximately 10% to 20% above baseline is advocated during the period of carotid clamping when neurophysiologic monitoring is not used. Blood pressure preservation or augmentation can be accomplished by maintaining light levels of general anesthesia or by administering sympathomimetic drugs such as phenylephrine and ephedrine. Some caution must be exercised when using vasopressors to augment blood pressure during carotid endarterectomy because the increases in blood pressure and heart rate may increase myocardial oxygen requirements, as well as the risk for myocardial ischemia[405] or infarction. The restrictive use of vasopressors for specific instances of cerebral ischemia has been advocated.[406] In one report, induced hypertension during the period of carotid occlusion was not associated with myocardial ischemia.[407]

Surgical manipulation of the carotid sinus with activation of the baroreceptor reflexes can cause abrupt bradycardia and hypotension. Cessation of surgical manipulation promptly restores the hemodynamics, and infiltration of the carotid bifurcation with 1% lidocaine usually prevents further episodes. Infiltration may, however, increase the incidence of both intraoperative and postoperative[408] hypertension. I do not advocate routine infiltration of the carotid bifurcation.[409]

With closure of the deep fascial layers in the neck, isoflurane is discontinued, nitrous oxide is increased to 70%, and ventilation is controlled manually. On application of the surgical dressings, neuromuscular reversal agents are administered, and oxygen is increased to 100%. At this time I decrease external stimuli to the patient by quieting the room, turning off the overhead surgical lights, and placing the patient in a head-up recumbent position. Ventilation is gently assisted until the patient exhibits spontaneous eye opening or movement. With rare exceptions, all patients are extubated after neurologic integrity is established. Neurologic deficits on emergence require immediate discussion with the surgeon about the need for angiography, reoperation, or both. The period of emergence and extubation may be associated with marked hypertension and tachycardia, which may require aggressive pharmacologic intervention. Tight hemodynamic control during this period is likely to be more demanding than during induction.[407] Greater hemodynamic stability and decreased pharmacologic intervention during emergence have been reported in patients undergoing carotid endarterectomy with propofol versus isoflurane.[407] In addition, a significantly lower incidence of myocardial ischemia on emergence was found in the propofol group than in the isoflurane group (1 of 14 versus 6 of 13). Of particular note, all patients with myocardial ischemia on emergence had systolic blood pressure higher than 200 mm Hg.

Regional and Local Anesthesia

Regional and local anesthetic techniques for carotid endarterectomy have been in use for more than 40 years, and many centers consider them to be the techniques of choice.[410,411] Regional anesthesia is accomplished by blocking the C2 to C4 dermatomes

by use of a superficial and deep cervical plexus block (see Chapter 52). Adequate anesthesia can be obtained with an isolated superficial cervical plexus block, possibly as a result of spread of local anesthetic to the cervical nerve roots.[412] Local infiltration of the surgical field can also provide the necessary sensory blockade. Regional anesthesia allows continuous neurologic assessment of awake patients, which is believed to be the most sensitive method for detecting inadequate cerebral perfusion and function.[413] Other advantages that have been reported include avoidance of expensive cerebral monitoring, reduced need for shunting,[414-416] greater stability of blood pressure and decreased vasopressor requirements,[415,417] and reduced hospital costs.[414,417,418]

Local or regional anesthesia requires significant patient cooperation throughout the procedure and is best maintained with constant communication and gentle handling of tissues. Supplemental infiltration of local anesthetic by the surgeon, especially at the lower border and ramus of the mandible, is frequently helpful. Sedation, if used at all, must be kept to a minimum to allow continuous neurologic assessment. Levels of consciousness, speech, and contralateral handgrip are assessed throughout the procedure. Handgrip can be assessed with the use of a squeaky toy. Blood pressure is augmented with phenylephrine when patients exhibit neurologic changes during carotid artery test clamping or after shunt placement. A 2- to 3-minute test clamp in awake patients allows prompt identification of those who would benefit from shunt placement.[419] Patient acceptance of regional anesthesia is high,[420] as evidenced by a 92% preference for repeat cervical plexus block for future carotid endarterectomy.[421] The surgical drapes are "tented" over the head and face area to minimize claustrophobic anxiety. It has been suggested that no absolute contradiction to regional anesthesia for carotid endarterectomy exists.[320] In my practice, I avoid regional anesthesia under the following circumstances: strong preference for general anesthesia expressed by the patient (i.e., claustrophobia), language barriers that make communication difficult, and difficult vascular anatomy. Difficult anatomy is usually manifested by a patient with a short neck and a high (more cephalad) bifurcation and may require vigorous submandibular retraction.

Regional versus General Anesthesia

Most reports comparing local or regional anesthesia with general anesthesia indicate no differences in the perioperative stroke or death rate on the basis of anesthetic technique.[27,320,321,326,418,422-424] Three reports have found an increased incidence of perioperative stroke in patients under general anesthesia.[325,425] An increased incidence of cardiopulmonary complications in patients under general anesthesia has been reported in five studies.[27,326,422,424] Potential disadvantages of local or regional anesthesia include an inability to use pharmacologic cerebral protection with anesthetics, patient panic or loss of cooperation, seizure or loss of consciousness with carotid clamping, and inadequate access to the airway should conversion to general anesthesia be necessary. The incidence of serious complications from a cervical plexus block is low; however, near-toxic levels of local anesthetic have been reported in almost half of patients after superficial and deep cervical plexus block.[426] Although no major complications related to local anesthetic toxicity occurred, some caution should be exercised when requesting the surgeon to supplement with additional local anesthetic. Phrenic nerve paresis is common after cervical plexus block[427] and is of little clinical consequence except in patients with severe chronic obstructive pulmonary disease or contralateral diaphragmatic dysfunction. Rates of conversion from regional anesthesia to general anesthesia of approximately 2% to 6% have been reported.[320,323,428] In patients undergoing carotid endarterectomy under cervical plexus blockade, ST-segment depression occurring during clamping or shortly after declamping was highly predictive of adverse cardiac complications.[429]

Intraoperative neurologic changes during carotid endarterectomy under local or regional anesthesia occur in 2.4% to 24% of patients.[428,430,431] Patients undergoing carotid endarterectomy under cervical plexus blockade who experience intraoperative neurologic changes are six times more likely (6.6% versus 1.1%) to have a postoperative stroke.[428] When compared with general anesthesia, regional anesthesia for carotid endarterectomy may be associated with increased levels of blood catecholamines.[432] A high incidence of tachycardia has been reported in patients undergoing regional anesthesia for carotid endarterectomy.[421] To date, no large-scale, prospective randomized trials have evaluated whether neurologic or cardiac outcomes differ with regional versus general anesthesia. The ultimate decision to use one technique over the other must be based on the surgeon's and the anesthesiologist's experience and the patient's preference.

Carbon Dioxide and Glucose Management

Cerebrovascular carbon dioxide reactivity is part of the complex autoregulatory system to control cerebral blood flow. Normal cerebral autoregulation responds to acute changes in $Paco_2$ by decreasing cerebral blood flow (i.e., vasoconstriction) with hypocapnia and increasing cerebral blood flow (i.e., vasodilatation) with hypercapnia. In patients with carotid artery stenosis or occlusion, ipsilateral cerebral blood flow may be impaired because of poor intracerebral collateral blood flow. In the setting of poor collateralization and resultant cerebral hypoperfusion, cerebral resistance vessels in the hypoperfused territories will dilate in an effort to maintain cerebral blood flow. These chronically dilated resistance vessels may demonstrate a diminished or absent (i.e., vasomotor paralysis) cerebral blood flow response to carbon dioxide. Impaired cerebrovascular reactivity to hypercapnia may play a significant role in the development of stroke ipsilateral to carotid stenosis or occlusion.[433,434] Although one might expect that impaired carbon dioxide reactivity would increase the risk for cerebral ischemia after carotid artery clamping, the results of intraoperative cerebral monitoring suggest that no such relationship exists.[435] Impaired cerebrovascular reactivity to carbon dioxide will significantly improve after carotid endarterectomy.[435]

Control of ventilation and carbon dioxide during general anesthesia is a matter of some controversy. Hypercapnia may cause a "steal" phenomenon (i.e., shunting of blood away from hypoperfused territories with dilated vasculature) and is generally avoided. Hypocapnia, with its associated cerebral vasoconstriction, has been advocated to promote a reversal of this steal phenomenon. However, there is little clinical evidence for this "reverse" steal effect.[436] Additionally, experimental data do not support the use of hypocapnia as a therapeutic maneuver to produce a favorable redistribution of blood flow during focal cerebral ischemia.[437] Indeed, in this animal model of focal cerebral ischemia, hypocapnia ($Paco_2$ of 23 mm Hg) actually increased the size of the region at risk for ischemia.[437] It is therefore common

practice to maintain normocapnia or mild hypocapnia during carotid endarterectomy.

There is evidence of increased ischemic injury to neural tissue when ischemia occurs in the presence of hyperglycemia. Recent data from The Johns Hopkins Hospital found that operative-day glucose greater than 200 mg/dL at the time of carotid endarterectomy was associated with an increased risk for perioperative stroke or transient ischemic attack, MI, and death.[438] Thus, until additional data become available, it may be beneficial to maintain a blood glucose level below 200 mg/dL in patients undergoing carotid endarterectomy. If hyperglycemia is treated with insulin preoperatively or intraoperatively, the blood glucose level should be carefully monitored, especially during general anesthesia, to avoid the dangers of hypoglycemia.

Neurologic Monitoring and Cerebral Perfusion

Intraoperative monitoring for cerebral ischemia or hypoperfusion and, more recently, for cerebral emboli during carotid endarterectomy is controversial (see Chapter 46). Monitoring techniques includes internal carotid artery stump pressure determinations, rCBF measurements, EEG and SSEP monitoring, and transcranial Doppler ultrasonography (TCD). Other modalities, such as cerebral oximetry and jugular bulb venous monitoring, are being evaluated as well. The rationale for the use of such monitoring is based on the need to prevent intraoperative strokes. The primary clinical utility of cerebral monitoring is to identify patients in need of carotid artery shunting. Secondarily, cerebral monitoring is used to identify patients who may benefit from blood pressure augmentation or change in surgical technique. Despite a tremendous amount of investigative effort, there are only limited data to support the assumption that cerebral monitoring actually improves patient outcome after carotid endarterectomy.

Stump Pressure

The internal carotid artery stump pressure represents the backpressure resulting from collateral flow through the circle of Willis via the contralateral carotid artery and the vertebrobasilar system. The advantages of monitoring carotid stump pressure are that it is inexpensive, relatively easy to obtain, and continuously available during carotid clamping (dynamic stump pressure). Despite these advantages, few centers use stump pressure monitoring because its accuracy in determining the adequacy of collateral flow and the need for selective shunting have been questioned.[431,439-441] Although the critical stump pressure is unknown, pressures below 50 mm Hg are associated with hypoperfusion.

Regional Cerebral Blood Flow

rCBF measurements during carotid endarterectomy are obtained by intravenous or ipsilateral carotid artery injection of radioactive xenon and analysis of decay curves obtained from detectors placed over the area of the ipsilateral cortex supplied by the middle cerebral artery. Measurements are typically obtained before, during, and immediately after carotid clamping. This technology, combined with the EEG monitoring, has provided important insight into the relationship between rCBF and EEG evidence of cerebral ischemia and the critical rCBF associated with various anesthetics.[310,311] The critical rCBF varies depending on the volatile anesthetic used. In patients receiving nitrous oxide plus a volatile anesthetic, rCBF is approximately 20, 15, 10, and 10 mL/100 g of brain tissue per minute for halothane, enflurane, isoflurane, and sevoflurane, respectively.[310-312] The expense and the expertise required to make and interpret these blood flow measurements have limited the use of this technology to only a few centers.

Electroencephalography

Many centers advocate intraoperative use of EEG monitoring for the detection of cerebral ischemia and subsequent selective shunting (see Chapter 46).[442-444] The full 16-channel strip-chart EEG and the processed (compressed spectral array) EEG monitor are used for this purpose. Although the processed EEG monitor is more easily interpreted, it is less sensitive than the raw EEG monitor. Significant ischemic EEG changes occur in 7.5% to 20% of monitored patients during carotid clamping under general anesthesia.[316,443,445-450] Significant EEG changes occur more frequently in patient with contralateral carotid disease than in those without (14.3% versus 5.1%).[449] The presence of a contralateral carotid occlusion may increase the rate of significant ischemic EEG changes to nearly 50% during carotid clamping.[447] Because contralateral occlusion is highly predictive of ischemic EEG changes with carotid clamping, it has been recommended that EEG monitoring be eliminated in this circumstance.[450] Ischemic EEG changes may also be seen with shunt malfunction, hypotension, or cerebral emboli.

When the electroencephalogram is used for cerebral ischemia monitoring during carotid endarterectomy, a stable physiologic and anesthetic milieu is mandatory. Isoflurane, desflurane, and sevoflurane produce similar ECG changes at equipotent levels and, when used at 0.5 MAC, allow for more reliable ECG cerebral ischemia monitoring.

The clinical usefulness of intraoperative EEG monitoring for ischemia during carotid endarterectomy is limited by several factors.[446] First, it may not detect subcortical or small cortical infarcts. Second, false-negative results (i.e., neurologic deficit with no ischemic EEG changes intraoperatively) are not uncommon. Patients with preexisting stroke or reversible neurologic deficits may have a particularly high incidence of such results. Third, EEG monitoring is not specific for ischemia and may be affected by changes in temperature, blood pressure, and anesthetic depth. Fourth, false-positive results (i.e., no perioperative neurologic deficit with significant ischemic EEG changes intraoperatively) occur because not all cerebral ischemia uniformly proceeds to infarction. Finally, intraoperative EEG monitoring is inherently limited because most intraoperative strokes are thought to be thromboembolic and most perioperative strokes occur postoperatively. At present, no consistent data demonstrate that EEG monitoring is clearly superior to other methods of intraoperative cerebral monitoring or that the use of EEG monitoring improves outcome.

Somatosensory Evoked Potentials

SSEP monitoring is based on the response of the sensory cortex to electrical impulses from peripheral sensory nerve stimulation. The sensory cortex, being primarily supplied by the middle cerebral artery, is at risk during carotid artery clamping. SSEP monitoring, unlike EEG monitoring, is able to detect subcortical sensory pathway ischemia. Characteristic SSEP tracings (i.e., decrease in amplitude, increase in latency, or both) occur with decreased rCBF and are abolished in primates when flow decreases

to less than 12 mL/100 g of brain tissue per minute. No specific reduction in amplitude or increase in latency has been established as a physiologic marker of impaired rCBF under operative conditions in humans. Anesthetics, hypothermia, and blood pressure may affect SSEPs significantly, and false-negative results have been reported.[451] The validity of SSEPs as an intraoperative monitor of cerebral ischemia during carotid endarterectomy has not been definitively established.

Transcranial Doppler Ultrasonography

TCD allows continuous measurement of mean blood flow velocity and detection of microembolic events in the middle cerebral artery (see Chapter 46). These parameters have important clinical implications because most perioperative neurologic deficits are thought to be thromboembolic in origin.[452] With TCD, intraoperative embolization has been detected in more than 90% of patients undergoing carotid endarterectomy.[453,454] Most intraoperative emboli are characteristic of air and are not associated with adverse neurologic outcomes. TCD may provide useful information regarding shunt function, malfunction, and the incidence of emboli during shunt insertion. Embolization during carotid artery dissection may indicate plaque instability and the need for early carotid artery clamping.[454] Embolization during dissection and wound closure is associated with operative stroke.[455] One center has reported that combined TCD monitoring and completion angiography resulted in a reduction in the intraoperative stroke rate from 4% to 0%.[456] Early postoperative embolization has been detected in more than 70% of patients after carotid endarterectomy[445] and is exclusively particulate in nature.[457] Most TCD-detected emboli occur in the first 2 to 3 hours after surgery.[458] Persistent particulate embolization in the early postoperative period has been shown to predict thrombosis and the development of a major neurologic deficit.[453] Frequent early postoperative TCD embolic signals have been demonstrated to be highly predictive of early postoperative ipsilateral focal cerebral ischemia.[454] Intervention with dextran has been shown to reduce and ultimately stop sustained embolization after carotid endarterectomy.[458] Perioperative microembolization is more common in women and patients with symptomatic carotid disease.[459,460] TCD monitoring has been reported to detect early asymptomatic carotid artery occlusion and hyperperfusion syndrome after carotid endarterectomy.[461,462] Although TCD monitoring holds some promise, conclusive evidence demonstrating improved outcome has not been reported. Additionally, the high rate of technical failures significantly limits the clinical utility of this monitoring modality.[463]

Cerebral Oxygenation

Direct monitoring of cerebral oxygenation can be obtained with jugular bulb venous monitoring. Such monitoring allows determination of the arterial—jugular venous oxygen content difference and jugular venous oxygen saturation and therefore provides information on global cerebral oxygen metabolism. Jugular venous samples are obtained from a catheter inserted into the jugular bulb ipsilateral to the surgical site. Continuous fiberoptic jugular venous oximetry catheters are available as well. Significant technical and methodologic shortcomings have limited the clinical application of this monitoring during carotid endarterectomy.

Near-infrared spectrophotometry is a noninvasive technique that allows continuous monitoring of regional cerebral oxygen saturation through the scalp and skull. Similar to pulse oximetry, cerebral oximetry is based on the different absorption characteristics of the near-infrared spectrum of oxygenated and deoxygenated hemoglobin. However, unlike pulse oximeters, cerebral oximeters measure the oxygen saturation of hemoglobin in the entire tissue bed (i.e., brain tissue and arterial and venous blood), which is predominately venous blood, and therefore approximates venous blood oxygen saturation. A commercially available cerebral oximetry sensor is applied to the forehead skin ipsilateral to the surgical site, and regional cerebral oxygen saturation from a small sample of the frontal cortex below the sensor is provided. To date, wide patient-to-patient variability in baseline cerebral oxygen saturation and the lack of a clinical threshold of a decrease in cerebral oxygen saturation predictive of the need for shunt placement have impeded the widespread use of this novel monitoring modality.

Postoperative Considerations

Most neurologic complications (transient and permanent) after carotid endarterectomy are explained by intraoperative embolization, hypoperfusion during carotid clamping, and embolization or thrombosis from the endarterectomy site. Other important, but less common factors include intracerebral hemorrhage and cerebral hyperperfusion. It is generally accepted that most neurologic complications are related to surgical technique. Thromboembolic rather than hemodynamic factors appear to be the major mechanism of perioperative neurologic complications,[452] and most perioperative neurologic deficits occur in the postoperative period.[464-466] Hemodynamic factors may account for up to 21% of perioperative strokes.[452] Neurologic complications attributable to carotid artery thrombosis may occur with an incidence as high as 3.3% and are associated with a high rate of major stroke or death despite immediate operative intervention.[337,453,467-469] The reported incidence of intracerebral hemorrhage after carotid endarterectomy ranges from 0.4% to 2.0%.[466] Most intracerebral hemorrhages occur 1 to 5 days after the operation and are associated with significant morbidity and mortality.[470,471]

Hypertension is common in the postoperative period after carotid endarterectomy. Not surprisingly, patients with poorly controlled preoperative hypertension often have severe hypertension postoperatively. The causes are not well understood, but surgical denervation of the carotid sinus baroreceptors is probably contributory. Regional anesthesia is associated with less hypertension. Other causes of postoperative hypertension, such as hypoxemia, hypercapnia, bladder distention, and pain, should be excluded or treated. Because neurologic and cardiac complications may be associated with postoperative hypertension,[472,473] blood pressure should be aggressively controlled to near preoperative values after surgery. Short-acting drugs are the safest and most effective. Patients with persistent hypertension are ultimately converted to longer-acting intravenous or oral agents before discharge from the ICU.

Postoperative cerebral hyperperfusion syndrome is an abrupt increase in blood flow with loss of autoregulation in the surgically reperfused brain and is manifested as headache, seizure, focal neurologic signs, brain edema, and possibly intracerebral hemorrhage.[473] Unfortunately, little is actually known about the etiology and management of this syndrome. Typically, this syn-

drome does not occur until several days after carotid endarterectomy. Patients with severe postoperative hypertension and severe preoperative internal carotid artery stenosis are believed to be at increased risk for this syndrome.[473,474] However, more recent data do not corroborate this common belief and suggest that recent contralateral carotid endarterectomy may be predictive of cerebral hyperperfusion.[475]

Postoperative hypotension occurs almost as frequently as hypertension after carotid endarterectomy.[476,477] Carotid sinus baroreceptor hypersensitivity or reactivation probably plays an important role. Postoperative hypotension may be more common after regional anesthesia.[338,472,476-478] To avoid cerebral and myocardial ischemia, hypotension should be corrected promptly. Cardiac output is frequently normal or elevated and systemic vascular resistance reduced in hypotensive patients after carotid endarterectomy.[476] Intensive surveillance for evidence of myocardial and cerebral ischemia and judicious use of fluids and vasopressors are recommended for postoperative hypotension. In most cases the hypotension resolves over a period of 12 to 24 hours.

Cranial and cervical nerve dysfunction after carotid endarterectomy is well documented in the literature.[479-482] Although most injuries are transient, permanent injuries can lead to significant disability.[479] Patients should be examined for injury to the recurrent laryngeal, superior laryngeal, hypoglossal, and marginal mandibular nerves shortly after extubation. Unilateral recurrent laryngeal nerve injury may result in ipsilateral true vocal cord paralysis in the paramedian position. Although most patients have hoarseness and an impaired cough mechanism, the injury is usually well tolerated. However, bilateral recurrent laryngeal nerve injury and resultant bilateral vocal cord paralysis can result in life-threatening upper airway obstruction. This situation must be anticipated in patients who have previously undergone contralateral carotid endarterectomy or neck surgery.

Carotid body denervation may occur after carotid endarterectomy as a result of surgical manipulation. Though rarely of clinical significance, unilateral loss of carotid body function may result in an impaired ventilatory response to mild hypoxemia.[483] Bilateral carotid endarterectomy is associated with loss of the normal ventilatory and arterial pressure responses to acute hypoxia and an increased resting partial pressure of arterial carbon dioxide. In this situation, the central chemoreceptors are the primary sensors for maintaining ventilation, and serious respiratory depression may result from opioid administration. Fortunately, most patients require little more than acetaminophen or ketorolac for postoperative pain.

Wound hematoma probably occurs more frequently than reported in the literature. In the North American Symptomatic Carotic Endarterectomy Trial,[358] 5.5% of patients had wound hematomas. Most cases are the result of venous oozing and require little more than external compression for 5 to 10 minutes. Expanding hematomas require prompt evaluation at the bedside and immediate evacuation if airway compromise is evident. Aggressive postoperative blood pressure control may help reduce the incidence of hematoma.

I believe that all patients should be monitored in an intensive care setting for at least 8 to 12 hours after carotid endarterectomy because most events requiring intervention occur within this timeframe.[484-486] Although some clinicians believe that intensive care monitoring is not routinely required, a significant number of patients do require intensive monitoring and active intervention.[484,487]

Endovascular Treatment of Carotid Disease: Carotid Artery Stenting

Endovascular therapy can be defined as the treatment of vascular pathology accomplished with the percutaneous transvascular passage of a therapeutic device, such as a catheter, guidewire, or stent. Over the past 2 decades, percutaneous revascularization techniques have become accepted alternatives to surgical revascularization of aortoiliac, renal, subclavian, and femoropopliteal lesions. Endovascular treatment of carotid artery disease is an innovation in evolution for stroke prevention and currently involves percutaneous transluminal angioplasty and stenting. Although the use of carotid artery stenting is increasing rapidly, the safety and efficacy of this approach have not been established.[488] A major concern is the potential for carotid artery stenting to produce embolic particles that may result in neurologic deficit.[489] Increasing attention is currently being focused on embolic protection devices to prevent embolization during catheter manipulation and balloon or stent deployment.[489,490] These devices are deployed distal to the lesion in the internal carotid artery and are designed to capture atheromatous debris released during the procedure.

Proponents of carotid stenting have recommended the procedure as an alternative to endarterectomy, particularly in specific patient subsets considered to be at high risk for open surgery.[491,492] A published consensus statement supports the use of carotid artery stenting in high-risk patients.[493] However, the concept of the high-risk endarterectomy patient has been questioned[290,291] because no data exist that clearly define any such large group of patients. Early randomized trial reports[494] have documented combined stroke and death rates of 10% to 12% with carotid artery stenting without embolic protection, thus raising significant safety concerns. The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy trial reported that carotid artery stenting with embolic protection was not inferior to endarterectomy.[495] This trial led to FDA approval of carotid artery stenting for the treatment of patients with symptomatic carotid stenosis. Two recently completed randomized trials reported much less favorable results for carotid artery stenting, which has refueled the debate between stenting and endarterectomy.[496,497] Additional large, multicenter randomized trials of carotid artery stenting versus endarterectomy are ongoing.[498]

Most carotid artery stenting procedures are performed under local anesthesia with light or no sedation in specialized endovascular suites. General anesthesia is used at some centers, particularly in the early phase of program development. Some degree of bradycardia and hypotension has been reported in 68% of patients undergoing carotid artery stenting.[499] A large percentage of these procedures are performed by cardiologists (57%) and radiologists (30%).[500]

Postoperative Management of Vascular Surgery Patients

Vascular surgery patients require special attention during the postoperative period because most cardiac complications occur postoperatively and other problems may arise that require imme-

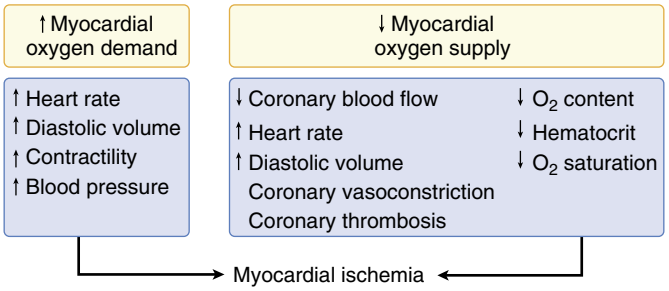

Figure 62-18 Determinants of myocardial oxygen supply and demand that lead to myocardial ischemia. During the perioperative period, virtually every determinant is altered by factors such as fluid shifts, blood loss, pain, catecholamines, altered coagulability, and ventilatory insufficiency. *(Adapted from Beattie C, Fleisher LA: Periopeative myocardial ischemia and infarction. Int Anesthesiol Clin 30:1-17, 1992.)*

diate attention. Conventional practice is to monitor all vascular surgery patients in an ICU setting after surgery. Some centers have set up specialized vascular step-down units in which lower-risk patients can be evaluated frequently by specialized nursing staff. There are, however, no clinical trials to support this practice, and most centers admit all vascular surgery patients to the ICU postoperatively.

Myocardial ischemia and cardiac morbidity occur most frequently in the postoperative period. Patients should be carefully monitored for signs and symptoms of ischemia, but up to 90% of these episodes are asymptomatic.[501-505] The determinants of myocardial oxygen supply and demand should be optimized for all patients (Fig. 62-18) to prevent ischemia before it develops. β-Blocker and statin therapy should be continued throughout the postoperative period. Dysrhythmias may be secondary to ischemia or to sympathectomy associated with regional anesthesia.

Besides myocardial ischemia and cardiac morbidity, other problems include coagulopathy, either from residual heparin or from dilutional coagulopathy after massive transfusion. Even in the absence of coagulopathy, bleeding through fresh vascular anastomoses may occur when significant postoperative hypertension is untreated. Hypovolemia occurs after aortic surgery as a result of significant third-space fluid loss and bleeding. Hypovolemia may lead to hypotension and hypoperfusion of the coronary arteries or lower extremity vascular grafts. Graft occlusion in the lower extremities occurs in 3% to 10% of patients[27,28,323] after lower extremity or aortic surgery and should be recognized immediately and surgically corrected. Lower extremity pulses should be checked at hourly intervals. Some patients require the administration of heparin or dextran to prevent thrombosis when the surgical repair is questionable or when patients have diffuse atherosclerotic disease.

Residual hypothermia in the early postoperative period is associated with an increased incidence of myocardial ischemia and cardiac morbidity; therefore, body temperature should be carefully monitored and controlled in all vascular surgery patients. In a prospective randomized trial, the relative risk for early postoperative cardiac morbidity was reduced by 55% when normothermia was maintained by use of a forced-air warming system.[165] In the early postoperative period, vascular surgery patients have a twofold to threefold greater incidence of myocardial ischemia when core temperature is less than 35°C.[166] Even mild hypothermia of approximately 35°C is associated with a 200% to 700% increase in norepinephrine levels,[163,506] generalized vasoconstriction,[507] and increased blood pressure in postoperative patients.[163] Shivering occurs and increases total-body oxygen consumption, but only by about 40% in the typical elderly vascular patient.[152]

It is important to control the stress response in the postoperative period. This includes preventing the potential triggers for myocardial ischemia (pain, anemia, hypothermia, hemodynamic extremes, and ventilatory insufficiency). In mechanically ventilated patients, the weaning period is especially stressful, and myocardial ischemia occurs frequently during this time.[508] Careful sedation and expeditious weaning are desirable. When possible, extubation in the operating room is less stressful and is preferable for carotid and lower extremity vascular surgery patients. For more invasive surgical procedures (TAA and abdominal aortic aneurysm), postoperative mechanical ventilation is usually necessary.

Vascular surgery continues to challenge the anesthesiologist, given the significant physiologic stress superimposed on a relatively elderly patient population with a high incidence of coexisting disease. Clinical studies provide insight into the preoperative assessment and optimization of cardiac risk, the implications of anesthetic technique, and the diagnosis, prevention, and treatment of myocardial ischemia in vascular surgery patients. These studies have improved our ability to care for vascular surgery patients with reduced morbidity and better overall outcome.

63 Neurosurgical Anesthesia

Key Points

1. For the purposes of planning a control strategy for intracranial pressure (ICP), the clinician should consider the four subcompartments of the intracranial space: cells, interstitial and intracellular fluid, cerebrospinal fluid, and blood.
2. The venous side of the cerebral circulation is a largely passive compartment that is often the cause of increased ICP or "tightness" of the surgical field, but that is commonly overlooked by clinicians.
3. Cerebral perfusion pressure (CPP) should be supported at or near waking normal levels in patients with recent cerebral injuries (e.g., traumatic brain injury [TBI], subarachnoid hemorrhage [SAH]) because of low resting cerebral blood flow and impaired autoregulation.
4. When patients are managed in the sitting position, blood pressure should be corrected to the level of the external auditory meatus, and mean arterial pressure (MAP) should be maintained at 60 mm Hg in normotensive adults.
5. The minimal standard of care for monitoring to detect venous air embolism in at-risk situations includes the precordial Doppler and end-tidal carbon dioxide analysis.
6. Despite encouraging preclinical data, therapeutic mild hypothermia cannot currently be advocated in the care of head-injured patients in the intensive care unit or during the operative management of patients with intracranial aneurysms because of negative human trials in those patient groups.
7. The most important consideration in the anesthetic management of patients undergoing clipping or coiling after acute SAH is the prevention of paroxysmal hypertension with its attendant risk of aneurysm rerupture. Nonetheless, adequate perfusion pressure is needed if temporary clips are used or during management of cerebral vasospasm.
8. Although induced hypotension is very rarely employed electively in aneurysm surgery, the clinician must be ready to reduce blood pressure immediately and accurately in the event of aneurysm rupture.
9. Tracheal intubation of a head-injured patient with an undefined cervical spine injury can be accomplished using a rapid-sequence induction with manual in-line stabilization (occiput held rigidly to the backboard) with only a very small risk of injury to the spinal cord.
10. CPP (CPP = MAP – ICP) should be supported at 60 mm Hg in the first 48 hours after TBI in adults.
11. Hypocapnia has the potential to cause cerebral ischemia, particularly in recently injured brain and in brain beneath retractors; it should be used only when absolutely necessary for the control of critically increased or uncertain ICP.

This chapter provides guidelines for the management of common situations in neurosurgical anesthesia. First, issues that arise in connection with a variety of neurosurgical procedures are reviewed. These issues constitute a checklist that the practitioner should review before undertaking anesthesia for any neurosurgical procedure. Procedure-specific discussions follow. This chapter assumes familiarity with the cerebral physiology and effects of anesthetics as described in Chapter 13. Neurologic monitoring is described in Chapter 46, and carotid endarterectomy is discussed in Chapter 62.

Recurrent Issues in Neuroanesthesia

Several basic elements of neurosurgical/neuroanesthetic management are recurrent and, in the absence of an established understanding between the surgeon and anesthesiologist, should be discussed and agreed on at the outset of every neurosurgical procedure. The list varies with the procedure and may include the

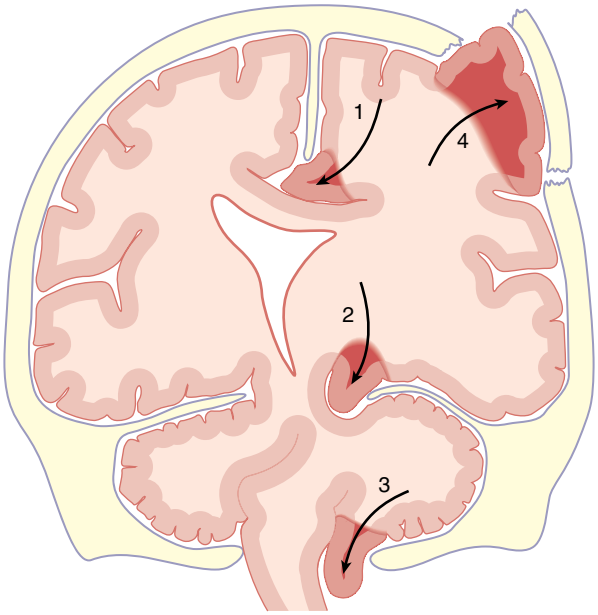

Figure 63-1 Schematic representation of various herniation pathways: (1) subfalcine, (2) uncal (transtentorial), (3) cerebellar, and (4) transcalvarial. *(From Fishman RA: Brain edema. N Engl J Med 293:706-711, 1975.)*

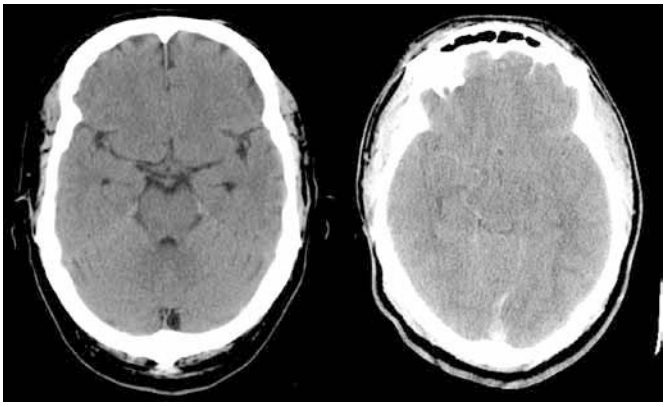

Figure 63-2 CT scan depicting normal (*left*) and compressed (*right*) basal cisterns. The basal, or perimesencephalic, cerebrospinal fluid space consists of the interpeduncular cistern (anterior), the ambient cisterns (lateral), and the quadrigeminal cisterns (posterior). In the *right panel,* in a patient with diffuse cerebral swelling (owing to sagittal sinus thrombosis), the cisterns have been obliterated. *(Image provided by Ivan Petrovitch, MD.)*

intended surgical position and requisite positioning aids; intentions with respect to the use of steroids, diuretics, anticonvulsants, and antibiotics; the surgeon's perception of the "tightness" of the intracranial space and the remaining intracranial compliance reserve; appropriate objectives for the management of blood pressure, $Paco_2$, and body temperature; anticipated blood loss; the intended use of neurophysiologic monitoring (which may impose constraints on the use of anesthetics or muscle relaxants, or both); and, occasionally, the perceived risk of air embolization. The considerations driving the decisions made about these issues are presented in this section. One additional recurrent issue, brain protection, is discussed briefly in the section on aneurysms and arteriovenous malformations and in detail in Chapter 13.

Control of Intracranial Pressure and Brain Relaxation

The necessity of preventing increases in intracranial pressure (ICP) or reducing an ICP that is already elevated is recurrent in neuroanesthesia. When the cranium is closed, the objective is to maintain adequate cerebral perfusion pressure (CPP) (CPP = mean arterial pressure [MAP] – ICP), and prevent the herniation of brain tissue between intracranial compartments or through the foramen magnum (Fig. 63-1). When the cranium is open, the issue may be one of providing relaxation of the intracranial contents to facilitate surgical access or, in extreme circumstances, reverse the process of brain herniation through a craniotomy. The principles that apply are similar whether the cranium is open or closed.

The various clinical indicators of increased ICP include headache (particularly headache that awakens the patient at night), nausea and vomiting, blurred vision, somnolence, and papilledema. Suggestive findings on computed tomography (CT) include midline shift, obliteration of the basal cisterns, loss of sulci, ventricular effacement (or enlarged ventricles in the event of hydrocephalus), and edema. Edema appears on a CT scan as a region of hypodensity. The basal cisterns appear on CT as a black (fluid) halo around the upper end of the brainstem (Fig. 63-2). They include the interpeduncular cistern, which lies between the two cerebral peduncles; the quadrigeminal cistern, which overlies the four colliculi; and the ambient cisterns, which lie lateral to the cerebral peduncles.

Figure 63-3 shows the pressure-volume relationship of the intracranial space. The plateau phase occurring at low volumes reveals that the intracranial space is not a completely closed one, and that there is some compensatory latitude. Compensation is accomplished principally by the translocation of cerebrospinal

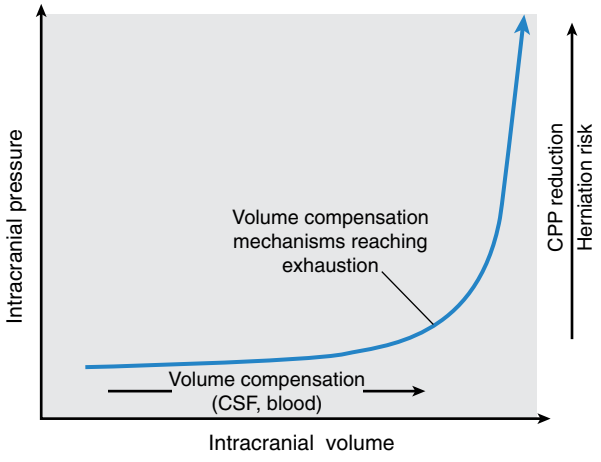

Figure 63-3 The intracranial pressure-volume relationship. The horizontal portion of the curve indicates that there is initially some latitude for compensation in the face of an expanding intracranial lesion. That compensation is accomplished largely by displacement of cerebrospinal fluid (CSF) and venous blood from intracranial to extracranial spaces. When the compensatory latitudes are exhausted, small volume increments result in large increases in intracranial pressure with the associated hazards of herniation or of decreased cerebral perfusion pressure (CPP) resulting in ischemia.

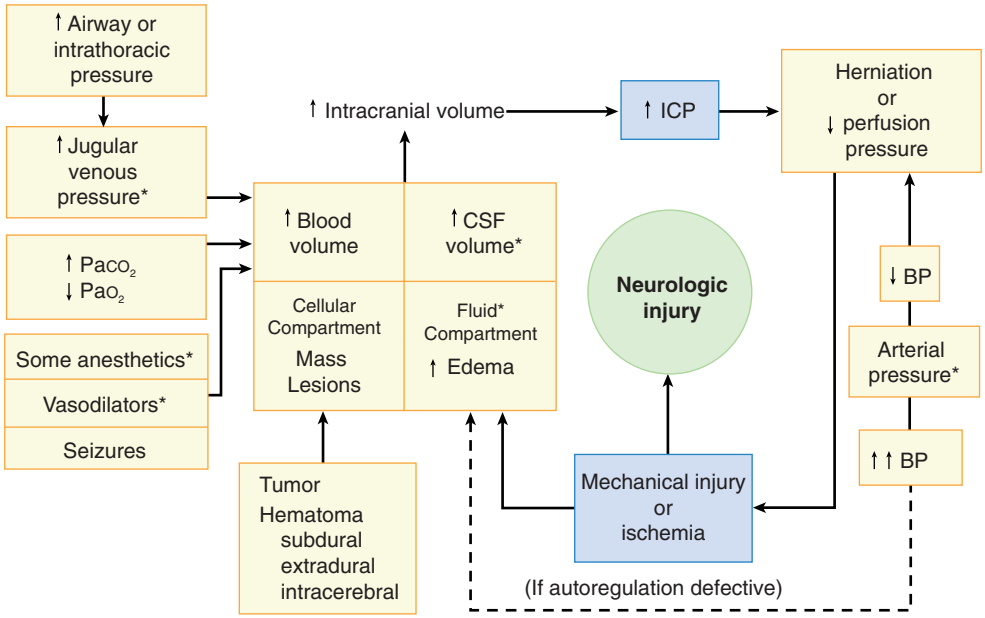

Figure 63-4 The pathophysiology of intracranial hypertension. The figure depicts the manner in which increases in the volumes of any or all of the four intracranial compartments—blood, cerebrospinal fluid (CSF), fluid (interstitial or intracellular) and cells—result in intracranial pressure (ICP) increases and eventual neurologic damage. The elements that are potentially under the control of the anesthesiologist are indicated by asterisks (*). (Control of CSF volume requires the presence of a ventriculostomy catheter.) BP, blood pressure.

fluid (CSF) to the spinal CSF space and venous blood to the extracranial veins. Ultimately, when the compensatory potential is exhausted, even tiny increments in volume of the intracranial contents can result in substantial increases in ICP. These increases have the potential to result in either herniation of brain tissue from one compartment to another (or into the surgical field) (see Fig. 63-1), with resultant mechanical injury to brain tissue, or reduction in perfusion pressure, leading to ischemic injury.

Several variables can interact to cause or aggravate intracranial hypertension (Fig. 63-4). For clinicians faced with the problem of managing increased ICP, the objective is, broadly speaking, to reduce the volume of the intracranial contents. For mnemonic purposes, the clinician can divide the intracranial space into four subcompartments (Table 63-1): cells (including neurons, glia, tumors, and extravasated collections of blood), fluid (intracellular and extracellular), CSF, and blood.

Table 63-1 Intracranial Compartments and Techniques for Manipulation of Their Volume

Compartment	Volume Control Methods
Cells (including neurons, glia, tumors, and extravasated blood)	Surgical removal
Fluid (intracellular and extracellular)	Diuretics Steroids (principally tumors)
CSF	Drainage
Arterial blood	Decrease CBF
Venous blood	Improve cerebral venous drainage

CBF, cerebral blood flow; CSF, cerebrospinal fluid.

1. *The cellular compartment*: This compartment is largely the province of the surgeon. It may be the anesthesiologist's responsibility, however, to pose a well-placed diagnostic question. When the brain is bulging into the surgical field at the conclusion of evacuation of an extradural hematoma, the clinician should ask whether a subdural or extradural hematoma is present on the contralateral side that warrants either immediate bur holes or immediate postprocedure radiologic evaluation.
2. *The CSF compartment*: There is no pharmacologic manipulation of the CSF space, the time course and magnitude of which are relevant to the neurosurgical operating room. The only relevant means for manipulating the size of this compartment is by drainage. A tight surgical field sometimes can be improved by passage of a brain needle by the surgeon into a lateral ventricle to drain CSF. Lumbar CSF drainage can be used to improve surgical exposure in situations with no substantial hazard of uncal or transforamen magnum herniation.
3. *The fluid compartment*: This compartment can be addressed with steroids and diuretics. The use of these agents is discussed subsequently.
4. *The blood compartment*: This is the compartment that receives the anesthesiologist's greatest attention because it is the most amenable to rapid alteration. The blood compartment should be considered as two separate components: venous and arterial.

We suggest giving first consideration to the venous side of the circulation. It is largely a passive compartment that is frequently overlooked. Passive though it is, engorgement of this compartment is a common cause of increased ICP or poor conditions in the surgical field (Fig. 63-5). A head-up posture to ensure

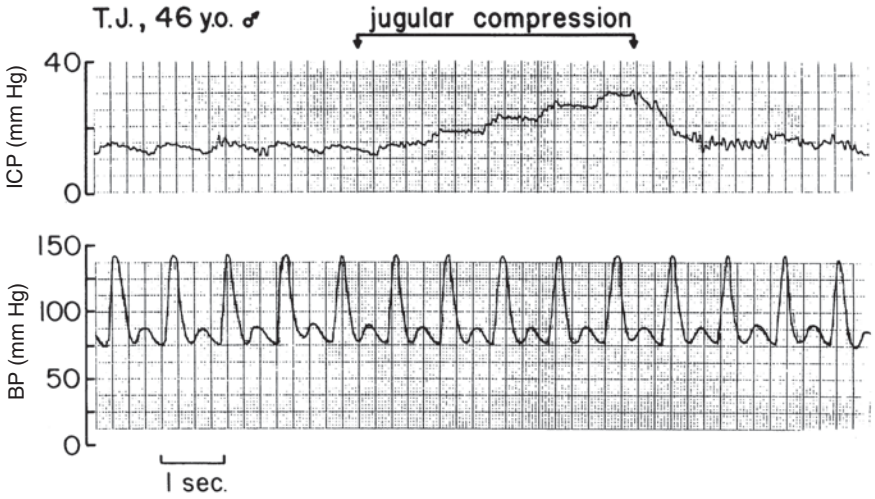

Figure 63-5 The effect of cerebral venous outflow obstruction on intracranial pressure (ICP) in a patient with an intracerebral hematoma. Bilateral jugular compression was applied briefly to verify the function of a newly placed ventriculostomy. The ICP response illustrates the importance of maintaining unobstructed cerebral venous drainage. BP, blood pressure.

good venous drainage is the norm in neurosurgical anesthesia and critical care. Obstruction of cerebral venous drainage by extremes of head position or circumferential pressure (e.g., Philadelphia collars, endotracheal tube ties) should be avoided. Phenomena occurring downstream from the venous structures of the neck also may be relevant, including any condition that can increase central venous pressure, such as positive end-expiratory pressure (PEEP) or cardiac failure. Anything that causes increased intrathoracic pressure can result in obstruction of cerebral venous drainage. Various commonplace events can lead to obstruction, including kinked or partially obstructed endotracheal tubes, tension pneumothorax, coughing or straining against the endotracheal tube, or gas trapping as a result of bronchospasm. These events also should be sought and remedied. Most practitioners carefully maintain paralysis during craniotomies, unless a contraindication is present, because a sudden cough can result in dramatic herniation of cerebral structures through the craniotomy.

Thereafter, the anesthesiologist should consider the arterial side of the circulation. Attention to the effect of anesthetic drugs and techniques on cerebral blood flow (CBF) (see Chapter 13) is an established part of neuroanesthesia. Such attention is relevant because increases in CBF generally are associated with increases in cerebral blood volume (CBV).[1-3] The notable exception to this rule occurs in the context of cerebral ischemia caused by hypotension or vessel occlusion, at which times CBV may increase as the cerebral vasculature dilates in response to a sudden reduction in CBF. The relationship generally applies, however, and attention to the control of CBF is relevant in situations in which volume compensation mechanisms are exhausted, or ICP is already increased. The general approach is to select anesthetics and control the physiologic parameters in a manner that avoids unnecessary increases in CBF. The parameters that influence CBF are listed in Table 63-2 and are discussed in Chapter 13.

Selection of Anesthetics

The question of which anesthetics are appropriate, especially in the context of unstable ICP, arises often. Chapter 13 provides relevant information in detail, and only broad generalizations are offered here. Generally, intravenous anesthetic, analgesic, and sedative drugs are associated with parallel reductions in CBF and cerebral metabolic rate (CMR) and do not have adverse effects on ICP. Ketamine, given in large doses to patients with a generally normal level of consciousness before anesthesia, may be the exception. Autoregulation and carbon dioxide (CO_2) responsiveness are generally preserved during the administration of intravenous drugs (see Chapter 13).

By contrast, all of the volatile anesthetics can be, depending on physiologic and pharmacologic circumstances, dose-dependent cerebral vasodilators. The order of vasodilating potency is approximately halothane >> enflurane > desflurane > isoflurane > sevoflurane. As noted in Chapter 13, the CBF differences among isoflurane, desflurane, and sevoflurane are probably not significant to the clinician. The net CBF effect of introducing a volatile anesthetic depends on the interaction of several factors, including the concentration of the anesthetic, the extent of previous CMR depression, simultaneous blood pressure changes acting in conjunction with previous or anesthetic-induced autoregulation abnormalities, and simultaneous changes in $Paco_2$ in conjunction with any disease-related impairment in CO_2 responsiveness.

Nitrous oxide (N_2O) is also a cerebral vasodilator, the CBF effect of which is the most profound when it is administered as a sole anesthetic, and least when it is administered against a back-

ground of narcotics, propofol, or benzodiazepines, and to a lesser extent when administered with volatile anesthetics (see Chapter 13). Nonetheless, experience dictates that N_2O and volatile anesthetics, the latter usually in concentrations less than the minimum alveolar concentration (MAC), when administered as components of a balanced anesthetic technique in combination with narcotics, can be used in most elective and many emergency neurosurgical procedures. Exceptions are rare, but when they occur (e.g., a somnolent, vomiting patient with papilledema, a large mass, and compressed basal cisterns, or a head injury victim with an expanding mass lesion or obliterated cisterns and sulci on CT scan), the clinician may be well advised to use a predominantly intravenous technique until the cranium and dura are open, and the effect of the anesthetic technique can be assessed by direct observation of the surgical field. Inhaled anesthetics are entirely acceptable components of most anesthetics for neurosurgery. In circumstances in which ICP is persistently elevated (in a closed-cranium procedure), or the surgical field is persistently "tight," N_2O and volatile anesthetics should be viewed as potential contributing factors,[4] however, and should be eliminated from the anesthetic in favor of intravenous anesthetics.

Muscle relaxants (see Chapter 29) that have the potential to release histamine (mivacurium, atracurium) should be given in small, divided doses. Although succinylcholine increases in ICP, these increases are small and transient. The increases can be blocked by a preceding dose of metocurine, 0.03 mg/kg[5] (and probably other nondepolarizers), and, in at least some instances, are not evident in patients with common emergency neurosurgical conditions (i.e., head injury, subarachnoid hemorrhage [SAH]).[6] In a clinical situation that calls for rapid relaxation for the purpose of controlling or protecting the airway, succinylcholine in conjunction with proper management of the airway and MAP is reasonable.

From the material just presented and the discussion of cerebral physiology in Chapter 13, a systematic clinical approach should follow readily. A schema for approaching the problem of an acute increase in ICP or acute deterioration in conditions in the surgical field is presented in Table 63-3. If the problem has not resolved satisfactorily after following the approach in Table 63-3, Table 63-4 presents other options.

Table 63-3 High Intracranial Pressure/"Tight Brain" Checklist

1. Are the relevant pressures controlled?
   - Jugular venous pressure
     - Extreme head rotation or neck flexion?
     - Direct jugular compression?
     - Head-up posture?
   - Airway pressure
     - Airway obstruction?
     - Bronchospasm?
     - Straining, coughing, adequately relaxed?
     - Pneumothorax?
   - $Paco_2$ and Pao_2
   - Arterial pressure
2. Is metabolic rate controlled?
   - Pain/arousal?
   - Seizures?
3. Are any potential vasodilators in use?
   - N_2O, volatile agents, nitroprusside, calcium channel blockers
4. Are there any unrecognized mass lesions?
   - Blood, air with or without N_2O

Table 63-4 Methods for Rapid Reduction of Intracranial Pressure and Brain Volume*

- Further titration of $Paco_2$ (≥25 mm Hg)
- CSF drainage (ventriculostomy, brain needle)
- Diuresis (usually mannitol)
- CMR suppression (barbiturates, propofol)
- MAP reduction (if dysautoregulation)
- Surgical control (i.e., removal of bone flap or lobectomy)

*After review of the checklist in Table 63-3.
CMR, cerebral metabolic rate; CSF, cerebrospinal fluid; MAP, mean arterial pressure.

CSF drainage was discussed earlier. The use of additional osmotic diuretics is theoretically limited by an upper acceptable osmolarity limit of approximately 320 mOsm/L. In extremis, the use is frequently empirical, however, and repeated doses (e.g., 12.5 g) are administered until a clinical response is no longer observed. Barbiturates have long been the most widely used drugs for inducing a reduction in CMR, with the objective of causing a coupled reduction in CBF and CBV. Propofol is gaining popularity for this application. Although the use of barbiturates is supported by intensive care unit (ICU) experience showing efficacy in ICP control[7] (if not outcome), no such experience has been accumulated for propofol. A frequently fatal syndrome of metabolic acidosis and rhabdomyolysis has been recognized in patients who have received prolonged propofol infusions in the ICU.[8,9] MAP reduction occasionally reduces vascular engorgement and reduces total brain bulk, but should be applied with extreme caution if patients have compromised intracranial collateral circulation. This approach is most likely to be relevant in the event of dysautoregulation occurring in the context of resection of arteriovenous malformations (AVMs) (see the later section on aneurysms and arteriovenous malformations).

Management of $Paco_2$

At the outset, the anesthesiologist and the surgeon should agree on the objectives with respect to $Paco_2$. Induction of hypocapnia is a time-honored part of the management of intracranial neurosurgical procedures. The rationale is principally that the concomitant reduction in CBF (see Fig. 13-4) and CBV results in a reduction in ICP, or "brain relaxation." The rationale is valid.[10] Two considerations should influence the clinician's use of hyperventilation, however. First, the vasoconstrictive effect of hypocapnia has the potential to cause ischemia in certain situations. Second, the CBF-lowering and ICP-lowering effect is not sustained.[11]

Hypocapnia-Induced Cerebral Ischemia

At first, clinicians were skeptical that hyperventilation could result in ischemia, and normal brain seems unlikely to be damaged by the typical clinical use of hyperventilation. This may not be the case, however, in certain pathologic conditions.

Normal Brain. Available data[12-16] indicate that in normal subjects, ischemia does not occur at a $Paco_2$ greater than 20 mm Hg. This generalization seems also to apply during induced hypotension.[17-19] Physiologic alterations, as evidenced by metabolic and electroencephalogram (EEG) abnormalities, have been observed,

however, in human volunteers[13,15,20] with severe hypocapnia. In one of these studies,[15] EEG abnormalities and paresthesias occurred in volunteers hyperventilating to $Paco_2$ values less than 20 mm Hg, and these effects were reversed by hyperbaric oxygenation, suggesting that they may truly have been caused by ischemia. Given that a $Paco_2$ of less than 20 to 25 mm Hg offers very little additional benefit in terms of improvement in intracranial compliance, it seems prudent to limit acute $Paco_2$ reduction to 25 mm Hg in previously normocapnic individuals. Normal brain should not be injured by this degree of hypocapnia.

Injured Brain. Although preventing herniation, maintaining ICP less than 20 mm Hg, minimizing retractor pressure, and facilitating surgical access remain priorities that may justify hypocapnia, evidence also is accumulating that hyperventilation is potentially deleterious and should not be overused. Available evidence indicates that hyperventilation can result in ischemia,[21-31] especially when baseline CBF is low,[32] as is commonly the case in the first 24 hours after injury.[33-39] An increased frequency of brain regions with very low CBF has been shown in head-injured patients who were acutely hyperventilated.[21,30,31] In addition, from centers that monitor jugular venous oxygen saturation ($Sjvo_2$), there have been numerous observations that low $Sjvo_2$ values can be increased, and that lactate levels in the jugular venous effluent can be decreased by reducing the degree of hyperventilation,[23,32,40] although the inability of $Sjvo_2$ monitoring to detect ischemia consistently also has been reported.[29-31]

At present, there is little information to confirm a deleterious effect of hyperventilation. The closest thing to "proof" resides in a subset analysis from a study of patients with moderate head injuries by Muizelaar and colleagues.[24] The study included a near-normocapnic group, in which $Paco_2$ was maintained at approximately 35 mm Hg, and a hypocapnic group, in which $Paco_2$ was maintained at approximately 25 mm Hg. Outcomes 3 and 6 months after injury revealed a poorer status in a subpopulation of the hyperventilation group. That subpopulation included patients with the best initial motor scores, a subgroup in which the severity of injury was such that they merited intubation by conventional criteria, but whose clinical condition may have been such that hyperventilation was not required for control of ICP and who had little to gain from hyperventilation.

Hyperventilation should not be an automatic component of every "neuroanesthetic." It should be treated in a manner any other therapeutic intervention. There should be an indication for instituting it (usually elevated or uncertain ICP or the need to improve conditions in the surgical field, or both). Hyperventilation should be used with the knowledge that it has the potential for causing an adverse effect, and as is the case with any other therapeutic intervention, it should be withdrawn as the indication for it subsides. The concern regarding the hazards of hypocapnia, which evolved in the context of head injury, has influenced all of neurosurgery. In particular, hyperventilation is now widely avoided in the management of SAH because of the low-CBF state that is known to occur.[41] In addition, brain tissue beneath retractors can have a similarly reduced CBF.[26,42]

Duration of Hypocapnia-Induced Reduction in Cerebral Blood Flow

The effect of hypocapnia on CBF is not sustained. Figure 63-6 is a nonquantitative representation of changes in CBF and CSF pH occurring in association with a sustained period of hyperventilation. With the onset of hyperventilation, the pH of CSF and the brain's extracellular fluid space increases, and CBF decreases abruptly. The cerebral alkalosis is not sustained, however. By alterations in the function of the enzyme carbonic anhydrase, the concentration of bicarbonate in CSF and the brain's extracellular fluid space is reduced, and in a time course of 6 to 18 hours, the pH of these compartments returns to normal.[43] Simultaneously, CBF returns toward normal levels.[43,44]

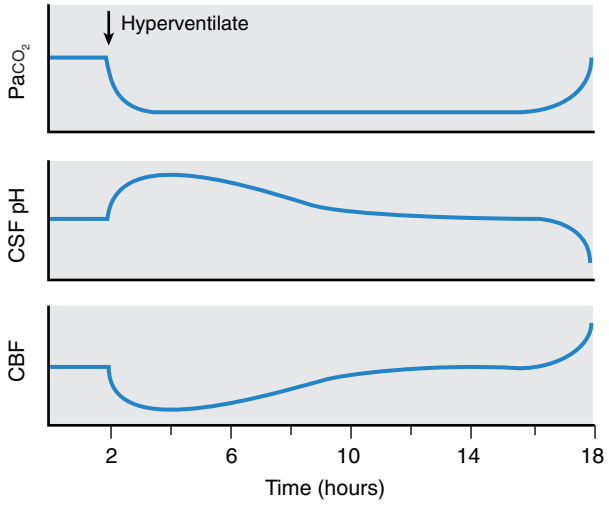

Figure 63-6 $Paco_2$, cerebral blood flow (CBF), and cerebrospinal fluid (CSF) pH changes with prolonged hyperventilation. Although the decreased arterial $Paco_2$ (and the systemic alkalosis) persist for the duration of hyperventilation, the pH of the brain and CBF return toward normal over 8 to 12 hours.

The implications are twofold. First, the clinician ideally should hyperventilate patients for only as long as a reduction in brain volume is required. Prolonged, but unnecessary, hyperventilation may lead to a circumstance wherein subsequent clinical events call for additional maneuvers to reduce the volume of the intracranial contents. However, if carbon dioxide tension is already in the 23 to 25 mm Hg range, it would be difficult to impose sufficient additional hyperventilation to once again accomplish the original reduction in CBF without the hazard of pulmonary barotrauma. Second, in a patient who has been hyperventilated for a sustained period (e.g., 2 days in the ICU), rapid restoration of $Paco_2$ from values in the vicinity of 25 mm Hg to typical normal values (e.g., 40 mm Hg) ideally should be accomplished slowly. A sudden increase in $Paco_2$ from 25 to 40 mm Hg in an individual who has been chronically hyperventilated would have the same physiologic effect that a rapid change from 40 to 55 mm Hg would have in a previously normocapnic subject. If hypocapnia has been required as an adjunct to brain relaxation during craniotomy, $Paco_2$ also should be allowed to increase when the retractors are removed (if dural closure requirements permit) to minimize the residual intracranial pneumatocele (see later section on pneumocephalus).

Management of Arterial Blood Pressure

Acceptable blood pressure limits should be agreed on at the beginning of a neurosurgical procedure. A prominent theme of contemporary neurosurgery is that CPP should be maintained at normal or even high-normal levels after acute central nervous

system insults and during most intracranial neurosurgical procedures. This concept has evolved from the growing understanding that CBF is frequently very low in some brain regions after acute neurologic insults, in particular, head injury (see discussion in the later section on head injury) and SAH. Two additional factors should be considered. The first is that the autoregulatory response to decreasing blood pressure may not be intact throughout the brain. Figure 63-7 depicts the ischemic hazard that attends the circumstance of a low resting CBF and absent autoregulation even at blood pressure levels considered safe when autoregulation is intact. Second, there is the understanding that maintenance of arterial pressure also is relevant to brain compressed under retractors[26] because the effective perfusion pressure there is reduced by increased local tissue pressure.

Although little other than anecdotal data support the notion, we believe that an aggressive attitude toward blood pressure support should be extrapolated to patients who have sustained a recent spinal cord injury, to patients whose spinal cord is under compression or at risk for compression or vascular compromise because of a disease process (most commonly cervical spinal stenosis with or without ossification of the posterior longitudinal ligament) or an intended surgical procedure, and to patients undergoing surgery involving retraction of the spinal cord. Were we empowered to "legislate" the standard of care, we would mandate that blood pressure during anesthesia in these patients be maintained as close as possible to, and certainly within 10% of, average awake values.

Steroids

The administration of steroids for the purpose of reducing or limiting the formation of edema is another time-honored practice in neurosurgery. The efficacy of steroids in reducing the edema and increasing blood-brain barrier permeability associated with tumors is well confirmed.[45-47] The time course of this effect is rapid, although not so rapid that it is relevant to the management of acute intraoperative events. Administration beginning 48 hours before an elective surgical procedure has the potential, however, to reduce edema formation and improve the clinical condition by the time of craniotomy.[45,48,49]

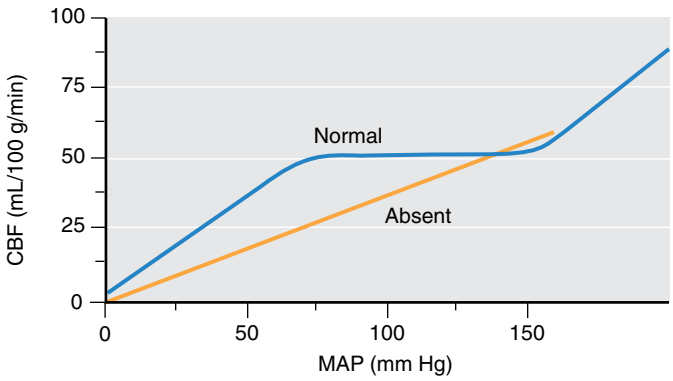

Figure 63-7 Normal and absent autoregulation curves. The "absent" curve indicates a pressure-passive condition in which cerebral blood flow (CBF) varies in proportion to cerebral perfusion pressure. This curve is drawn to indicate subnormal CBF values during normotension, as have been shown to occur immediately after head injury[23] and subarachnoid hemorrhage.[41] The potential for modest hypotension to cause ischemia is apparent. MAP, mean arterial pressure.

Although clinical improvement—specifically, a decreased frequency of ICP plateau waves and an improvement in the pressure-volume response (the increment in ICP in response to a standardized intracranial volume challenge)—occurs within 24 hours,[48] a reduction in ICP may not occur for 48 to 72 hours after the initiation of therapy.[48] This finding has been interpreted to indicate that steroids in some way improve the "viscoelastic properties" of the intracranial space before a reduction in edema occurs, although the mechanism is undefined.[49] Steroids are often given intraoperatively and postoperatively to maintain the effects achieved by preoperative treatment. The practice of administering steroids to adult head injury patients has been abandoned as a result of controlled trials that showed either no benefit or deleterious effects.[50]

Diuretics

Diuretics are used widely in neurosurgery to reduce the volume of the brain's intracellular and extracellular fluid compartment. It is probably largely the extracellular compartment that is influenced because neurons and glia have quick and efficient cell volume regulation mechanisms. Osmotic and loop diuretics have been employed. Although data suggest that loop diuretics can be effective,[51] osmotic diuretics, principally mannitol, are preferred clinically because of their speed and efficacy. The only U.S. Food and Drug Administration approved osmotic diuretic available on most formularies is mannitol. Hypertonic saline is an understudied alternative for which there is a small favorable experience and some enthusiasm in the neurosurgical community.[52,53] There is no confirmation of superiority to mannitol, however.

Data indicate that mannitol enters brain and, over a short time course, appears in the CSF space.[54] The possibility that the mannitol that gains access to the parenchyma aggravates swelling has resulted in varying degrees of reluctance among clinicians to administer mannitol.[55] Nonetheless, most clinicians find it a mainstay of ICP management. There is the concern that mannitol is effective only when some degree of blood-brain barrier integrity is preserved in a significant portion of the brain. Most clinicians respond to this concern by making empirical use of this agent (i.e., if it is effective in reducing ICP or improving conditions in the surgical field, repeated doses can be administered). If it is ineffective (or if serum osmolarity reaches the traditional limit of 320 mOsm/L), its administration is withheld.

The doses of mannitol employed vary from 0.25 g/kg to 100 g "for all comers"; 1.0 g/kg seems to be the most common dose. A systematic study in head-injured patients showed, however, that an equivalent initial ICP-reducing effect can be achieved with 0.25 g/kg, although that effect may not be as well sustained as with greater doses.[56] Mannitol should be administered by infusion (e.g., over 10 to 15 minutes). Sudden exposure of the cerebral circulation to extreme hyperosmolarity can have a vasodilatory effect, which can produce brain engorgement and increased ICP that does not occur with slower infusions.

Some clinicians advocate the combined administration of a loop diuretic (usually furosemide) and an osmotic diuretic. The superficial rationale is that mannitol establishes an osmotic gradient that draws fluid out of brain parenchyma, and that the furosemide, by hastening excretion of water from the intravascular

space, facilitates the maintenance of that gradient. A second mechanism may add additional justification for the practice of combining the two agents. Neurons and glia, as mentioned earlier, seem to have powerful homeostatic mechanisms to ensure regulation of cell volume. Neurons and glia that shrink in response to an increased osmolarity in the external environment recover their volume rapidly as a consequence of the accumulation of so-called idiogenic osmoles that serve to minimize the gradient between the internal and external environment. One of those idiogenic osmoles is chloride. The loop diuretics inhibit the chloride channel through which this ion must pass and retard the normal volume-restoring mechanism.[57,58]

The normal volume regulatory mechanisms of neurons and glia also may be relevant to the phenomenon of rebound swelling. Rebound is commonly attributed to the prior use of mannitol and assumed to be a function of the accumulation of mannitol in cerebral tissue. Although this may be part of the story, the rebound may be "hypertonic rebound," rather than "mannitol rebound." After a sustained period of hyperosmolarity of any etiology, rebound swelling of neurons and glia (which have accumulated idiogenic osmoles) may occur in the event that systemic osmolarity decreases rapidly toward normal levels. It is well known that rebound cerebral swelling can occur after an episode of extreme increases in blood glucose concentration. Hypertonic saline rather than mannitol may not obviate this phenomenon.

Anticonvulsants

The general principle is that any acute irritation of the cortical surface has the potential to result in seizures; this includes acute neurologic events such as head injury and SAH.[59,60] Cortical incisions and brain surface irritation by retractors may similarly be potential foci. Given the benign nature of diphenylhydantoin, routine administration in patients undergoing most supratentorial craniotomies and in patients who have sustained a significant recent head injury[59] or SAH seems appropriate in the absence of a contraindication. Diphenylhydantoin should be administered at rates not more rapid than 50 mg/min. There is no need for rapid administration to prevent *postoperative* seizures, and it should be administered at a significantly slower rate.

Positioning

The intended surgical position and the necessary position aids should be agreed on at the outset. Table 63-5 lists the commonly used positions and positioning aids and supports (see also Chapter 36).

General Considerations

The prolonged duration of many neurosurgical procedures should be taken into account in all positions. Pressure points should be identified and padded carefully. Pressure and traction on nerves must be avoided. Given the high risk of thromboembolic complications in neurosurgical patients, precautions including support hose and sequential compression devices are indicated. For cranial procedures, almost invariably some component of head-up posturing (e.g., 15 to 20 degrees) is appropriate to ensure optimal venous drainage. The conspicuous exception occurs with evacuation of a chronic subdural hemorrhage, after which patients are usually nursed flat to discourage reaccumulation. Patients also are often maintained flat after CSF shunting to avoid too-rapid collapse of the ventricles.

Table 63-5 Common Neurosurgical Positions and Positioning Aids

Positions
Supine
Lateral (park bench)
Semilateral (Janetta)
Prone
Sitting
Positioning Aids and Supports
Pin (Mayfield) head holder
Radiolucent pin head holder
Horseshoe head rest
Foam head support (e.g., Voss, O.S.I., Prone-View)
Vacuum mattress ("bean bag")
Wilson-type frame
Andrews ("hinder binder")-type frame
Relton-Hall (four-poster) frame

Supine

The supine position is used with the head neutral or rotated for frontal, temporal, or parietal access. Extremes of head rotation can obstruct the jugular venous drainage, and a shoulder roll can attenuate this problem. The head is usually in a neutral position for bifrontal craniotomies and transsphenoidal approaches to the pituitary. The head-up posture is best accomplished by adjusting the operating table to a chaise lounge (lawn chair) position (flexion, pillows under the knees, slight reverse Trendelenburg). This orientation, in addition to promoting cerebral venous drainage, decreases back strain.

Semilateral

The semilateral position, also known as the Janetta position after the neurosurgeon who popularized its use for microvascular decompression of the fifth cranial nerve, is used for retromastoid access. It is achieved by lateral tilting of the table 10 to 20 degrees combined with a generous shoulder roll. Extreme head rotation, sufficient to cause compression of the contralateral jugular by the chin, should be avoided.

Lateral

The lateral position can be used for access to the posterior parietal and occipital lobes and the lateral posterior fossa, including tumors at the cerebellopontine angle and aneurysms of the vertebral and basilar arteries. An axillary roll is important for preventing brachial plexus injury.

Prone

The prone position is used for spinal cord, occipital lobe, craniosynostosis, and posterior fossa procedures. The prone position also has been referred to, aptly, as the Concorde position because, for cervical spine and posterior fossa procedures, the final position commonly entails neck flexion, reverse Trendelenburg, and elevation of the legs. This orientation brings the surgical field to a horizontal position.

The anesthesiologist should have a plan for detaching and reattaching monitors in an orderly manner to prevent an excessive monitoring "window." Awake tracheal intubation and prone positioning can be employed in patients with an unstable cervical

spine, in whom an unchanged neurologic status should be confirmed before induction of anesthesia in the final surgical position. It also is occasionally done in very obese patients.

The head can be positioned in a pin head holder (applied before the turn), a horseshoe head rest, or a disposable foam head rest. A complication of the prone position is retinal ischemia and blindness owing to orbital compression causing central retinal vessel occlusion; constant attention must be directed toward avoiding this complication. It must be intermittently confirmed (e.g., every 15 minutes), and confirmed after any surgery-related head or neck movement that pressure has not come to bear on the eye.

Not all postoperative visual loss is a result of direct orbital compression, however. Ischemic optic neuropathy (ION) seems to be a more frequent cause of postoperative visual loss than pressure causing occlusion of central retinal vessels. The cause-and-effect relationships associated with ION are uncertain, but low arterial pressure, low hematocrit, and lengthy surgical procedures are statistically associated with the phenomenon.[61] Ophthalmologists have long recognized the phenomenon of anterior ION in nonanesthetized patients, and have identified as risk factors many causes of vascular disease (e.g., hypertension, diabetes, smoking, hyperlipidemia) and hypotension, especially when it occurs in hypertensives.[62,63] It also is suspected that certain normal anatomic and physiologic variations, including poor collateralization or absence of autoregulation of the vasculature of the optic nerve head,[62] a small and anatomically "crowded" optic nerve head (the "disk at risk"[64]), an increase in intraocular pressure that has been observed to occur during prolonged prone spine surgery,[65] and impaired cerebral venous drainage,[66] may contribute to the intraoperative occurrence of ION. The notion that ION is merely a function of arterial hypotension is probably an inaccurate oversimplification of a phenomenon that almost certainly involves the interplay of numerous preoperative and intraoperative factors.[67,68]

Direct pressure also can result in various degrees of pressure necrosis of the forehead, maxillae, and chin, especially with prolonged spinal procedures. The clinician should ensure that pressure is as evenly distributed as possible over facial structures. Other pressure points to be checked include the axillae, breasts, iliac crests, femoral canals, genitalia, knees, and heels. When the arms are placed in the "stick-em up" position, traction on the brachial plexus must be avoided. That can usually be accomplished by not exceeding a "90-90" position (arms abducted not greater than 90 degrees; elbows extended not greater than 90 degrees) with care taken to ensure that the elbow is anterior to the shoulder to prevent wrapping of the brachial plexus around the head of the humerus. An antisialogogue (e.g., glycopyrrolate) and adhesive (e.g., benzoin) may help reduce loosening of tape used to secure the endotracheal tube.

An objective during prone positioning, especially for lumbar spine surgery, is the avoidance of compression of the inferior vena cava. Impairment of vena caval return diverts blood to the epidural plexus and increases the potential for bleeding during spinal surgery. Optimizing venous return is an objective of all of the spinal surgery frames and is accomplished very effectively by the Relton-Hall, Wilson, and Andrews variants. Use of these frames introduces a risk of air embolism,[69,70] although clinical occurrences have been very rare.[71]

Attention should be directed toward preventing injury to the tongue in the prone position. With cervical and posterior fossa procedures, it is frequently necessary to flex the neck substantially to facilitate surgical access. This flexion reduces the anterior-posterior dimension of the hypopharynx, and compression ischemia of the base of the tongue (and the soft palate and posterior wall of the pharynx) can occur in the presence of foreign bodies (i.e., endotracheal tube, esophageal stethoscope, oral airway). The consequence can be macroglossia, caused by accumulation of edema after reperfusion of the ischemic tissue causing postextubation airway obstruction of rapid onset (see later). Unnecessary paraphernalia in the oral cavity and pharynx should be avoided. Omitting the oral airway entirely is unwise because the tongue may then protrude between and be trapped by the teeth as progressive swelling of facial structures occurs during a prolonged prone procedure. A rolled gauze bite block prevents this problem without adding bulk to the hypopharynx.

Sitting

There have been several reviews of large experiences with the sitting position.[72-76] All concluded that the sitting position can be employed with acceptable rates of morbidity and mortality. These reports were prepared by groups that perform 50 to 100 or more of these procedures per year, however, and the hazards of the sitting position may be greater for teams who have less frequent occasion to use it. With increasing frequency, the sitting position is being avoided through the use of one of its alternatives (i.e., prone, semilateral, lateral). We are likely to continue encountering it, however, because even surgeons who are inclined to use alternative positions may opt for the sitting position when access to midline structures (i.e., the floor of the fourth ventricle, the pontomedullary junction, and the vermis) is required. Nonetheless, alternative positions for posterior fossa surgery exist and should be considered when there are contraindications to the sitting position.

Achieving the Sitting Position. A properly positioned patient is more commonly in a modified recumbent position as shown in Figure 63-8, rather than truly sitting. The legs should be kept as high as possible (usually with pillows under the knees) to promote venous return. Ideally, the head holder should be attached to the back portion of the table (see Fig. 63-8A), rather than to the portions under thighs or legs (see Fig. 63-8B). This permits lowering of the head, and closed chest massage if necessary, without the necessity of first taking the patient out of the head holder.

When procedures are performed in the sitting position, the clinician should think in terms of measuring and maintaining perfusion pressure at the level of the surgical field. This is best accomplished by referencing transducers to the interaural plane. If a manual blood pressure cuff on the arm is employed, a correction* to allow for the hydrostatic difference between the arm and the operative field should be applied.

A series of hazards are associated with the sitting position. Circulatory instability, macroglossia, and quadriplegia are discussed in this section. Pneumocephalus is discussed in the section on pneumocephalus. Venous air embolism (VAE) and paradoxical air embolism (PAE) are discussed in the section on venous air embolism. Several of these hazards also are relevant when cervical spine and posterior fossa procedures are done in nonsitting positions, but occur with greater frequency in the sitting position.

*A column of water 32 cm high exerts a pressure of 25 mm Hg.

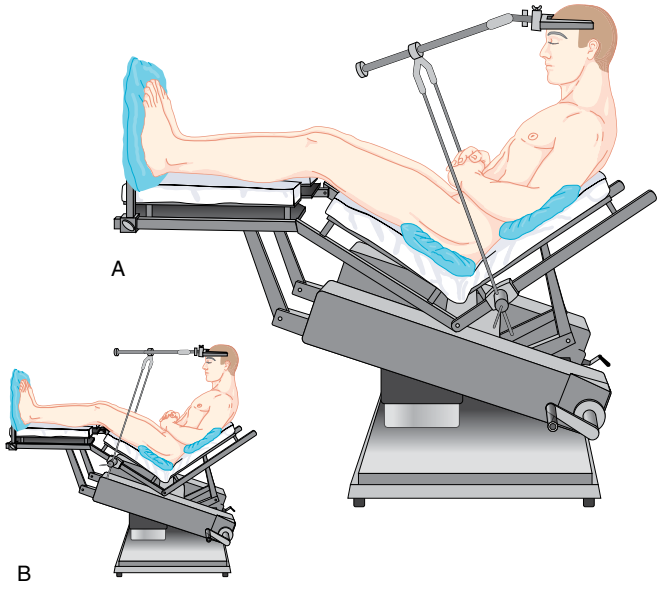

Figure 63-8 **A** and **B,** The sitting position. The patient is typically semirecumbent rather than sitting. In **A,** the head holder support is correctly positioned such that the head can be lowered without the need to detach the head holder first. The configuration in **B,** with the support attached to the thigh portion of the table, should be avoided. *(From Martin JT: Positioning in Anesthesia and Surgery. Philadelphia, WB Saunders, 1988.)*

Cardiovascular Effects of the Sitting Position. Placing the anesthetized patient in the sitting position conveys some risk of impaired cardiovascular function, in particular, hypotension. Pressor administration is required in some patients. Measures to avoid hypotension include prepositioning hydration, wrapping of the legs with elastic bandages to counteract gravitational shifts of blood, and slow, incremental adjustment of table position. Aggressive volume loading and the G suit (also known as pneumatic antishock trousers or military antishock trousers) attenuate the effects of assuming the sitting position.[77-79] Neither of these measures has been widely applied, however.

In most healthy subjects, the hemodynamic changes are of a nonthreatening magnitude. In a study of healthy anesthetized adult subjects, 22 to 64 years old, Marshall and colleagues[80] observed modest changes. MAP was relatively unaffected, whereas wedge pressure, stroke volume, and cardiac index decreased—the last-mentioned by approximately 15%—although there was some variation with the anesthetic drugs employed. The combination of an unchanged MAP (which generally requires the use of a "light," high sympathetic tone anesthetic) and a reduced cardiac index implies that systematic vascular resistance increased. Their calculations and the observations of other investigators[81] reveal significant elevation of systematic vascular resistance. For patients in whom an abrupt increase in systematic vascular resistance may be poorly tolerated, the sitting position may represent a physiologic threat, and alternative positions should be considered. A pulmonary arterial catheter may be warranted when there is clinical or historical evidence of antecedent coronary artery or valvular heart disease and arbitrarily in patients older than 60 to 65 years.

During procedures performed in the sitting position, MAP should be corrected to head level to obtain a meaningful index of CPP. Specifically, CPP (MAP − estimated ICP) should be maintained at a minimum value of 60 mm Hg in healthy patients in whom it is reasonable to assume a normal cerebral vasculature. The safe lower limit should be increased for elderly patients, for patients with hypertension or known cerebrovascular disease, and for patients with degenerative disease of the cervical spine or cervical spinal stenosis who may be at risk for decreased spinal cord perfusion, and in the event that substantial or sustained retractor pressure must be applied to brain or spinal cord tissue.

Macroglossia. There have been sporadic reports of upper airway obstruction after posterior fossa procedures in which swelling of pharyngeal structures, including the soft palate, posterior wall, pharynx, and base of the tongue, has been observed.[82] These episodes have been attributed to edema formation at the time of reperfusion after trauma or prolonged ischemia occurring as the result of foreign bodies (usually oral airways) causing pressure on these structures in the circumstances of lengthy procedures with sustained neck flexion (which is usually required to improve access to posterior structures). It is customary (and we think ideal, although there is no science to support the practice) to maintain at least two fingerbreadth's distance between the chin/mandible and the sternum/clavicle to prevent excessive reduction of the anterior-posterior diameter of the oropharynx. In addition, we position patients with the oral airway in place and then, after the final head position is achieved, withdraw it until its tip functions as a bite block between the teeth. The macroglossia phenomenon also may be relevant as clinicians contemplate the use of transesophageal echocardiography (TEE) in the neurosurgery suite. The centers that routinely employ TEE in neurosurgery, for the most part, use either pediatric or custom-made small-diameter probes to avoid trauma to pharyngeal and perilaryngeal structures.

Quadriplegia. The sitting position per se has been implicated as a cause of rare instances of unexplained postoperative paraplegia. It has been hypothesized[83] that the neck flexion that is a common concomitant of the seated position may result in stretching or compression of the cervical spinal cord. This possibility may represent a relative contraindication to the use of this position in patients with significant degenerative disease of the cervical spine, especially when there is evidence of associated cerebrovascular disease. The implications for blood pressure management are mentioned in the preceding section on cardiovascular effects. It also may represent a justification for somatosensory evoked response monitoring during the positioning phase of a sitting procedure for patients perceived to be at high risk.

Pneumocephalus

The issue of pneumocephalus arises most often in connection with posterior fossa craniotomies performed with a head-up posture.[84,85] During these procedures, air may enter the supratentorial space, much as air enters an inverted bottle. Depending on the relationship of the brainstem and temporal lobes to the incisura, the pressure in the air collection may or may not be able to equilibrate with atmospheric pressure. This phenomenon has relevance to the use of N_2O because any N_2O that enters a trapped gas space would augment the volume of that space. In (probably

uncommon) intraoperative circumstances in which there is a completely closed intracranial gas space, the use of N_2O may result in an effect comparable to that of an expanding mass lesion. We do not view N_2O as absolutely contraindicated because, before dural closure, intracranial gas is probably only rarely trapped. Nonetheless, attention to this possibility is important when one is presented with the problem of an increasingly "tight" brain during a posterior fossa craniotomy.[86,87]

During a posterior fossa procedure done in a head-up posture, when surgical closure has reached a stage such that the intracranial space has been completely sealed from the atmosphere, N_2O should not be given because of the possibility of contributing to a tension pneumocephalus. The use of N_2O up to the point of dural closure may represent a clinical advantage[88] because the gas pocket can be expected to shrink more rapidly owing to the presence of N_2O (because N_2O diffuses out much more quickly than nitrogen does). Tension pneumocephalus is often naively viewed as exclusively a function of the use of N_2O. Tension pneumocephalus can occur, however, as a complication of intracranial neurosurgery entirely *un*related to the use of N_2O.[89]

Tension pneumocephalus is one of the causes of delayed awakening or nonawakening after posterior fossa and supratentorial procedures (Fig. 63-9).[89,90] It occurs because air enters the cranium while the patient is in a head-up position at a time when the volume of the intracranial contents has been reduced as a result of some combination of hypocapnia, good venous drainage, osmotic diuresis, and CSF loss from the operative field. When the cranium is closed, and the patient is returned to the near-supine position, CSF, venous blood volume, and extracellular fluid return or reaccumulate, and the air pocket becomes an unyielding mass lesion (because of the very slow diffusion of nitrogen). This mass may cause delayed recovery of consciousness or severe headache. Among supratentorial craniotomies, the largest residual airspaces occur after frontal skull base procedures in which energetic brain relaxation measures are used to facilitate subfrontal access (see Fig. 63-9). At the end of these procedures, typically done in a supine/brow-up position, it is not feasible to fill the intracranial dead space with normal saline as is commonly done with smaller craniotomy defects, and there may be a large residual pneumatocele. We doubt that the possible occurrence of this phenomenon represents a contraindication to N_2O. Withdrawal of N_2O may be appropriate at the time of cranial closure, however. The diagnosis of pneumocephalus is confirmed by a brow-up lateral x-ray or CT scan. The treatment is a twist-drill hole followed by needle puncture of the dura.

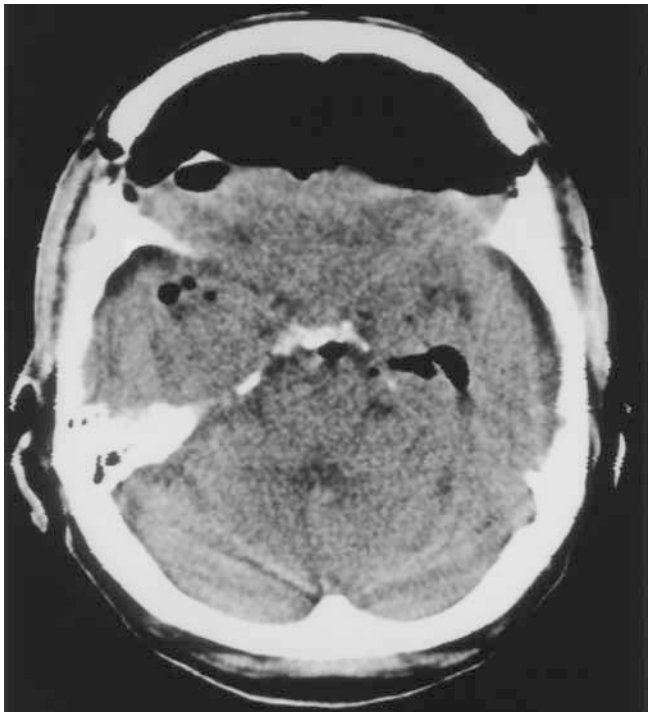

Figure 63-9 Postoperative CT scan shows a large pneumocephalus after a subfrontal approach to a suprasellar glioma. Immediately postoperatively, the patient was confused and agitated and complained of severe headache.

Residual intracranial air should be considered at the time of repeat anesthesia, neurosurgical or non-neurosurgical. Air frequently remains evident on CT scan for more than 7 days after a craniotomy.[91] Pneumocephalus also can develop de novo in the postoperative period in patients who have a residual dural defect and a communication between the nasal sinuses and the intracranial space.[92]

Venous Air Embolism

The rate of occurrence of VAE varies according to the procedure, the intraoperative position, and the detection method used. During posterior fossa procedures done in the sitting position, VAE is detectable by precordial Doppler in approximately 40% of patients and by TEE in 76%.[93-96] The incidence of VAE during posterior fossa procedures performed in nonsitting positions is much less (12% using precordial Doppler in the report of Black and colleagues[74]), and it is probable, but unproven, that the average volume of air entrained per event also is smaller. The rate of VAE is apparently lower with cervical laminectomy (25% using TEE in the sitting position versus 76% for posterior fossa procedures[95]). Although VAE is principally a hazard of posterior fossa and upper cervical spine procedures, especially when they are performed in the sitting position, it can occur with supratentorial procedures. The most common situations involve tumors, most often parasagittal or falcine meningiomas, that encroach on the posterior half of the sagittal sinus (Fig. 63-10) and craniosynostosis procedures, typically performed in children.[97,98] Pin sites and trapped gas under pressure also can lead to VAE, although clinically relevant events have been very rare.

The common sources of critical VAE are the major cerebral venous sinuses, in particular, the transverse, the sigmoid, and the posterior half of the sagittal sinus, all of which may be noncollapsible because of their dural attachments. Air entry also may occur via emissary veins, particularly from suboccipital musculature, the diploic space of the skull (which can be violated by the craniotomy and pin fixation), and the cervical epidural veins. We believe, although this has not been confirmed by systematic study, that the VAE risk associated with cervical laminectomy is greatest when the exposure requires dissection of suboccipital muscle with the potential to open emissary veins to the atmosphere at their point of entry into occipital bone. There also is anecdotal evidence[99] that air under pressure in the ventricles or subdural space occasionally can enter the venous system, perhaps following the normal egress route of the CSF.

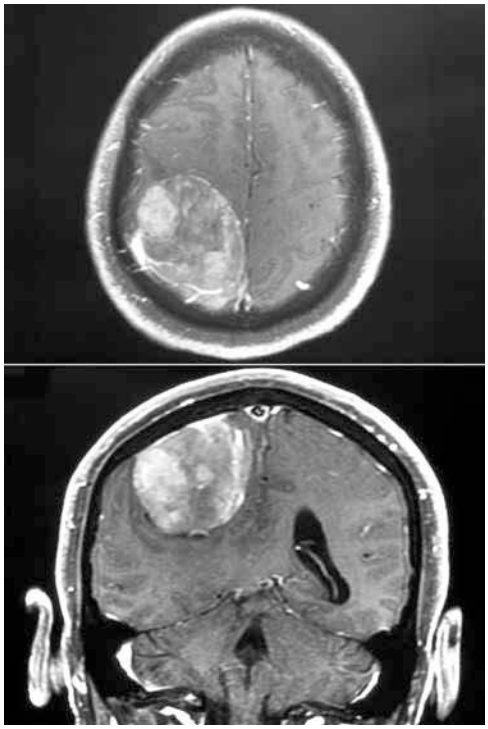

Figure 63-10 Horizontal (*top*) and coronal (*bottom*) MR images of a parasagittal meningioma. Resection of meningiomas arising from the dural reflection overlying the sagittal sinus or from the dura of the adjacent convexity or falx entails a risk of venous air embolism because of the proximity of the sagittal sinus (the triangular structure at the superior end of the interhemispheric fissure in the *bottom panel*).

Detection of Venous Air Embolism

The monitors employed for the detection of VAE should provide (1) a high level of sensitivity, (2) a high level of specificity, (3) a rapid response, (4) a quantitative measure of the VAE event, and (5) an indication of the course of recovery from the VAE event. The combination of a precordial Doppler and expired CO_2 monitoring meet these criteria and are the current standard of care. Doppler placement in a left or right parasternal location between the second and third or third and fourth ribs has a very high detection rate for gas embolization,[100] and when good heart tones are obtained, maneuvers to confirm adequate placement seem to be unnecessary. TEE is more sensitive than precordial Doppler to VAE (Fig. 63-11),[101] and offers the advantage of identifying right-to-left shunting of air.[95,102-104] Its safety during prolonged use (especially with pronounced neck flexion) is not well established, however. Expired nitrogen analysis is theoretically attractive. The expired nitrogen concentrations involved in anything less than catastrophic VAE are very small, however, and push the available instrumentation to the limits of its sensitivity (see Fig. 63-11).[105]

Figure 63-12 shows the physiologic and monitor response to an air embolic event. Table 63-6 presents an appropriate management response to such an event.

Right Heart Catheter

Essentially all patients who undergo sitting posterior fossa procedures should have a right heart catheter. Although catastrophic, life-threatening VAE is relatively uncommon, a catheter that permits immediate evacuation of an air-filled heart occasionally is the sine qua non for resuscitation. The latitudes are much wider

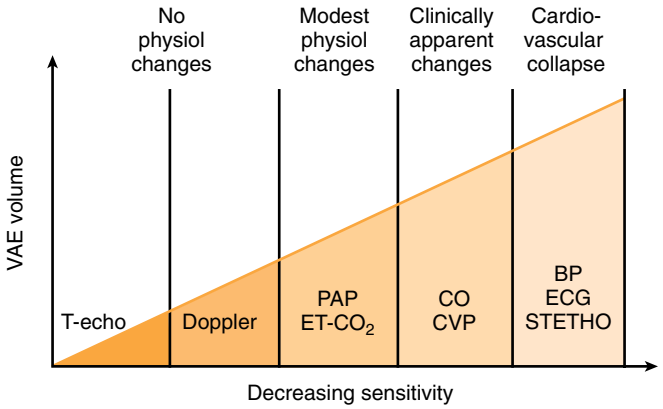

Figure 63-11 The relative sensitivity of various monitoring techniques to the occurrence of venous air embolism (VAE). BP, blood pressure; CO, cardiac output; CVP, central venous pressure; ECG, electrocardiogram, ET-CO_2, end-tidal carbon dioxide; PAP, pulmonary arterial pressure; physiol, physiological; T-echo, transesophageal echo.

with the nonsitting positions, and it is frequently appropriate, after a documented discussion with the surgeon, to omit the right heart catheter. The variables that contribute to this decision are the perceived risks of VAE associated with the intended procedure and the patient's physiologic reserve.

An example of a procedure for which the right heart catheter is usually omitted is microvascular decompression of the fifth cranial nerve for tic douloureux or the seventh cranial nerve for hemifacial spasm. The essentially horizontal semilateral position and the very limited retromastoid craniectomy these procedures require have resulted (at our institution) in a very low incidence of Doppler-detectable VAE. One should come to know the local surgical practices, however, particularly with respect to the degree of head-up posture, before becoming casual about omitting the right atrial catheter. With regard to the Janetta procedure, the necessary retromastoid craniectomy is performed in the angle between the transverse and sigmoid sinuses, and venous sinusoids and emissary veins in the suboccipital bone are common. If this procedure is performed with any degree of head-up posturing, the risk of VAE may still be substantial.

Which Vein Should Be Used for Right Heart Access. Although some surgeons may ask that neck veins not be used, a skillfully placed jugular catheter is usually acceptable. In a very few patients, high ICP may make the head-down posture undesirable. In others, unfavorable anatomy with an increased likelihood of a difficult cannulation and hematoma formation also may encourage the use of alternative access sites. Access to the brachial

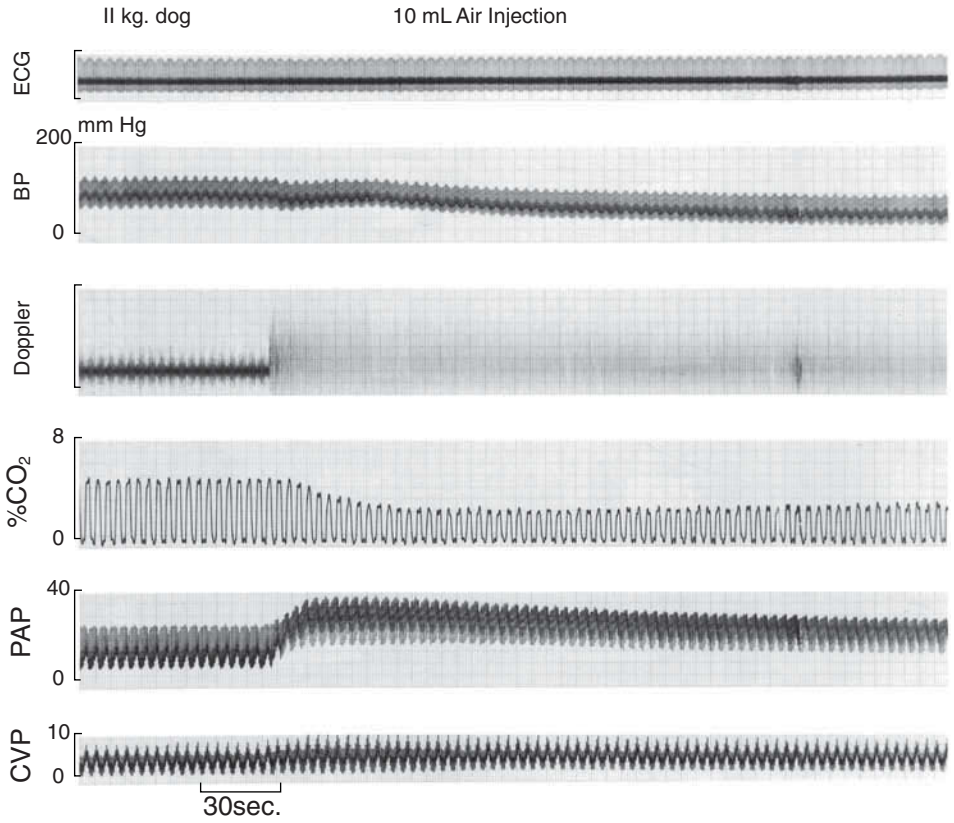

Figure 63-12 The responses of electrocardiogram (ECG), arterial pressure (blood pressure [BP]), pulmonary arterial pressure (PAP), pan-tidal carbon dioxide (CO_2) concentration, precordial Doppler, and central venous pressure (CVP) to the intravenous administration of 10 mL of air over 30 seconds to an 11-kg dog.

veins has been greatly facilitated by the commercial availability of multiorificed catheters that use a Seldinger cannulation technique and a lengthy J-tipped guidewire to negotiate the axilla or deltopectoral groove.

Positioning the Right Heart Catheter. Bunegin and colleagues[106] suggested that a multi-orificed catheter should be located with the tip 2 cm *below* the superior vena caval–atrial junction, and a single-orificed catheter should be located with the tip 3 cm *above* the superior vena caval–atrial junction. Although these small distinctions in location may be relevant for optimal recovery of small volumes of air when cardiac output is well maintained, for the recovery of massive volumes of air in the face of cardiovascular collapse, anywhere in the right atrium should suffice. Right heart placement can be confirmed by (1) x-ray, (2) pull back from the right ventricle while monitoring intravascular pressure, or (3) intravascular electrocardiogram (ECG).[107] Although there is no literature to support the practice, with catheter access via the right internal jugular vein, a measured placement to the level of the second or third right intercostal space should suffice when the catheter passes readily.

The intravascular ECG technique makes use of the fact that an ECG "electrode" placed in the middle of the right atrium initially "sees" an increasing positivity as the developing P-wave vector approaches it (Fig. 63-13), and then an increasing negativity as the wave of atrial depolarization passes and moves away from it. The resultant biphasic P wave is characteristic of an intra-atrial "electrode" position. The technique requires that the CVP catheter becomes an exploring ECG electrode. This is accomplished by filling the catheter with an electrolyte solution (bicarbonate is best) and attaching an ECG lead (the leg lead if lead II is selected) to the hub of the CVP catheter. Commercial CVP kits with an ECG adapter are available. The ECG configurations that are observed at various intravascular locations are shown in Figure 63-13. To minimize the microshock hazard, a battery-operated ECG unit is preferable, and unnecessary electric apparatus should be detached from the patient during catheter placement (see Table 63-6).

Paradoxical Air Embolism

There has been much concern about the possibility of the passage of air across the interatrial septum via a patent foramen ovale (known to be present in approximately 25% of adults).[108] The concern is that this phenomenon carries the risk of major cerebral or coronary morbidity, although there has been no precise definition of the morbidity that can realistically be attributed to PAE. Although the minimal pressure required to open a probe patent foramen ovale is not known with certainty, it is thought that the necessary gradient may be 5 mm Hg. In a clinical investigation, Mammoto and colleagues[104] observed that PAE occurred only in the context of major air embolic events, suggesting that significant increases in right heart pressures are an important predisposing factor of the occurrence of PAE.

Several clinical investigations have examined factors that influence the right atrial pressure (RAP) to left atrial pressure (LAP) gradient. The use of PEEP was shown to increase the inci-

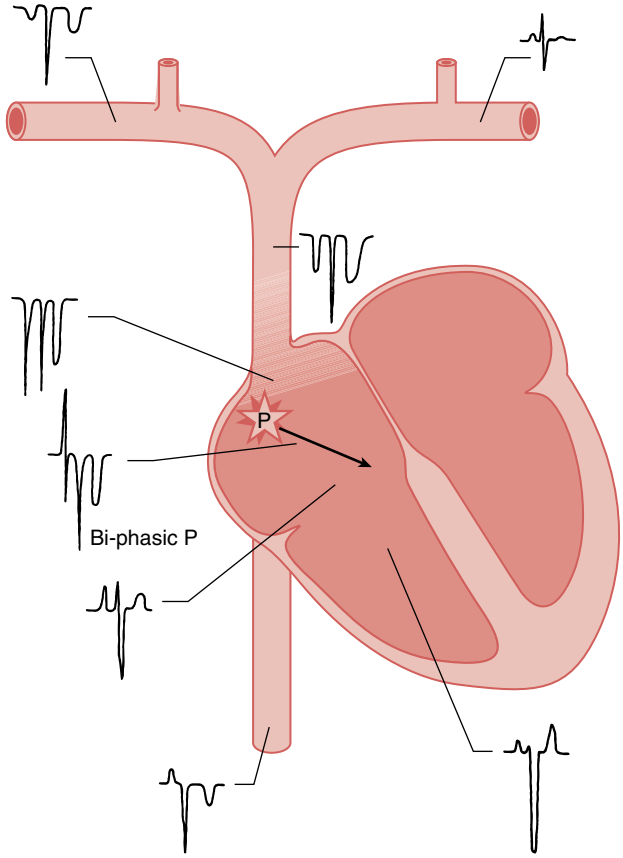

Figure 63-13 Electrocardiogram (ECG) configurations observed at various locations when a central venous catheter is used as an intravascular ECG electrode. The configurations in the figure are observed when "lead II" is monitored and the positive electrode (the leg electrode) is connected to the catheter. P indicates the sinoatrial node. The *heavy black arrow* indicates the P wave vector. Note the equi-biphasic P wave when the catheter tip is in the mid right atrial position.[107]

dence of a positive RAP to pulmonary wedge pressure gradient,[109] and generous fluid administration (e.g., 2800 mL/patient versus 1220 mL/control patient[110]) was shown to reduce it. As a result, the use of PEEP, which was previously advocated as a means of preventing air entrainment, diminished, and the practice of more generous fluid administration for patients undergoing posterior fossa procedures evolved. Subsequent data indicated, however, that even when *mean* LAP exceeds mean RAP, PAE can still occur because transient reversal of the interatrial pressure gradient can occur during each cardiac cycle.[111]

Some centers have advocated performing bubble studies preoperatively with either precordial echocardiography[96] or transcranial Doppler (TCD)[112] or prepositioning TEE[113] to identify patients with a patent foramen ovale with a view to using alternatives to the sitting position in this subpopulation.[95,114] Some centers thereafter advocate the use of TEE to identify PAE intraoperatively.[95,103] This practice is not universal,[76] however, and at the time of writing (2009) it is not a community-wide standard of care. Because the morbid events attributable to PAE have been infrequent, surgeons who are convinced that the sitting position is optimal for a given procedure[76] are loath to be dissuaded from using it on the basis of what may seem like the very minor possibility of an injury to the patient occurring by this mechanism.

Transpulmonary Passage of Air

Air apparently can occasionally traverse the pulmonary vascular bed to reach the systemic circulation.[115,116] Transpulmonary passage is more likely to occur when large volumes of air are presented to the pulmonary vascular "filter."[117,118] There is also evidence suggesting that pulmonary vasodilators, including volatile anesthetics, may decrease the threshold for transpulmonary passage.[117-119] Differences among anesthetics are negligible. N_2O should be discontinued promptly after even apparently minor VAE events, however, because of the possibility that air may reach the left-sided circulation via a patent foramen ovale or the pulmonary vascular bed.

Techniques for Reducing the Incidence of Venous Air Embolism

As noted previously, PEEP has been advocated in the past as a means of reducing the incidence of VAE or of responding to an acute VAE event to prevent further air entry. Perkins and Bedford[109] suggest that PEEP increases the risk of PAE, however, and argue against the use of PEEP in seated neurosurgical procedures. As these authors point out, even 10 cm of PEEP would be unlikely to result in positive venous pressures in cerebral venous structures, which may be 25 cm above the heart. The ineffectiveness of PEEP[120] and the relative superiority of jugular venous compression[121,122] in increasing cerebral venous pressures have been confirmed by several investigations. An inflatable neck tourniquet available for rapid inflation in the event of VAE has been studied in animals and used in humans by Pfitzner and McLean.[123] There are additional arguments against the acute use of increased positive airway pressure in the event of VAE. The release of a Valsalva maneuver promotes paradoxical embolism. In addition, the impairment of systemic venous return caused by the sudden application of substantial PEEP may be undesirable in the face of the cardiovascular dysfunction already caused by the VAE event.

It has been associated that a patient who has sustained a hemodynamically significant VAE should be placed in a lateral position with the right side up. The rationale is that air would remain in the right atrium, where it would not contribute to an air lock in the right ventricle, and where it would remain amenable to recovery via a right atrial catheter. The first difficulty is that this repositioning is all but impossible with a patient in a pin head holder. In addition, the only systematic attempt to examine the efficacy of this maneuver, albeit performed in dogs, failed to identify any hemodynamic benefit.[124]

Nitrous Oxide. N_2O diffuses into air bubbles trapped in the vascular tree; N_2O should be eliminated after a clinical VAE event to avoid aggravating the cardiovascular impact. As noted earlier, the PAE phenomenon adds an additional reason for eliminating N_2O *after* the occurrence VAE. When major VAE occurs, no matter how the RAP-LAP gradient was manipulated before the event, RAP increases abruptly with respect to LAP,[125] and major VAE results in an acutely increased risk of PAE in patients with a patent foramen ovale.[104] Should N_2O be used at all in patients at risk for VAE? Some clinicians may decide that it is the "path of least resistance" simply to avoid it, and to avoid having to worry

about the considerations it creates. N_2O can be used, however, with the knowledge that it neither increases the incidence of VAE[126] nor aggravates the hemodynamic response to VAE, provided that it is eliminated when VAE occurs.[127]

Monitoring

Neurologic monitoring techniques are discussed in Chapter 46. Invasive monitoring is frequently appropriate in neurosurgery Table 63-7 lists indications for an arterial catheter.

Patients with increased ICP may be intolerant of the vascular engorgement associated with sudden hypertension occurring as a consequence of light anesthesia. Surgical relief of increased ICP may be associated with sudden hypotension as brainstem compression is relieved. Beat-by-beat arterial pressure monitoring also serves as an important monitor of depth of anesthesia and as an early warning system for neurologic injury. Much of the brain is insensate. Consequently, the intracranial portion of many neurosurgical procedures is not very stimulating, and to achieve circulatory stability, light anesthesia is often necessary. The anesthesiologist should be constantly aware of the possibility of sudden arousal (most often associated with cranial nerve traction or irritation). This is especially important when paralysis is precluded by the use of electromyographic recording from facial muscles to monitor cranial nerve integrity. Blood pressure responses may reveal imminent arousal. Blood pressure responses also may serve to warn a surgeon of excessive or unrecognized irritation, traction, or compression of neurologic tissue.

Table 63-7 Relative Indications for Intra-arterial Pressure Monitoring

Elevated ICP
Ischemia or incipient ischemia of neurologic tissue
Recent SAH
Recent head injury
Recent spinal cord injury
Intended or potential temporary vessel occlusion
Circulatory instability
Trauma
Spinal cord injury (spinal shock)
Sitting position
Possible barbiturate coma
Possibility of induced hypotension
Possibility of induced hypertension
Anticipated/potential major blood loss
Aneurysm clipping
Arteriovenous malformations
Vascular tumors
Tumors involving major venous sinuses
Craniofacial reconstruction
Extensive craniosynostosis procedures
Anticipated light anesthesia without paralysis
Brainstem manipulation/compression/dissection
Anticipated cranial nerve manipulation (especially CN V)
Advantageous for postoperative intensive care
Hypervolemic therapy
Head injury
Diabetes insipidus
Incidental cardiac disease

CN, cranial nerve; ICP, intracranial pressure; SAH, subarachnoid hemorrhage.

These occur most often with posterior fossa procedures involving brainstem or cranial nerves, and abrupt changes should be reported to the surgeon immediately.

The use of right heart catheters for air retrieval is discussed in the section on venous air embolism. Thereafter, anticipated blood loss and fluid flux (including aggressive mannitol use) and an evaluation of the patient's physiologic reserve should determine the necessity for CVP or pulmonary arterial catheters. The use of the precordial Doppler also is described in the section on venous air embolism.

Intravenous Fluid Management

The general principles of fluid management (see Chapter 54) for neurosurgical anesthesia are (1) maintain normovolemia, and (2) avoid reduction of serum osmolarity. The first principle is a derivative of the concept presented in the section on management of blood pressure that it is generally ideal to maintain a normal MAP in patients undergoing most neurosurgical procedures and neurosurgical critical care. Maintaining normovolemia is simply one element of maintaining a normal MAP. The second principle is a derivative of the often repeated observation that reducing serum osmolarity results in edema of normal and abnormal brain.[128] Administering fluids that provide free water (i.e., fluids that do not have sufficient nonglucose solutes to render them iso-osmolar with respect to blood) reduces serum osmolarity if the amount of free water administered is greater than that required to maintain ongoing free water loss.

Normal saline and lactated Ringer's solution are the fluids most often used intraoperatively. At 308 mOsm/L, normal saline is slightly hyperosmolar with respect to plasma (295 mOsm/L). It has the disadvantage that in large volumes it can cause a hyperchloremic metabolic acidosis.[129] The physiologic significance of this acidosis, which involves the extracellular, but not the intracellular, fluid space, is unclear. At a minimum, it has the potential to confuse the diagnostic picture when acidosis is present. As a result, many clinicians use predominately lactated Ringer's solution. Although lactated Ringer's solution (273 mOsm/L) theoretically is not ideal for individual replacement of blood and third space loss or insensible losses, it serves as a reasonable compromise for meeting both needs simultaneously and is very suitable in most instances. It is a hypo-osmolar fluid, however, and in a healthy experimental animal, it is possible to reduce serum osmolarity and produce cerebral edema with a large volume of lactated Ringer's solution.[128] In the setting of large-volume fluid administration (e.g., significant blood loss, multiple trauma), we alternate, liter by liter, lactated Ringer's solution and normal saline.

The crystalloid versus colloid discussion is a recurrent one. This discussion usually arises in the context of a head injury victim. Although there are numerous fervent beliefs regarding this issue, there has been only a single demonstration that the reduction of colloid oncotic pressure in the absence of a change of osmolarity can contribute to an augmentation of cerebral edema in the setting of experimental head injury.[130] The transcapillary membrane pressure gradients that can be produced by reduction of colloid oncotic pressure are very small compared with those created by changes in serum osmolarity. Nonetheless, it seems that those small gradients have the potential—probably in the setting of a blood-brain barrier injury of intermediate severity—to augment edema. It seems reasonable then to select a

fluid administration pattern that, in addition to maintaining normal serum osmolarity, would prevent substantial reductions in colloid oncotic pressure. For most elective craniotomies, this would *not* require the administration of colloid solutions. In situations requiring substantial volume administration (e.g., multiple trauma, aneurysm rupture, cerebral venous sinus laceration, fluid administration to support filling pressure during barbiturate coma), a combination of isotonic crystalloid and colloid may be appropriate.

Which Colloid Solutions Should Be Employed

On the basis of empirical local experience, we view albumin to be a reasonable choice as a colloid solution. There are conflicting opinions and cross-currents in the literature, however. A more recent analysis of the subset of patients in the Saline versus Albumin Fluid Evaluation (SAFE) trial with severe head injury (Glasgow Coma Scale [GCS] score 3 to 8) revealed increased mortality in patients who received saline.[131] There is no accepted explanation. The formation of cerebral edema, which is more difficult to clear, is an inevitable suspicion. By contrast, a nonconcurrent, retrospective (i.e., less than scientifically ideal) comparison of outcome after volume support in patients with vasospasm after SAH revealed deterioration in outcomes when albumin was abandoned in favor of saline.[132] Finally, an evolving literature, containing preclinical and clinical data, suggests an improvement in neurologic outcome when albumin is administered after stroke.[133] These data have been sufficient to justify a phase III trial in human stroke, which began in 2006.[134] At most, the existing literature might justify consideration of limiting albumin volumes in patients with severe head injury, although the driving observations should be replicated before any firm principle is established.

The dextran-containing solutions are generally avoided because of their effects on platelet function. The various starch-containing solutions should be used cautiously in neurosurgery because, in addition to a dilutional reduction of coagulation factors, they interfere directly with platelets and the factor VIII complex.[135] The literature addressing the coagulation effects of starches should be read with the understanding that the effects on coagulation are proportional to the average molecular weight of the starch preparation. In North America, preparations with the greatest molecular weights are used. When hetastarch solutions are used in neuroanesthesia, the clinician should respect the manufacturers' recommended dose restrictions, and should use additional restraint in situations where there are other reasons for impairment of the coagulation mechanism. Several reported instances of bleeding in neurosurgical patients have been attributed to hetastarch administration. All of those instances have involved circumstances in which the manufacturer's recommended limit of 20 mL/kg/day was exceeded,[136] or in which hetastarch was administered up to the recommended limit on successive days, probably resulting in an accumulation effect.[137] The decision to use or not use these products frequently is a matter of local bias. If the products are used, the manufacturers' recommended limit (20 mL/kg/24 hr) should be observed.

There is substantial current interest in the use of hypertonic fluids for the resuscitation of multiple trauma victims in general[138] and of patients with neurologic injuries in particular.[52,139] Improvement in outcome has yet to be shown in the latter group in association with hypertonic solutions, however.[139] It seems unlikely that the initial ICP effect of these fluids on the brain is substantially different from an equiosmolar exposure to mannitol[140,141] (although that notion should be qualified that there are reports of patients who had become refractory to mannitol who then responded to hypertonic saline).[53,142] For the time being, when decisions about the appropriateness and relevance of these fluids in the resuscitation process are eventually made, it seems unlikely that those decisions should be made on the basis of specific cerebral effects. It seems more likely that the final judgment regarding this class of fluids would be made on the basis of their effects on the systemic circulation. Generally, an intervention that has the advantage of more effectively restoring systemic hemodynamics is likely to be advantageous to the injured brain. That assertion is made with the proviso that sustained hyperosmolarity (e.g., >320 mOsm/L) caused by any fluid has the potential to result in rebound swelling of the brain.

Hypothermia

The effects of hypothermia on cerebral physiology and its potential cerebral protective mechanisms are presented in Chapter 13. The efficacy of mild hypothermia (32°C to 34°C) in reducing the neurologic injury occurring after standardized cerebral and spinal cord ischemic insults has been shown in numerous laboratories. On that basis, the use of induced hypothermia in the management of cerebrovascular procedures, in particular, aneurysms and occasionally AVMs, became widespread. An international, multicenter trial of mild hypothermia in 1001 relatively good-grade patients undergoing aneurysm surgery revealed no improvement, however, in neurologic outcome.[143] The routine use of intraoperative hypothermia is likely to diminish.

Although mild hypothermia is perceived to increase the risk of coagulation dysfunction and dysrhythmias, neither of those problems has been evident in the temperature ranges typically used (32°C to 34°C). The issue of where body temperature should be recorded to reflect best brain temperature during craniotomy has been addressed.[144] Esophageal, tympanic membrane, pulmonary artery, and jugular bulb temperature all are similar and provide a reasonable reflection of deep brain temperature, whereas bladder temperature does not. Superficial layers of cortex may be substantially cooler than deep brain and central temperatures.

Because ischemia is recognized to make a post insult contribution to neuronal injury after head injury,[23,145] hypothermia was also studied in the laboratory in the context of traumatic brain injury.[146] It was effective and this resulted in at least four single institution trials of 24 to 48 hours of mild hypothermia after head injury.[147-150] These investigations revealed some physiologic dysfunction associated with more prolonged mild hypothermia, all of which was reversible with restoration of normal temperature. This included decreased creatinine clearance, elevation of pancreatic enzymes, and a suggestion of an increased infection rate. A decreased incidence of seizures was an apparent adjunctive benefit in one study. As a result, a multicenter, prospective trial of hypothermia was performed but did not show a benefit of hypothermia (33°C) induced within 8 hours of injury and maintained for 48 hours.[151] Post hoc subgroup analysis indicated that patients younger than age 45 years who arrived at the tertiary care facility with a temperature less than 35°C who were randomly assigned to the cooling limb of the trial did have an improved outcome. A follow-up trial in which the protocol seeks to achieve cooling more rapidly is under way.

On the basis of lack of demonstrated efficacy in humans, routine use of hypothermia in neurosurgery cannot be advocated in a standard text. The decision to employ it, usually in the context of aneurysm surgery, will be a local one. We continue to use mild hypothermia selectively, most commonly in patients perceived to be at especially high risk of intraoperative ischemia. If hypothermia is employed, it should be done so with attention to the possibility of cardiac dysrhythmias and coagulation dysfunction if temperatures become too low and with attention to the necessity to rewarm adequately before emergence to avoid shivering and hypertension.

Yet another application of mild hypothermia is evolving. Two multicenter trials have shown improved neurologic outcome among survivors of witnessed cardiac arrest cooled to 32°C to 34°C within 4 hours and maintained at that temperature for 12 to 24 hours.[152,153] Widespread clinical application has been advocated by an international task force.[154] Systematic clinical application is evolving slowly, however, probably because of the time necessary for technical and ICU protocol developments.

Emergence from Anesthesia

Most practitioners of neuroanesthesia believe that there is a premium on a "smooth" emergence—one free of coughing and straining and arterial hypertension. The avoidance of arterial hypertension is considered desirable because of the belief that arterial hypertension can contribute to intracranial bleeding and increased edema formation.[155-158] In the face of a poorly autoregulating cerebral vasculature, hypertension also has the potential, through vascular engorgement, to contribute to elevation of ICP. Much of the concern with coughing and straining has a similar basis. The sudden increases in intrathoracic pressure are transmitted to arteries and veins, producing transient increases in cerebral arterial and venous pressure with the same potential consequences: edema formation, bleeding, and elevation of intracranial pressure.

Coughing is a specific concern with certain individual procedures. In transsphenoidal pituitary surgery in which a surgeon has opened, and subsequently taken pains to close, the arachnoid membrane to prevent CSF leakage, coughing has the potential to disrupt this closure because of the sudden and substantial increases in CSF pressure. Opening a pathway from the intracranial space to the nasal cavity conveys a substantial risk of postoperative meningitis. In other procedures, notably operations that have violated the floor of the anterior fossa, there is also the theoretical potential for air to be driven into the cranium and, in the event of a flap-valve mechanism, to cause a tension pneumocephalus. This latter event can occur only when coughing occurs after the endotracheal tube has been removed.

There is a paucity of systematically obtained clinical data to give a perspective to the actual magnitude of the risks associated with emergences that are not "smooth." A retrospective study revealed that elevated postoperative arterial blood pressure was a correlate of intracerebral bleeding after craniotomy.[159] Hypertension occurring at emergence is not correlated with postoperative intracerebral bleeding, however. Although one clinical investigation reported an association of increased CBF velocity with hypertension occurring during emergence,[160] a second study observed that 60% increases in CBF velocity occurred even in the absence of hypertension, and concluded that hyperemia may be a normal concomitant of arousal at the end of an anesthetic.[161] A relationship between hypertensive transients at emergence and edema formation also is unconfirmed. Sudden, substantial increases in arterial pressure in anesthetized animals can result in a breach of the blood-brain barrier with extravasation of tracers such as Evans blue.[156] There are no data, however, to confirm that the pressure transients associated with the typical coughing episode or typical emergence hypertensive transient are associated with increased edema formation. Nonetheless, it seems reasonable to take measures, to the extent that these measures do not themselves add potential patient morbidity, to prevent these occurrences.

A common method for managing systemic hypertension during the last stages of a craniotomy is the expectant or reactive (or both) administration of vasoactive agents, most commonly labetalol and esmolol.[162] Other agents, including enalapril, nicardipine, and diltiazem, have been used to good effect. Administration of dexmedetomidine during the procedure also has been reported to reduce the hypertensive response to emergence.[163]

There are also many approaches to the prevention of coughing and straining. We have several biases. We encourage trainees to include in their anesthetic technique "as much narcotic as is consistent with spontaneous ventilation at the conclusion of the procedure." This practice is based on the same physiologic effect that justifies the administration of codeine and related compounds as antitussive medication (i.e., the depression of airway reflexes by narcotics). We also have the bias that patients emerge more rapidly and smoothly when the last inhaled agent to be withdrawn is N_2O, and that clinicians should seek to avoid the "neither here nor there" phase of anesthesia that occurs in patients who are stimulated in the face of residual exhaled concentrations of volatile agent on the order of 0.2 to 0.3 MAC. A common practice among neuroanesthesiologists near the conclusion of a craniotomy is the relatively early discontinuation of the volatile agent with supplementation of residual N_2O with propofol by either bolus increments or infusion at rates of 25 to 100 μg/kg/min.

An additional principle relevant to the emergence from neurosurgical procedures that practitioners may learn from a book or by bad experience is that emergence should be timed to coincide not with the final suture, but rather with the conclusion of the application of the head dressing. Good anesthetics for neurosurgery have been spoiled by severe coughing and straining occurring in association with endotracheal tube motion during the application of the head dressing. Another nuance of our practice has been to withhold administration of neuromuscular antagonists as long as possible as a "hedge" against misjudgment while lightening a patient in the later stages of the procedure. The administration of lidocaine is another apparently effective technique for reducing airway responsiveness and the likelihood of coughing and straining as depth of anesthesia is reduced in anticipation of emergence. Bolus doses of approximately 1.5 mg/kg, usually given as the application of the head dressing begins, are appropriate for this purpose.

The premium placed on minimizing coughing and straining and hypertension results, in most instances, in patients being extubated expediently when extubation is appropriate. In some instances, anesthesiologists may be tempted to extubate patients before complete recovery of consciousness. This early extubation may be acceptable in some circumstances. It should be undertaken with caution, however, when the circumstances of the surgical

procedure make it possible that neurologic events have occurred that would delay recovery of consciousness, or when there may be lower cranial nerve dysfunction. In these circumstances, it generally is best to wait until the likelihood of the patient's recovery of consciousness is confirmed or wait until patient cooperation and airway reflexes are likely to have recovered.

Specific Procedures

Many of the considerations relevant to individual neurosurgical procedures are generic ones that have been presented in the preceding section on recurrent issues. The descriptions that follow highlight only procedure-specific issues.

Supratentorial Tumors

Craniotomies for excision or biopsy, or both, of supratentorial tumors are common neurosurgical procedures. Gliomas and meningiomas are among the most frequent tumors. Relevant preoperative considerations include the patient's ICP status and the location and size of the tumor. Location and size give the anesthesiologist an indication of the surgical position and the potential for blood loss, and occasionally reveal a risk of air embolism. Risk of VAE is quite low for most supratentorial tumors. However, lesions (usually convexity meningiomas) that encroach on the sagittal sinus may convey a substantial risk of VAE. Full VAE precautions, including a right atrial catheter, are usually reserved for only supratentorial tumors that lie near the posterior half of the superior sagittal sinus.

Excision of craniopharyngiomas and pituitary tumors with suprasellar extension may entail dissection in and around the hypothalamus. Irritation of the hypothalamus can elicit sympathetic responses, including hypertension. Damage to the hypothalamus can result in a spectrum of physiologic disturbances, notably in water balance. Diabetes insipidus is the most likely disturbance, although cerebral salt-wasting syndrome can potentially occur. The latter has been very rare. The various disturbances of water balance typically have a delayed onset, beginning 12 to 24 hours postoperatively, rather than in the operating room. Postoperative temperature homeostasis also may be disturbed.

Patients who undergo a craniotomy involving a subfrontal approach occasionally may manifest a disturbance of consciousness in the immediate postoperative period. Retraction and irritation of the inferior surfaces of the frontal lobes can result in a patient who is lethargic and does not awaken "cleanly," and who may exhibit delayed emergence or some degree of disinhibition, or both. Patients exhibiting this phenomenon are sometimes referred to as "frontal lobey." The phenomenon is more likely to be evident when there has been bilateral subfrontal retraction than when it occurs only unilaterally. The anesthetic implication is that the clinician should be more inclined to confirm return of consciousness before extubating the patient than to extubate expectantly. We also believe (although this has not been confirmed by any systematic study) that a less liberal use of intravenous anesthetics (e.g., narcotics, benzodiazepines) may be appropriate when there is to be bilateral, subfrontal retraction. This is based on the rationale that low residual concentrations of these agents that would be compatible with reasonable recovery of consciousness in the majority of patients, may be less well tolerated in this population. Subfrontal approaches are most commonly employed in patients with olfactory groove meningiomas and patients with suprasellar tumors (craniopharyngiomas and pituitary tumors with suprasellar extension).

Preoperative Preparation

Patients with a significant tumor-related mass effect, especially if there is tumor-related edema, should receive preoperative steroids. A 48-hour course is ideal (see previous discussion of steroids), although 24 hours is sufficient for a clinical effect to be evident. Dexamethasone is the most commonly used agent; a regimen such as 10 mg intravenously or orally followed by 10 mg every 6 hours is typical. Because of the concern about producing CO_2 retention in a patient whose intracranial compliance is already abnormal, patients with any substantial mass effect are usually not premedicated outside of the operating room.

Monitoring

Frequently, the nature of the procedure does not require anything more than routine monitoring (see Chapter 46). Some situations may warrant invasive monitors (see Table 63-7). Preinduction placement of an arterial catheter may be appropriate in patients with severe mass effect and little residual compensatory latitude. It is the period of induction during which hypertension, with its attendant risks in a patient with impaired compliance and autoregulation, is most likely to occur. Procedures with a substantial blood loss potential (e.g., tumors encroaching on the sagittal sinus, large vascular tumors) also may justify arterial or CVP catheters. If not already present for other indications, is ICP monitoring ever warranted for intraoperative management? In our opinion, the answer is generally "no." Anesthesiologists have a sufficient understanding of the potential impact of anesthetic agents and techniques that they should be able to manage induction of anesthesia "blind." When the cranium is open, observation of conditions in the surgical field provides equivalent information.

Management of Anesthesia

The principles governing the choice of anesthetic agents were presented earlier in the section on control of intracranial pressure and brain relaxation.

Aneurysms and Arteriovenous Malformations

Contemporary management of intracranial aneurysms calls for early intervention after SAH, ideally within 24 hours and definitely within 48 hours. Intervention may entail either operative clipping or an endovascular approach. The latter is discussed in the subsequent section on interventional neuroradiology.

Early intervention was originally undertaken only in patients in the better neurologic grades—grades I through III and perhaps IV of the World Federation of Neurosurgeons classification (Table 63-8) or grades I through III of the Hunt-Hess classification (Table 63-9)—but more recently has been extended to patients of higher grades.[164] If early intervention is not feasible, and a surgical approach is intended, surgery is usually delayed for

Table 63-8 World Federation of Neurosurgeons (WFNS) Subarachnoid Hemorrhage Scale

WFNS Grade	GCS Score	Motor Deficit
I	15	Absent
II	14-13	Absent
III	14-13	Present
IV	12-7	Present or absent
V	6-3	Present or absent

GCS, Glasgow Coma Scale.

10 to 14 days to be safely beyond the period of maximal vasospasm risk (i.e., days 4 to 10 post-SAH).

The rationale for early intervention is severalfold. First, the sooner the aneurysm is clipped or obliterated, the less likelihood of rebleeding (and rebleeding is the principal cause of death for patients hospitalized after SAH[165]). Second, the management of the ischemia caused by vasospasm involves volume loading and induced hypertension. Early occlusion of the aneurysm eliminates the risk of rebleeding associated with this therapy. Vasospasm seems to be related to the presence of blood in the basal cisterns in the vicinity of the circle of Willis. Some of this blood can be removed at the time of the aneurysm clipping, and intracisternal fibrinolytics (for which there is limited proof of efficacy[166]) can be administered. Early operative clipping not only makes the therapy of vasospasm safer, but also may reduce the incidence and severity of the problem. Prior surgical practices entailed maintaining the patient at bed rest until approximately day 14, when the period of spasm risk had passed. Early aneurysm clipping reduces the period of hospitalization and reduces the incidence of the medical complications (e.g., deep vein thrombosis, atelectasis, pneumonia) associated with a lengthy period of enforced bed rest.

Early intervention can make the surgeon's task more difficult. The brain in the early post-SAH period is likely to be more edematous than after a 2-week delay. A mild degree of hydrocephalus is common after blood contaminates the subarachnoid space. Ten percent to 20% of SAH patients may require CSF diversion at some point in their course.[167] Early intervention also may enhance the risk of intraoperative aneurysmal rupture because of the shorter period of time for clot to organize over the site of the initial bleed. All of this places a substantial premium on techniques designed to reduce the volume of the intracranial contents (see the section on control of intracranial pressure and brain relaxation) to facilitate exposure and minimize retraction pressures.

Preoperative Evaluation

Many patients scheduled for intracranial aneurysm clipping come directly from the ICU, and elements of their management in the ICU may influence their immediate preoperative status.

Fluid Management. Some patients develop the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) after SAH and are appropriately managed with fluid restriction. However, hyponatremia after SAH is more likely to be the result of the cerebral salt-wasting syndrome, which probably occurs as a result of the release of a natriuretic peptide by the brain (similar to that which occurs in the heart).[168] Cerebral salt-wasting syndrome is characterized by the triad of hyponatremia, volume contraction, and high urine sodium concentrations (>50 mmol/L). The distinction between this syndrome and SIADH is important. SIADH, which is characterized by normovolemia or mild hypervolemia, is treated by volume restriction. Cerebral salt wasting is associated with a *contracted* intravascular volume. Fluid restriction and further volume contraction may be especially deleterious in a patient after SAH[169,170] and should be avoided. Although the clinical distinction between these two causes of hyponatremia (SIADH and cerebral salt-wasting syndrome) may be difficult, management of both is simple: administration of isotonic fluids using intravascular normovolemia as the end point.

Vasospasm. The anesthesiologist should determine whether vasospasm has occurred, and what, if any, therapies for it have been undertaken. Vasospasm is thought to be caused by the breakdown products of hemoglobin from the blood that has accumulated around the vessels of the circle of Willis after SAH. A specific mechanism/mediator has not been identified, but the current focus is on endothelin.[171,172] A phase II trial of the endothelin A receptor antagonist clazosentan indicated effective reversal of established vasospasm and a substantial reduction in the incidence of new infarctions.[173] A phase III trial is under way, and a preliminary report of drug-related reductions in vasospasm-related hypoperfusion in those patients has appeared.[174]

When there is a clinical suspicion of vasospasm (typically because of a change in sensorium or new neurologic deficit), surgery is deferred, and TCD, angiography, or other imaging is performed.[175-177] Confirmed vasospasm is commonly treated with the "triple H" therapy described in the next paragraph and sometimes by balloon angioplasty or intra-arterial vasodilators.

For patients proceeding to surgery, CPP should be maintained intraoperatively in a high-normal range. Despite the former popularity of induced hypotension, the potential for induced hypotension to cause or aggravate cerebral ischemia in a patient with some degree of vasospasm is now recognized.[178,179] This concern extends even to a patient classified as World Federation of Neurosurgeons grade I who may have regions of cerebral ischemia[41] that are subclinical when the patient is normotensive.

In the ICU, the regimens employed to treat vasospasm usually involve some combination of hypervolemia, hemodilution, and hypertension. The science behind hypervolemic-

Table 63-9 Hunt-Hess Classification of Neurologic Status after Subarachnoid Hemorrhage

Grade	Criteria*
I	Asymptomatic, or minimal headache and slight nuchal rigidity
II	Moderate to severe headache, nuchal rigidity, no deficit other than cranial nerve palsy
III	Drowsiness, confusion, or mild focal deficit
IV	Stupor, moderate to severe hemiparesis, possibly early decerebrate rigidity and vegetative disturbances
V	Deep coma, decerebrate rigidity, moribund appearance

*Serious systemic diseases, such as hypertension, diabetes, severe arteriosclerosis, chronic pulmonary disease, and severe vasospasm seen on arteriography, result in placement of the patient in the next less favorable category.

hypertensive therapy is "soft," and the efficacy of neither "triple H" therapy nor volume expansion in isolation has been proved by prospective study.[180,181] The importance of the rheologic and the pressure effects is undefined, although there is evidence for the relevance of blood pressure elevation in isolation.[182,183] Phenylephrine and dopamine are the most commonly employed pressors; the specific pressor choice should be governed primarily by systemic cardiovascular considerations. The end point for pressor administration varies. Most commonly, the objective is an increase in MAP of approximately 20 to 30 mm Hg above "baseline" systolic pressure. It has been reported, however, that augmentation of cardiac output with dobutamine, without simultaneous MAP increase, augments CBF in vasospastic territories.[184] Some authors believe that the hematocrit should be reduced to the low 30s. Commonly, hematocrit reduction occurs secondarily as a result of attempts to produce hypervolemia (usually with colloid solutions) as a part of the effort to increase blood pressure.

Calcium Channel Blockers. Calcium channel blockers are now an established part of the management of SAH. Administration of nimodipine has been shown to decrease the incidence of morbidity from cerebral ischemia occurring after SAH.[185-187] These studies failed to show any reduction in the incidence of vasospasm, however, as detected by angiography.[186] The beneficial effect of these agents may be the result of effects on neurons, rather than vascular smooth muscle. Patients coming to the operating room after SAH should be receiving nimodipine. Nimodipine must be administered orally; nicardipine has been evaluated as an intravenous alternative. The multicenter nicardipine trial[188,189] revealed a reduced incidence of symptomatic vasospasm, but no improvement in outcome. Consequently, nimodipine is more commonly employed. Because papaverine may be neurotoxic, intra-arterial calcium entry blockers, including verapamil and nicardipine, are being increasingly used as a primary treatment for medically refractory vasospasm.

Magnesium, Statins, and Endothelin Antagonists. More recent clinical trials have identified several agents that may soon become part of the routine management of patients with SAH. The endothelin antagonist clazosentan was mentioned earlier in this section. A randomized, blinded, placebo-controlled trial reported fewer new ischemic deficits and improved outcome among patients who received magnesium sulfate starting within 4 days of SAH. Two phase II trials have examined the post-SAH administration of statins. Together, these trials showed reductions in vasospasm, delayed ischemic deficits, and improvement in outcome.[190,191] Although some centers have already implemented some of these therapies as part of the local routine, widespread adoption is not likely until the completion of larger trials that confirm these initial results.

Antifibrinolytics. Antifibrinolytics have been administered in an attempt to reduce the incidence of rebleeding. Meta-analysis suggests, however, that although they accomplish the latter, they do so at the cost of an increased incidence of ischemic symptoms and hydrocephalus with the result being no net improvement in outcome.[192]

Subarachnoid Hemorrhage–Associated Myocardial Dysfunction. SAH can result in a reversible, "stunning"-like myocardial injury. The severity of the dysfunction correlates best with the severity of the neurologic injury,[193] and occasionally is sufficient to require pressor support.[194] The mechanism is uncertain, but it is thought to be catecholamine mediated.[195] This suspicion is supported by the observation that more severe dysfunction occurs in SAH patients with genetic polymorphisms associated with greater catecholamine receptor sensitivity. Troponin elevation occurs commonly, although typically reaching levels less than the diagnostic threshold for myocardial infarction.[196] Peak troponin levels correlate with the severity of neurologic injury and echocardiographic myocardial dysfunction.[194]

ECG abnormalities are common after SAH.[193] In addition to the classic "canyon T waves" (Fig. 63-14), nonspecific T-wave changes, Q-T prolongation, ST-segment depression, and U waves have been described. There is typically no relationship between the ECG changes and echocardiographic myocardial dysfunction.[196] ECG abnormalities do not herald evolving or impending cardiac disease.[197] When ECG patterns other than those that are typical of myocardial ischemia are observed, no specific interventions or modifications of patient management are warranted, other than attention to the possibility of dysrhythmias. In particular, an increased Q-T interval (>550 msec) occurs frequently after SAH, especially in patients with more severe SAH,[198] and has been associated with an increased incidence of malignant ventricular rhythms, including torsades de pointes.[199,200]

Anesthetic Technique

The important considerations in anesthetic technique include the following:

1. Absolute avoidance of acute hypertension with its attendant risk of rerupture
2. Provision of intraoperative brain relaxation to facilitate surgical access to the aneurysm
3. Maintenance of a high-normal mean arterial (perfusion) pressure to prevent critical reduction of CBF in recently insulted and now marginally perfused areas of brain, or regions critically dependent on collateral pathways
4. Preparedness to perform precise manipulations of MAP as the surgeon attempts to clip the aneurysm or to control bleeding from a ruptured aneurysm, including management of temporary vascular occlusion

Monitoring. An arterial line is invariably appropriate. CVP may be relevant if the institutional practices involve large doses of mannitol to promote brain relaxation and may be used in older patients to guide volume replacement in the event of bleeding.

Anesthetic Selection. Any technique that permits proper control of MAP is acceptable. In the face of increased ICP or a tight surgical field, an inhaled agent technique may be less suitable. The prevention of paroxysmal hypertension is the only absolute requirement in patients undergoing aneurysm clipping. Rebleeding kills,[165] and a poorly organized clot over the aneurysms of patients undergoing early post-SAH clipping makes them particularly prone to rebleeding. A rebleed at induction is frequently fatal. The escaping arterial blood is more likely to penetrate brain substance because it cannot dissect through the CSF space (filled with clot), and the ICP increase is extreme because of the poor compliance of the intracranial space (swollen brain, hydrocephalus).

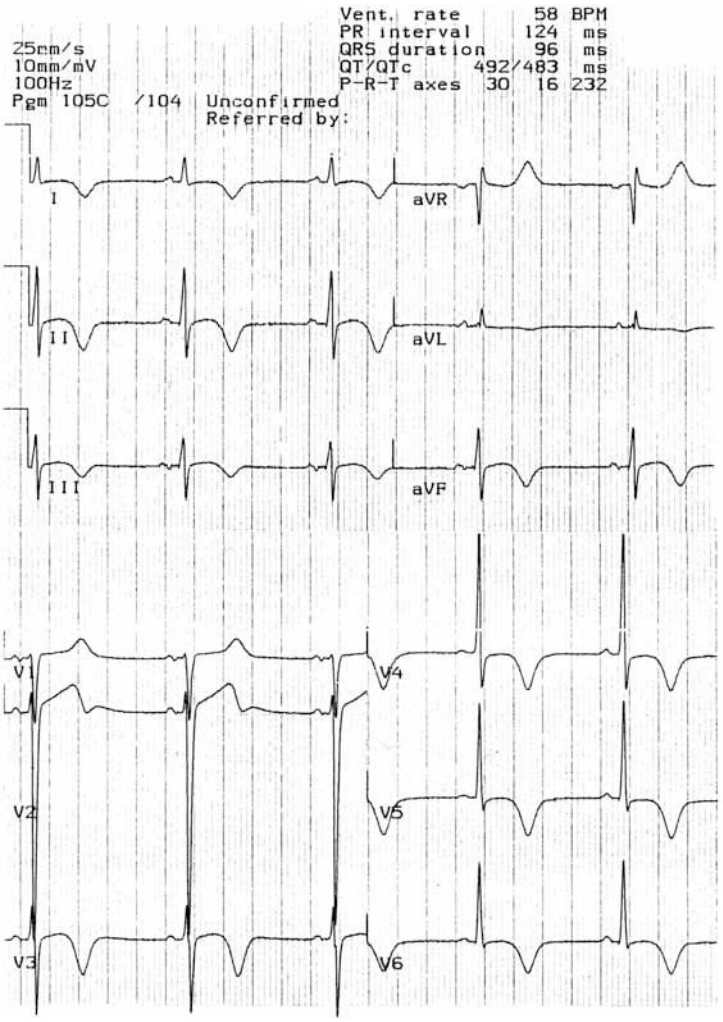

Figure 63-14 Electrocardiogram abnormalities associated with subarachnoid hemorrhage (SAH). The "canyon" T waves that may be seen after SAH are evident.

Induced Hypotension. The routine use of induced hypotension is diminishing (see previous section on management of arterial blood pressure). Nonetheless, the anesthesiologist should be prepared to reduce blood pressure immediately and precisely if called on to do so. Preparation must occur before the episode of bleeding. We prepare a sodium nitroprusside infusion before induction. It is placed in line at a Y-injection port at the hub of the CVP or intravenous catheter. A carrier drip flows steadily such that any change in nitroprusside infusion rate is reflected as rapidly as possible in the central compartment. There are theoretical pros and cons for various hypotensive agents. The data indicate that regimens that entail the use of an agent that is also a cerebral vasodilator (e.g., isoflurane, nitroprusside) are preferable in terms of brain oxygen delivery to approaches that do not involve cerebral vasodilation (e.g., trimethaphan, controlled hypovolemia).[201] The choice should ultimately be made on the basis of which regimen, in the hands of the individual practitioner, results in the most precise control of MAP. Occasionally, the anesthesiologist may be asked to control MAP in the range of 40 to 50 mm Hg, in the face of the active arterial bleeding. This can be extremely difficult in a patient who is hypovolemic at the beginning of the bleeding episode. It is our practice to maintain normovolemia.

Induced Hypertension. Hypertension may be requested during periods of temporary arterial occlusion (see the later section on trapping) to augment collateral CBF. In addition, after clipping of the aneurysm, some surgeons puncture the dome of the aneurysm to confirm adequate clip placement, and may request transient elevation of the systolic pressure to 150 mm Hg. Phenylephrine is suitable in either instance.

Hypocapnia. Hypocapnia traditionally has been employed as an adjunct to brain relaxation. The practice has been questioned, however, because of the concern that it would aggravate ischemia (see the earlier section on management of $Paco_2$). The circumstances regarding ICP and brain relaxation should probably dictate its use or avoidance.

Lumbar Cerebrospinal Fluid Drainage. Some surgeons employ elective CSF drainage to facilitate exposure. Its use seems to be diminishing, however, because surgeons have appreciated that the same brain-relaxing effect can be achieved by release of CSF from the basal cisterns. It is appropriate, when placing a lumbar CSF drain, to avoid excessive loss of CSF. Sudden reduction of the transmural pressure gradient across the dome of the aneurysm (by sudden reduction of ICP consequent on substantial

CSF drainage) should be avoided because of the theoretical concern that this decompression might encourage rebleeding. The common practice is, having verified the patency of the lumbar drainage system, to leave it closed until such time as the surgeon is opening the dura. The drain may be opened at that time and allowed to drain freely with the bag at floor level. Drainage should be discontinued promptly after final withdrawal of the retractors to allow CSF to reaccumulate and to reduce the size of the potential pneumocephalus. The drain is usually removed immediately postoperatively.

Mannitol. Some surgeons make relatively aggressive use of mannitol (e.g., 2 g/kg). It is used, in part, to shrink the brain and to facilitate exposure and reduce retractor pressures. There is evidence that mannitol may have additional benefits. Specifically, data derived in animals and humans indicate that mannitol may have a CBF-enhancing effect in regions of moderate CBF reduction.[202-205] The mechanism is not defined. Reduction of interstitial tissue pressure around capillaries or an alteration of blood rheology, or both, have been proposed to contribute. Typically, mannitol is administered in a dose of 1 mg/kg just before dural opening. Surgeons who believe in the flow-enhancing effect may request a second 1 mg/kg dose approximately 15 minutes before an anticipated temporary occlusion.

Trapping

It is occasionally necessary for the surgeon to "trap" the aneurysm (i.e., to occlude the vessel on either side of the aneurysm temporarily) to complete dissection of the neck and apply the clip. The need for trapping is more common with larger aneurysms. With giant aneurysms in the vicinity of the carotid siphon, the inferior occlusion may be performed at the level of the internal carotid artery via a separate incision in the neck. A clinical survey by Samson and coworkers[206] of the neurologic outcome after temporary occlusion in normothermic, normotensive adults revealed that occlusion times of less than 14 minutes were invariably tolerated. The likelihood of an ischemic injury increased with longer occlusions and reached 100% with occlusions longer than 31 minutes.[206] In another institution, the threshold for ischemic injury was 20 minutes of occlusion.[207] Typically, it is appropriate to support MAP at high normal levels during periods of occlusion to facilitate collateral CBF.

Brain Protection

Important brain protection techniques include maintenance of MAP to ensure collateral flow and perfusion under retractors, efficient brain relaxation to facilitate surgical access and reduce retractor pressures, limitation of the duration of episodes of temporary occlusion, and perhaps mild hypothermia. Specific anesthetic agents also have been used to protect the brain (see the discussion in Chapter 13). Propofol and etomidate are currently used. However, no convincing laboratory studies have shown that propofol provides any greater tolerance to a standardized ischemic insult than anesthesia with a volatile agent. Attempts to show protection by etomidate in an animal model of focal ischemia showed an adverse effect of etomidate.[208] A clinical investigation during aneurysm clipping revealed decreases in brain tissue Po_2 in association with administration of etomidate, which contrasted with the brain Po_2 increases that occurred with the introduction of desflurane. During subsequent temporary vessel occlusion, tissue pH decreased alarmingly in patients receiving etomidate and was unchanged with desflurane.[209]

Although the available data collectively do not support an assertion that etomidate is harmful in the setting of aneurysm surgery, we think that they should dissuade any anesthesiologist from advocating the administration of etomidate as a uniquely protective substance in the context of aneurysm surgery. With respect to the volatile agents, attempts in the laboratory to confirm the once proclaimed protective efficacy of isoflurane have shown that there are no differences among the various volatile agents in terms of their influence on outcome after focal or global ischemia.[208,210-212] In addition, there has been no demonstration of greater protective efficacy with concentrations of volatile agents sufficient to cause EEG suppression as opposed to more modest (e.g., 1.0 MAC) levels.[212,213] Nonetheless, these animal investigations suggest that a standardized experimental ischemic insult is better tolerated, relative to the awake state, by animals receiving a volatile anesthetic.[211,212,214] Data derived in animals also suggest that there may be a relative protective advantage to an anesthetic that includes a volatile agent compared with a strict N_2O-narcotic technique.[212,214]

The magnitude of the differences among anesthetics and the absence of proof of relevance in patients precludes advocacy of a particular anesthetic regimen in a standard text. The important anesthetic objectives are precise hemodynamic control and timely wake-up, and these two constraints should dictate the choice of the anesthetic regimen for most aneurysm procedures. Among anesthetic agents, only for the barbiturates has additional protective efficacy been shown convincingly (see Chapter 13). Because of their potentially adverse effects on hemodynamics and wake-up, barbiturates are not ideal for routine administration. They probably should be reserved for situations in which a prolonged vessel occlusion is unavoidable, and in that circumstance it would be ideal that the ischemic hazard be first confirmed by observation of the EEG response to a temporary occlusion.[215]

Hypothermia

As noted in the earlier section on hypothermia, a prospective trial of mild hypothermia in patients undergoing aneurysm surgery revealed no improvement in neurologic outcome. Nonetheless, many neurosurgical teams that were already employing mild hypothermia (32°C to 34°C) are continuing its use for procedures in which temporary vessel occlusion may occur. Institutions that use the lower temperatures are those in which the team is willing to accept a delay in emergence from anesthesia to achieve sufficient rewarming to avoid the extreme hypertension that can occur when a patient is awakened during hypothermia.

Neurophysiologic Monitoring

Evoked responses and EEG (see Chapter 46) have been employed for monitoring,[215,216] although neither technique has been used widely. EEG monitoring can be used as a guide to management during the period of flow interruption or to guide the administration of CMR-reducing anesthetic agents given before occlusion.[215] An electrode strip can be placed over the region of cortex at risk during the intended occlusion. However, the more commonly used skin surface frontal-mastoid derivation is probably sufficient to reveal a major ischemic event. The EEG can be either the conventional "raw" polygraph or a processed derivative. In most circumstances, if occlusion is deemed necessary, a temporary

occlusion is done, and the EEG is observed. If the EEG shows significant slowing, the clip can be repositioned, or MAP can be increased by some combination of phenylephrine and lightening of anesthesia to find a way of temporary clipping without a major EEG disturbance. If this cannot be accomplished, and a sustained period of occlusion seems likely, barbiturates (see earlier) should be given to produce burst suppression.

Intraoperative Angiography

Intraoperative angiography is an increasingly common component of the management of intracranial aneurysms. It does not have substantial implications for the anesthesiologist. Apparatus around the patient's head must be organized, however, so as to allow C-arm access without snagging of airway and monitoring equipment. In addition, the radiologist must have access to groin vessels. The vascular access sheath, for a patient who will ultimately be in the lateral position, is easiest to use when the nondependent femoral artery is chosen. The rate of administration of heparin "flush" via the vascular access sheath should be monitored.

Special Considerations for Specific Aneurysms

The most common procedures are done for aneurysms arising in or close to the circle of Willis. The vessel of origin may be the anterior communicating artery, the middle cerebral artery, the anterior cerebral artery, the ophthalmic artery, the tip of the basilar artery, the posterior communicating artery, or, less frequently, the posterior cerebral artery. These procedures all are similar for the anesthesiologist and typically require a supine position with the head turned slightly away from the operative side.

Ophthalmic Artery Aneurysms. Access to the origin of the ophthalmic artery, which is the first intradural branch of the carotid artery, is made difficult by the anterior clinoid process and the optic nerve. As a result, these aneurysms frequently require temporary vascular occlusion. The surgeon commonly first exposes the carotid artery in the neck. When the surgeon reaches the stage of seeking definitive access to the neck of the aneurysm, he or she will occlude first the carotid artery in the neck and then the intracranial portion of the carotid artery immediately proximal to the origin of the posterior communicating artery.

Vertebrobasilar Aneurysms. These procedures are typically performed in the lateral position. The exposure may involve a combined middle and posterior fossa approach, with some attendant, although minor, risk of venous air embolism. Cortical or skin surface EEG monitoring is of less relevance with vertebrobasilar aneurysms. Auditory or somatosensory evoked responses, or both, have been employed.[217] As in any other procedure involving the potential for mechanical or vascular injury to the brainstem, cardiovascular responses should be monitored, and sudden changes in response to surgical manipulation should prompt immediate notification to the surgeon. Spontaneous ventilation may be appropriate for procedures involving surgical manipulation of the vertebral arteries, the vertebrobasilar junction, and the middle portion of the basilar artery. Apnea, gasping, or other sudden changes in ventilatory pattern during manipulation of the vasculature provide important, although nonspecific, warning of compromise of the vascular supply of the brainstem.[218]

Now largely supplanted by endovascular approaches, management of these aneurysms occasionally requires cardiopulmonary bypass and deep hypothermic circulatory arrest.[219]

Vein of Galen Aneurysms. Vein of Galen "aneurysms" are congenital dural arteriovenous fistulas, usually treated in neonates using endovascular methods, and share considerations relevant to AVMs. These include anticipation of the possibility of the cerebral dysautoregulation phenomenon and are considered subsequently.

Arteriovenous Malformations

For most intracranial AVMs, the general considerations are similar to the considerations appropriate to aneurysm surgery: avoidance of acute hypertension and the capability to manipulate blood pressure accurately in the event of bleeding. A problem that is specific to AVMs is the phenomenon known as "perfusion pressure breakthrough," or cerebral dysautoregulation.[220,221] It is characterized by an often sudden engorgement and swelling of the brain, sometimes with a relentless cauliflower-like protrusion from the cranium. This phenomenon tends to occur in the advanced stages of lengthy procedures on large AVMs, or accounts for otherwise unexplained postoperative swelling and hemorrhage. The phenomenon is not entirely understood and is almost certainly related to the "hyperemic" complications seen after carotid endarterectomy or angioplasty.

In textbooks, this syndrome has been described as relating to the acute obliteration of a high-volume, low-resistance pathway (the AVM) that has chronically diverted blood from adjacent, marginally perfused vascular territories. It has been theorized that these tissues have long been maximally vasodilated without the need ever to vasoconstrict and have become incapable of doing so. Experimental data are not generally consistent with this mechanism, however.[221-223] The observed "hyperemic" complications are probably not passive. One might speculate that the vasodilation is neurogenic in origin, or involves some kind of paracrine signaling. Such events might lead to vascular wall protease activation and vasogenic edema or vascular rupture. Supranormal flow rates also can activate protease activity. The area is in need of further study.

Anesthetic Technique

The management constraints are essentially the same as those relevant to aneurysm surgery, although the risk of intraoperative rupture is much less. Institutional practices vary. We do not employ induced hypotension unless required to by bleeding. We reason that the effects on the surrounding brain of devascularizing the AVM would be best appreciated if the devascularization occurs at normal pressures. If refractory brain swelling occurs, tight blood control is essential; decreasing MAP may be useful to control swelling. The hyperemic complications with carotid surgery seem to be related, but not uniquely determined, by poor post-treatment blood pressure control. The speculation is that blood flow through the involved area is pressure-passive and decreases as MAP is reduced.

With severe episodes of swelling, we have employed (in addition to hypotension, which we use cautiously because of the associated ischemia risk) hypocapnia, hypothermia, and barbitu-

rates. These three techniques probably reduce the bulk of only normal brain tissue—hypocapnia via a direct effect on CBF, and barbiturates and hypothermia via the coupled effects of reduction of CMR on CBF. Induced hypothermia also is an adjunct to minimizing the barbiturate doses. In all of neurosurgery, we seek to prevent postoperative hypertension; however, in AVM surgery, this should be accomplished with greatest care because of the concern that the "dysautoregulating" brain adjacent to the resected AVM will develop edema or hemorrhage if hypertension occurs.

Head Injury

Intubating a Head-Injured Patient

The anesthesiologist's first encounter with a patient who has sustained a traumatic brain injury (TBI) may come as a result of a request for assistance with airway management. Patients with GCS scores of 7 or 8 or less (Table 63-10) require intubation and controlled ventilation for ICP or airway control or both. Patients with less severe head injuries also may require intubation because of trauma-related cardiopulmonary dysfunction or, when uncooperative, to facilitate diagnostic procedures.

In choosing the intubation technique, the anesthesiologist may encounter numerous conflicting constraints (Table 63-11), including (1) elevated ICP, (2) a full stomach, (3) uncertain cervical spine status, (4) uncertain airway status (e.g., presence of blood, possible laryngotracheal injury, possible skull base fracture), (5) uncertain volume status, (6) an uncooperative or combative patient, and (7) hypoxemia. There is no "correct" way, and the "best" approach is determined by the relative weight of these various factors along with the degree of urgency. The anesthesiologist must not become distracted by placing an excessive initial emphasis on ICP. The anesthesiologist needs to keep sight of the ABCs of resuscitation: Securing the airway, guaranteeing gas exchange, and stabilizing the circulation are higher initial priorities than ICP. One must not risk losing the airway or causing severe hypotension for the sake of preventing coughing on the tube or brief hypertension with intubation.

Table 63-10 Glasgow Coma Scale

Table 63-11 Factors That May Be Relevant during Intubation of a Head-Injured Patient

- Full stomach
- Uncertain cervical spine
- Uncertain airway
  - Blood
  - Airway injury (larynx, cricoarytenoid cartilage)
  - Skull base fracture
- Uncertain volume status
- Uncooperative/combative
- Hypoxemia
- Increased ICP

ICP, intracranial pressure.

Cervical Spine

The possibility of causing or aggravating an injury to the cervical spine is a relevant concern. Approximately 2% of blunt trauma victims who survive to reach a hospital and 8% to 10% of TBI victims with GCS less than 8 have a fracture of the cervical spine.[224,225] This incidence suggests that a "hypnotic-relaxant-direct laryngoscopy" approach for all patients with a closed-head injury might convey a measurable risk of injuring the cervical cord. Nonetheless, although the literature contains contradictions, several published series have concluded that a rapid-sequence induction does not convey significant risk of neurologic injury.[226-230] It is possible, however, that the incidence of intubation-related neurologic injury is underreported. An informal survey reported by Criswell and colleagues[226] indicated that there have been more such events than one can infer from the published literature.[231,232]

Nonetheless, the literature argues that we will "get away with it" most of the time, and most TBI patients requiring airway control are intubated using a hypnotic-relaxant-direct laryngoscopy sequence. It is our (probably minority) opinion, however, that the possibility of devastating spinal cord injury exists, probably most so with injuries in the atlanto-occipital region, which are also difficult to identify radiologically,[233] and that the anesthesiologist should identify circumstances in which time latitudes allow more detailed examination or radiologic evaluation. When there is any uncertainty regarding the airway or the cervical spine, direct laryngoscopy (with vigorous atlanto-occipital extension) should probably be avoided, unless the exigencies of airway control demand it (which often is the case). The nasal route can be considered if the clinical context warrants, bearing in mind that risk of infection may be increased with skull base fracture and CSF leak. The anesthesiologist needs to use discretion (e.g., in the presence of an obvious facial smash, the nasal route should be avoided because of the possibility of entering the cranium) and be sensitive to unusual resistance in passing the endotracheal tube.

When a hypnotic muscle-relaxant sequence is used, the standard approach includes the use of cricoid pressure and in-line axial stabilization. In-line traction previously was favored, but has been supplanted by stabilization because of the perceived risk of overdistraction and cord injury in the event of gross instability. The largest of the clinical series that concluded that oral intubation with anesthesia and relaxation is reasonable[227] used in-line stabilization with the patient's occiput held firmly on the backboard, limiting the amount of "sniff" that was feasible (Fig. 63-15). There is no question that in-line stabilization, properly performed, makes laryngoscopy more difficult, but it decreases the amount

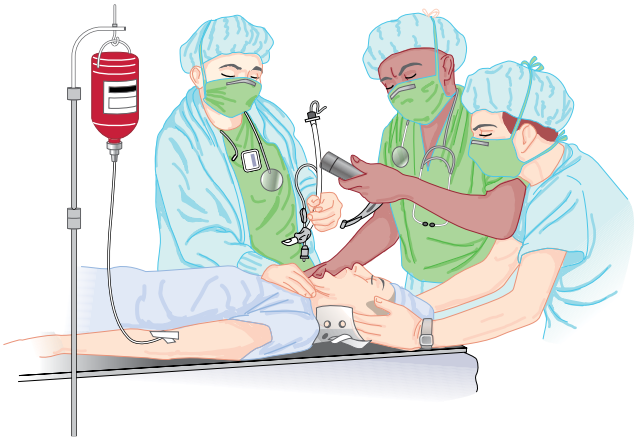

Figure 63-15 Intubating an acute trauma patient with an uncertain cervical spine injury . A hypnotic and a relaxant have been administered. One assistant maintains in-line axial stabilization with the occiput held firmly to the back-board; a second applies cricoid pressure. The posterior portion of the cervical collar remains in place to "discourage" atlantoaxial extension. *(From Stene JD: Anesthesia for the critically ill trauma patient.* In *Siegel JH [ed]: Trauma: Emergency Surgery and Critical Care. Melbourne, Churchill Livingstone, 1987, pp 843-862.)*

of atlanto-occipital extension necessary to achieve visualization of the glottis.[234] This is probably because performing the laryngoscopy against the assistant's counter pressure results in greater compression of the soft tissue structures of the tongue and floor of the mouth. Some recommend leaving the back half of the Philadelphia collar in place during laryngoscopy (see Fig. 63-15) because it functions as a strut between the shoulder and the occiput limits atlanto-occipital extension.

In the resuscitation situation, before initiating a hypnotic-relaxant sequence, the anesthesiologist should confirm the availability of cricothyrotomy equipment and of someone to make immediate, skilled use of it if necessary. The recently injured brain is very intolerant of hypoxia and hypotension.[235] The occasional failed intubation is inevitable. In the extensive experience of the Cowley Shock-Trauma Center in Baltimore, the cricothyrotomy/tracheostomy rate is 0.3%.[236] As is the case in many other situations, the laryngeal mask may be a useful device for temporizing in the face of a failed intubation, and may provide access for intubation as an alternative to cricothyrotomy.

As noted Chapter 13, although succinylcholine can cause ICP increases, these increments are small; they probably do not occur at all in patients with serious cerebral injuries.[6] Succinylcholine should not be contraindicated in a patient with TBI. If there is an urgent need to secure the airway (to guarantee oxygenation and control $Paco_2$), and if succinylcholine is in other respects the appropriate drug to achieve that end, it should be used.

The situation of a patient whose cervical spine has not been "cleared" should arise with decreasing frequency in unconscious patients because of the proliferation of multidetector CT scanners, which allow rapid, thin-slice evaluation, with sagittal reconstruction, of the cervical spine. The combination of a three-view plain film series and CT scanning (and most of these patients require CT evaluation for other reasons) is reported by one reviewer to have a false-negative rate for serious injury of less than 0.1%.[237] Another survey reported, however, that CT may miss a significant number of ligamentous injuries.[238] With respect to a conscious patient who has not yet undergone complete radiologic evaluation, several clinical surveys have confirmed that patients who are alert, nonintoxicated, and free of significant distracting injuries invariably have pain, midline tenderness, limitation of voluntary movement, or neurologic signs[239-241] if they have a cervical spine fracture.

Despite the frequency with which an anesthesiologist may encounter a patient still wearing a Philadelphia collar because his or her neck has not yet been "cleared," no special precautions seem warranted in an asymptomatic, alert patient. If the clinical situation or examination is suspicious for a cervical spine injury, a normal lateral x-ray (the anteroposterior and through-the-mouth odontoid views are frequently not taken during initial evaluation) cannot provide complete reassurance. The lateral view has been reported to miss 15%[242] to 26%[239] of fractures.

Anesthetic Technique

Choice of Anesthetic Drugs. Craniotomies most commonly are performed for the evacuation of subdural, epidural, or intracerebral hematomas. The anesthetic approach is similar for all three. The guiding principles have been discussed in the section on control of intracranial pressure and brain relaxation. Generally, anesthetics that are cerebral vasoconstrictors are preferable to anesthetics that have the potential to dilate the cerebral circulation. All of the intravenous anesthetics except perhaps ketamine cause some cerebral vasoconstriction and are reasonable choices, provided that they are consistent with hemodynamic stability. All of the inhaled anesthetics (N_2O and all of the vapors) have some cerebral vasodilatory effect. Although their administration frequently is consistent with acceptable ICP levels and appropriate conditions in the surgical field, when the ICP is out of control (or unknown), or the surgical field is "tight," eliminating the inhaled agents in favor of fixed agents is appropriate.

For patients who are likely to remain intubated postoperatively, an anesthetic based primarily on a narcotic (e.g., fentanyl) and a muscle relaxant usually serves well. Any muscle relaxant is acceptable with the proviso that agents that can release histamine should be titrated in careful increments. When immediate tracheal extubation is a possibility (e.g., a patient with an acute epidural hematoma who had a lucid interval before witnessed deterioration), the technique should be modified after the opening of the cranium. Introduction of inhaled anesthetics or the use of shorter acting intravenous anesthetics, or both, can be undertaken as guided by observation of the surgical field. If N_2O is contemplated at any time, the anesthesiologist must remember the possibility, in the setting of missile injury or compound skull fracture, of intracranial air.

Monitoring. The anesthesiologist should appreciate that the priority is to open the cranium as rapidly as possible. After achieving intravenous access, the risks and benefits of delaying craniotomy for line placement should be carefully considered. An arterial line, often placed after induction in urgent situations, is appropriate for essentially all acute trauma craniotomies. The decision to achieve central venous access can be made on the basis of the patient's hemodynamic status. Cardiovascular collapse after dural opening with high ICP may occur[243]; adequate volume resuscitation may mitigate this complication. Infrequently, the management of a depressed skull fracture over the sagittal sinus justifies

a precordial Doppler and, subject to the surgeon's assessment of VAE risk, a right heart catheter.

Blood Pressure Management. The concept that the injured brain is extremely vulnerable to what would otherwise be a minor insult (e.g., modest hypotension, moderate hypoxia) has been well confirmed in the laboratory.[244,245] Although there are as yet no completely conclusive data derived in humans, several clinical surveys confirm the association of otherwise minor degrees of hypotension and hypoxia and poor outcome in TBI patients.[235,246-250] The explanation for this vulnerability to hypotension probably relates partly to the observation that some patients in the postinjury period have regions of brain with precariously low CBF,[23,33,38,251] in which autoregulation also may be defective.[37,252] Although it has been argued that reduced CBF is partly a normal concomitant of the reduced CMR that commonly occurs after TBI, there is nonetheless ample reason to worry about the occurrence of ischemia. First, a large percentage of patients who die after TBI have pathologic changes consistent with ischemia.[145] Second, there is considerable evidence that the low postinsult CBF values correlate with a poor eventual outcome.[23,36,247,253,254] These observations have resulted in a much greater emphasis among neurosurgeons, neurointensivists, and anesthesiologists on aggressive support of blood pressure in the TBI patient.

What constitutes an appropriate blood pressure? Systematic studies, in particular the studies conducted at the University of Edinburgh, revealed that indices of the adequacy of cerebral perfusion derived from $SjvO_2$ and TCD data begin to deteriorate below a mean CPP (CPP = MAP − ICP) of 70 mm Hg,[247,255,256] and many centers adopted 70 mm Hg as the target CPP. A clinical investigation by Robertson and colleagues[257] comparing the ICU management of TBI patients at CPPs of 70 mm Hg and 50 mm Hg showed that although indices of cerebral well-being were improved by the former, there was no outcome advantage, apparently because of the cardiopulmonary morbidity associated with achieving a sustained CPP of 70 mm Hg. As a result, many groups and authorities have adopted 60 mm Hg as the minimum CPP management objective.[258-261] The most recent recommendations of the Brain Trauma Foundation give clinicians wide latitude in recommending CPP target values "within the range of 50-70 mm Hg."[59]

There are at least two alternative opinions regarding blood pressure management (Fig. 63-16). The first, promoted by the neurosurgery group at the University of Alabama, Birmingham, is that induced hypertension can be employed as an adjunct to ICP control.[23,262] This idea is based on the belief that autoregulation is at least partially preserved after head injury, and that an increased CPP results in autoregulation-mediated vasoconstriction with a concomitant reduction in CBV and ICP. These investigators reported a very satisfactory local experience[262] with this approach, but it has not been applied widely, and others have reported that induced hypertension was either ineffective or deleterious as a means of reducing increased ICP.[10,263] The second alternative is the so-called Lund concept, which is based on the premise that high blood volume and hydrostatically driven edema accumulation make a substantial contribution to increased ICP.[264-266]

As originally described, the Lund approach entailed dehydration; hyperosmolarity; and the administration of metoprolol, clonidine, and dihydroergotamine to reduce blood pressure to a

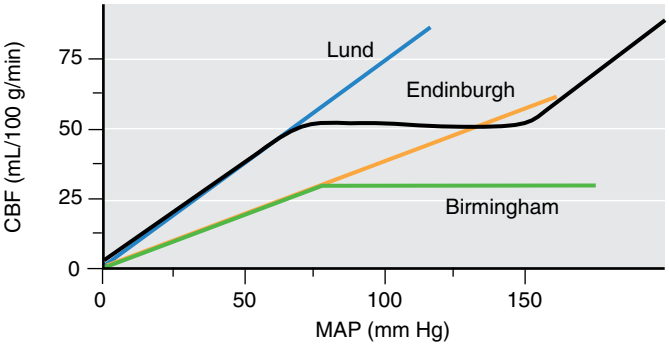

Figure 63-16 The relationship of cerebral blood flow (CBF) to blood pressure after head injury. There are three cerebral perfusion pressure (CPP) management strategies (see text) driven by differing beliefs about common pathophysiologic derangements. The most commonly used strategy, "Edinburgh" (named for the institution of the original proponents), emphasizes low postinjury CBF, impaired autoregulation, and the necessity to support CPP (mean arterial pressure [MAP] – intracranial pressure [ICP]) to 70 mm Hg. The "Lund" concept emphasizes the contribution of hyperemia to the occurrence of elevated ICP. This approach uses antihypertensive agents to reduce blood pressure, while maintaining CPP greater than 50 mm Hg.[264] That CPP target has increased, in the most recent iteration, to 60 to 70 mm Hg with allowance for occasional reduction to 50 mm Hg.[266] An approach from the University of Alabama, identified as "Birmingham," entails pharmacologically induced hypertension. This approach is based on the belief that autoregulation is largely intact, and that hypertension would result in cerebral vasoconstriction with concomitantly reduced cerebral blood volume and ICP.[262,331]

CPP target of 50 to 55 mm Hg. At its inception, the approach was controversial because it ran counter to the perceptions of many clinicians of the importance of maintaining a CPP of 70 mm Hg, and because of the later demonstration that a negative fluid balance in patients with TBI is deleterious.[249] Over time (and in parallel with a relaxation the CPP targets by others[59,258-260]), the Lund proponents have modified their approach, and now "a CPP of 60-70 is considered optimal," and normovolemia is the clinical objective.[266]

The essence of the previously controversial Lund approach is no longer the aggressive CPP reduction that was the originally proclaimed cornerstone, although sedatives, clonidine, and metoprolol are administered to prevent hypertension. The Lund concept's distinguishing features are now (1) the routine infusion of low-dose thiopental (to reduce the "stress response" and to decrease CMR and CBV); (2) the maintenance of colloid osmotic pressure at unspecified levels by the generous administration of albumin; and (3) the cautious administration of dihydroergotamine, also to reduce CBV (by a putative selective cerebral venoconstrictive effect).[266] Although there is a theoretical basis for each of the components, the existing literature provides no compelling support. Although the proponents of the Lund approach assert improvements in outcome, those reports invariably entail either no control group or comparisons with nonconcurrent controls.[267-269] The approach has not been adopted in North America.

What should an anesthesiologist managing a TBI patient do in the face of these various approaches? The approaches have in common perfusion pressure support of varying degrees. The characteristic behavior of CBF after head injury is an initially low CBF followed by a gradual increase over 48 to 72 hours to normal or sometimes even slightly hyperemic levels.[23,33,37,38,251,258,270] Aggressive support of CPP in the 60 to 70 mm Hg range during

that period would be the most reasonable general approach. In patients with subarachnoid blood, a second period of low CBF may occur from days 2 to 13 postinjury, apparently on a vasospasm-related basis.[35,271] Phenylephrine, norepinephrine, and dopamine all have been employed to increase blood pressure. Norepinephrine has been reported to accomplish CBF augmentation more consistently than dopamine.[272]

There are exceptions to the foregoing generalizations about CBF after TBI. Although an initially low postinjury CBF is probably the most common clinical occurrence, hyperemia does occur.[35,39,270,271,273] It tends to occur in patients with mass lesions rather than contusions, although patients with contusions have an immediate postinjury period of low CBF, with delayed hyperemia peaking at 24 hours or later.[34,35,253,270,273] Hyperemia also may be common in children.[274] In the ideal situation, CPP management should be "targeted" to the pathophysiology that prevails in the individual patient.[275] There is substantial evidence that not all TBI patients benefit from increases in perfusion pressure. Patients with impaired autoregulation, low baseline flows, and increased ICP are most likely to benefit.[276-278] Techniques to discriminate the various flow states (CBF measurement, TCD, $Sjvo_2$, brain tissue Po_2—see later) are not universally available or applied, however, and in their absence, the common practice is to maintain CPP 60 to 70 mm Hg in the first 72 hours after TBI.[256,258,261,279-281] A CPP target of 45 mm Hg has been recommended for children.[282] With these firm recommendations offered, it must be acknowledged that convictions vary, and anesthesiologists should come to an understanding with the local traumatologists and neurosurgeons regarding blood pressure targets.

Hyperventilation. The use of hypocapnia has been reviewed in detail in the section on management of $Paco_2$. Hyperventilation has long been a component of the management of TBI patients, and the effectiveness of acute hypocapnia in reducing ICP is well confirmed.[10] There is substantial evidence, however, that hyperventilation is potentially deleterious[23,24,29-31,283] and should not be overused. The evidence suggests that hyperventilation and the concomitant vasoconstriction can result in ischemia,[21,29-32] especially when baseline CBF is low,[32] as is likely to be the case in the first 48 to 72 hours after head injury.[23,33,38,39] The expert panel convened by the Brain Trauma Foundation specified that prophylactic hyperventilation is "not recommended," and that "hyperventilation should be avoided during the first 24 hours after injury when CBF is often critically reduced."[59] The available information argues that hyperventilation should be used selectively rather than routinely in the management of TBI patients. Maintaining ICP less than 20 mm Hg, preventing or reversing herniation, minimizing retractor pressure, and facilitating surgical access are still important objectives in the management of TBI patients and to the extent that hyperventilation contributes to these objectives, it is still appropriate. The anesthesiologist should agree on management parameters with the surgical team at the outset of a procedure.

Fluid Management. Fluid management of head-injured patients was addressed in the earlier section on intravenous fluid management. The important principles are that fluids should be chosen invariably to prevent reduction of serum osmolarity and should probably be chosen to prevent profound reduction of colloid oncotic pressure; in the circumstances of a large-volume resuscitation (arbitrarily, greater than half a circulating volume), a mix of colloids and crystalloids is probably appropriate. The clinical objective should be to maintain intravascular normovolemia, in part as an adjunct to MAP and CPP support. A chronic negative fluid balance, as can occur with the combination of modest fluid restriction and liberal use of osmotic diuretics, has been shown to be deleterious and should be avoided.[249] The severely injured brain can liberate sufficient thromboplastin into the circulation to result in a consumptive coagulopathy.[284] Appropriate laboratory tests and replacement should be performed. The clinician also may find a serum osmolarity determination early in the course of anesthetic management useful in appreciating the cumulative effects of prior mannitol administration. The use of hypertonic solutions and the relevant attributes of colloid solutions were discussed in the section on intravenous fluid management.

Jugular Venous Oxygen Saturation

Numerous centers have studied or made use of $Sjvo_2$ monitoring as a guide to the clinical management of head-injured patients.[29-32,40,247,256,257,281,285] The underlying concept is that a marginal or inadequate CBF results in an increasing oxygen extraction, a widening arteriovenous content difference, and reduction of $Sjvo_2$. Normal subjects at rest may have $Sjvo_2$ values between 55% and 75%. $Sjvo_2$ less than 50% for 5 minutes is commonly accepted as constituting "jugular desaturation." There have been numerous reports of low $Sjvo_2$ values improving with interventions including reducing hyperventilation, increasing MAP, or inducing hypervolemia. $Sjvo_2$ measurement makes an assessment of *global* oxygen extraction. It might be expected to have limited sensitivity to highly *focal* events, and instances in which focal inadequacy of perfusion was not reflected by low $Sjvo_2$ have been reported.[29-31,39] One of those investigations offers a possible explanation for normal $Sjvo_2$ in the face of significant focal ischemia. Coles and colleagues[39] showed the coexistence of areas of hyperemia and hypoperfusion in individual TBI patients. The former would tend to mask the $Sjvo_2$ reduction that would occur if the latter (hypoperfusion) were to occur in isolation. An additional limitation inherent to the unilateral placement of the catheter was found by Stocchetti and associates,[286] who observed that there was an average side-to-side difference between simultaneous jugular bulb saturations of 5.3 ± 5%, and that side-to-side differences in hemoglobin saturation of 15% were common.

Despite the reported successes with $Sjvo_2$ monitoring,[40,287,288] we do not believe that the method is sufficiently well defined to justify advocating widespread intraoperative application. In the ICU, it seems potentially useful as a trend monitor that may serve to identify the level of CPP or hyperventilation below which cerebral perfusion *begins* to be compromised, with the proviso that there is a significant potential for false-negative results.[29-31,39] The technique also has a potential use beyond using $Sjvo_2$ values to warn of inadequate perfusion. High $Sjvo_2$ values may serve to identify a patient with elevated ICP in whom hyperemia is an important contributing factor, and in whom aggressive attempts to decrease CBF (e.g., hyperventilation, barbiturates) may be beneficial.

Brain Tissue Po_2 Monitoring

There are small-diameter intraparenchymal electrodes that allow measurement of brain tissue Pbo_2 (and sometimes pH and $Pbco_2$). They have been used to monitor cerebral well-being during the ICU management of TBI and SAH patients, and to

assess the effect of operative interventions.[289] A Pbo_2 of 20 mm Hg or greater is viewed as normal, and values of 10 mm Hg or less are assumed to convey a substantial risk of hypoxic injury. Pbo_2 monitors have the inverse of the problem that prevails with $Sjvo_2$ monitoring—they provide very focal information about the oxygenation status of only small regions of brain surrounding the tip. If they are placed remote from focal injuries to provide a "global" measure of oxygenation, they may not "see" adverse events in at-risk but salvageable perilesional tissue. They may similarly fail to be a useful therapeutic guide if they are within irredeemably injured brain.

So far, the use of Pbo_2 monitoring is neither standardized nor widespread. One center has reported, however, on the basis of a comparison with a historic control group, a reduction in mortality when established management guided by CPP and ICP was supplemented with Pbo_2-directed care, with the probe placed in white matter adjacent to, but not within, areas of severe injury.[290] The same group has reported that 29% of TBI patients with a GCS score of 8 or less have brain regions with Pbo_2 of 10 mm Hg or less despite meeting CPP and ICP targets of 60 mm Hg and greater (CPP) or less than 25 mm Hg (ICP).[261]

Hypothermia

There is clearly an ischemic component to the pathophysiology of TBI, and mild induced hypothermia was shown to be highly protective in experimental cerebral ischemia (see also the preceding section on hypothermia). On that basis, study of hypothermia after experimental head injury was undertaken, and improvements in outcome were shown.[146] Hypothermia in the management of TBI patients was the subject of at least four small, prospective controlled trials.[147-150] Because those trials seemed to indicate good patient tolerance of sustained mild hypothermia (32°C to 34°C) and improvement in ICP, cerebral oxygen supply and demand, and outcome, a multicenter trial was performed. This trial revealed no overall benefit of hypothermia.[151] As a result, there is no established role for hypothermia in head injury management as of this writing.

Post hoc analysis showed that patients younger than age 45 who were already hypothermic (≤35°C) at the time of admission to the hospital did have an improved outcome. This finding led to the concern that the protocol, which required induction of hypothermia within 8 hours of injury, was not achieving hypothermia rapidly enough to achieve the potential benefits. A follow-up trial is under way. Patients 16 to 45 years old, with a GCS score less than 8, who arrive at the hospital with a bladder temperature of 35°C or less are to be randomly assigned to cooling to 32.5°C to 33.5°C (within 4 hours of injury) for 48 hours or passive rewarming to normothermia. Outcome is to be assessed at 6 months.

Intracranial Pressure Monitoring for Non-neurologic Surgery in a Head-Injured Patient

In the ideal situation, neurosurgical consultation will be readily available, and, appropriately, the anesthesiologist will rarely have to make the decision regarding ICP monitoring. It may be necessary, however, for the anesthesiologist to participate in this decision. The relevant variables are as follows:

1. *The level of consciousness*. If there has been a loss of consciousness at any time, or if the GCS score is less than 15, a CT scan should be obtained. If the CT scan reveals compressed basal cisterns (indicative of an exhaustion of supratentorial compensatory latitudes), midline shift, or effaced ventricles, and probably any intracranial lesion (e.g., contusion, small subdural), an ICP monitor should be placed. Excessive comfort should not be taken from a good GCS score. Patients with good GCS scores can "talk and deteriorate" or "talk and die" after a head injury associated with loss of consciousness. Delayed deterioration has been observed 48 hours after the initial injury (average 17 hours).[291] Patients with lesions, usually contusions, in the frontotemporal region and especially patients with medial temporal lesions are most at risk for this phenomenon. Modest expansion of lesions in this location (i.e., close to the uncus and the incisura where herniation occurs) can result in herniation even at relatively low ICPs (e.g., approximately 20 mm Hg). At our institution, neurosurgeons would recommend avoiding an anesthetic in these patients and would advise ICP monitoring if general anesthesia were unavoidable.
2. *Time since injury*. The longer the patient has had to declare his or her clinical course, the less pressing is the need for ICP monitoring. Delayed deterioration, as noted previously, has been observed for up to 48 hours,[291] however, and a patient with a demonstrable CT lesion is a candidate for a monitor for at least this period of time.
3. *Intended aortic occlusion* (i.e., repair of ruptured aorta). Dramatic increases in ICP have been associated with aortic occlusion. This may in large part be the result of the abrupt increase in blood pressure or the agents used to control it, or both. In addition, the increased airway and venous pressures associated with the lateral position and one-lung ventilation plus occasional difficulties in maintaining hypocapnia during one-lung ventilation should result in a low threshold for ICP monitoring in this situation. The intent to heparinize systemically essentially precludes the placement of a monitor, although lumbar drains have been used with cardiopulmonary bypass.[219]
4. *Nature and duration of the intended procedure*. The risks of an untoward ICP event are inevitably greater in a 6-hour spine instrumentation in the prone position than for a 20-minute débridement and suturing of an arm laceration.

Posterior Fossa Procedures

Most of the topics relevant to posterior fossa procedures (Table 63-12) have been discussed in the section on recurrent issues. These include the sitting position and its cardiovascular effects and complications (e.g., quadriplegia, macroglossia), pneumocephalus, and VAE and PAE. The use of the sitting position to facilitate surgery in the posterior fossa increases the likelihood of all of these phenomena, although they are relevant to nonsitting positions as well. This section reviews the cardiovascular events associated with direct stimulation of the brainstem and their possible implications for postoperative management.

Brainstem Stimulation

Irritation of the lower portion of the pons and of the upper medulla and of the extra-axial portion of the fifth cranial nerve can result in numerous cardiovascular responses. The former two areas are most often stimulated during procedures on the floor of

Table 63-12 Considerations Relevant to Posterior Fossa Procedures and the Location (Section, Subsection) of the Related Discussion in Chapter

Consideration	Section, Subsection
Hemodynamic effects of sitting position	Positioning, Sitting
Venous air embolism	Venous Air Embolism
Paradoxical air embolism	Venous Air Embolism
Hemodynamic effects of brainstem and cranial nerve manipulation	Posterior Fossa Procedures
Macroglossia	Positioning, Sitting
Pneumocephalus	Pneumocephalus
Quadriplegia	Positioning, Sitting

the fourth ventricle and the last during surgery at or near the cerebellopontine angle (e.g., acoustic neuromas, microvascular decompression of fifth [tic douloureux], seventh [hemifacial spasm], or ninth [glossopharyngeal neuralgia] cranial nerves). The cardiovascular responses may include bradycardia and hypotension, tachycardia and hypertension, bradycardia and hypertension, and ventricular dysrhythmias.[292] Meticulous attention to the ECG and a directly transduced arterial pressure during manipulation in this region are necessary to provide the surgeon with immediate warning of the risk of damage to the adjacent cranial nerve nuclei and respiratory centers. Pharmacologic treatment of the dysrhythmias that occur may attenuate the very warning signs that should be sought.

Balloon compression of the trigeminal ganglion is another situation in which a dysrhythmia may occur. The procedure attempts to produce a neurapraxia of the fifth cranial nerve by the rapid inflation of a Fogarty-type balloon within Meckel's cave.[293,294] The balloon is introduced percutaneously through the cheek and beneath the maxilla. The procedure is best accomplished with a general anesthetic because the entry of the needle into Meckel's cave and the balloon compression (lasting several minutes) are intensely stimulating. A relatively profound, although transient, bradycardia occurs and is sought as confirmation of adequate compression. External pacemaker pads have been advocated, but in our experience are unnecessary.

Irritation and injury of posterior fossa structures that may have occurred during surgery should be taken into account in planning extubation and postoperative care. In particular, procedures involving dissection on the floor of the fourth ventricle entail the possibility of injury to cranial nerve nuclei or postoperative swelling in that region, or both. Cranial nerve dysfunction, particularly of cranial nerves IX, X, and XII, can result in loss of control and patency of the upper airway, and swelling of the brainstem can result in impairment of cranial nerve function and respiratory drive. The posterior fossa is a small space, and its compensatory latitudes are even more limited than those of the supratentorial space. Relatively little swelling can result in disorders of consciousness, respiratory drive, and cardiomotor function. A meeting should occur between the anesthesiologist and the surgeon to make decisions as to whether extubation is appropriate, and where postoperative observation should occur (i.e., ICU or non-ICU).

Spontaneous ventilation was previously advocated for procedures that entailed a risk of damage to the respiratory centers. Spontaneous ventilation is now rarely used because the proximity of the cardiomotor areas to the respiratory centers should permit cardiovascular signs to serve as an indicator of impending injury to the latter. In our opinion, respiratory pattern is more likely to be a relevant monitor when the "threat" to the brainstem is the result of vessel occlusion (as might occur with accidental interruption of perforating vessels during vertebrobasilar aneurysm surgery[295]) than when it is because of direct mechanical damage caused by retraction of or dissection in the brainstem.

Various electrophysiologic monitoring techniques may be used during posterior fossa surgery, including somatosensory evoked responses, brainstem auditory evoked responses, and electromyographic monitoring of the facial nerve. Electromyography requires that the patient not be paralyzed or have a constant state of incomplete paralysis. Somatosensory evoked response monitoring imposes some constraints with respect to the selection of anesthetic agents. These are discussed in Chapter 46.

Transsphenoidal Surgery

The transsphenoidal approach to the sella turcica is used for the excision of tumors that lie within the sella or that have extended to or originated in the immediate suprasellar area. The most common lesions are prolactin-secreting microadenomas and nonsecreting macroadenomas. Patients with the former are usually women who present with secondary amenorrhea. Nonsecreting adenomas tend to manifest with mass effects (i.e., headache, visual disturbance, hypopituitarism) and are typically larger at the time of diagnosis. There are three other, less common pituitary tumors: Growth hormone–secreting lesions result in acromegaly, adrenocorticotropic hormone (ACTH)–secreting tumors cause Cushing's disease, and a very rare thyroid-stimulating hormone–secreting lesion results in hyperthyroidism. A detailed review of the perioperative management of this group of patients is available.[296]

Preoperative Evaluation

The important preoperative considerations relate to the patient's endocrine status. Generally, as a pituitary lesion expands and compresses the pituitary tissue, the sequence in which hormonal function is lost is first gonadotropins; second, growth hormone; third, ACTH; and fourth and last, thyroid-stimulating hormone. The precise definition of the adrenal status of these patients is often not critical because the patients commonly receive adrenal hormone supplementation at least temporarily. Profound hypocortisolism, with associated hyponatremia, should be corrected preoperatively. It is uncommon for thyroid deficiency to occur. Hypothyroidism should be sought and corrected preoperatively, however, because hypothyroid patients have a diminished tolerance to the cardiovascular depressant effects of anesthetic agents. Hypertension, diabetes, and central obesity are common concomitants of ACTH-secreting adenomas (Cushing's disease). Patients with advanced acromegaly can develop an enlarged tongue and a narrowed glottis, and the airway should be evaluated accordingly (Table 63-13).

Monitoring

Many practitioners place an arterial catheter, but it is not absolutely necessary. Access for blood sampling is a valuable adjunct to postoperative care if diabetes insipidus develops. Blood loss is

Table 63-13 Tumors of the Pituitary Region

Location	Hormone Secreted	Clinical Presentation	Comment
Anterior pituitary	Prolactin	Galactorrhea, amenorrhea, hypogonadism, infertility	Bromocriptine sensitive
	Adrenocorticotropin	Cushing's disease (hypercortisolism)	Basophilic adenoma; centripetal obesity; diabetes mellitus; friable tissues
	Growth hormone	Acromegaly/gigantism, glucose intolerance	Eosinophilic adenoma; difficult airway; thick skin (difficult cannulation); hypertension/cardiomyopathy
	Nonsecretory	Mass effect, panhypopituitarism	Chromophobic adenoma; consider preoperative hormone replacement
Suprasellar	Nonsecretory	Panhypopituitarism, SIADH, visual symptoms, hydrocephalus	Craniopharyngioma, Rathke cleft cyst, or suprasellar extension of pituitary lesion

SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

usually modest. The cavernous sinus is in immediate lateral relation of the pituitary, however, and may be entered during the resection of large tumors. The carotid arteries pass through the cavernous sinuses and are similarly at risk. In addition, in some patients, there is a venous sinusoid that lies in front of the pituitary gland and connects the two cavernous sinuses. This can be the origin of substantial blood loss. It has occasionally precluded this approach to the pituitary gland.

Anesthetic Technique

The latitudes are broad with respect to choice of agent, although tumors with suprasellar extension can cause hydrocephalus and add increased ICP constraints to the anesthetic technique. The procedure is performed in a supine position usually with some degree of head-up posture to avoid venous engorgement. A pharyngeal pack prevents an accumulation of blood in the stomach (which causes vomiting) or in the glottis (which contributes to coughing at extubation). A RAE-type tube secured to the lower jaw at the corner of the mouth opposite the surgeon's dominant hand (e.g., left corner of mouth for a right-handed surgeon) is suitable. A small esophageal stethoscope and temperature probe can lie with the endotracheal tube. Covering the entire bundle with a towel drape (a plastic sheet with an adhesive edge) placed just below the lower lip so that it hangs from the lower jaw like a veil protects it from the preparation solutions.

The procedure is commonly performed with a C-arm image intensifier (lateral views), and the head and arms are relatively inaccessible when the patient is draped. It is appropriate to establish the nerve stimulator at a lower extremity site. The surgical approach is via the nasal cavity, usually through an incision made under the upper lip. During the approach, the mucosal surfaces within the nose are infiltrated with a local anesthetic and epinephrine solution, and the patient should be observed for the occurrence of dysrhythmias.

Surgical preferences for CO_2 management vary. In some instances, hypocapnia is requested to reduce brain volume and minimize the degree to which the arachnoid bulges into the sella. An important surgical consideration is the avoidance, where possible, of opening the arachnoid membrane. Postoperative CSF leaks can be persistent and are associated with a considerable risk of meningitis. By contrast, when there is suprasellar extension of a tumor, normal or increased CO_2 helps to deliver the lesion into the sella for excision.[297] As an alternative way to accomplish this, some surgeons have resorted to "pumping" of saline or air into the lumbar CSF space.[298,299]

Diabetes insipidus is a potential complication of this procedure. Antidiuretic hormone is synthesized in the supraoptic nuclei of the hypothalamus and is transported down the supraoptic-hypophyseal tract to the posterior lobe of the pituitary. This portion of the pituitary gland is frequently spared. Even when it is excised, water homeostasis commonly normalizes, presumably because antidiuretic hormone is released from the cut-end of the tract. When the pituitary stalk is transected, and occasionally even when the posterior lobe of the pituitary is left intact, transient diabetes insipidus may occur. Diabetes insipidus very rarely arises intraoperatively. It usually occurs 4 to 12 hours postoperatively and is typically transient. The clinical picture is one of polyuria in association with an increasing serum osmolality. The diagnosis is made by comparison of the osmolalities of urine and serum. Hypo-osmolar urine in the face of an increased and increasing serum osmolality strongly supports the diagnosis. Urine specific gravity is a useful bedside test. In the presence of bona fide diabetes insipidus, specific gravity is low (i.e., ≤1.002).

When the diagnosis of diabetes insipidus is established, an appropriate fluid management regimen is hourly maintenance fluids plus two thirds of the previous hour's urine output. (An acceptable alternative is previous hour's urine output minus 50 mL plus maintenance.) The choice of fluid is dictated by the patient's electrolyte picture. Generally, the patient is losing fluid that is hypo-osmolar and relatively low in sodium. Half-normal saline and 5% dextrose in water are commonly used as replacement fluids. Hyperglycemia is a risk when large volumes of 5% dextrose in water are employed. An *un*acceptable fluid regimen that has been employed calls for maintenance fluids plus previous hour's urine output. This has the potential to put the anesthesiologist and the patient in a "chase your tail" situation. Should the patient become iatrogenically fluid overloaded, this regimen precludes his or her returning to isovolemia, and when the maintenance fluid allowance is generous, it guarantees that the patient will become increasingly hypervolemic. If the hourly requirement exceeds 350 to 400 mL, desmopressin (DDAVP) is usually administered.

A smooth emergence (see the section on emergence from anesthesia) is desirable especially if the CSF space has been opened (and resealed with fibrin glue or by packing the sphenoid sinus with fat or muscle). Repeated, intense Valsalva maneuvers,

as with coughing or vomiting, may contribute to the reopening of a CSF leak and worsen the risk of a subsequent meningitis. The airway should be cleared of debris, including formed clot. In situations in which there is concern that a persistent CSF leak may occur, the surgeon may place a lumbar CSF drain to maintain CSF decompression in the early postoperative period.

Awake Craniotomy and Seizure Surgery

Awake craniotomies are performed when tumors or epileptic foci lie close to cortical areas required for either speech or motor function or to mesiotemporal structures critical to short-term memory. Many patients have so-called temporal lobe epilepsy. There is commonly a structural lesion visible on magnetic resonance imaging (MRI). Sometimes there is a history of trauma. More commonly, the etiology is presumed to be an asphyxial birth injury.

Presurgical Evaluation

Before the resection, most patients have undergone a Wada test or video-telemetry or both. More recently, functional testing employing MRI or positron emission tomography, or both, has been introduced to the presurgical evaluation. The Wada test involves selectively anesthetizing the cerebral hemispheres, usually by injection of sodium amytal into the carotid artery to localize the hemisphere that controls speech or to confirm that there is bilateral representation for short-term memory, or both. Speech is an issue when the posterolateral portions of the temporal lobe are involved, and memory is the concern when the involvement is medial.

Anesthesia for Electroencephalogram Electrode Placement

Video-telemetry is performed to permit localization of the seizure focus that is responsible for the clinically problematic events. This evaluation usually requires prior placement of either subdural strip electrodes (via bur holes) or a subdural electrode grid (requiring a craniotomy). Occasionally, electrodes are placed deep into parenchyma, usually within the temporal lobe (placed stereotactically via bur holes), or are positioned so as to "look at" the inferior surfaces of the temporal lobe. The latter is commonly accomplished with so-called foramen ovale electrodes. These are placed using a needle similar to an epidural needle. The point of entry is about 2 cm lateral to the angle of the mouth. The needle is passed through soft tissue, under the temporal process of the zygomatic bone and medial to the ramus of the mandible, up to the base of the skull in the vicinity of the foramen ovale. Typically, this procedure is performed as a "MAC," although small doses of anesthetics, most often propofol, are usually required at the time of stimulation by the needle of the periosteum at the base of the skull. After placement of the relevant electrodes, the patient's seizure medication is discontinued, and the patient remains in an observation unit with EEG and patient behavior recorded continuously. In this manner, the EEG events associated with the clinically significant seizure events and their anatomic origin can be identified.

Preanesthetic Evaluation and Preparation

At the preoperative interview, the patient should be educated about the nature and duration of the procedure and the limitations on patient movement. One should obtain a description of the aura and the seizures to facilitate recognition of them. One should ascertain whether the patient is subject to grand mal convulsions. If intraoperative electrocorticography to identify seizure foci is intended, it is common to discontinue or reduce by half the anticonvulsants according to the perceived risk of uncontrolled seizures. Premedicants with an anticonvulsant effect (e.g., benzodiazepines) should not be used because they may interfere with intraoperative EEG localization.

Anesthetic Technique

The objectives of the anesthetic technique are as follows:

1. To minimize patient discomfort associated with the potentially painful portions of the procedure and with the prolonged restriction of movement
2. To ensure patient responsiveness and compliance during the phases of the procedure that require assessment of either speech or motor/sensory responses to cortical stimulation
3. To select anesthetic techniques that produce minimal inhibition of spontaneous seizure activity.

There are probably many ways of providing sedation that are consistent with the above-listed objectives. The techniques employed range from minimal sedation approaches, to deep sedation during which intermittent unresponsiveness is achieved with spontaneous ventilation and an unprotected airway, to asleep-awake-asleep techniques with intermittent airway management with a laryngeal mask airway (LMA), sometimes with positive-pressure ventilation.

At the outset, the anesthesiologist should appreciate that the essential element of an "anesthetic" for an awake craniotomy is the surgeon's local anesthetic technique. "Sedation" cannot compensate for inadequate anesthesia of the scalp, as accomplished by nerve blocks (Fig. 63-17), and pin site infiltration. Although the anesthesiologist can contribute enormously to the patient's comfort and tolerance of the painful components of the procedure and the prolonged immobilization, the anesthesiologist must not get trapped into thinking that it is his or her responsibility to provide a general anesthetic-equivalent in a spontaneously breathing patient with an unprotected and all but inaccessible airway.

For sedation, some clinicians use principally propofol by either physician-controlled or patient-controlled infusion.[300,301] The combination of propofol with either fentanyl or remifentanil in low dose (e.g., remifentanil, 0.02 to 0.05 μg/kg/min) also is reasonable.[302,303] Great care should be taken in administering additional sedative agents, especially narcotics, whose respiratory depressant effects would be synergistic with propofol. This is especially relevant with the use of pin fixation, which severely restricts the anesthesiologist's capacity to intervene quickly in the event of excessive respiratory depression or loss of patency of the airway.

Propofol should be discontinued at least 15 minutes before EEG recording. Despite prompt awakening, propofol leaves a residual EEG "footprint" characterized by high-frequency, high-amplitude beta activity, which can obscure the abnormal activity that is being sought in the cortical surface EEG.[300] The use of dexmedetomidine, which in addition to sedation and anxiolysis provides some analgesia with minimal respiratory depression, is

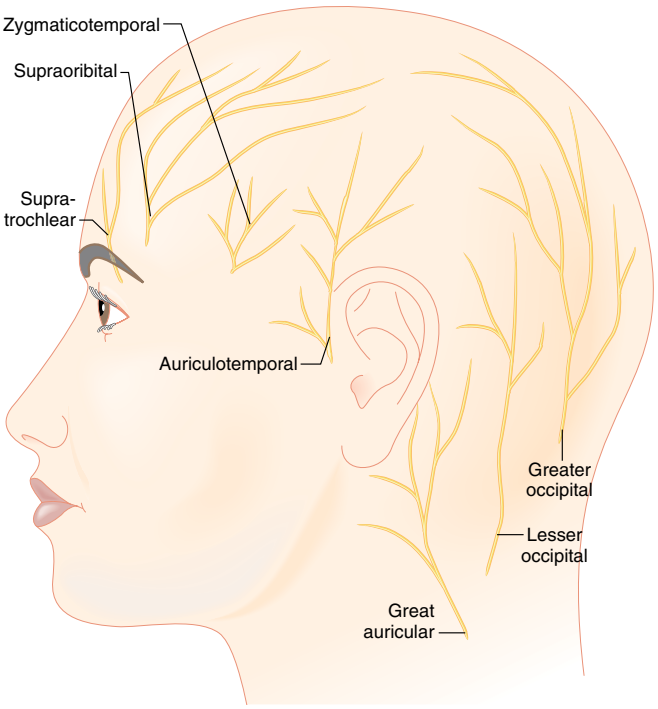

Figure 63-17 Cutaneous nerves to the scalp.

increasing.[304-306] The authors of those series report satisfactory conditions for functional testing, including brain stimulation for speech mapping and electrocorticography with the dexmedetomidine infusion ongoing at 0.1 to 0.5 µg/kg/hr during the testing.[305,307,308] The occurrence of delays in achieving satisfactory patient responsiveness has been reported,[306,309] however, and employing modest infusion rates (i.e., 0.1 to 0.3 µg/kg/hr) during neurocognitive testing seems advisable.[307] Administration of antiemetics (i.e., ondansetron, dexamethasone, or both) probably should be routine, especially if narcotics are administered.

Various groups have reported the use of the LMA, commonly with narcotic-propofol sedation and spontaneous ventilation during the craniotomy, with cessation of sedative administration and LMA removal after the brain surface is exposed.[304-307,310] Many approaches can be effective, but, to our knowledge, the LMA techniques have not been reported in patients in pin fixation.

Routine, noninvasive monitors are almost always sufficient. Reliable capnography, to provide breath-by-breath confirmation of airway patency and respiratory drive, is an essential component of the technique if deep sedation is intended for any portion of the procedure. These procedures are often lengthy, and attention to the details of patient comfort (e.g., warming blankets, a sheepskin, room temperature) improves patient tolerance.

The uncomfortable phases of the procedure are pin head holder placement (not all groups use a pin head holder) and the craniotomy. Many patients also find manipulation of the dura, in particular traction on subtemporal dura, painful. The actual manipulation of supratentorial brain parenchyma is painless. The volume of local anesthetic used to infiltrate pin sites and perform the scalp nerve blocks can be substantial. It is appropriate for the anesthesiologist to keep track of the doses of local anesthetic agents used.

The anesthesiologist should participate actively at the time of head positioning. The more "sniff" that can be achieved before the final lock-down of the head holder, the wider the latitudes will be for sedating the patient, while maintaining spontaneous ventilation and a patent airway. During positioning of the patient, the clinician also should pay attention to the need to maintain visual access to the face. A clear line of sight to the face is necessary to present the patient with images to name as part of speech testing and to identify the occurrence of facial motor responses during mapping of the motor strip.

Generally, after the dural opening is complete, cortical surface EEG recording is performed to locate the seizure focus. If no seizure activity is observed, provocative maneuvers may be requested.[311] Methohexital in a dose of approximately 0.3 mg/kg is generally safe and effective. Etomidate, approximately 0.05 to 0.1 mg/kg, also has been used. Localization of seizure focus also can be accomplished during light general anesthesia (e.g., N_2O/fentanyl/low-dose isoflurane). During general anesthesia, alfentanil in a bolus dose of 30 to 50 µg/kg,[312,313] etomidate in doses of 0.2 to 0.3 mg/kg,[314,315] and remifentanil in a bolus dose of 2.5 µg/kg[316] have been reported to be effective in activating seizure foci.

After localization by EEG, functional testing may be performed by stimulating the cortical surface electrically and observing for motor, sensory, or speech interruption effects. During stimulation, the anesthesiologist should be prepared to treat grand mal convulsions when they are not self-limited (e.g., with propofol in 0.5 to 1 mg/kg increments). Propofol should be withheld, however, until it is clear that the seizure is not going to terminate spontaneously because propofol may interfere with subsequent EEG localization of the seizure focus for some time.[300]

Stereotactic Procedures

Stereotactically guided procedures are done for numerous indications, including biopsy of small, deep-seated lesions; placement of deep brain stimulation electrodes, the latter; occasionally for seizure control and, more commonly, for the treatment of movement disorders (e.g., Parkinson's disease, essential tremor, dystonias).[317] Procedures related to movement disorders most often target the subthalamic nucleus, the internal segment of the globus pallidus, or the ventral intermediate nucleus of the thalamus (Fig. 63-18).[317] The mechanism of the beneficial effect is not well understood. A prominent theory is that the abnormal motor patterns are caused by abnormally synchronized oscillations in neural circuits involving several basal ganglia nuclei and the cortex, and that high-frequency stimulation of any of several points along the pathway can interfere with the oscillation.[318]

The issues with which the anesthesiologist must contend include restriction of airway access by the frame, restriction regarding choice of sedative when electrophysiologic recordings are to be performed as a guide to device placement, and the detection and management of complications (principally, seizures and intracerebral hematomas). Preoperative evaluation should include attention to ensuring that the coagulation process is intact, and that the patient has not been taking platelet-inhibiting agents (including herbal medications). There should be careful explana-

tion of the procedure, its likely duration, and the necessary restraints on patient movement.

Commonly, the stereotactic frame, of which there are many variations, is placed using local anesthetic, and the patient undergoes an imaging study before being brought to the operating room. In some instances, the frame prevents mask application and ventilation, laryngoscopy, and neck extension. If a general anesthetic is to be employed, an awake intubation occasionally may be required. If sedation is to be employed, the anesthesiologist should have certain knowledge as to how to remove the device rapidly in an urgent situation (including knowledge of the whereabouts of the requisite "key" or spanner device).

When electrophysiologic recordings are not intended, sedative regimens similar to those used for awake craniotomy (see earlier) may be appropriate. For thalamic and subthalamic nucleus stimulator placements, part of the localization process entails identifying the typical electrophysiologic "footprint" of specific nuclei. Because the nature and duration of the effects of anesthetic agents on these signals have not been systematically defined, some surgeons and electrophysiologists may request that no sedative agent whatsoever be given. The patient's tremor is an important end point for determining the adequacy of stimulator position and current and must not be suppressed by the sedative agents. Such suppression may occur with propofol. However, Rozet and colleagues[319] reported satisfactory electrophysiologic recordings and preservation of tremor when dexmedetomidine was used for deep brain stimulator placement in patients with Parkinson's disease. They administered dexmedetomidine in a dose sufficient to maintain a lethargic response to normal speech.

An additional issue that arises in some patients with movement disorders is the problem of obtaining high-quality radiologic images in the presence of a persistent tremor. Sedation immediately preceding the stereotactic placement may be inevitable. Propofol has been employed, but the window between propofol administration and subsequent recording should be as long as possible. If sedatives are administered, they must be given in a manner that ensures the ability to perform precise intermittent neurologic examinations of the patient.

During the subsequent procedure, among the anesthesiologist's objectives is the prevention or treatment of hypertension. The concern is that, in the face of multiple needle passes through the brain, hypertension would precipitate development of an intracerebral hematoma. Dexmedetomidine has the added advantage that it may reduce hypertension. In the event of a substantial hematoma, an urgent craniotomy may be required, and the anesthesiologist should be prepared from the outset for this eventuality.

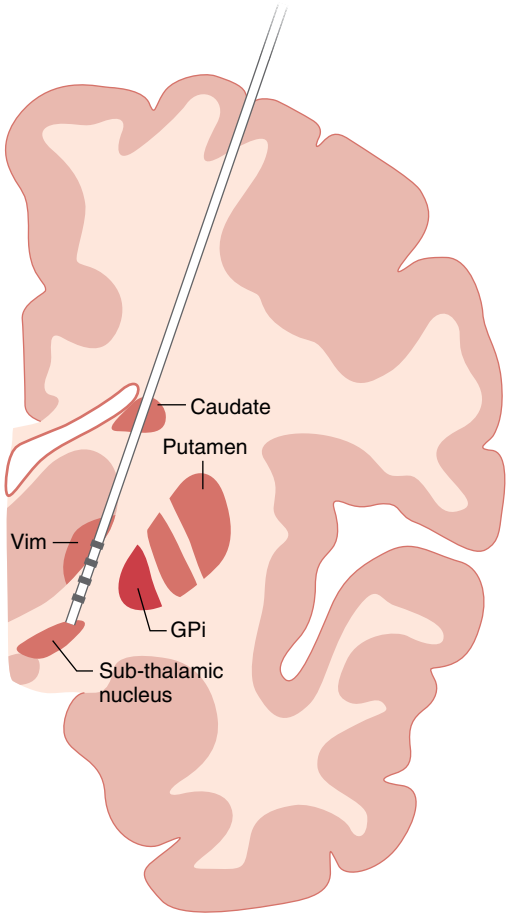

Figure 63-18 Deep brain stimulation electrode target sites. The most commonly targeted nuclei for the treatment of movement disorders are the subthalamic nucleus, the ventral intermediate nucleus of thalamus (Vim), and the internal segment of globus pallidus (GPi).

Neuroradiologic Procedures

Magnetic Resonance Imaging

The major constraints of MRI are created by the powerful magnetic field employed. It creates at least two conditions that have an impact on anesthetic technique. First, any ferromagnetic object that approaches the magnet has the potential to become a dangerous projectile. Second, many of the monitoring devices used in the operating room do not function properly in the vicinity of the magnet. The equipment limitations have largely been circumvented, however. MRI-compatible ECG machines, oximeters, capnographs, noninvasive blood pressure monitors, and gas machines are now widely available. Only temperature monitoring cannot be readily accomplished, and with that exception, there is no longer any justification for incomplete monitoring of patients undergoing MRI.

Most frequently, it is children, claustrophobic adults, and patients with painful conditions who require anesthesia to undergo MRI. Sedation with propofol and an unprotected airway, and general anesthesia with either an LMA or an endotracheal tube have been employed successfully.

Interventional Neuroradiology

A wide variety of procedures are available to evaluate and treat intracranial and extracranial disease. These include, principally, attempts to obliterate aneurysms or devascularize tumors and AVMs. An extensive review is available.[320]

Tumors and Arteriovenous Malformations. Hyperventilation may be appropriate in an attempt to divert flow away from normal brain and toward a lesion that is intended to receive the occlusive device or material. The anesthesiologist may be asked

to reduce systemic blood pressure, which reduces flow through fistulous lesions. Hypotension is usually requested to obtain greater precision for delivery of cyanoacrylate glues and to prevent glue passage into the draining veins or systemic venous system. The choice of hypotensive agent depends on the anesthesiologist's experience and systemic cardiovascular considerations. Adenosine is occasionally effective.[321]

Intracranial Aneurysms. A discussion of the relative merits of open clipping and endovascular management (usually coiling) for intracranial aneurysms is beyond the scope of this chapter. The International Subarachnoid Aneurysm Trial (ISAT) has confirmed the broad applicability of endovascular treatment,[322] and most aneurysms are currently managed by endovascular approaches. Nonetheless, numerous patients continue to undergo operative clipping[323]—primarily patients with wide-necked aneurysms or otherwise complex anatomies. At present, the durability of coil therapy is inferior to direct clipping[324]; a small but significant number of patients treated with coils need additional treatment, usually determined during routine follow-up angiography. Attempts to define the characteristics of patients best managed by operative clipping are ongoing.

Many of these procedures—in particular, procedures involving the treatment of vasospasm by selective intra-arterial installation of papaverine or more commonly by balloon dilation—can be accomplished without the involvement of an anesthesiologist. The duration of a procedure, individual patient factors, and, occasionally, the necessity for precise physiologic control may result in requests for monitored anesthesia care or general anesthesia. A chin-tucked position (to remove the bones of the face from the line of the anteroposterior x-ray source) and absolute immobility are commonly needed by the radiologist, and, consequently, when the anesthesiologist's assistance is requested, a general anesthetic often is necessary. In addition, anesthesiologists may become involved during the resuscitation stage in the event of vascular rupture or of the migration of an intravascular device to an incorrect location. In the event of rupture, the interventionist may request blood pressure reduction while the coil packing of the aneurysm is completed hastily. Immediate reversal of heparinization also would be required. When detachable devices (i.e., coils, balloons) are misplaced, and ischemia ensues, fluid loading and pressor administration may be requested to improve collateral CBF while the device is retrieved.

Carotid Angioplasty and Stenting. The role of carotid angioplasty is undefined. Carotid angioplasty and stenting (CAS) was originally proposed as an alternative for patients deemed to be of the highest medical risk. An early prospective comparison of CAS and carotid endarterectomy (CEA) among moderately high-risk patients revealed similar outcomes for the two procedures.[325] Reports have subsequently appeared of two additional trials, one of which was halted when an interim data analysis revealed a greater "any stroke or death" rate among CAS patients.[326] The second trial reported similar rates of any stroke or death for CAS and CEA.[327] There was a nonsignificant trend, however, toward an increase in the rate of occurrence of "disabling stroke or death" in the CAS group.

Finally, an interim report on patients enrolled in the ongoing Carotid Revascularization versus Stent Trial (CREST) revealed an unexpectedly high rate of stroke and death among patients older than 75 years of age, which was not explained by adjustment for comorbidities.[328] The suspicion is that the increased stroke incidence may be related to embolism from the arch of the aorta or the carotid, and it has been reported unofficially that some centers have discontinued enrollment of patients older than 75 years. It may evolve that some of the patients who were originally viewed as part of the target population (the very elderly) for this procedure may be among the patients for whom the procedure is relatively contraindicated.

It seems probable that the future holds a place for CAS and CEA, in part, because there are numerous relative contraindications to both procedures. The relative contraindications to CAS include antiplatelet agent intolerance, other pending surgery that precludes antiplatelet agents, aortic arch disease (age), and various elements of carotid morphology, including carotid tortuosity, concentric calcification (which entails a risk of vessel rupture), heavy thrombus burden, and unstable plaque (the latter two entail increased embolization risk). The relative contraindications to CEA include prior irradiation, prior radical neck surgery, tracheostomy, restenosis after CEA, high carotid bifurcation, contralateral recurrent laryngeal nerve palsy, and (perhaps) severe coronary or pulmonary disease (or both).

The procedure is almost always accomplished using monitored anesthesia care. Vascular access is most often achieved via the femoral artery. The anesthesiologist is usually asked to titrate heparin by bolus and infusion to achieve an activated clotting time of 250 to 300 seconds. Thereafter, the principal concern is the occurrence of what may be a profound bradycardia first with balloon dilation of the stenotic region and subsequently with expansion of the stent across the same region. Our practice is to titrate glycopyrrolate from the beginning of the procedure to achieve a heart rate of about 70 beats/min before the dilation and to have atropine at the ready and an external pacemaker in the room. We have never had to use the latter. In our institution, the presence of an anesthesia provider for this procedure is typically requested for only the most physiologically compromised patients. In this population, we have found it advantageous to have an independent (i.e., radial) arterial line.

Cerebrospinal Fluid Shunting Procedures

CSF shunts are inserted for the relief of various hydrocephalic states and pseudotumor cerebri. Hydrocephalus can be communicating or noncommunicating. In a noncommunicating hydrocephalus, CSF egress from the ventricular system is obstructed. This can occur as a result of blood or infection in the ventricular system or tumors in or adjacent to the ventricular system. In communicating hydrocephalus, the CSF escapes from the ventricular system, but is not absorbed by the arachnoid villi; this occurs most commonly secondary to infection or blood in the CSF space. Some degree of communicating hydrocephalus is particularly common after SAH.

The ventriculoperitoneal shunt is the most commonly employed device. Usually, a catheter is inserted via a bur hole into

the frontal horn of the lateral ventricle on the nondominant (usually the right) side. A reservoir is placed subcutaneously adjacent to the bur hole, and the drainage limb passes via a subcutaneous tunnel to a point near the epigastrium, where it is inserted into the peritoneal space via a very small laparotomy. A moderate degree of muscle relaxation may be helpful. A distended stomach can result in an inadvertent "gastrostomy." Occasionally, most commonly in pediatric patients, there may be an obstruction at more than one level in the ventricular system, and a so-called double-barreled shunt becomes appropriate. In this instance, there are two proximal ends—usually one in the lateral ventricle and one in the fourth ventricle. This latter procedure is usually performed in the prone position, whereas most ventriculoperitoneal shunts are done supine.

Occasionally, when there is a communicating hydrocephalus, a lumboperitoneal shunt is inserted. The patient is placed in a lateral position, and a catheter is put in the lumbar CSF space via a Tuohy-type needle. The catheter is tunneled subcutaneously around to the anterior abdominal wall and inserted into the peritoneal space via a small laparotomy.

Anesthetic Management

Invasive monitoring is generally not required. The anesthetic technique should be chosen to avoid further increases in ICP. Moderate hyperventilation ($Paco_2$ 25 to 30 mm Hg) is customary. The procedure is usually performed in the supine position, with the table turned 90 degrees and the head turned toward the anesthesiologist. Blood pressure may decrease abruptly (as brainstem pressure is relieved) when the ventricle is first cannulated. Infrequently, brief pressor support is required. Burrowing the subcutaneous tunnel can produce a sudden painful stimulus. There is only minor postoperative discomfort.

In contrast to most neurosurgical patients, shunt patients are often nursed flat after their procedures in an attempt to prevent an excessively rapid collapse of the ventricular system. Empirically, there is a small incidence of subdural hematoma after shunting, and the tearing of bridging veins at the time of rapid brain shrinkage is a suspected cause.

Pediatric Ventriculoperitoneal Shunts

Shunts are probably more commonly performed in children than in adults. Common indications are hydrocephalus occurring in association with meningomyelocele, neonatal intraventricular hemorrhage, and posterior fossa tumors. Although one can never be casual about the management of these patients, open fontanelles seem to provide some margin for error in younger patients, and palpation of the fontanelles provides online trend monitoring of "ICP." Despite the theoretical considerations, inhaled inductions using volatile agents are empirically well tolerated, even in children with closed fontanelles. We would avoid inhaled induction in a child who was already stuporous, however. When an intravenous line is available, we usually employ a propofol-relaxant induction sequence. For children in whom cannulation of a peripheral vein cannot be accomplished readily, an inhalation induction with sevoflurane is a common approach, with initiation of controlled ventilation, by bag and mask, as rapidly as possible. After establishing controlled ventilation, an ideal course at this point is to establish an intravenous line and administer a muscle relaxant and perhaps an intravenous anesthetic, and to intubate the trachea in these optimal circumstances.

Anesthesia is most commonly maintained thereafter with 60% to 70% N_2O, mechanical hyperventilation, and isoflurane or sevoflurane as required. For children older than 6 months who were not stuporous at the outset, we commonly administer 2 to 3 µg/kg of fentanyl in the belief that this procedure is not entirely pain-free postoperatively, and that a smoother emergence can be accomplished with a narcotic background.

Pediatric Neurosurgery

Table 63-14 lists common pediatric procedures and their anesthetic considerations (see Chapter 82). The most frequent procedures are probably the placement and revision of CSF shunts. These are discussed in the preceding section. Most pediatric tumors occur in the posterior fossa. Most are near the midline, and many are associated with hydrocephalus. For pediatric posterior fossa procedures, VAE risk, monitoring, and treatment are similar for adults and children and have been discussed previously. A Doppler is invariably indicated, and right heart catheters are generally placed when procedures are done in the sitting position. Craniosynostosis procedures have the potential for substantial blood loss that is roughly proportional to the number of sutures involved. There is a significant VAE risk that justifies the use of a precordial Doppler.[97]

Spinal Surgery

Table 63-15 summarizes the many issues that may arise in the context of spinal cord or spinal column procedures undertaken by neurosurgeons. The physiology of the spinal cord is generally similar to that of the brain: CO_2 responsiveness, blood-brain barrier, autoregulation, high metabolic rate and blood flow (although less than the brain), and substantial ischemic vulnerability of gray matter. Measures to reduce spinal cord swelling, analogous to ICP reduction maneuvers, are, however, rarely used. The relevant electrophysiologic monitoring techniques are described in Chapter 46. Prone positioning considerations and the phenomenon of postoperative visual loss are addressed in the discussion of the prone position.

Acknowledgment

The authors gratefully acknowledge the contribution of Harvey M. Shapiro to the origins of this chapter.

Table 63-14 Common Pediatric Neurosurgical Disorders and Anesthetic Considerations

Age Group	Lesion	Pathogenesis	Anesthetic Considerations
Neonates	Intraventricular hemorrhage	Subependymal vascular rupture	Associated problems of prematurity
	Depressed skull fracture	Forceps injury	Associated cerebral edema
Infants	Hydrocephalus	Varied	Increased ICP, especially dangerous in shunt-dependent revisions
	Meningocele	Outpouching of meninges through skull defect	Large size creates airway management problems Prone or lateral position Substantial blood loss Repair may increase ICP
	Encephalocele	Outpouching of meninges through skull defect with brain tissue enclosed	
	Myelomeningocele	Protrusion of spinal meninges and roots through spina bifida	Prone or lateral position Substantial blood loss Respiratory restriction after covering large defects
	Arnold-Chiari malformation	Impaction of posterior fossa contents into foramen magnum	Brainstem compression with head flexion
		With or without hydrocephalus	Increased ICP Latex allergy
		With or without myelomeningocele	Postoperative respiratory depression
	Craniosynostosis	Premature cranial suture fusion	Substantial blood loss Air embolism Supine or prone position
	Craniofacial dysostosis	Developmental abnormality	Lengthy procedures Substantial blood loss Brain retraction Air embolism Endotracheal tube damage
	Vascular malformations	Varied	Congestive heart failure Large blood loss Elective hypotension
	Subdural hematoma/effusion	Trauma	Associated injuries
Older children	Posterior fossa tumors	Ependymoma Astrocytoma	Malnutrition/dehydration Hydrocephalus Increased ICP Prone or sitting position Air embolism Brainstem compression Postoperative cranial nerve dysfunction or brainstem swelling or compression

ICP, intracranial pressure.

Table 63-15 Anesthetic Considerations and Position Requirements Associated with Various Spinal Surgical Procedures

Spinal Segment and Surgical Condition	Problems/Considerations	Positions Used and Comments
Thoracolumbar region: degenerative disease, spinal stenosis, trauma	Major position change	Prone, lateral, or knee-chest position
	Awake intubation and position	If unstable after trauma and major position change required
	Blood loss	Especially with redos, instrumentation, and spinal stenosis; risk of occult aortoiliac or major venous injury
	Air embolism	Infrequent; perhaps increased with knee-chest position and Relton-Hall frame
	Postoperative visual loss	Etiology unclear; associated with long prone procedures, low hematocrit, large estimated blood loss, and hypotension. Patient variables may contribute
		See Section on Positioning, Prone

Table 63-15 Anesthetic Considerations and Position Requirements Associated with Various Spinal Surgical Procedures—cont'd

Spinal Segment and Surgical Condition	Problems/Considerations	Positions Used and Comments
Cervical region: degenerative disk disease, stenosis, trauma, rheumatoid arthritis	Maintain neutral neck position to avoid cord compression	Supine/anterior approach for most diskectomies. Posterior approach (prone or sitting) for laminectomy and occasional diskectomy
	Maintain perfusion pressure at waking normal levels	If existing cord compression or recent cord injury or if cord retraction required
	Hypotension (spinal shock)	Occurs with complete cervical cord injury
	Postoperative respiratory insufficiency	Occurs with cervical cord injury
	Methylprednisolone[329,330]	30 mg/kg over 1 hr period, then 5.4 mg/kg for 23 hr
	Air embolism	With sitting laminectomies
Anterior cervical diskectomy	Traction required for anterior graft insertion	
	Retractor compression of airway	
	Postoperative swelling/airway compression	
	Postoperative cranial nerve dysfunction	
Cervical instability	Awake intubation	
	Awake positioning	Prone or supine
	Axial stabilization for intubation	If awake intubation not feasible
Vertebral metastasis	Large blood loss	Prone or anterolateral/retroperitoneal
		Double-lumen tube for lesions above L1
Spinal cord tumors	Maintain perfusion pressure during retraction	Prone
	Methylprednisolone	
Procedures with major neurologic risk	Wake-up test	Prone. Rehearse with patient
	Somatosensory evoked responses	Anesthetic restrictions
	Motor evoked responses	Anesthetic/relaxant restrictions
	Pedicle screw electromyogram	Relaxant restriction

EMG, electromyogram.

64 Anesthesia for Bariatric Surgery

Key Points

1. In the United States, 200 million people are overweight or obese. Across the globe, more people are obese than malnourished. Obesity may become the largest single preventable cause of death, and it results in major morbidity and mortality.
2. Metabolic syndrome includes abdominal obesity, decreased high-density lipoprotein, increased insulin, glucose tolerance, and hypertension and is present in nearly 50 million people in the United States alone.
3. The biggest single risk factor for sleep apnea is obesity; a majority of patients affected have increased oral and pharyngeal tissue, which makes ventilation, intubation, and extubation more challenging.
4. Choices for medical management of obesity are limited, and success with just medical management is uncommon. Changes in behavior are important for success.
5. Surgery for obesity is recommended at a body mass index (BMI) of 40 kg/m^2 or at a BMI greater than 30 kg/m^2 with comorbid conditions expected to respond to weight loss secondary to surgical therapy, such as hypertension, diabetes, and hypercholesterolemia. In clinical trials, long- term survival is better in the surgically treated group than in those managed medically.
6. Preoperative evaluation should focus on cardiopulmonary issues and securing an airway, along with the problems of diabetes, hypertension, sleep apnea, and other conditions.
7. Anesthetic drugs should be tailored according to their lipid solubility and knowledge of their lingering depressive effects on respiration.
8. Preparation and positioning are key to successful airway management. Preoperative pressure-support ventilation should be used adjunctively if possible.
9. Intraoperative ventilation is assisted by complete paralysis, moderate positive end-expiratory pressure, tidal volumes based on ideal body weight, and recruitment maneuvers as needed.
10. Common serious postoperative complications are deep venous thrombosis and staple line issues.
11. Obese patients undergoing non–weight loss surgery would benefit from an approach similar to that for bariatric surgery.

Obesity As a Disease

Globally obesity was considered a rarity until the middle of the 20th century.[1] Today, a significant proportion of the adult population in the United States and throughout the developed world suffers from obesity.[2-4] It is currently estimated that more than 200 million Americans, or 65% of the U.S. adult population, are overweight or obese. Obesity and its associated health concerns now represent major causes of morbidity and mortality and have an enormous impact on health care spending. More than 300,000 deaths per annum in the United States and more than $100 billion in annual health care spending are attributable to obesity. It is second only to smoking as a preventable cause of death.[5]

Obesity can be defined as a "disease" because it is a physiologic dysfunction of the human organism with environmental, genetic, and endocrinologic causes.[5]

Obesity most frequently develops when food calorie intake exceeds energy expenditure over a long period. Factors influencing obesity involve energy intake or expenditure (or both) and are influenced by genetic, behavioral, cultural, and socioeconomic factors. For example, syndromes associated with obesity include leptin deficiency, Prader-Willi syndrome, and Lawrence-Moon-Biedl syndrome.[3] Metabolic factors, including hormones, peptides, nutrients, uncoupling proteins, and neural regulatory substances emanating from gut, liver, brain, and fat cells, can influence energy regulation, but most of them are not well understood.

The body mass index (BMI) has become the most widely applied classification tool used to assess individual weight status.[6] BMI is defined as the patient's weight, measured in kilograms, divided by the square of the patient's height, measured in meters, which yields a measurement bearing the unit kg/m^2. Figure 64-1

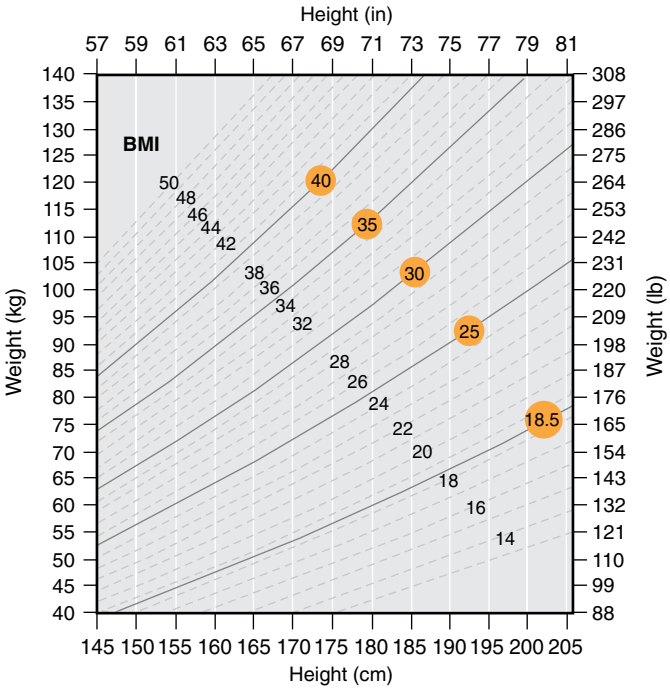

Figure 64-1 A family of iso-BMI curves for BMI ranging from 13 to 50 and mapped on axes for height (in both centimeters and inches) and weight (in both kilograms and pounds). BMI, body mass index.

shows a family of iso-BMI curves for BMI ranging from 13 to 50 and mapped on axes for height (in both centimeters and inches) and weight (in both kilograms and pounds). Using this system, patients are classified according to BMI, and the associated risk of health problems developing is shown in Table 64-1. Patients are considered to be overweight with a BMI between 25 and 29.9 kg/m^2 and obese with a BMI between 30 and 49.9 kg/m.^{2} The obese classification is further subdivided into class 1 (BMI range of 30 to 34.9 kg/m^2), class 2 (35 to 39.9 kg/m^2), and class 3 (40 to 49.9 kg/m^2). Patients with a BMI of 50 kg/m^2 or greater are considered superobese. As BMI increases beyond normal weight, the risk of serious health problems developing rises greatly (Table 64-2). Malnourishment and malnutrition are commonly offered as explanations for the fact that underweight patients are also at increased risk for contracting illnesses.

Table 64-1 Levels of Risk Associated with Increasing Body Mass Index

Classification	BMI (kg/m^2)	Risk of Health Problems Developing
Underweight	<18.5	Increased
Normal weight	18.5-24.9	Least
Overweight	25.0-29.9	Increased
Obese		
Class 1	30.0-34.9	High
Class 2	35.0-39.9	Very high
Class 3	40.0-49.9	Extremely high
Superobese	≥50	Exceedingly high

Table 64-2 Waist Circumference and Risk

Waist Circumference	Body Mass Index (kg/m^2)		
	Normal Weight	Overweight	Obese Class 1
<102 cm (♂) <88 cm (♀)	Least risk	Increased risk	High risk
≥102 cm (♂) ≥88 cm (♀)	Increased risk	High risk	Very high risk

Specific diseases are commonly associated with obesity, and obesity is often accompanied by multiple comorbid states.[7] Such states frequently include insulin resistance, type 2 diabetes mellitus, obstructive sleep apnea (OSA), hypoventilation, cardiovascular disease, hypertension, certain malignancies, and osteoarthritis.[7-14] Virtually all organ systems can be included in the extended list of health risks associated with having an increased BMI. A listing of the most common specific disease states along with their obesity-associated risk is detailed in Table 64-3. As a result of these concomitant conditions, obesity is also associated with early death.[6] Of the health risks listed in Table 64-3, metabolic syndrome and OSA merit additional attention because they pose special concerns for the anesthetic care of the obese population.

Metabolic Syndrome

The clustering of a group of defined metabolic and physical abnormalities is now referred to as "metabolic syndrome."[15] Patients with metabolic syndrome commonly have abdominal obesity, reduced levels of high-density lipoprotein (HDL), hyperinsulinemia, glucose intolerance, hypertension, and other characteristic features (Box 64-1).[15] Clinical criteria for diagnosing metabolic syndrome require at least three of the following: abdominal obesity, elevated fasting glucose, hypertension, low HDL levels, and hypertriglyceridemia. Specific diagnostic criteria are presented in Table 64-4. Weight gain with visceral obesity is a major predictor of metabolic syndrome. The clinical approach uses waist circumference rather than BMI to define the adipose mass component contributing to metabolic syndrome because BMI has been shown to be a relatively insensitive indicator of the risk for obesity-associated metabolic and cardiovascular disease. Waist circumference, but not BMI, reflects abdominal subcutaneous adipose tissue, as well as abdominal visceral adipose tissue, and is therefore a better index of central, or truncal, fat mass.

In the United States, nearly 50 million people have metabolic syndrome, for an age-adjusted prevalence of almost 24%. Of such people, more than 83% meet the criterion of abdominal obesity. The incidence of metabolic syndrome increases with age, with more than 40% of the U.S. population affected by the age of 60 years.[15] Men are affected more commonly than women, and Hispanics and south Asians appear to be particularly susceptible. Its frequency is lower in African American than in white men. Metabolic syndrome may result from the use of some commonly prescribed drugs, including corticosteroids, antidepressants, and antipsychotic agents. The protease inhibitors used to treat human immunodeficiency virus infection can induce metabolic syndrome secondary to insulin resistance.

Table 64-3 Health Risks Associated with Increasing Body Mass Index

Metabolic syndrome	30% of middle-aged people in developed countries have features of metabolic syndrome
Type 2 diabetes	90% of type 2 diabetics have a BMI > 23 kg/m^2
Hypertension	5× the risk with obesity 66% of hypertension is linked to excess weight 85% of hypertension is associated with a BMI >25 kg/m^2
Coronary artery disease and stroke	3.6× the risk for coronary artery disease for each unit change in BMI Dyslipidemia progressively develops as BMI increases from 21 kg/m^2 with a rise in small-particle low-density lipoprotein 70% of obese women with hypertension have left ventricular hypertrophy Obesity is a contributing factor to cardiac failure in >10% of patients Overweight/obesity plus hypertension is associated with an increased risk for ischemic stroke
Respiratory effects	Neck circumference >43 cm in men and >40.5 cm in women is associated with obstructive sleep apnea, daytime somnolence, and development of pulmonary hypertension
Cancer	10% of all cancer deaths among nonsmokers are related to obesity (30% of endometrial cancers)
Reproductive function	6% of primary infertility in women is attributable to obesity Impotency and infertility are frequently associated with obesity in men
Osteoarthritis	Frequent association in the elderly with increasing body weight—the risk of disability attributable to osteoarthritis is equal to that for heart disease and greater than that for any other medical disorder of the elderly
Liver and gallbladder disease	Overweight and obesity are associated with nonalcoholic fatty liver disease and NASH; 40% of NASH patients are obese and 20% have dyslipidemia 3× the risk for gallbladder disease in women with a BMI >32 kg/m^2; 7× the risk if the BMI >45 kg/m^2

BMI, body mass index; NASH, nonalcoholic steatohepatitis.

Patients with metabolic syndrome have a higher risk for cardiovascular disease and are at increased risk for all-cause mortality. Metabolic syndrome increases the risk for type 2 diabetes, which itself is an important risk factor for atherosclerotic disease and may be considered a coronary heart disease equivalent.[9,15] Metabolic syndrome is also associated with a variety of other conditions, such as polycystic ovary syndrome, nonalcoholic fatty liver disease, gallstones, sleep disturbances, sexual impotence, and some forms of cancer, thus giving it considerable overlap with obesity for the comorbid states detailed in Table 64-3.

Inflammatory processes appear to play an important role in the metabolic syndrome.[12] Adipose tissue has two major functions: storage and release of energy-rich fatty acids and secretion of proteins required for endocrine and autocrine regulation of energy metabolism. Adipocytes exert their metabolic effects by release of free fatty acids, which is enhanced by the presence of catecholamines, release of glucocorticoids, increased β-agonist receptor activity, and reduction of lipid storage mediated by insulin. Visceral adipose tissue has been identified as an important source of proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-6 (IL-6), as well as anti-inflammatory cytokines such as adiponectin. Increased levels of proinflammatory cytokines probably contribute to the cause of insulin resistance. This works primarily by obstructing insulin signaling and contributing to downregulation of peroxisomal proliferator–activated receptor-γ—fundamentally important regulators of adipocyte differentiation and control. Additionally, insulin resistance may promote inflammation through diminution of insulin's anti-inflammatory effects. Finally, oxidative stress is increased with obesity, largely as a result of excessive intake of macronutrients and a concomitant increase in metabolic rate. These factors may also contribute to the inflammatory response noted with obesity.[12]

Cytokines (primarily IL-6 and TNF-α) and adipokines (leptin, adiponectin, adipose-derived resistin) are the two major groups of inflammatory proteins produced and released by adipose and adipose-associated tissue.[12] Serum and adipose tissue obtained from obese subjects consistently have elevated levels of IL-6 and TNF-α, and circulating levels of IL-6 are consistently increased in individuals with type 2 diabetes or impaired glucose tolerance. Proteins such as leptin and adiponectin, which are produced mainly by adipocytes, are classified as adipokines.

Box 64-1 Features Associated with Metabolic Syndrome

Abdominal obesity

Atherogenic dyslipidemia (TGs, ↓ HDL-C, ApoB, small LDL particles)

Elevated blood pressure

Insulin resistance with or without glucose intolerance

Proinflammatory state (hsCRP)

Prothrombotic state (PAI-1, ↓ FIB)

Other (endothelial dysfunction, microabuminuria, polycystic ovary syndrome, hypoandrogenism, nonalcoholic fatty liver disease, hyperuricemia)

ApoB, apolipoprotein B; FIB, fibrinogen; HDL-C, high-density lipoprotein cholesterol; hsCRP, high-sensitivity C-reactive protein; LDL, low-density lipoprotein; PAI, plasminogen activator inhibitor; TGs, triglycerides.

Table 64-4 Clinical Criteria for Diagnosing Metabolic Syndrome*

Criteria	Defining Value
Abdominal obesity	Waist circumference >102 cm in men and >88 cm in women
Triglycerides	≥150 mg/dL
High-density lipoprotein cholesterol	<40 mg/dL in men and <50 mg/dL in women
Blood pressure	≥130/85 mm Hg
Fasting glucose	≥110 mg/dL

*Three of five criteria must be met.

Although leptin is primarily involved in appetite control, its immunologic effects include protection of T lymphocytes from apoptosis and regulation of T-cell activation and proliferation. Reduced leptin levels may increase appetite and slow metabolism, but it may also increase susceptibility to the toxicity of proinflammatory stimuli such as endotoxin and TNF-α. High levels of leptin are proinflammatory, which probably plays an important role in the progression of heart disease and diabetes, especially in obese patients. Serum levels of adiponectin, another adipokine, correlate with insulin sensitivity and do not rise in obesity. Significantly reduced adiponectin levels are found in patients with type 2 diabetes. Adiponectin reduces both TNF-α production and activity. It also inhibits IL-6 production. Resistin, an adipokine that causes insulin resistance, is induced by endotoxin and cytokines. Resistin acts at the cellular level to upregulate the production of pro-inflammatory cytokines, most likely through the nuclear factor κB (NFκB) pathway. Resistin appears to represent a molecular link between metabolic signaling, inflammatory processes, and the development of cardiovascular disease. Increased resistin levels have been associated with inflammatory markers in humans, apparently independent of BMI.[12]

An understanding of the role of NFκB in insulin resistance is required to fully appreciate the link between obesity and inflammation. Free fatty acids and TNF-α act via intracellular inflammatory cascade pathways to arrest insulin signaling. This process is mediated by activation of transcription factors present within the cell cytoplasm. After translocation to the nucleus, they eventually bind to transcription factors regulating the inflammatory process. The cytoplasm also contains NFκB, another transcription factor whose activation is implicated in a number of diseases, including diabetes. NFκB is also induced by hypoxia, and it increases production of the proinflammatory cytokines TNF-α and IL-6, both of which are frequently increased in patients with OSA syndrome.[12] Hence, inflammation provides the common linkage underlying the association between obesity, metabolic syndrome, and OSA.[16]

Obstructive Sleep Apnea/Hypopnea Syndrome

OSA and obstructive sleep hypopnea are related conditions characterized by recurrent episodes of upper airway obstruction occurring during sleep (see Chapter 34).[17] OSA is defined as complete cessation of airflow during breathing lasting 10 seconds or longer despite maintenance of neuromuscular ventilatory effort and occurring five or more times per hour of sleep, accompanied by a decrease of at least 4% in Sao_2. Obstructive sleep hypopnea is defined as partial reduction of airflow of greater than 50% lasting at least 10 seconds, occurring 15 or more times per hour of sleep, and accompanied by a decrease of at least 4% in Sao_2. The diagnosis can be made only in patients who undergo polysomnography, or a sleep study, during which the patient's electroencephalogram, electrocardiogram, electro-oculogram, capnogram, nasal or oral airflow, esophageal pressure, blood pressure, pharyngeal and extremity electromyelograms, pulse oximetry, and room noise are typically monitored and recorded.[17] The results of polysomnography are reported as the apnea/hypopnea index (AHI), which is derived from the total number of episodes of apnea and hypopnea divided by the total sleep time. A normal lower limit for AHI has not yet been defined in an epidemiologic study of healthy subjects. Most sleep centers commonly use an AHI of between 5 and 10 events per hour as a normal limit. The severity of obstructive sleep apnea/hypopnea syndrome (OSAHS) is defined arbitrarily, but a recent recommendation for classification of the disease is as follows[17]:

Mild disease—AHI of 5 to 15 events per hour
Moderate disease—AHI of 15 to 30 events per hour
Severe disease—AHI of greater than 30 events per hour

Because of risk for the development of systemic and pulmonary hypertension, left ventricular hypertrophy, cardiac arrhythmias, cognitive impairment, persistent daytime somnolence, and other conditions, treatment is recommended for patients with moderate or severe disease. Treatment depends partly on the severity of the sleep-disordered breathing, but the consensus is that patients with moderate or severe apnea should be treated with continuous positive airway pressure (CPAP) during sleep. Other conservative measures may include weight loss, avoidance of alcohol before bedtime, and sleeping on one's side.

Numerous studies have confirmed that obesity is the greatest risk factor for OSAHS, and about 70% of patients (up to 80% of males and 50% of females) with OSAHS are obese. Severe sleep apnea is more common in men, and a strong negative correlation between AHI and the minimum Sao_2 has been observed. Importantly, the diagnosis of OSAHS may be missed until the patient undergoes surgery. In a study of 170 patients about to undergo surgery, in which only 15% had sleep apnea previously been diagnosed, preoperative testing demonstrated that 76% were found to have OSAHS.[18] We believe that it is important that obese patients scheduled for bariatric surgery undergo preoperative polysomnographic testing for OSAHS. Preoperative diagnosis and appropriate interventional management can have the following benefits: less postoperative sleep deprivation, improved response to analgesic and anesthetic drugs, and normalization of cardiovascular disturbances.[19]

Anatomically, obese patients with OSAHS typically have increased amounts of adipose tissue in their oral and pharyngeal tissues, including the uvula, tonsils, tonsillar pillars, tongue, aryepiglottic folds, and lateral pharyngeal walls. An inverse relationship exists between the degree of obesity and pharyngeal area. Deposition of fat in the lateral walls decreases the size of the airway and changes the shape of the oropharynx into an ellipse with a short transverse and long anteroposterior axis.[20-22] This can contribute to the development and severity of airway obstruction and also increase the probability that it will be more difficult to maintain airway patency during mask ventilation and perform direct laryngoscopy for endotracheal intubation with general anesthesia.[23,24] Additionally, airway obstruction after extubation is likely to be complicated by the use of opiate and sedative drugs needed for postoperative pain management because such medications tend to decrease pharyngeal dilator tone and increase the likelihood of upper airway collapse.[23]

OSA also plays an important role in inflammation and the metabolic syndrome.[12,16] The hypopneic and apneic events that occur in OSAHS are part of a cycle of events that involves arousal from random eye movement (REM) sleep and oxyhemoglobin desaturation. The sympathetic nervous system is activated as patients with untreated OSA undergo cyclic episodes of hypoxia

and reoxygenation; such activation leads to elevated levels of proinflammatory cytokines and potentially oxidative stress of vascular endothelium, which induces an even more heightened state of systemic inflammation in obese patients with OSA.[16] Levels of many different inflammatory mediators, including IL-6, C-reactive protein, leptin, TNF-α, IL-1, reactive oxygen species, and adhesion molecules such as intracellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1), are increased in patients with OSAHS.[12] Thus, obesity, metabolic syndrome, and OSAHS are interrelated diseases that significantly alter a patient's inflammatory disease profile and result in multiple health risks, particularly those of cardiovascular- and airway-related origin.

Nonsurgical Management of Obesity

The primary goals of nonsurgical management of obesity involve weight loss, treatment of the abnormalities associated with metabolic syndrome, and prevention of events related to type 2 diabetes and cardiovascular disease. Treatment of metabolic syndrome needs to follow an aggressive, multifaceted approach to simultaneously address multiple underlying metabolic abnormalities and coexistent risk factors.[15] An appropriate initial treatment of obesity and metabolic syndrome is therapeutic lifestyle change, including dietary modification, weight loss, physical activity, and potentially discontinuation of smoking. The goal of treatment is improved health, which is the primary reason for advocating weight loss. It is therefore important to monitor the effects of treatment on risk factors and comorbid conditions. Success of treatment should be reflected in a decreased need to treat other coexisting diseases.

The goal of weight loss in therapeutic lifestyle change is not to achieve normal or ideal body weight (IBW). Even modest weight loss, in the range of 5% to 10%, can result in significant initial improvement in the comorbid conditions of diabetes, dyslipidemia, and hypertension by lowering total cholesterol and triglyceride levels, raising HDL cholesterol (HDL-C), lowering blood pressure and blood glucose, and reducing insulin resistance.[15,25] Guidelines for the management of obesity stress the need for weight reduction via behavioral change to reduce caloric intake and increase physical activity. Reduced-energy diets are more effective and more healthful for achieving long-term weight loss. Long-term maintenance of any weight loss achieved is best accomplished with the inclusion of regular exercise as a staple of the weight reduction regimen. Regular physical exercise improves several risk factors associated with obesity and metabolic syndrome.[26] The standard recommendation for exercise is a daily minimum of 30 minutes of moderate-intensity physical activity that is practical to perform. Larger weight loss goals are more appropriate for the more profoundly obese individuals who are contemplating surgical interventions. Even with surgery, IBW is hardly ever achieved, and after a number of years at a plateau, weight gain often recurs. In some patients, especially in the presence of severe comorbid conditions, simple prevention of additional weight gain may be the most reasonable goal.

Beyond the beneficial effects of therapeutic lifestyle change, specific intervention may be required to treat the dyslipidemia and hypertension associated with obesity and metabolic syndrome.[27] Most commonly, patients with metabolic syndrome have elevated triglyceride levels and low HDL-C levels. Many patients receive statin therapy as the treatment of choice when low-density lipoprotein cholesterol (LDL-C) levels are excessive. Statins have been shown to reduce the risk for cardiovascular disease in patients with type 2 diabetes and metabolic syndrome. Ezetimibe, which selectively inhibits intestinal absorption of cholesterol, can be combined with statin therapy to further reduce LDL-C by 15% to 20%. Fibrates effectively decrease triglyceride levels while increasing HDL-C. Fibrates lower LDL-C levels mildly, but when combined with statin therapy, fibrates may increase the risk for myopathy. Omega-3 fatty acids decrease triglyceride levels and improve insulin resistance in patients with metabolic syndrome. They are often used in combination therapy with other classes of hypolipidemic drugs. Nicotinic acid is highly effective in raising HDL-C levels in patients with metabolic syndrome. Nicotinic acid decreases the concentration of small, dense LDL particles and also lowers serum levels of lipoprotein(a).[27]

Dietary salt restriction and therapeutic lifestyle changes are the primary means of addressing hypertension in obesity and metabolic syndrome. Patients with blood pressure higher than 140/90 mm Hg require antihypertensive drug therapy. There is no specific antihypertensive agent that is recommended as a first-line treatment in these patients, and generally, achievement of the goal of antihypertensive therapy requires the use of polypharmacy. A considerable amount of the reduction in risk with antihypertensive therapy results solely from lowering of blood pressure.

Treatment of insulin resistance and hyperglycemia in patients with metabolic syndrome, type 2 diabetes, and obesity is usually achieved with oral hypoglycemic agents.[27] A number of different drug groups (and drugs within each group) that work through various mechanisms of action are available to treat hyperglycemia. Such drugs include α-glucosidase inhibitors, sulfonylureas, meglitinides, D-phenylalanine derivatives, diguanides, and thiazolidinediones.[27] Anesthetic implications include the need to assess and treat abnormal blood glucose levels in the perioperative period while being especially careful in the use of insulin in patients who are insulin resistant and temporarily unable to continue oral medication. Presently, there is considerable uncertainty regarding the anesthetic management of patients who are taking metformin because of the potential for the postoperative development of lactic acidosis. This has led some physicians to routinely cancel or delay surgical procedures if metformin has been ingested within 48 hours of scheduled surgery. Some physicians, however, continue metformin administration, before and after surgery, without interruption if possible. Recent evidence indicates that patients taking metformin have a reduced risk for complications. It thus appears that metformin may be used safely in the perioperative period.[28]

Patients with metabolic syndrome and obesity may also be prescribed antiplatelet therapy. The American Heart Association presently recommends that low-dose aspirin be used as a form of primary prevention in patients with metabolic syndrome whose 10-year risk for cardiovascular disease is 10% or greater as determined by Framingham risk scoring.

Behavioral Modification and Interventions

Behavioral interventions and behavioral modification are essential for obese patients to change their learned habits regarding

eating and physical activity so that they can achieve weight loss and maintain long-term weight reduction.[27] The key features of typical behavioral programs include self-monitoring, goal setting, nutrition and exercise education, stimulus control, problem solving, cognitive restructuring, and prevention of relapse. Patients often benefit from referral to multidisciplinary weight loss programs that incorporate diet, physical activity, and behavioral interventions to achieve their weight loss goals because these combined interventions provide the best weight loss and weight maintenance results without pharmacologic or surgical intervention. However, it is essential to identify patients with eating disorders or major psychiatric disorders so that they can receive the specialized psychiatric and psychological treatment that they require to achieve meaningful weight loss.

Pharmacotherapy for Weight Loss

Recommendations for pharmacotherapy as a treatment of obesity first and foremost stress lifestyle and behavioral modifications as the initial approach to a weight loss program.[27] Patients who do not achieve reasonable weight loss goals through a combination of diet and exercise may be given pharmacotherapy to increase weight loss. Several weight loss drugs have been approved by the Food and Drug Administration (FDA) and are currently prescribed for long-term use. They are typically used as an adjunct to diet and exercise for patients with a BMI of 30 or greater (≥27 for patients with obesity-related risk factors or comorbid diseases). In current practice, there are only two categories of weight loss drugs—appetite suppressants and lipase inhibitors—and only three drugs are approved for the specific indication of weight loss—phentermine, sibutramine, and orlistat.[27] Phentermine, an adrenergic reuptake inhibitor, augments adrenergic signaling within the central nervous system and peripheral tissues. Phentermine decreases appetite and food intake and increases the resting metabolic rate to promote weight loss. Its side effects include tachycardia and hypertension. Sibutramine is an adrenergic and serotoninergic agent that suppresses appetite and increases thermogenesis. Common side effects include hypertension, tachycardia, insomnia, and dry mouth. Sibutramine is relatively contraindicated in patients taking serotonin-selective reuptake inhibitors because of the potentially increased risk for serotonin syndrome. Orlistat, a lipase inhibitor, reversibly binds to lipase and prevents both absorption and digestion of certain dietary fats. Because orlistat also interferes with the absorption of fat-soluble vitamins, patients taking this drug need to be supplemented with the fat-soluble vitamins A, D, E, and K. It has significant gastrointestinal side effects, including diarrhea, steatorrhea, flatulence, fecal incontinence, and oily rectal discharge.

Dietary and Herbal Medications

In 2001, Allison and colleagues[29] reviewed the literature on dietary and herbal medications for weight loss. These agents are marketed as "food supplements" and thus escape the purview of the FDA. Even though these supplements cannot legally claim to treat a disease, they can claim to reduce the risk of contracting a disease.

According to the review, claims for weight loss have been made for multiple products, including chitosan, chromium picolinate, conjugated linoleic acid, ephedra alkaloids (ma huang),[30] and *Garcinia cambogia*.[29] Most of the reports involving these compounds come from poor-quality studies without any randomization, control groups, or blinding, thereby placing in question the efficacy and safety of these compounds. The only studies involving herbals that have consistently demonstrated weight loss involve combinations of ephedrine and caffeine.[31-33] Pharmacologically, this is expected because ephedrine, an adrenergic agonist, is known to be an appetite suppressant and a thermogenic agent. For this reason, ma huang, a natural source of the ephedra alkaloid, is added to most, if not all, dietary supplements marketed for weight loss. Ephedrine's success as a weight loss agent, in combination with caffeine or aspirin (or both), is well established. Unfortunately, multiple cases of cardiac and neurologic sequelae, including hypertension, stroke, seizure, and even death, have been reported,[34] possibly related to the inconsistent doses in the preparations and lack of medical supervision in people consuming these products for weight loss. Consequently, the National Institutes of Health has banned these products from any recommended weight loss regimen.

Implanted Electrical Stimulators

Implantable gastric stimulators are subcutaneously placed, cardiac pacemaker–like devices that stimulate regions along the lesser curvature of the stomach. They have been tried in the last decade and found to have modest weight loss with few side effects.[35,36] These studies have been performed in Europe and trials are ongoing in the United States. One study documented a 25% excess weight loss, improved response to the oral glucose tolerance test, decreases in blood pressure, and an improvement in symptoms of gastroesophageal reflux disease, along with increased parasympathetic drive. No serious side effects were noted in the first 65 patients reported in this study[35] or in the 20 patients in the other.[36] Modification of Ghrelin levels may play a role in the success of these devices.

Surgical Management of Obesity

Adult obesity has the bulk of its roots in childhood obesity. One of the principal predictors of adult obesity is childhood obesity. Large children grow up to be large adults. Unfortunately, pediatric obesity is the most common childhood nutritional disorder in the United States. The significant and increasing prevalence of obesity in the young is one of the tragedies of the current obesity epidemic. The diagnosis of pediatric obesity, however, is commonly made by using BMI, age, and sex-specific clinical growth charts according to a definition promulgated by the Centers for Disease Control and Prevention (CDC).[37] These percentile curves apply to the ages of 2 to 20 years, and because BMI exhibits nonlinear variation during growth, percentile ranges are used. The CDC defines children with a BMI in the 5th to 85th percentile as having "healthy weight." BMI values in the 85th to 95th percentile are "at risk for overweight," whereas those greater than the 95th percentile are classified as "overweight," previously regarded as "overweight" and "obese," respectively. This switch in terminology continues to be a source of confusion. Exceeding the 99th percentile is referred to as extreme pediatric obesity.

Data from the National Health and Nutrition Examination Survey (2003-2004) show that the prevalence of overweight children 2 to 5, 6 to 11, and 12 to 19 years of age is 13.9%, 18.8%, and 17.4%, respectively. There does not appear to be an influence of gender on the prevalence of overweight children older than 6 years. However, in a cohort of children aged 2 to 5 years, girls exhibited a doubling in prevalence during the past 20 years, whereas boys exhibited an increase of only 25%. Developing countries such as Egypt, Algeria, Peru, South Africa, and Jamaica have childhood prevalence rates higher than those in the United States,[38] indicating that adolescent obesity is no longer simply a problem of the "developed world."

Treatment of pediatric obesity is based on the balance of caloric intake and expenditure. Adoption of lifestyle changes is most successful with family intervention and support. The three pillars of success in such treatment are better eating habits, increased physical activity, and decreased sedentary activity.[39] Success involves more than education of the child and family; it also incorporates goal setting, self-monitoring, incentives, and stimulus control. Drugs approved for the treatment of pediatric obesity include orlistat and sibutramine (see the earlier section "Pharmacotherapy for Weight Loss").

Even though less than 1% of all bariatric surgery patients in the United States in 2003 were younger than 20 years,[40] the total number continues to increase. Unfortunately, more and more teenagers are now undergoing weight loss surgery, usually gastric banding, after failing to reduce weight or comorbid conditions in medically supervised and pharmacologically assisted weight loss programs. Although many adult bariatric surgery programs are well qualified to provide safe and effective perioperative care for these patients, they may not be as well equipped to handle the unique metabolic and psychological needs of teenagers. Because of the shorter duration of obesity and fewer age-related comorbid diseases, adolescent patients have a shorter length of hospital stay and lower immediate postoperative mortality than adults do.[40]

Consent is an important issue in this population. Is parental consent for a semi-elective, relatively high-risk procedure appropriate? Does the child really understand the concept of a high risk of death in the month after surgery? These and other such questions need to be addressed in the future but are beyond the scope of this chapter.

The rapid increase in the prevalence of morbid obesity and superobesity, together with the increased risk for early demise within the obese population, has significantly increased the number of bariatric surgical procedures performed annually. The term *bariatric surgery* refers to surgical alteration of the small intestine or stomach with a view toward producing weight loss. It is estimated that more than 175,000 bariatric surgeries were performed in 2006 and that more than 200,000 will be performed in 2008 and beyond. Care of obese patients is not limited to obesity surgery, however, because these patients undergo all types of operations. Nonetheless, the benefits of surgical treatment of obesity now appear to have clear endocrinologic and cardiovascular value for reversing the pathophysiologic effects of metabolic syndrome, type 2 diabetes, and other comorbid diseases of obesity, in addition to providing a mechanical means of enhancing weight loss.[41-47] There are several alternative procedures in bariatric surgery, but the operations all fall into one of two groups: gastric-restrictive procedures and procedures that combine gastric restriction with induction of nutrient malabsorption.[48-57]

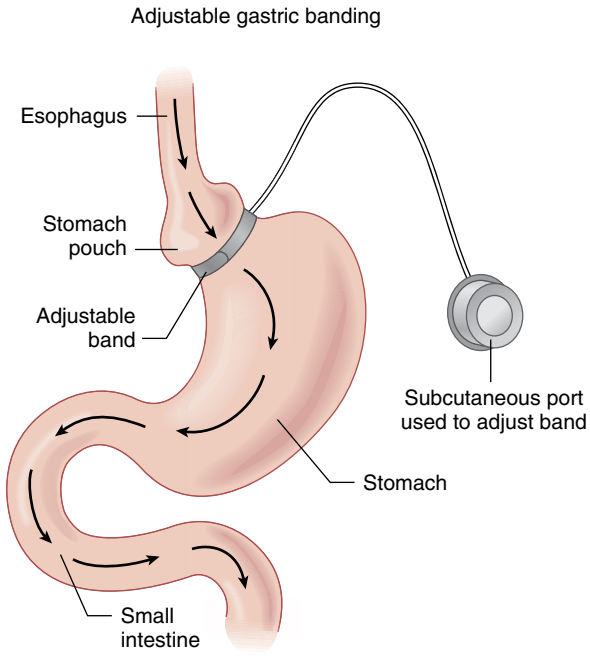

Figure 64-2 Gastric banding. An adjustable band is placed on the stomach. Connected to the band is a piece of tubing with a port at the other end. The port is placed just under the skin. To adjust the tightness of the band, a special needle is inserted in the port. Fluid can be added to the band to make the passageway smaller or remove fluid from the band to make the passageway larger.

Restrictive Procedures

The surgical goal of restrictive operative procedures is to reduce and limit the patient's capacity for intake of food.[54] This goal is most commonly achieved by creating a small pouch from the proximal part of the stomach just distal to the gastroesophageal junction. Construction of the newly created pouch allows it to drain through only a narrow opening. This increases mechanical resistance to gastric emptying of ingested solids, whereas emptying of liquids proceeds normally. Vertical band gastroplasty (VBG) was a widely practiced restrictive procedure in the previous 2 decades, but it has largely been replaced by the minimally invasive laparoscopic gastric band (LGB) procedure (Fig. 64-2). A specific advantage of the LGB procedure is avoidance of permanent alteration of gastric anatomy by tissue stapling. The LGB procedure has an exceptional safety record with exceedingly low operative mortality, although reoperation rates for minor problems are not trivial.[57]

Malabsorptive Procedures

The surgical goal of malabsorptive procedures is to cause weight loss by gastric restriction and malabsorption of nutrients. Historically, early surgical procedures involved the creation of a long jejunoileal bypass. Patients achieved significant weight reduction, but this was commonly accompanied by an unacceptable incidence of serious vitamin and protein malabsorption, osteoporosis, and hepatic failure.

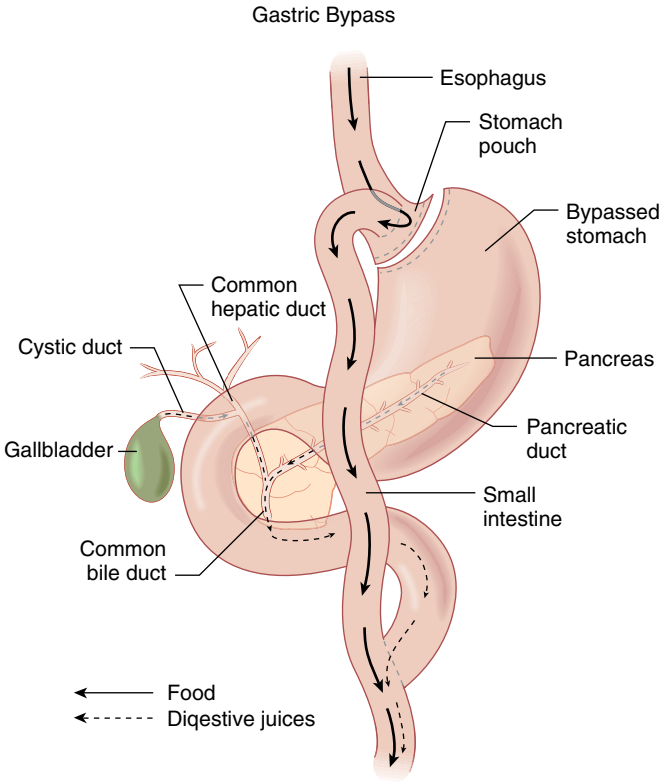

Figure 64-3 Roux-en-Y gastric bypass. Part of the stomach is detached from the rest to create a small pouch. The pouch is connected to a lower part of the small intestine by a piece of small intestine, resembling a Y. As a result, parts of the stomach and small intestine are bypassed. However, digestive juices (bile acids and pancreatic enzymes) can still mix with the food to enable the body to absorb vitamins and minerals, thereby reducing the risk for nutritional deficiencies.

Presently, gastric bypass (GBP) (Fig. 64-3) and biliary pancreatic diversion (BPD) are the two commonly performed malabsorptive operations, and both have been shown to be safe and effective.[54] GBP is performed more commonly than BPD and it is considered the safer of the two malabsorptive procedures. GBP surgery involves the creation of a small gastric pouch by stapling or banding the stomach, which results in an element of gastric restriction. GBP also involves the creation of a Roux-en-Y anastomosis in which the small gastric pouch is directly connected to the middle portion of the jejunum.[58] The path of food through the gastrointestinal tract subsequently bypasses the gastric remnant and the upper portion of the duodenum. This procedure can be performed with a laparotomy incision or by using laparoscopic techniques.[59] Although GBP is considered to be a safe operation, the associated perioperative mortality is higher than that of LGB.[51] Additionally, there are some important long-term complications such as vitamin B_{12} deficiency, anemia, incisional hernia, cholelithiasis, and staple line failure, which occur at significant frequency. Often, a cholecystectomy is performed concurrently to prevent future cholelithiasis.[60] BPD is also a form of Roux-en-Y GBP for reconstructing the alimentary anatomy in which the bypassed intestinal segment includes the portion of duodenum at the point of entry of biliary and pancreatic secretions. This procedure allows the bypassed intestine to be exposed to bile and pancreatic juice. The antrum is removed to avoid peptic ulceration, and food intake is affected to only a limited degree. The essential element of this operation is division of the small intestine about its midlength, with the distal end of the alimentary limb being anastomosed to a generous gastric remnant. The more proximal biliopancreatic limb is anastomosed to the alimentary limb about 50 cm from the ileocecal valve. After either the GBP or BPD form of weight loss surgery, patients require lifelong follow-up and may need long-term micronutrient replacement.

Health Benefits of Bariatric Surgery

The two most significant outcome measures of the success of bariatric surgery are weight loss and resolution of comorbid conditions. The major effects of bariatric operations have been well summarized in two published meta-analyses.[43,61] Absolute weight loss averaged 46.4 kg for BPD, 43.5 kg for GBP, 39.8 kg for VBG, and 28.6 kg for gastric banding. This magnitude of weight loss is far greater than that commonly achievable by nonsurgical methods, and it is considerably closer to patients' desired and expected weight loss. Long-term maintenance of weight loss of this magnitude can also be sustained for well over a decade.

Improvement in the comorbid diseases associated with obesity and metabolic syndrome has also been evaluated.[43,61] Diabetes improved in more than 85% of patients and resolved in more than 75% overall (98.9% for BPD, 87.3% for GBP, 71.6% for VBG, and 47.9% for gastric banding). Resolution of diabetes after surgery is inversely related to the preoperative duration of the disease and occurs more in patients whose diabetes is controlled with oral hypoglycemic agents. This clearly distinguishes surgical treatment of obesity as an important endocrinologic intervention, especially because the modest improvement in diabetes management that is produced by nonsurgical weight loss is accompanied by relapsing disease in nearly 100% of patients within 5 years. Surgical effects on hyperlipidemia are similarly impressive. Approximately 70% of the entire population experienced improvement, with greatest, intermediate, and least change occurring after BPD, GBP, and gastric banding, respectively. Hypertension resolved in more than 60% of patients and improved in more than 18%. Postsurgical effects on hypertension were greatest after BPD (83%), intermediate after GBP (67.5%) and VBG (69%), and least after gastric banding (43%). Resolution of OSAHS seems to be independent of the specific bariatric surgical procedure used, with resolution occurring in 85.7% of patients overall. Postsurgical improvement in other comorbid diseases has also been demonstrated, with improvement in fatty infiltration of the liver, improvement in respiratory function and asthmatic symptoms, reversal of the cardiomyopathy of obesity, and improvement in joint pain and mobility all having been reported.[47,62-66]

Anesthetic Management of Bariatric Surgical Patients

Preoperative Evaluation

The preoperative assessment for anesthesia should include consideration of hypertension, diabetes, heart failure, and obesity-

hypoventilation syndrome. The results of the sleep study that the patient underwent are important. An AHI score greater than 30, implying severe sleep apnea, is a warning sign and a predictor for rapid and severe desaturation at induction. CPAP levels greater than 10 imply a patient with the potential for difficult mask ventilation.

Another useful piece of information in the preoperative evaluation is gleaned by examining the history of previous surgeries, their anesthetic challenges (i.e., ease or difficulty in securing the airway, intravenous access), need for ICU admission, surgical outcomes, and the weight of the patient at that time. This information may help ease some concerns or allow us to better prepare for the upcoming anesthetic care. Recommended preoperative laboratory evaluations include fasting blood glucose, lipid profile, serum chemistries (to evaluate renal and hepatic function), complete blood count, ferritin, vitamin B_{12}, thyrotropin, and 25-hydroxyvitamin D.

If appropriately evaluated, ideally prepared, and optimally managed perioperatively, even patients with known coronary artery disease (CAD) have comparable morbidity and mortality to those without CAD.[67] The effect of OSA on perioperative risk remains controversial,[68] but most patients are screened for OSA by means of overnight oximetry or polysomnography, or both, if appropriate. If identified with OSA and CPAP is recommended, patients are encouraged to initiate therapy at home, and it should be continued throughout the perioperative period.

Liver function abnormalities are common in this patient population, especially nonalcoholic fatty liver disease, with the extent of disease being a determining factor for perioperative risk and postoperative outcomes. Cirrhotic liver disease with portal hypertension may be considered a contraindication to bariatric surgery.[68] Gastrointestinal symptoms of dyspepsia may indicate the presence of *Helicobacter pylori*, which requires treatment by the standard medical regimen.

Factors that may be considered contraindications to bariatric surgery include unstable CAD, uncontrolled severe OSA, uncontrolled psychiatric disorder, mental retardation (IQ < 60), inability to understand the surgery, perceived inability to adhere to postoperative restrictions, continued drug abuse, and malignancy with a poor 5-year survival prognosis. In most situations, preoperative management of any medical morbidity can help optimize risk and convert high-risk patients to ones with acceptable risk.

The anesthetic care of patients with OSA is complicated by the side effects of anesthetic drugs on an already compromised respiratory system. The commonly present comorbid conditions in this patient population accentuate the problem.[69,70] The change in perioperative risk based on the anesthetic agent used has been deduced only from anecdotal reports of different cases. There has been a paucity of trials to definitively answer that question. The question that commonly arises and cannot yet be answered on the basis of scientific evidence involves the safety of outpatient procedures in patients with sleep apnea. What procedures pose sufficient risk to the patient to recommend an overnight hospital stay? Does narcotic use affect this decision? Would the increased role of nonsteroidal anti-inflammatory drugs change these recommendations? Factors such as neck size and open versus laparoscopic surgery are being studied regarding their impact on outcomes. Further research on these questions is ongoing.

Intraoperative Care

Obese patients present special challenges for the anesthesiologist in airway management, positioning, monitoring, choice of anesthetic technique and anesthetic agents, pain control, and fluid management. Many of these issues are equally important in their postoperative care. The most significant and best studied are airway management, including endotracheal intubation, pulmonary physiology, and techniques of maintaining adequate blood oxygenation and lung volume. Specific interventions, techniques, and approaches used by the anesthesia care team providing anesthesia for obese patients are important determinants of outcome.

Patient Positioning (also see Chapter 36)

Despite the lack of evidence-based studies demonstrating that obese patients have more frequent complications from positioning, it seems fairly intuitive that morbidly obese patients do require extra care in positioning. Even in the supine position, rhabdomyolysis from pressure on the gluteal muscles leading to renal failure[71] and death[72] has been reported. For obese patients placed in the prone position, cushioning gel pads or other weight-bearing rolls may have excessive weight placed on them. Pressure points must be checked carefully, and even though pressure sites may be carefully padded, skin breakdown can still occur. This may cause tissue necrosis and infections, especially with lengthy surgery.[73] It is difficult to protect the dependent hip from pressure effects when patients are placed in the lateral decubitus position. Obese patients have excess axillary tissue, which may make it impossible or unnecessary to place a traditional axillary roll in this position. In the lithotomy position, the challenge may be in supporting the weight of the patient's legs with regular, not oversized stirrups. To minimize the risk of tissue compression injury or the development of compartment syndrome, the duration during which the legs are held in stirrups should be kept as short as possible.[74]

Airway Management (also see Chapter 50)
